Again, since AC is a diameter of the sphere, its square is double the square on the edge AD [Margin: (h) XIII.14], and therefore equal to the two squares on the edges AD and DC. Hence the angle ADC is a right angle [Margin: (i) I.48]. In the same way the angles DAB, ABC, and BCD will be right angles. Therefore the quadrilateral ABCD is a rectangle; but it is also equilateral, since its sides are edges of the octahedron. So it is a square; and since it is described on the octahedron's edge AB, it follows that it is half the square on the sphere's diameter

[Margin: (k) XIII.12]. Therefore an octahedron described in a sphere, and so on. Which was to be shown.

Diagram. The regular octahedron ABCDEF of Proposition 16, drawn with all its face-edges and internal diagonals meeting at the center G. The square "equatorial" section ABCD is shown with its two apexes E and F above and below.

- E (top): upper apex of the octahedron
- A (upper left): vertex of the equatorial square
- D (upper right): vertex of the equatorial square
- G (center): center of the octahedron (and of the circumscribing sphere)
- B (lower left): vertex of the equatorial square
- C (lower right): vertex of the equatorial square
- F (bottom): lower apex of the octahedron

SCHOLIUM

We demonstrated this proposition far more briefly in the second corollary to *Elements* XIII.14, namely from the very construction of the octahedron. Nevertheless, since it is here proved by Campanus without reference to the construction of the octahedron, it seemed good to set down his demonstration in this place as well.

THEOR. 17. PROPOS. 17.

[Margin: outer dual-numbering "o. xvij."]

A tetrahedron inscribed in a sphere is to an octahedron described in the same sphere as the rectangle contained by a line whose square is twenty-seven sixty-fourths ($27/64$) of the square on the tetrahedron's edge, and by a line containing eight ninths ($8/9$) of the same edge, is to the square on the sphere's diameter.

Or, as Campanus puts it:

A tetrahedron inscribed in a sphere is to an octahedron described in the same sphere as the rectangle under a line whose square is subsestertian [3:4] to three quarters of the tetrahedron's edge, and under a line that is superquintupartient-of-twenty-sevenths [in the ratio 32:27] to those same three quarters of the tetrahedron's edge, is to the square on the sphere's diameter.

Demonstration. Let there be a tetrahedron ABCD and an octahedron EFGHIK in one and the same sphere, whose center is L. From the vertex D, through the center L, draw the sphere's diameter DM, meeting the base ABC at the point N. Then N will be the center of the base ABC, and DN will be perpendicular to that base [Margin: (a) XIV.15]. Now the part of the diameter LN, lying between the sphere's center and the base of the tetrahedron, is a sixth part of the diameter and a third of the semidiameter (by *Elements* XIII.13, cor. 2). So DL, the semidiameter, will be 3 such parts as LN is 1; and therefore DN will be 4 such parts. Next, by the scholium to *Elements* XI.15, draw through the center L a plane OPQ parallel to the plane ABC; then the lines QO, OP, PQ will be parallel to the lines AB, BC, CA [Margin: (b) XI.16]; and therefore the triangle QOP will be equiangular with the equilateral triangle ABC [Margin: (c) XI.10], since the angles of the one are equal to the angles of the other, each to each. But ABC is equiangular (by *Elements* I.5, cor.). Therefore QOP too will be equiangular, and consequently equilateral (by *Elements* I.6, cor.), and so similar to ABC itself. Moreover, the triangles DQO, DOP, DQP are similar to the equilateral triangles DAB, DBC, DAC (by *Elements* VI.4, cor.). Therefore the pyramids ABCD and QOPD are similar (by *Elements* XI, def. 9) [Margin: (d) XII.17]. Again, since the parallel planes ABC and QOP cut the lines DN and DC proportionally, DN will be to DL as DC is to DP. But DN was to DL as 4 to 3 (since

Diagram. The composite figure for Proposition 17, comprising three parts: (1) the tetrahedron ABCD with its inscribed parallel triangle QOP; (2) the octahedron EFGHIK; and (3) an auxiliary triangle-and-baseline construction with apex R. (The same composite figure is repeated at the top of the following page.)

Tetrahedron (left):

- D (top): apex, from which the diameter DM is drawn
- A (left), B (bottom), C (right): vertices of the base triangle ABC
- N (center of base): center of ABC, foot of the perpendicular DN
- L (mid-height): center of the sphere, lying on DN
- Q, O, P (mid-height triangle): vertices of the triangle QOP, parallel to base ABC and passing through L (Q upper-left, O center, P right)
- M (below B): the far end of the diameter, opposite D

Octahedron (center):

- I (top): upper apex
- E (upper left), H (upper right): two vertices of the equatorial square
- L (center): center

- F (lower left), G (lower right): two vertices of the equatorial square
- K (bottom): lower apex
- R (right of K): auxiliary apex point (belongs to the baseline construction below)

Auxiliary construction (baseline, left to right): X, Y, S, V, T, with apex R above; the equilateral triangle RST has perpendicular RV, TS is extended to X, and TX is bisected at Y.

- R (apex): apex of the auxiliary triangle
- X (far left): extension of TS beyond S
- Y: midpoint of TX
- S: base vertex of triangle RST
- V: foot of the perpendicular RV
- T (far right): base vertex of triangle RST

Diagram. Repeat of the Proposition 17 composite figure from the preceding page: the tetrahedron ABCD with inscribed parallel triangle QOP (labels D, A, Q, L, P, N, O, C, B, M), the octahedron EFGHIK with center L and auxiliary point R, and the baseline construction with apex R over the points X, Y, S, V, T. (Labels as described at fig-p583-2.)

Proposition 17 (continued) — demonstration

it has been shown that DN is 4 such parts as DL is 3.) Therefore DC will be to DP as 4 to 3. And consequently, since similar pyramids have the triplicate ratio of their edges [Margin: (e) XII.8], the pyramid ABCD will be to the pyramid QOPD as 64 to 27; for this is the triplicate of the ratio 4 to 3, as is clear from the numbers 64, 48, 36, 27. For these are the least numbers in the ratio 4 to 3 (as is clear from *Elements* VIII.2). Again, since squares have the duplicate ratio of their sides [Margin: (f) VI.20], the square on DC will be to the square on DP as 64 to 36, as is likewise clear from those same numbers.

Now let there be an equilateral triangle RST equal to the triangle DQP, and from R let the perpendicular RV be dropped to ST. Then the side RT — that is, DP — will be equal to it, and in square four-thirds (sesquitertian) of the perpendicular RV [Margin: (g) XIV.12]. And accordingly, as the square on DP was 36 such parts, the square on RV will be 27 of them. But the square on DC was 64 of those same parts. Therefore the line RV is capable of [has for its square] twenty-seven sixty-fourths of the square on the tetrahedron's edge.

Again, let TS be extended so that TX is to TS as 64 to 27 (by *Elements* X.6, cor.), and let TX be bisected at Y, so that TY is 32 such parts as TS — that is, its equal DP — is 27. Now since the ratio of DC to DP was as 4 to 3, that is, sesquitertian, DC will be 36 such parts as DP is 27 (for the ratio 36 to 27 is sesquitertian), and therefore as TY is 32. So the line TY contains eight ninths of the tetrahedron's edge DC. I say, then, that the tetrahedron ABCD is to the octahedron EFGHIK as the rectangle contained by the line RV (which is capable of twenty-seven sixty-fourths of the square on the edge DC) and by the line TY (which contains eight ninths of the same edge) is to the square on the sphere's diameter.

For when the lines RX, RY are drawn: since the triangle RTX is double the triangle RTY (because the base TX is double the base TY) [Margin: (h) VI.1], and the rectangle under RV, TY is likewise double the same triangle RTY [Margin: (i) I.41], the triangle RTX will be equal to the rectangle under RV, TY. And therefore, as the triangle RTX is to the triangle RST, so the rectangle under RV, TY is to that same triangle RST [Margin: (k) V.7]. But the triangle RTX is to the triangle RST as the base TX is to the base ST [Margin: (l) VI.1], namely as 64 to 27. Therefore the rectangle under RV, TY is to the triangle RST — that is, to the triangle QDP, or its equal QOP — as 64 to 27. But the pyramid ABCD was also to the pyramid QOPD as 64 to 27. Therefore, as the rectangle under RV, TY is to the triangle QOP, so the pyramid ABCD is to the pyramid QOPD. And as the triangle QOP is to the square on the sphere's diameter DM, so is the pyramid QOPD to the octahedron EFGHIK.

(For since DN is perpendicular to the plane ABC, it will also be perpendicular to the plane QOP, by the scholium to *Elements* XI.14; and therefore the sphere's semidiameter DL will be the height of the pyramid, or tetrahedron, QOPD. But the octahedron EFGHIK is divided into two equal pyramids EFGHI and EFGHK [Margin: (m) XIV.16], whose common base is the square EFGH — half the square on the sphere's diameter — and whose heights are the equal semidiameters of the sphere LI and LK. So the pyramids QOPD and EFGHI have equal heights. Therefore, by the scholium to *Elements* XII.5, as the base QOP is to the base EFGH, so is the pyramid QOPD to the pyramid EFGHI; and consequently, by what we showed in the scholium to *Elements* V.22, as the base QOP is to double the base EFGH — that is, to the square on the sphere's diameter DM — so is the pyramid QOPD to double the pyramid EFGHI, that is, to the octahedron EFGHIK.) Ex aequo, then, as the rectangle contained by RV (capable of twenty-seven sixty-fourths of the square on the tetrahedron's edge DC) and by TY (eight ninths of the same edge DC) is to the square on the sphere's diameter DM, so is the pyramid, or tetrahedron, ABCD to the octahedron EFGHIK. Therefore a tetrahedron inscribed in a sphere is to an octahedron, and so on. Which was to be demonstrated.

SCHOLIUM

Now since DC was 4 such parts as DP was 3, DP — or its equal RT — will contain three quarters of the tetrahedron's edge DC. And accordingly, since the line RT is in square sesquitertian [4:3] to the line RV [Margin: (n) XIV.12], RV will be in square subsesquitertian [3:4] to RT — that is, to three quarters of the tetrahedron's edge. Again, since TY was 32 such parts as ST — or DP — was 27 (that is, three quarters of the tetrahedron's edge), TY will be superquintupartient-of-twenty-sevenths [in the ratio 32:27] to ST, namely to three quarters of the tetrahedron's edge. Hence it is established that the tetrahedron ABCD is to the octahedron EFGHIK as the rectangle under RV — which is in square subsesquitertian to three quarters of the tetrahedron's edge — and under TY — which is superquintupartient-of-twenty-sevenths to those same three quarters of the tetrahedron's edge — just as Campanus maintained.

THEOR. 18. PROPOS. 18.

[Margin: outer dual-numbering "o. xvij." [?] — possibly "xviiij"; small and foxed]

A perpendicular dropped from any angle of an equilateral triangle to the opposite base is triple the perpendicular that is drawn from the center of the triangle to the same base.

Demonstration. Let there be an equilateral triangle ABC whose center is D. From A, through D, draw the line AE, which will be perpendicular to BC and will bisect it (by *Elements* XIII.10, cor. 2). I say that AE is triple the line DE — the perpendicular, that is, drawn from the center to the base. For when the lines BD, CD are drawn: since the sides DA, DB of the triangle ADB are equal to the sides DB, DC of the triangle BDC (for they are drawn from the center), and the base AB is also equal to the base BC, the triangles ABD and BDC will be equal (by *Elements* I.8, cor.). And by the same

Diagram. The equilateral triangle ABC of Proposition 18, with its center D and the perpendicular AE dropped from the apex A to the base BC; lines BD and CD are also drawn.

- A (top): apex
- D (center): center of the triangle
- B (bottom left): base vertex
- E (bottom middle): foot of the perpendicular AE on BC (midpoint of BC)
- C (bottom right): base vertex

Proposition 18 (continued) — demonstration

reasoning the triangles ADB and ADC will be equal. Therefore, because of the equality of the three triangles ADB, BDC, CDA, the triangle ABC is triple the triangle BDC. Now since the rectangle under AE, EB is equal to the triangle BDC (by the scholium to *Elements* I.41), because the base of the triangle BDC is double the base BE, which belongs to each rectangle, the rectangle under AE, EB will also be triple the rectangle under DE, EB. But as the rectangle under AE, EB is to the rectangle under DE, EB — of the same height EB — so is the base AE to the base DE [Margin: (a) VI.1]. Therefore AE too is triple DE. So a perpendicular from any angle, and so on. Which was to be shown.

COROLLARIUM

And so the same perpendicular AE is one-and-a-half times (sesquialter) the remaining line AD, contained between the angle and the center. For since AE is triple DE, if AE is set at 3 such parts, DE will be 1; the remaining line AD will therefore contain 2 of those same parts; and consequently AE will be sesquialter to AD.

From which it further follows that the line AD is double the line DE.

THEOR. 19. PROPOS. 19.

[Margin: outer dual-numbering "o. xvij." [?] — small and foxed]

If an octahedron is inscribed in a sphere, the semidiameter of the sphere will be in square triple the perpendicular that is drawn from the center of the sphere to any base of the octahedron.

Demonstration. Let there be some base of an octahedron inscribed in a sphere whose center is D — the equilateral triangle ABC — and from the center D of the sphere let a perpendicular DE be dropped onto it; and draw the semidiameter of the sphere DB. I say that the semidiameter DB is in square triple the perpendicular DE. For since, by the corollary to Lemma 1 of Proposition 10 of this book, the perpendicular DE falls on the center of the circle of the sphere that circumscribes the triangle ABC, E will be the center of the triangle. So when the line BE is drawn: since the square on the sphere's diameter is double the square on the octahedron's edge AB [Margin: (a) XIII.14], and quadruple the square on the sphere's semidiameter DB (by the scholium to *Elements* II.4) — if the square on the diameter is set at 12 parts, the square on the edge AB will be 6, and the square on the sphere's semidiameter DB will be 3. Now since the square on the

edge AB is triple the square on the semidiameter of the circle enclosing the triangle — namely the line BE [Margin: (b) XIII.12] — the square on the line BE will be 2 such parts as the square on the edge AB was 6. Therefore, since the square on the line DB is equal to the squares on the lines BE and DE [Margin: (c) I.47], and the square on DB has been shown to be 3 parts, the remaining square on the perpendicular DE will be 1 such part. And accordingly the square on the line DB is triple the square on the line DE. So if an octahedron is inscribed in a sphere, and so on. Which was to be shown.

Diagram. The figure for Proposition 19: the equilateral triangle ABC (one base of the octahedron), with the sphere's center D drawn to the left, the perpendicular DE falling on the triangle's center E, and the semidiameter DB drawn to the base vertex B.

- A (top): apex of the triangle
- D (left): center of the sphere
- E (interior/center): center of the triangle ABC, foot of the perpendicular DE
- B (bottom left): base vertex; DB is the drawn semidiameter
- C (bottom right): base vertex

THEOR. 20. PROPOS. 20.

[Margin: outer dual-numbering "o. xviiij." [?]]

Double the square described on the diameter of any sphere is equal to the surface of a cube placed in that sphere; and the perpendicular dropped from the center of the sphere onto any base of the cube is equal to half the cube's edge.

Demonstration. Let there be a cube ABCDEFGH described in a sphere whose center is I, and from I let the perpendicular IK be drawn to one base of the cube, namely to ADEF. I say that double the square on the sphere's diameter is equal to the surface of the cube, and that the perpendicular IK is equal to half the cube's edge. For since the square on the sphere's diameter is triple the square on the cube's edge — that is, equal to three squares of the cube [Margin: (a) XIII.15] — double that same square described on the sphere's diameter will be equal to six squares of the cube, that is, to the whole surface of the cube.

Now let KI be produced to the opposite base BCHG, as far as the point L. Since KL is perpendicular to the plane AE, it will also be perpendicular to the plane BH, which is parallel to it (by the scholium to *Elements* XI.14) [Margin: (b) XI.6]. Again, since AB and KL are parallel — because they are both perpendicular to the plane

AE — let a plane be drawn through them, making common sections in the opposite parallel planes AE, BH: the straight lines AK, BL, which will also be parallel to each other [Margin: (c) XI.16]; and therefore ABLK will be a parallelogram, and so the line KL will be equal to the cube's edge AB. Now since the perpendicular KL, from the sphere's center I, falls on the bases AE, BH at the points K and L, the points K and L will be the centers of the circles enclosing those bases in the sphere (by the corollary to Lemma 1 of Proposition 10 of this book). Therefore KL will be bisected at the center I by the said diameter CF, as we showed in the first corollary to *Elements* XIII.15; and consequently, since KL has been shown equal to the cube's edge, IK will be half of that same edge of the cube. Therefore double the square described on the diameter of any sphere, and so on. Which was to be shown.

Diagram. The cube ABCDEFGH of Proposition 20, drawn in perspective, with center I, the perpendicular IK to the top face ADEF, and IK produced to L, the center of the opposite face BCHG. The internal lines AK, BL and the diameter CF are shown.

- F (top left): vertex of the top face
- E (top right): vertex of the top face
- K (upper interior): center of the top face ADEF, foot of the perpendicular IK
- A (left): front-upper vertex
- D (right): vertex of the top face
- I (center): center of the cube (and of the sphere)
- G (lower left): vertex of the bottom face
- H (lower right): vertex of the bottom face
- L (lower interior): center of the bottom face BCHG
- B (bottom left): front-lower vertex
- C (bottom right): front-lower vertex

COROLLARIUM

From what has been said, it follows that the solid formed from half the cube's edge multiplied by two thirds of the square on the diameter of the sphere enclosing the said cube is equal to the cube. For since the square on the sphere's diameter is triple the square on the cube's edge, the two squares AE and BH will be two thirds of the square on the sphere's diameter [Margin: (d) XIII.15]. And it is evident that the solid formed from IK (half the cube's edge) multiplied by AE (a third of the square on the sphere's diameter) is equal to the solid formed from IL (half the cube's edge) multiplied by BH (a third of the square on the sphere's

diameter) [Margin: (e) XI.31], because the said solids have equal bases and equal heights. Therefore, since the said two solids fill out the whole cube, it is manifest that what is formed from half the cube's edge multiplied by two thirds of the square on the sphere's diameter is equal to the whole cube. Which was what was proposed.

Book XIV (continued)

Proposition 20 — Alternative proof of the Corollary

This corollary can also be stated in another way, namely: the solid produced by the edge of the cube times a third of the square of the diameter of the sphere is equal to the cube. For the cube BE is produced from BA — the edge of the cube — times the square AE, which is a third of the square of the diameter of the sphere. As is evident.

SCHOLIVM

More generally: the solid produced by the perpendicular drawn from the center of any regular body to one of its bases, times a third part of the surface of the body, is equal to the given regular body.

Let ABCD be any regular body, contained by the planes ABC, ABD, ACD, BCD; and let EFGH be a solid contained by EI — a third part of the surface of the body ABCD — and by the height FG, which is equal to the perpendicular KL drawn from the center K to the base ABC. I say that the solid EFGH is equal to the given regular body ABCD.

For when the straight lines KA, KB, KC, KD are drawn from the center K to all the vertices of the body, the regular body is resolved into equal pyramids, since they have equal bases and equal heights. For since the circles surrounding the said bases are equal, they are equally distant from the center, by lemma 2 of the [relevant] proposition of this book. And therefore the perpendiculars drawn from the center K to their planes — namely the heights of the pyramids — will be equal.

Now the prism contained by the base ABC and the height KL is triple the pyramid ABCK, by corollary 1 of proposition 6 of book 12; and by the same reasoning the prisms contained by the remaining bases, at the same height KL, are triple their own pyramids. Therefore the prism contained by the whole surface of the regular body, at the height KL (namely the prism composed of all those prisms), will be triple the regular body ABCD. Consequently, since this same prism is triple the

prism EFGH — because the base of the whole-surface prism is set as triple the base of EFGH — by what we demonstrated at proposition 7 of book 12, the solids EFGH and ABCD will be equal. Which is what was proposed.

Diagram. Two solids side by side. On the left, a tetrahedron with an interior center; on the right, a rectangular solid (right prism) representing the solid EFGH.

- D (apex, top): top vertex of the tetrahedron

- K (interior center): center of the regular body, from which the radii KA, KB, KC, KD are drawn
- L (below K): foot of the perpendicular KL to the base ABC
- H (top-left rear of the box): upper vertex of the rectangular solid
- I (top-right front of the box): upper vertex of the rectangular solid
- E (bottom-left front): lower vertex
- F (bottom-right front): lower vertex
- G (right side, mid): vertex of the rectangular solid EFGH

THEOR. 21. PROPOS. 21.

[Margin: o. / xj. (dual Hypsicles/Campanus proposition number)]

The same circle comprehends both the square [face] of the cube and the triangle [face] of the octahedron of the same sphere.

In a sphere whose diameter is A, let a cube be imagined described, of which one square face is BCDE, and an octahedron, of which one triangular face is FGH. I say that the circles BCDE, FGH circumscribing them are equal. For let there be radii from the centers, IB and KF. [Margin: a 15.tertij dec. (Elements XIII.15)]

Now the square of the diameter A is triple the square of the edge of the cube BC, and the square of the edge BC is double the square of the line BI. (For when the line IC is drawn, the angle BIC becomes a right angle, since it subtends the square [Margin: b 47.pri. (Elements I.47)]; and therefore the square on BC will be equal to the squares on BI, IC. And since the lines BI, IC are equal, their squares [?] are equal; so the square on BC will be double the square on BI.) Therefore, if the square of the diameter A be set at 6 such parts, the square of the edge BC will be 2 of them, and the square of the line BI will be 1.

Again [Margin: c 14.tertij dec. (Elements XIII.14)], since the square of the diameter A is double the square of the edge of the octahedron FG, and the square of the edge FG is triple the square of the line FK drawn from the center [Margin: d 12.tertij dec. (Elements XIII.12)]: if the square of the diameter A be set at 6 such parts, the square of the edge FG will be 3, and the square of the line FK will be 1. Since therefore the square on the line BI and the square on the line FK have each been shown to be 1 of the same parts, the squares on BI, FK are equal; and therefore the lines themselves, and the circles BCDE, FGH described from them, are equal. Therefore the same circle comprehends [both], etc. Which was to be shown.

Diagram. Two circles side by side sharing a common diameter drawn below. In the left circle a square face BCDE is inscribed; in the right circle an equilateral triangular face FGH is inscribed.

- B (top-left), E (top-right), C (bottom-left), D (bottom-right): the four vertices of the inscribed square BCDE
- I (center of left circle): center of the circumscribing circle
- F (top), G (bottom-left), H (bottom-right): the three vertices of the inscribed triangle FGH
- K (center of right circle): center of the circumscribing circle
- A (line drawn beneath both circles): the diameter of the sphere

COROLLARIVM

From this it follows that the perpendicular lines joining the centers of the circles which circumscribe the opposite bases — both of the cube and of the octahedron — are equal.

For if perpendiculars are drawn from the center of the sphere to the bases of the cube and of the octahedron, they fall on the centers of the circles circumscribing those bases, by the corollary of lemma 1 of proposition 10 of this book. And since these have been shown equal, they are equally distant from the center of the sphere, by lemma 2 of the same proposition. [Margin: e 21.quartidec. (Elements XIV.21)] And therefore the said perpendiculars will be equal. Now these are the halves of the lines that join the centers of the opposite bases. (For if they are produced, they will also be perpendicular to the opposite bases, by the scholium of proposition 14 of book 11, because the opposite bases in the octahedron are parallel, by corollary 4 of proposition 14 of book 13, just as the opposite bases of the cube are parallel.) Therefore the perpendiculars joining the centers of the

opposite bases will be equal, both in the cube and in the octahedron. Which is what was proposed.

THEOR. 22. PROPOS. 22.

If an octahedron and a tetrahedron are inscribed in the same sphere, the octahedron will be to triple the tetrahedron as the edge of the octahedron is to the edge of the tetrahedron.

In the same sphere let both an octahedron $ABCDEF$ and a tetrahedron $GHIK$ be inscribed. I say that the octahedron is to triple the tetrahedron as the edge BF is to the edge HI . For, when the diameter AD is drawn in the octahedron, the octahedron is divided into four pyramids whose common edge is the diameter AD itself and whose common vertex is A , namely: $BCDA$, whose base is BCD ; $BDFA$, whose base is BDF ; $CDEA$, whose base is CDE ; and $DEFA$, whose base is

DEF . All of these bases lie below the square $BCEF$, and together with it contain half of the octahedron. And since each of these pyramids consists of two equilateral triangles of the octahedron together with two other triangles which — because their common side is the diameter AD , while their remaining sides are edges of the octahedron itself — are equal to one another [Margin: a 8.pri. (Elements I.8)], it follows that these four pyramids are equal to one another, since they are contained by planes equal in both number and magnitude.

Let a prism $GHIKLM$ be set up on GHI , the base of the tetrahedron, of the same height as the tetrahedron; this will be triple the tetrahedron itself, by corollary 1 of proposition 7 of book 12. Again, on the base of the octahedron NOP , and on TVX (equal to the base of the tetrahedron), let two prisms $NOPQRS$ and $TVXYZ\alpha$ be set up, of the same height as the octahedron, or the pyramid $ACDE$. [Margin: b 14.quartidec. (Elements XIV.14)] Since therefore GHI — that is, TVX — the base of the tetrahedron, is 4:3 [sesquitertia] of NOP , the base of the octahedron, the prism $TVXYZ\alpha$ will also be 4:3 of the prism $NOPQRS$, since prisms of the same height are as their bases, by what we demonstrated at proposition 7 of book 12. But the octahedron $ABCDEF$ is likewise 4:3 of such a prism $NOPQRS$ (for a prism is equal to three pyramids, by corollary 1 of proposition 7 of book 12, four of which we said the octahedron contains). Therefore the octahedron is equal to the prism $TVXYZ\alpha$.

But since the prism $TVXYZ\alpha$ has to the prism $GHIKLM$ the proportion which the height of the former has to the height of the latter, by the scholium of proposition 14 of book 12; and the height of the prism $TVXYZ\alpha$ (which is equal to the octahedron) is the same as the height of the octahedron, by construction: the

octahedron will also be to the prism GHIKLM — that is, to triple the tetrahedron GHIk — as the height of the octahedron is to the height of the tetrahedron. Now the height of the octahedron — namely the perpendicular joining the centers of the opposite bases — is equal to the edge of the cube, that is, to the perpendicular connecting the centers of the opposite bases, by the corollary of proposition 21 of this book. And as the edge of the cube is to the height of the tetrahedron, so is the edge of the octahedron to the edge of the tetrahedron.

(For both the square of the edge of the cube to the square of the height of the tetrahedron, and the square of the edge of the octahedron to the square of the edge of the tetrahedron, is as 3 to 4. For if the square of the diameter of the sphere be set at 9, the square of the edge of the cube will be 3, by proposition 15 of book 13, and the square of the height of the tetrahedron 4, by corollary 2 of proposition 13 of book 13; and therefore the square of the edge of the cube to the square of the height of the tetrahedron is as 3 to 4. Again, if the square of the diameter of the sphere be set at 6, the square of the edge of the octahedron will be 3, and the square of the edge of the tetrahedron 4, and so on.)

Therefore the octahedron is to triple the tetrahedron as the edge of the octahedron is to the edge of the tetrahedron. If therefore an octahedron and a tetrahedron are inscribed in the same sphere, etc. Which was to be demonstrated.

Diagram. A group of figures for Proposition 22 : an octahedron (upper left), a prism shown as a solid (upper right), and two triangular prisms (lower left and lower right).

- Octahedron ABCDEF: A (top apex), B (upper-left), F (upper-right), C (lower-left), E (lower-right), D (bottom apex)
- Prism GHIKLM: L (top apex), M (left), K (right), G (interior center), H (bottom-left), I (bottom-right)
- Lower-left triangular prism NOPQRS: R (top apex), S (upper-left), N (interior), O (bottom-left), P (bottom-center); the sixth vertex letter (Q) is not individually resolvable [?]
- Lower-right triangular prism TVXYZα: Z (top apex), Y (upper-right), T (interior), V (bottom-center), X (bottom-right); the vertex α (and one further letter) not individually resolvable [?]

COROLLARIVM

From what has been said it is inferred that the height of the octahedron is to the height of the tetrahedron as the edge of the octahedron is to the edge of the

tetrahedron. For it was shown that the edge of the cube — which is equal to the height of the octahedron — is to the height of the tetrahedron as the edge of the octahedron is to the edge of the tetrahedron. Likewise it is gathered that the diameter of the sphere is to the edge of the tetrahedron as the edge of the octahedron is to the edge of the cube. [Margin: c 18.tertij dec. (Elements XIII.18)] For both the square of the diameter to the square of the edge of the tetrahedron, and the square of the edge of the octahedron to the square of the edge of the cube, has the ratio 3:2 [sesquialter].

THEOR. 23. PROPOS. 23.

If a given straight line is such that its square equals [the squares on] a whole line cut in extreme and mean ratio together with its greater segment; and likewise [equals the squares on] another whole line similarly cut together with its lesser segment: then the greater segment of the first line will be the edge of the icosahedron, and the lesser segment of the latter line the edge of the dodecahedron, of that sphere whose diameter the given straight line is.

Let the straight line AB be equal in square to the line CD together with its greater segment CE; and likewise to the line FG together with its lesser segment HG. I say that CE is the edge of the icosahedron, and HG the edge of the dodecahedron, of the sphere whose diameter AB is.

For let there be imagined, in the sphere whose diameter is AB, an icosahedron AIBk described, and a dodecahedron ANBO. Then let the opposite edges of the icosahedron, AI and Bk, be joined by the straight line IB, which will subtend one angle of the pentagon composed of the edges of the icosahedron, as is established from proposition 16 of book 13. (For in that figure, when the line ZF is drawn, RSHZF will be a pentagon, on account of the five equal edges of the icosahedron GR, GS, GH, GZ, GF falling on the surface of the sphere; and in it the line RH, joining the opposite sides RX, HI, subtends the angle RSH.) And it will appear more clearly from the construction of the icosahedron which we shall bring forward at the end of book 16 from Pappus; and it may also be seen in some material icosahedron.

But since AI, Bk are opposite parallel sides, by corollary [of] proposition 16 of book 3 [recte: book 13] [Margin: a 9.pri. (Elements I.29 — the "2" appears dropped)], the angles AIB, IBk will be equal to two right angles; and therefore, since they are equal to one another —

— (for when another diameter IK is drawn: since the sides AI, IB of the triangle AIB are equal to the sides KB, BI, and the bases AB, IK also equal [Margin: b 8.pri. (Elements I.8)], the angles AIB, IBK will be equal) — they will be right angles; and therefore [Margin: c 47.pri. (Elements I.47)] the square on the proposed line AB will be equal to the squares on the lines AI, IB. But the same square on AB was, by hypothesis, equal to the squares on the lines CD, CE. Therefore the squares on the lines IB, IA are equal to the squares on the lines CD, CE.

And therefore [Margin: d 8.tertij dec. (Elements XIII.8)], since CE is the greater segment of CD cut in extreme and mean ratio, and likewise IA is the greater segment of IB similarly cut (for IB subtends an angle of the pentagon whose side is IA, an edge of the icosahedron; and it is established that when a line subtending an angle of a pentagon is cut in extreme and mean ratio, its greater segment is equal to the side of that same pentagon) [Margin: e 2.quartidec. (Elements XIV.2)], CE, the greater segment, will be equal to IA, the edge of the icosahedron. [Margin: f 22.sex. (Elements VI.22)] For since as CD is to CE, so is IB to IA, it will also be as the square on CD to the square on CE, so the square on IB to the square on IA; and, componendo, as the squares on CD, CE to the square on CE, so the squares on IB, IA to the square on IA. But the squares on IB, IA were shown equal to the squares on CD, CE. [Margin: g 14.quin. (Elements V.14)] Therefore the square on IA is also equal to the square on CE; and therefore the lines CE, IA are equal. Which is what was proposed.

Diagram. Two projected polyhedra with two divided reference segments drawn above them. On the left, an icosahedron with its interior diagonals; on the right, a dodecahedron. (The same figure is repeated on the following page.)

- Reference segment CD divided at E: C (left), E (middle), D (right)
- Reference segment FG divided at H: F (left), H (middle), G (right)
- Icosahedron AIBK: I (top-left), A (top-right), B (bottom-left), K (bottom-right); the interior pentagon labels (R, S, H, Z, F, X, G) are not individually resolvable on the tile [?]
- Dodecahedron ANBO: N (top-left), L (top-center), A (top-right), B (bottom-left), M (bottom-center), O (bottom-right)

Diagram. The same icosahedron-and-dodecahedron figure of Proposition 23, repeated at the head of this page, with the two divided reference segments above.

- Reference segments: CD (divided at E) and FG (divided at H) above
- Icosahedron AIBK: I (top-left), A (top-right), B (bottom-left), K (bottom-right); interior pentagon labels not individually resolvable [?]

- Dodecahedron ANBO: N (top-left), L (top-center), A (top-right), B (bottom-left), M (bottom-center), O (bottom-right)

Again, let the opposite edges of the dodecahedron, AN and BO, be bisected at the points L and M; let the line LM join these points, and let the edges themselves be joined by the straight line NB. Since therefore NL, BM are equal and parallel, by corollary 3 of proposition 17 of book 13 [Margin: h 33.pri. (Elements I.33)], LM and NB will also be equal and parallel. But the line LM, bisecting the opposite edges, is perpendicular to those opposite edges, by the same corollary. Therefore NB will also be perpendicular to them. [Margin: i 47.pri. (Elements I.47)] And therefore the square on the proposed line AB will be equal to the squares on the lines NB, NA. And since the same square on AB was set equal to the squares on the lines FG, HG, the squares on NB, NA will be equal to the squares on FG, HG.

And therefore, since HG is the lesser segment of FG cut in extreme and mean ratio, and likewise NA is the lesser segment of NB — that is, of LM — similarly divided, by corollary 4 of proposition 17 of book 13: HG, the lesser segment, will be equal to NA, the edge of the dodecahedron. This we shall show in no other way than we demonstrated above, that CE, the greater segment, is equal to IA, the edge of the icosahedron. If therefore a proposed straight line is equal in square to a whole line cut in extreme and mean ratio together with its greater segment, and likewise to another line similarly cut together with its lesser segment: then the greater segment of the first line will be the edge of the icosahedron, and the lesser segment of the latter line the edge of the dodecahedron of that sphere whose diameter the proposed line is. Which was to be shown.

THEOR. 24. PROPOS. 24.

If the edge of the octahedron is equal in square to the greater and lesser segments of a straight line cut in extreme and mean ratio: then the edge of the icosahedron described in the same sphere will be equal in square to double the [square on the] lesser segment.

Let the edge AB of the octahedron ABC be equal in square to the greater segment DE and the lesser segment EF of the line DF cut in extreme and mean ratio. Let there also be inscribed in the same sphere an icosahedron GHI whose edge is GH; let GI subtend an angle of the pentagon composed of the edges of the icosahedron, and let HI be the diameter. I say that the square of the edge GH is double the square of the lesser segment EF.

For since GH is the side of the pentagon one of whose angles the line GI subtends [Margin: a 8.tertij dec. (Elements XIII.8)], GH will be the greater segment of GI cut

in extreme and mean ratio; and therefore [Margin: b 5.tertij dec. (Elements XIII.5)] the line composed of GI, GH will likewise be cut at the point G in extreme and mean ratio. [Margin: c 47.pri. (Elements I.47)] Now since the square of the diameter HI is equal to the squares on the lines GI, GH — because the angle IGH is right, as was shown in the preceding proposition — and the square of the edge AB is set equal to the squares on the lines DE, EF: it follows that as the square of the diameter HI is to the square of the edge AB, so are the squares on the lines GI, GH to the squares on the lines DE, EF. [Margin: d 14.tertij dec. (Elements XIII.14)] But the square of the diameter HI is double the square of the edge of the octahedron AB. Therefore the squares on the lines GI, GH are also double the squares on the lines DE, EF.

And as the squares on the lines GI, GH are to the squares on the lines DE, EF, so is the square on the line GH to the square on the line EF. ([Margin: e 2.quartidec. (Elements XIV.2)] For since as GI is to GH, so is DE to EF, it will also be, as the square on GI to the square on GH, so the square on DE to the square on EF; and, componendo, as the squares on GI, GH to the square on GH, so the squares on DE, EF to the square on EF; and, permutando, as the squares on GI, GH to the squares on DE, EF, so the square on GH to the square on EF.) [Margin: f 22.sex. (Elements VI.22)] Therefore the square on the line GH is also double the square on the line EF. Wherefore, if the edge of the octahedron is equal in square to the greater and lesser segments, etc. Which was to be shown.

Diagram. An octahedron (left) and an icosahedron (right), with a divided reference segment drawn above.

- Reference segment DF divided at E: D (left), E (middle), F (right)
- Octahedron ABC: A (top apex), B (left), C (bottom apex)
- Icosahedron GHI: G (top-left), H (top-right), I (bottom apex)

THEOR. 25. PROPOS. 25.

If a straight line cut in extreme and mean ratio forms a right angle with its lesser segment, and a straight line is subtended to that right angle: then the straight line whose square is half of the [square on the] subtending line will be the edge of the octahedron of that sphere in which the said lesser segment is the edge of the dodecahedron.

(continuation of the demonstration of Theorem 25 / Proposition 25, whose enunciation was given at the end of the preceding pages)

Let the straight line AB, cut at C, be set in extreme and mean ratio with the straight line AD (which is equal to the lesser segment AC), forming a right angle at A; let BD be subtended to that right angle, and let E be a line whose square is half the square on BD. I say that E is the octahedron edge of that sphere in which AD, or AC, is the dodecahedron edge.

For since — by Corollary 2 of Proposition 17, Book 13 — the greater segment BC is the edge of the cube of that sphere whose lesser segment AC (or AD) is the dodecahedron edge, the diameter of that sphere will be, in square, triple the greater segment BC, that is, triple the cube edge. [Margin (a): 4. tertijdec. — *Elements* XIII.4] But the squares on the straight lines AB and AD, namely on the whole line and on the lesser segment, are also together triple the same square on the greater segment BC. Therefore the square on the diameter of the sphere will be equal to the squares on AB and AD, that is, to the square on BD; and consequently BD is the diameter of the sphere. [Margin (b): 14. tertijdec. — *Elements* XIII.14] Now since the square on the diameter of the sphere is double the square on the octahedron edge, and since the square on BD is double the square on E — because E is posited to be half of BD in square — E will be the octahedron edge of that same sphere in which AD is set as the dodecahedron edge. If, therefore, a straight line be cut, and so on. Which was to be demonstrated.

COROLLARIUM.

[Margin (c): 18. tertijdec. — *Elements* XIII.18]

Since the octahedron edge E is, in square, the sesquialter (3:2) of the cube edge BC — of which cube edge the greater segment [when BC is itself cut in extreme and mean ratio] is AD, the dodecahedron edge, as is established from what we showed at Proposition 4, Book 13, seeing that BC is the greater segment and AD the lesser of the line AB cut in extreme and mean ratio — it is evident that: if any straight line whatever (namely BC) be cut in extreme and mean ratio, and another line (for example E) be such that its square taken in the ratio 3:2 gives the octahedron edge, then the greater segment (namely AD) is the dodecahedron edge of that same sphere in which the octahedron will have been inscribed.

THEOR. 26. PROPOS. 26.

If the edge of the tetrahedron has for its square the greater and the lesser segment together of a straight line cut in extreme and mean ratio, then

the edge of the icosahedron inscribed in the same sphere is, in square, the sesquialter (3:2) of the lesser segment.

Let the edge BC of the tetrahedron ABCD have for its square the greater segment EF together with the lesser segment FG of the straight line EG cut in extreme and mean ratio; and let HI likewise be the edge of the icosahedron HIK of the same sphere. I say that the straight line HI is, in square, the sesquialter of the lesser segment FG.

For let the straight line HK subtend one angle of the pentagon formed from the edges of the icosahedron, and let the straight line IK, a diameter, be joined. [Margin (a): 8. tertijd. — *Elements* XIII.8] Since, then, HI is the greater segment of the straight line HK cut in extreme and mean ratio, [Margin (b): 5. tertijd. — *Elements* XIII.5] the composite line KHI will also be cut in the same way at H, its greater segment being HK and its lesser HI. [Margin (c): 22. prim. — *Elements* I.22] From the straight lines BC, EF, FG let the triangle BCL be constructed, so that BL is equal to EF and CL to FG; [Margin (d): 48. pri. — *Elements* I.48] then the angle L will be right, because BC is posited to have for its square the lines BL and CL, that is, the lines EF and FG. But the angle IHK is also right, as we showed at Proposition 23 of this book; [Margin (e): 2. quartidec. — *Elements* XIV.2] and as BL is to LC, so is KH to HI. [Margin (f): 6. sexti. — *Elements* VI.6] Therefore the triangles BLC and KHI are equiangular. [Margin (g): 4. sexti. — *Elements* VI.4] And consequently, as KI is to IH, so is BC to CL; and, alternately, as KI is to BC, so is HI to CL. [Margin (h): 13. tertijdec. — *Elements* XIII.13] But the diameter IK is, in square, the sesquialter of the tetrahedron edge BC. Therefore HI, the icosahedron edge, will also be, in square, the sesquialter of CL, that is, of the lesser segment FG. If, then, the tetrahedron edge have for its square the greater and the lesser segment, and so on. Which had to be shown.

Diagram. The figure for Proposition 25 (top right of the page): a right-angled figure standing on a vertical line, with a separate short segment beside it.

- A (top left): right-angle vertex; the vertical line AB descends from here, and the horizontal line AD runs right.
- D (top right): far end of the horizontal top line; the hypotenuse BD is drawn from B up to D.
- C (on line AB, below A): the point cutting AB in extreme and mean ratio.
- B (bottom left): foot of the vertical line; endpoint of the subtending line BD.
- E (center right, a short standalone vertical segment): the line whose square is half the square on BD.

Diagram. The figure for Proposition 26: at the left a tetrahedron with an appended triangle, at the right an icosahedron shown in outline, and below a divided straight line.

- A (apex, upper left): top vertex of the tetrahedron ABCD.
- D (interior of the tetrahedron): the far/interior vertex.
- B (lower left): base vertex.
- C (lower right): base vertex.
- L (below the base, near E): apex of the constructed triangle BCL.
- H (icosahedron, top left) and I (icosahedron, top right): upper vertices; HI is the icosahedron edge.
- K (icosahedron, bottom vertex): the point to which HK is subtended.
- E, F, G (horizontal line along the bottom, left to right): the straight line EG cut at F, with greater segment EF and lesser segment FG.

THEOR. 27. PROPOS. 27.

The cube is to the octahedron inscribed in the same sphere with it as the surface of the cube is to the surface of the octahedron; and likewise as the edge of the cube is to the semidiameter of the sphere.

Let there be, in the same sphere, the cube ABCDEFGH and the octahedron IKLMNO, whose centers are P and Q. I say that the ratio of the cube to the octahedron is the same as the ratio of the surface of the cube to the surface of the octahedron; and likewise the same as the ratio of the cube's edge to the semidiameter of the sphere.

For if straight lines are drawn from the centers P and Q to all the vertices, both of the cube and of the octahedron, the cube will be resolved into six equal pyramids, since these have equal bases and equal heights. (For since the circles described about the pyramids' bases — that is, about the cube's faces — are equal, they are equally distant from the center of the sphere; and therefore the perpendiculars drawn from the center P to the planes of the circles, or of the said bases — namely the heights of the pyramids — are equal, by Lemma 2 of Proposition 10, Book 14.) And, for the same reason, the octahedron is resolved into eight equal pyramids.

[Margin (a): 21. quartidec. — *Elements* XIV.21]

Since, moreover, one and the same circle encloses both the cube's square face and the octahedron's triangular face, the bases of the cube's pyramids and of the

octahedron's pyramids are equally distant from the center of the sphere, by the aforesaid lemma; and consequently the heights of the cube's pyramids and of the octahedron's pyramids will be equal. For this reason, as one pyramid of the cube is to one pyramid of the octahedron, so is the base of the cube's pyramid to the base of the octahedron's pyramid, by the scholium to Proposition 6, Book 12. And accordingly — from what we demonstrated in the scholium to Proposition 22, Book 5 — as six times the cube's pyramid (that is, the cube itself) is to the octahedron's pyramid, so is six times the base of the cube's pyramid (that is, the whole surface of the cube) to the base of the octahedron's pyramid. And so again, from the same scholium, as the cube is to eight times the octahedron's pyramid (that is, to the octahedron itself), so is the surface of the cube to eight times the base of the octahedron's pyramid (that is, to the surface of the octahedron itself). Which was the point proposed to be shown in the first place.

Let there be again, in the same sphere, the cube ABCD and the octahedron EFGHIK, let EG be the diameter of the sphere (or of the octahedron), and let L be the center. From AB, the cube's edge, let a third part AM be taken away; likewise from the semidiameter EL let a third part EN be taken away. Now since the square IFKH, the octahedron's edge, being the base of the two pyramids into which we said the octahedron is divided at Proposition 16 of this book, [Margin (b): 18. tertijdecim. — *Elements* XIII.18] is, in the ratio 3:2, the square BD on the cube's edge BC; and since the straight line AB is, by construction, three-to-two of the straight line BM; the bases IFKH and BD, and the heights AB and BM, will be reciprocally proportional. [Margin (c): 34. vnd. — *Elements* XI.34] And consequently the parallelepiped on the base IFKH and under the height BM will be equal to the parallelepiped on the base BD and under the height AB, that is, to the cube ABCD.

Again, since the straight line EL is triple the straight line EN, the parallelepiped on the base IFKH and under the height EL will be triple the parallelepiped on the same base and under the height EN, as we showed in the scholium to Proposition 14, Book 12. But this same parallelepiped on the base IFKH and under the height EL is also triple the pyramid IFKHE, by Corollary 1 of Proposition 7, Book 12. Therefore the pyramid IFKHE will be equal to the parallelepiped on the base IFKH and under the height EN. But of this parallelepiped the double is the parallelepiped on the same base and under the height LN, by the scholium to Proposition 14, Book 12, since the height LN is also double the height EN. [Margin (d): 16. quartidecim. — *Elements* XIV.16] Likewise the octahedron EFGHIK is double the pyramid IFKHE. Therefore the parallelepiped on the base IFKH and under the height LN will be equal to the octahedron EFGHIK.

Furthermore, since the parallelepiped on the base IFKH and under the height BM is to the parallelepiped on the same base and under the height LN as the height BM is to the height LN, by the scholium to Proposition 14, Book 12 — and since, as BM is to LN, so is AB to EL (for as AM is to MB, so is EN to NL; and by composition, as AB is to BM, so is EL to LN; and therefore, alternately, as AB is to EL, so is BM to LN) — and since the parallelepiped on the base IFKH and under the height BM was shown to be equal to the cube ABCD, while the parallelepiped on the same base and under the height LN is equal to the octahedron EFGHIK: it follows that, as the cube ABCD is to the octahedron EFGHIK, so is AB, the cube's edge, to EL, the semidiameter of the sphere. Which was the point proposed to be demonstrated in the second place. Therefore the cube is to the octahedron inscribed in the same sphere with it, and so on. Which was to be shown.

Diagram. The first figure for Proposition 27: a cube with all its diagonals drawn to its center, beside an octahedron with all its diagonals drawn to its center. (The cube also appears, partly, at the foot)

- Cube ABCDEFGH, center P:
- F (top left), E (top right): upper front vertices.
- A (upper-left interior), D (upper-right interior): rear upper vertices.
- P (center): center of the cube, to which all vertices are joined.
- G (lower left), B (bottom left), C (bottom right): lower vertices.
- H (lower-right interior): rear lower vertex.
- Octahedron IKLMNO, center Q:
- I (top vertex), L (bottom vertex).
- K (left vertex), M (right vertex).
- N (upper interior), O (lower interior): the remaining two vertices.
- Q (center): center of the octahedron, to which all vertices are joined.

Diagram. The second figure for Proposition 27: a cube beside an octahedron drawn with interior lines.

- Cube ABCD:
- A (upper left), D (upper-right interior): upper vertices.
- M (mid left, marked with a tick): the point cutting off the third part AM of the edge AB.
- B (bottom left), C (bottom right): lower vertices.
- Octahedron EFGHIK:
- E (top vertex), G (bottom vertex): EG is the diameter.

- F (left vertex), H (right vertex).
- I (upper interior), K (lower interior): the two vertices flanking the axis.
- L (center, marked with a tick): the center of the octahedron and of the sphere.

SCHOLIUM.

[Margin (e): 13. tertijdec. — *Elements* XIII.13]

Since it has been demonstrated that the diameter of the sphere in which all five regular solids are inscribed is, in square, the sesquialter (3:2) of the tetrahedron edge — so that, if the square on the diameter be set at 3 parts, 2 of the same parts are the square on the tetrahedron edge — it is evident that, if from the square on a given diameter one takes away a square containing two-thirds of it (as we showed in the scholium to Proposition 33, Book 6), the side of this remaining square is the tetrahedron edge. Or again: if two equal squares be set up on [i.e. summing to] the square on the diameter, standing to one another in the ratio 2:1 (by the same scholium), the side of the larger square is the tetrahedron edge. For if from the square on the diameter, of 3 parts, one subtracts the square on the tetrahedron edge, of 2 parts, there necessarily remains a square of 1 part, to which the square on the tetrahedron edge has the ratio 2:1. So, if the diameter of the sphere be set as AB, from whose square one subtracts the square on the straight line AC, containing two-thirds of the square on the diameter AB; or if two squares on the straight lines AC and BC be set up equal to the square on the diameter AB, so that the square on AC is double the square on BC: then AC will be the tetrahedron edge.

[Margin (f): 14. tertijdec. — *Elements* XIII.14]

Again, since it has been shown that the diameter of the sphere is, in square, double the octahedron edge, it comes about that — if from the square on the diameter AB one removes the square on the straight line AD, which is half the square on the diameter AB; or if two squares on the straight lines AD and BD be set up equal to the square on the diameter AB and standing in a ratio of equality to one another, according to the teaching of the scholium to Proposition 33, Book 6 — the straight line AD is the octahedron edge.

[Margin (g): 15. tertijd. — *Elements* XIII.15]

Next, since we taught that the diameter of the sphere is, in square, triple the cube edge, it results that — if from the square on the diameter AB one takes away the square on the straight line BC, which is a third part of the square on the diameter

AB; or if on the square on the diameter AB two equal squares on the straight lines AC and BC be constructed, so that the square on AC is double the square on BC, according to the teaching of the same scholium to Proposition 33, Book 6 — the straight line BC is the cube edge. Or indeed, since the diameter AB has for its square both the tetrahedron edge and the cube edge, by Corollary 2 of Proposition 15, Book 13, it is manifest that if from the square on the diameter AB one takes away the square on the tetrahedron edge AC, the square on the cube edge BC is left; just as, conversely, if from the square on the diameter AB one removes the square on the cube edge BC, the square on the tetrahedron edge AC remains.

[Margin (h): 23. quartidecim. — *Elements* XIV.23]

Furthermore, since — if some straight line have for its square a whole straight line cut in extreme and mean ratio together with the greater segment of that line — the greater segment is the icosahedron edge of that sphere whose diameter is the former line: it is established that, if on the square on the diameter AB there be exhibited (according to what we demonstrated in the scholium to Proposition 33, Book 6) two equal squares on the straight lines AE and BE,

standing in the proportion that any straight line cut in extreme and mean ratio has to its greater segment: then the lesser line BE is the icosahedron edge.

[Margin (i): 23. quartidec. — *Elements* XIV.23]

Lastly, since — if some straight line have for its square a whole straight line cut in extreme and mean ratio together with the lesser segment of that line — the lesser segment is the dodecahedron edge of that sphere whose diameter is the former line: it is clear that, if on the square on the diameter AB there be set up two equal squares on the straight lines AF and BF, standing in the proportion that any straight line cut in extreme and mean ratio has to its lesser segment: then the lesser line BF is the dodecahedron edge.

Thus far, then, have Hypsicles, Campanus, and François de Foix, Count of Candale [Franciscus Candalla], written on the comparison of the regular solids inscribed in the same sphere. The following five propositions, bearing on the same matter, I have gathered from Cardano [Gerolamo Cardano], Book 5 of *On Proportions*, in the manner that here follows. Then, at the end of Book 16, I shall add some further matters that bear on the inscribing of these same five regular solids in a sphere and on their comparison.

Diagram. The figure for the Scholium: a fan of straight lines rising from a base line, illustrating the several squares compared in the text.

- A (bottom left) and B (bottom right): endpoints of the base line AB (the diameter).
- D, C, E, F (upper points, left to right): the upper endpoints of the lines drawn up from A (and toward B), marking the edges of the various regular solids compared (tetrahedron, cube, octahedron, icosahedron, dodecahedron).

THEOR. 28. PROPOS. 28.

If there are four straight lines in continued proportion, and also another four, such that the first term of all is the same: then the ratio of the third to the third will be the duplicate of the ratio of the second to the second; and the ratio of the fourth to the fourth will be the triplicate of that same ratio of the second to the second.

Let there be four straight lines A, B, C, D in continued proportion, and also four, A, E, F, G, such that A is the first term of all. I say that the ratio of C to F — of the third to the third — is the duplicate of the ratio of B to E, of the second to the second; and that the ratio of D to G — of the fourth to the fourth — is the triplicate of that same ratio of B to E, of the second to the second.

For since the straight line C, by Definition 10, Book 5, has to the straight line A the duplicate of the ratio of the straight line B to the straight line A; [Margin (a): 20. sexti. — *Elements* VI.20] and since the square on B also has to the square on A the duplicate of that same ratio of B to A: then, as C is to A, so is the square on B to the square on A. By the same reasoning, as F is to A, so is the square on E to the square on A; and, by inversion, as A is to F, so is the square on A to the square on E. Since, then, the square on B is to the square on A as C is to A, and the square on A is to the square on E as A is to F, it follows *ex aequo* that the square on B is to the square on E as C is to F.

square on B,
square on A.
square on E.

line C,
line A.
line F.

[Margin (b): 20. sexti. — *Elements* VI.20] But the ratio of the square on B to the square on E is the duplicate of the ratio of B to E. Therefore the ratio of C to F is likewise the duplicate of the ratio of B to E. Which is the first point.

Again, since the straight line D, by Definition 10, Book 5, has to the straight line A the triplicate of the ratio of B to A; [Margin (c): 33. vnde. — *Elements* XI.33] and since the cube on B also has to the cube on A the triplicate of that same ratio of B to A: then, as D is to A, so is the cube on B to the cube on A. By the same reasoning, as G is to A, so is the cube on E to the cube on A; and, by inversion, as A is to G, so is the cube on A to the cube on E. Since, then, the cube on B is to the cube on A as D is to A, and the cube on A is to the cube on E as A is to G, it follows *ex aequo* that the cube on B is to the cube on E as D is to G.

cube on B.	line D.
cube on A.	line A.
cube on E.	line G.

[Margin (d): 33. vnde. — *Elements* XI.33] But the ratio of the cube on B to the cube on E is the triplicate of the ratio of B to E. Therefore the ratio of D to G is likewise the triplicate of the ratio of B to E. Which is the second point. And so, if there are four straight lines, and so on. Which had to be demonstrated.

Diagram. The figure for Proposition 28: two sets of straight line-segments of differing lengths, laid out for the continued-proportion argument.

- A (short segment at the top center): the common first term of both series.
- B, C, D (left column, top to bottom): the remaining terms of the first series A, B, C, D.
- E, F, G (right column, top to bottom): the remaining terms of the second series A, E, F, G.

SCHOLIVM.

We demonstrated this same thing at Proposition 10, Book 8, concerning any number of numbers in two series of continued proportionals beginning from some one and the same number.

THEOR. 29. PROPOS. 29.

The square on the side of an equilateral triangle has to the triangle itself a ratio which is the duplicate of the ratio of the side of the triangle to the

mean proportional between the perpendicular drawn from one angle to the opposite side, and half of that side.

In the equilateral triangle ABC, from the angle A to the opposite side BC let the perpendicular straight line AD be drawn, which will bisect the side BC, as was demonstrated in the corollary to Proposition 12 of this book; and consequently BD is half of the side AB. [Margin (a): 13. sexti. — *Elements* VI.13] Let, then, the straight line E be found as the mean proportional between AD and BD. I say that the square on the side AB has to the triangle ABC a ratio which is the duplicate of the ratio of AB to the line E.

For since the triangle ABC is equal to the rectangle contained by AD and BD, as is evident from the scholium to Proposition 41, Book 1; [Margin (b): 17. sexti. — *Elements* VI.17] and since the square on E is equal to that same rectangle under AD and BD: the triangle ABC and the square on E will be equal. [Margin (c): 20. sexti. — *Elements* VI.20] And since the square on the side AB has to the square on E a ratio which is the duplicate of the ratio of AB to E, it is established that the square on the side AB has also to the triangle ABC a ratio which is the duplicate of the ratio of AB to E. For which reason, the square on the side of an equilateral triangle, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 29: an equilateral triangle with its altitude drawn, and a separate segment to the right.

- A (apex, top): the angle from which the perpendicular is drawn.
- B (bottom left), C (bottom right): the base vertices.
- D (midpoint of BC): the foot of the perpendicular AD, which bisects BC.
- E (a standalone vertical segment to the right): the mean proportional between AD and BD.

Book XIV — conclusion of Proposition 29 (Corollary)

COROLLARIUM

Therefore, if in an equilateral triangle a perpendicular is drawn from one angle to the opposite side, then the square on the straight line that is the mean proportional between that perpendicular and half the base is equal to the triangle itself. For it has been shown that the square on the straight line E — the mean proportional between AD and DB — is equal to the triangle ABC.

THEOR. 30. PROPOS. 30.

If a cube and a tetrahedron are described in the same sphere, then the square of the cube will be to the triangle of the tetrahedron as the side of the tetrahedron is to the perpendicular drawn from one angle of the tetrahedron's triangle to the opposite side.

Diagram. Two figures set side by side. On the left, a square ABCD — A upper-left, D upper-right, B lower-left, C lower-right — representing the square on the cube's side. Between the two figures stands a short vertical segment marked I (top) and K (below it), the mean proportional IK. On the right, a triangle EFG with apex E and base FG, and the perpendicular EH dropped from E to the base, meeting it at H (so the base reads F–H–G left to right).

- A (square, upper-left)
- D (square, upper-right)
- B (square, lower-left)
- C (square, lower-right)
- I / K (mean-proportional segment between the figures)
- E (triangle apex)
- F (base, left)
- H (foot of the perpendicular EH)
- G (base, right)

Let ABCD be the square on the side of any cube, and let EFG be the triangle of a tetrahedron described in the same sphere, in which the perpendicular EH is drawn from the angle E to the opposite side FG, bisecting the side FG (by the corollary to Proposition 12 of this book). I say that the square AC is to the triangle EFG as the side EF of the triangle is to the perpendicular EH.

For let IK be placed as the mean proportional between EH and FH. [Margin: a — *Elements* XIII.28] Since the square on the tetrahedron's side EF is double the square on the cube's side AB, [Margin: b — *Elements* VI.1] and is also double the rectangle contained by the side EF and half of it, FH — because that square and rectangle have the same height, namely EF — the rectangle contained by EF and FH will be equal to the square on the side AB. [Margin: c — *Elements* VI.17] Consequently AB will be the mean proportional between EF and FH; that is, the three straight lines FH, AB, EF are in continued proportion. But by construction the three straight lines FH, IK, EH are also in continued proportion. Therefore, since FH is the antecedent of both series, [Margin: d — *Elements* XIV.28] the ratio

of the straight line EF to the straight line EH — third term to third term — is the duplicate of the ratio of the straight line AB to the straight line IK, second term to second term. And since the square AC on the straight line AB likewise has, to the square on the straight line IK — that is, to the triangle EFG (for by the corollary to Proposition 29 of this book the square on IK is equal to the triangle EFG) — [Margin: e — *Elements* VI.20] a ratio that is the duplicate of the ratio of AB to IK, it follows that the square of the cube AC is to the triangle of the tetrahedron EFG as the side EF is to the perpendicular EH. And so, if a cube and a tetrahedron are described in the same sphere, and so on. Which was to be demonstrated.

THEOR. 31. PROPOS. 31.

The side of the tetrahedron, taken in square, is sesquialter to its own altitude; and the axis, or altitude, of the tetrahedron, taken in square, is sesquitercius to the side of the cube described in the same sphere.

Diagram. A circle with the inscribed triangle ABC — A at the top, B lower-left, C lower-right. D is the centre of the circle; from A the radius AD is drawn to the centre, and AE is drawn to the point E lying to the right (E, D and the base being joined so as to display the axis DE). Below the circle, set apart, is a short horizontal segment labelled F, standing for the side of the cube.

- A (triangle apex, top of circle)
- B (triangle, lower-left)
- C (triangle, lower-right)
- D (centre of the circle; foot of the axis)
- E (point to the right; end of AE / the axis DE)
- F (separate segment below — the side of the cube)

Let ABC be the triangle of a tetrahedron, DE its altitude or axis, and F the side of the cube of the same sphere. I say that the side AB of the tetrahedron is sesquialter in square to the axis DE, and that the axis DE is sesquitercius in square to the side F of the cube. For let a circle ABC be circumscribed about the triangle; [Margin: a — *Elements* IV.5] to its centre D — into which, as is clear from Proposition 15 of this book, the axis DE falls — let the radius AD be drawn, and AE, the side of the tetrahedron. Now since the square on the side AE — that is, on the side AB — [Margin: b — *Elements* I.47] is equal to the squares on the straight lines AD and DE, [Margin: c — *Elements* XIII.12] and is triple the square on the radius AD, it follows that, if the square on the side AB (or AE) is set at 6 parts, the square on the straight line AD is 2 of those same parts. Hence the remaining

square, that on the axis DE, is 4 such parts. Therefore the square on the tetrahedron's side is sesquialter to the square on the tetrahedron's axis.

And since the side AB of the tetrahedron [Margin: d — *Elements* XIII.18] is double in square to the side F of the cube, the square on the side F will be 3 parts of the kind of which the square on side AB was set at 6; but it has been shown that the square on the axis DE is 4 of the same. Therefore the square on the axis DE is sesquitercius to the square on the side F of the cube. And so the side of the tetrahedron is sesquialter in square, and so on. Which was to be demonstrated.

COROLLARIUM I.

Now since, when the square on the side AB is set at 6 parts, the square on the diameter of the sphere is 9 such parts — [Margin: e — *Elements* XIII.13] because the diameter is sesquialter in square to the side of the tetrahedron — while the square on the axis DE has been shown to be 4 of those same parts, it is evident that the diameter of the sphere is, in square, dupla-sesquiquarta (9 to 4) to the axis of the tetrahedron. And accordingly, [Margin: f — *Elements* VI.20] since squares have the duplicate ratio of their sides, it is plain that the diameter is sesquialter to the axis of the tetrahedron. For the duplicate of the sesquialter ratio is the dupla-sesquiquarta ratio, as appears in these numbers: 4, 6, 9. This too we taught in the second corollary to Proposition 13 of Book XIII.

COROLLARIUM II.

It is likewise established that the axis, or altitude, of the tetrahedron is to the side of the cube inscribed in the same sphere as the side of the tetrahedron is to the perpendicular drawn from one angle of the base to the opposite side. This is because [Margin: g — *Elements* XIV.12] the side of the equilateral triangle — that is, the side of the tetrahedron — is sesquitercius in square to the perpendicular drawn from one angle to the opposite side, just as, by this proposition, the axis of the tetrahedron itself is sesquitercius in square to the side of the cube.

LIBER XIV — THEOR. 32. PROPOS. 32.

The cube is triple the tetrahedron inscribed in the same sphere.

Diagram. Two solids drawn in oblique projection. On the left, a cube: its visible near corners are labelled B (upper-left) and C (upper-right, at the back), with A at the lower front; the remaining vertices are unlettered. On the right, a triangular prism DEFGHI standing on the triangular base DEF, of the same height as the tetrahedron: H is the top apex, I the upper-left corner and G the upper-right corner of the top triangle, F lies at the front centre, and D (lower-left) and E

(lower-right) mark the base, with the several internal diagonals of the prism drawn in.

- B (cube, upper-left)
- C (cube, upper-right/back)
- A (cube, lower front)
- H (prism, top apex)
- I (prism, upper-left)
- G (prism, upper-right)
- F (prism, front centre)
- D (prism base, lower-left)
- E (prism base, lower-right)

Let a cube ABC and a tetrahedron DEFG be described in the same sphere. I say that the cube is triple the tetrahedron. Upon DEF, the base of the tetrahedron, let a prism DEFGHI be set up, having the same height as the tetrahedron. [Margin: a — *Elements* XIV.30] Now since the base of the prism (that is, of the cube) ABC is to the base of the prism (that is, of the tetrahedron) DEF as the side of the tetrahedron is to the perpendicular drawn from any angle of the base DEF to the opposite side — and as the side of the tetrahedron is to that perpendicular, so too, by the second corollary to Proposition 31 of this book, is the altitude of the tetrahedron (and hence of the prism DEFGHI) to the side of the cube, and therefore to the altitude of the cube, that is, of the prism ABC — it follows that the base of the prism ABC is to the base of the prism DEFGHI as the altitude of the latter is to the altitude of the former. Consequently, by what we demonstrated at Proposition 9 of Book XII, the prisms ABC and DEFGHI are equal, since their bases and altitudes are reciprocally proportional. But the prism DEFGHI is triple the pyramid, that is, the tetrahedron DEFG, by the first corollary to Proposition 7 of Book XII. Therefore the cube ABC is likewise triple the same tetrahedron DEFG. And so the cube is triple the tetrahedron inscribed in the same sphere. Which was to be shown.

COROLLARIUM.

Hence a prism having the same base and altitude as the tetrahedron is equal to the cube described in the same sphere in which the tetrahedron is described; for it has been shown that the cube ABC is equal to the prism DEFGHI, and so on.

And the Fifth of the Solids, as some think; but, as others hold, **the Fifth Element of Hypsicles of Alexandria, On the Five Bodies.**

LIBER SECVNDVS. [Second Book.]

PROBL. 1. PROPOS. 1.

To describe a pyramid in a given cube.

Diagram. A cube ABCDEFGH drawn in oblique projection, with the inscribed tetrahedron (pyramid) ACGE traced by its face-diagonals. The vertices read: E at the upper-left (back), F at the upper-right (back), C at the right, D as the upper-left inner corner, G near the lower centre, H at the lower-left, A at the lower front, and B at the lower right. The diagonals EA, EG, EC and AG, GC, CA are drawn, forming the four equilateral triangles of the inscribed tetrahedron.

- E (cube, upper-left back; apex from which the three diagonals issue)
- F (cube, upper-right back)
- C (cube, right)
- D (cube, upper-left inner corner)
- G (cube, lower centre)
- H (cube, lower-left)
- A (cube, lower front)
- B (cube, lower right)

(Enunciation:) In a given cube to describe a pyramid, that is, a tetrahedron.

In the given cube ABCDEFGH it is required to describe a pyramid, that is, a tetrahedron. From one of its angles — namely from E — let three diagonals EA, EG, EC be drawn in the three bases that form it; and from the extremities A, G, C of these let diagonals AG, GC, CA likewise be drawn in the remaining three bases, connecting the ends of the three former diagonals. Now since the diagonals of equal squares are equal — because they are double in square to the sides of the equal squares, as we demonstrated in the scholium to Proposition 47 of Book I — it is evident that the four triangles ACE, GAC, GAE, GCE, composed of the said diagonals, are equilateral and equal to one another; and consequently a pyramid, that is, a tetrahedron, is formed from them. And since all the angles of the tetrahedron are set at the angles of the cube, it is manifest that it is inscribed in

the cube, by Definition 31 of Book XI. Therefore in the given cube we have described a pyramid. Which was to be done.

PROBL. 2. PROPOS. 2.

To describe an octahedron in a given pyramid.

Diagram. An equilateral triangle ABC — A at the apex, B lower-left, C lower-right — with the inscribed octahedron drawn from the midpoints of the tetrahedron's edges. The labelled points are: A (apex), E (mid-left), G (mid-right), H (upper centre), D (centre), I (lower-left), K (lower-right), and F (bottom centre), with B and C at the base corners. The twelve connecting straight lines are drawn, marking out the eight triangular faces of the octahedron.

- A (triangle apex)
- E (mid-left)
- G (mid-right)
- H (upper centre)
- D (centre)
- I (lower-left)
- K (lower-right)
- F (bottom centre)
- B (base, lower-left)
- C (base, lower-right)

(Enunciation:) In a given pyramid to describe an octahedron.

Let an octahedron be described in the pyramid, that is, the tetrahedron ABCD. When all the edges have been bisected at E, F, G, H, I, K, and the twelve straight lines EF, FG, GE, HI, IK, KH, EI, IF, FK, KG, GH, HE have been drawn, eight triangles will be formed: four of them — EHI, IHK, KHG, HGE — standing above the plane EIKG, and four others — IFE, EFG, GFK, KFI — below the same plane. Now since the sides AE, AH of the triangle AEH are equal to the sides AG, AH of the triangle AGH — being halves of the equal straight lines AB, AD, AC — and the contained angles EAH, GAH are likewise equal, being angles of the equilateral triangles ABD, ACD, [Margin: a — *Elements* I.4] the bases EH, GH will be equal. And by the same reasoning the straight lines EH, HI will be equal, and the rest in the same way. Therefore the said eight triangles are equilateral and equal to one another; and so they compose an octahedron EIGHF, which by Definition 31 of Book XI is described within the tetrahedron, since all its angles touch all the edges

of the tetrahedron, by construction. Therefore in the given pyramid we have described an octahedron. Which was to be done.

COROLLARY [to Proposition 2, continued]

Now the three planes EIKG, GHIF, FKHE are equal squares, cutting one another mutually at right angles, as we demonstrated in the first corollary to Proposition 14 of Book 13; and each of them cuts the pyramid ABCD in half. (For the square EIKG divides it into the pyramid HIKD and the prism HIKGAE, and again into the pyramid EBFH and the prism EFCGKI; and it is established [Margin: b — "8. duod." (Elements XII.8)] that the one pyramid is equal to the other, and the one prism to the other. In the same way the remaining squares GHIF and FKHE each divide the same pyramid ABCD in half.) It is therefore clear that, if an octahedron is inscribed in a tetrahedron, the tetrahedron is cut in half by three equal squares, which likewise cut the octahedron in half and intersect one another at right angles.

PROBL. 3. PROPOS. 3.

[Margin: iii.]

To inscribe an octahedron in a given cube.

Let the octahedron to be described be in the given cube AH. Let the sides of the base ABCD be bisected at the points I, K, L, M, and let these be joined by the straight lines IL and KM, which cut one another at N — a point that is the center of the square ABCD, as is clear from the demonstration of Proposition 8 of Book 4. Next, by the same reasoning let the centers O, P, Q, R, S of the remaining bases be found. Then all the straight lines drawn from the said centers to the midpoints of the bases — such as NI, RI, NK, SK, and so on — will be equal to the halves of the sides of the cube, that is, of its squares, as is evident from the aforesaid demonstration of Proposition 8 of Book 4.

Finally, if the said centers are joined by the twelve straight lines NO, OP, PQ, QR, RS, SN, NP, PR, RN, SO, OQ, QS, eight triangles will be constituted: four of them — NSR, RSQ, QSO, OSN — lie above the plane NOQR, while the other four — OPQ, QPR, RPN, NPO — lie below the same plane. Now the sides IN, IR of triangle INR are equal to the sides KN, KS of triangle KNS, since all are halves of equal sides of the cube, as has been said; and likewise the angles they contain are equal. For, since NI and IR are parallel to the straight lines BA and AF, [Margin: a — "10. vnde." (Elements XI.10)] the angle NIR is equal to the right angle KAF in the square AG; and by the same reasoning the angle NKS is equal to the right angle

IAF in the square AE. [Margin: b — "4. primi" (Elements I.4)] Therefore the bases NR and NS will be equal.

In no other way shall we show that all the remaining lines are equal both to one another and to these two — namely, if from the centers straight lines are drawn to the midpoints of the sides, under this rule: that any two are drawn to the midpoint of that side which is common to two squares of the cube, the two points from which the straight lines issue being the centers of those squares. For thus you see that the two straight lines NI, RI are drawn to I, the midpoint of the side AD, which is common to the squares AC and AE, whose centers are the points N and R; and likewise the two straight lines NK, SK are drawn to K, the midpoint of the side AB, which is common to the squares AC and AG, whose centers are the points N and S; and so on. For this reason the eight triangles, once constituted, are equilateral and equal to one another, and therefore they constitute the octahedron NOQRSP. And this, by Definition 31 of Book 11, is described within the cube, since all its six angles touch all six bases of the cube at their centers. We have therefore inscribed an octahedron in the given cube. Which was to be done.

Diagram. An oblique (cavalier) projection of the cube AH with the octahedron NOQRSP inscribed within it, its six vertices resting at the centers of the cube's six faces. The cube is drawn with its front-top-left corner at A and its network of face-diagonals and octahedron edges shown. Readable labels:

- A (top-left cube corner)
- F (top-center cube corner)
- E (right cube corner, mid-right)
- B (left cube corner, mid-left)
- C (bottom-left cube corner)
- H (bottom-right cube corner)
- G (bottom-center cube corner)
- D (interior, center — rear cube corner)
- I (upper interior, below A — base-edge midpoint)
- K (left interior — base-edge midpoint)
- L (lower-left interior — base-edge midpoint)
- M (bottom-center interior — base-edge midpoint)
- N (left-center interior — octahedron vertex / face-center)
- O (bottom-center interior — octahedron vertex)
- P (right-center interior — octahedron vertex)
- Q (right interior — octahedron vertex)

- R (upper-center interior, below F — octahedron vertex)
- S (center-left interior — octahedron vertex)

ALITER [Another way]

[Margin: c — "2. quintidec." (Elements XV.2)] Let a pyramid be inscribed in the given cube; [Margin: d — "1. quintidec." (Elements XV.1)] then let an octahedron be figured within this pyramid, and what was proposed will have been accomplished. For since, by the demonstration of Proposition 2 of this book, the angles of the octahedron touch the edges of the pyramid, while the edges of the pyramid, by the demonstration of Proposition 1 of this book, lie in the planes of the cube's bases (being the diagonals of those bases), it is evident that the angles of the octahedron also touch the bases of the cube; and thus the octahedron is inscribed in the cube.

COROLLARY

Now the diameters of the octahedron described in the cube, NQ and RO (were they to be drawn), cut one another mutually at right angles, by the first corollary to Proposition 14 of Book 13 — these being the lines that join the centers of the cube's opposite bases. It is therefore clear that the straight lines connecting the centers of the cube's opposite bases not only bisect one another mutually, as we taught in the first corollary to Proposition 15 of Book 13, but also divide one another at right angles, as we here show.

PROBL. 4. PROPOS. 4.

[Margin: iv.]

To inscribe a cube in a given octahedron.

Let the given octahedron be ABCDEF, in which a cube is to be described. Since an octahedron contains six quadrangular pyramids — whose vertices are the six solid angles of the octahedron, and any two of which constitute the octahedron — let one of them be the pyramid ABCDE, whose base ABCD is a square and whose triangles ABE, EBC, CED, DEA are equilateral; and let the centers of these triangles be G, H, I, K, through which are drawn the straight lines LM, MN, NO, OL parallel to the sides AB, BC, CD, DA. Then the triangles LME, EMN, NEO, OEL will also be equilateral, since they are similar to the equilateral triangles ABE, EBC, CED, DEA, by the corollary to Proposition 4 of Book 6,

and hence equal to one another, because they have their sides in common. For EM is the side common to the triangles LME and EMN; EN is common to the triangles EMN and NEO; and lastly EO is common to the triangles NEO and OEL. Hence it comes about that triangle LME is equal to triangle EMN, this to NEO, and this to OEL. For the straight lines LM, MN, NO, OL meet at the points L, M, N, O, as we shall show presently. Therefore the four straight lines LM, MN, NO, OL are also equal to one another. [Margin: a — "18. quartidec." (Elements XIV.18)] Now since the straight line EK, drawn through P, is triple the line KP, [Margin: b — "2. sexti" (Elements VI.2)] and as EP is to KP, so is EA to LA, EA too will be triple the line LA. By the same reasoning EB, EC, ED will be triple the lines MB, NC, OD. Therefore the straight lines LM, MN, NO, OL will meet at the points L, M, N, O, at which the sides are cut in that proportion, and they will constitute the quadrilateral LMNO.

Again, since LO and LM are parallel to the straight lines AD and AB, though not lying in the same plane with them, [Margin: c — "10. vn de." (Elements XI.10)] the angle MLO will be equal to the angle BAD, which is a right angle (since ABCD is a square, as we showed in the first corollary to Proposition 14 of Book 13 and in Proposition 16 of Book 14). And therefore the angle MLO too will be a right angle. In just the same way we shall demonstrate that the remaining angles LMN, MNO, NOL are right angles. Now since both the plane drawn through LO, LM and that drawn through NM, NO [Margin: d — "15. vn de." (Elements XI.15)] are parallel to the plane ABCD, [Margin: e — "15. vn de." (Elements XI.15)] they themselves, since they meet at the points M and O, will make one plane, by the scholium to Proposition 16 of Book 11. Therefore LMNO will be a square, since it has both equal sides and right angles.

Next, since the sides EL, EK of triangle ELK are equal to the sides EO, EK of triangle EOK, and the angles contained by them are likewise equal — because the straight line EK, drawn from the angle E through the center K of the equilateral triangle EAD, bisects the angle AED, by the corollary to Proposition 12 of Book 13 — [Margin: f — "4. prim." (Elements I.4)] the bases KL, KO will also be equal; that is, the straight line LO will be bisected at K. By the same reasoning LM, MN, NO will be bisected at G, H, I. And therefore the straight lines GL, GM, HM, HN, IN, IO, KO, KL, being halves of the sides of the square LN, will be equal to one another; and hence, since they also contain equal angles — namely right angles — [Margin: g — "4. prim." (Elements I.4)] the straight lines GH, HI, IK, kG connecting the centers G, H, I, k will likewise be equal. Now since these straight lines lie in the plane of the square LN and comprehend right angles — (for since the angles LkG, GkI, IkO are together equal to two right angles, [Margin: h — "13. prim."])

(Elements I.13)] while LkG and IkO are each half a right angle, by the second corollary to Proposition 32 of Book 1, the angle GkI will be a right angle; and by the same reasoning the angles kGH, HIk will be right angles) — GHIk will be a square, since it has both equal sides and right angles.

And if by the same art the centers of the triangles are joined by straight lines in the remaining five pyramids of the octahedron, squares will likewise be described; and since these have their sides in common, they will be equal to one another. Therefore six squares of this kind will compose a cube, which, by Definition 31 of Book 11, will be described within the octahedron, since its eight angles touch the eight bases of the octahedron at their centers. Therefore we have described a cube in the given octahedron. Which was to be done.

Diagram. The octahedron ABCDEF drawn upright, with the apex E at top and F at bottom and the square ABCD across the middle; the cube (whose upper face is the square GHIk) is inscribed with its eight vertices at the centers of the octahedron's eight triangular faces. Numerous face-medians and cube edges are drawn.

Readable labels:

- E (top apex)
- F (bottom apex)
- A (left vertex of the middle square)
- D (right vertex of the middle square)
- B (lower-left vertex)
- C (lower-right vertex)
- I (upper-left interior — triangle center)
- K (upper-center interior — triangle center)
- O [?] (upper-right interior — triangle center; glyph could be O or Q)
- G (interior, left of center)
- P (center)
- I [?] (interior, right of center — a second I-glyph; reading uncertain)
- M (lower-left interior)
- H (lower-center interior)
- N (lower-right interior)

PROBL. 5. PROPOS. 5.

[Margin: v.]

To inscribe a dodecahedron in a given icosahedron.

Of the twelve pentagonal pyramids contained in the icosahedron — whose bases are pentagons composed of five sides of the icosahedron, and whose vertices are the twelve solid angles of the icosahedron — let one pyramid be ABCDEF, whose base is the pentagon ABCDE and whose equilateral triangles are ABF, BCF, CDF, DEF, EAF; and let the centers of these triangles be G, H, I, K, L, which are connected by the straight lines GH, HI, IK, KL, LG. Again, from the vertex F, let the straight lines FM, FN, FO, FP, FQ be dropped through the centers of the triangles; these, by the scholium to Proposition 12 of Book 13, will bisect the sides AB, BC, CD, DE, EA at M, N, O, P, Q, so that the ten straight lines MA, MB, NB, NC, OC, OD, PD, PE, QE, QA are equal; and since they comprehend equal angles — namely the angles of the pentagon — [Margin: a — "4. prim." (Elements I.4)] the straight lines MN, NO, OP, PQ, QM connecting the points M, N, O, P, Q will also be equal. [Margin: b — "8. primi" (Elements I.8)] And accordingly the angles MFN, NFO, OFP, PFQ, QFM will be equal, because the sides FM, FN, FO, FP, FQ are also equal — being the perpendiculars dropped from the angles of equal equilateral triangles to the opposite bases. For since the sides FB, BM of triangle FBM are equal to the sides FB, BM of triangle FBM, and contain equal angles — namely those of equilateral triangles — [Margin: c — "4. primi" (Elements I.4)] the bases FM, FN will be equal; and so with the rest. And since the straight lines FG, FH, FI, FK, FL — namely the radii of the equal circles that circumscribe the equal equilateral triangles — are equal and comprehend equal angles, as has been demonstrated,

[Margin: d — "4. prim." (Elements I.4)] the straight lines GH, HI, IK, KL, LG will also be equal. [Margin: e — "13. prim." (Elements I.13)] Again, since both the angles AMQ, QMN, NMB and the angles BNM, MNO, ONC are equal to two right angles, [Margin: f — "4. primi" (Elements I.4)] and the angles AMQ, NMB are equal to the angles BNM, ONC, the remaining angles QMN, MNO will be equal; and by the same reasoning the remaining angles NOP, OPQ, PQM will be equal both to one another and to these. Therefore the pentagon MNOPQ, lying in the plane of the pentagon ABCDE, will be equilateral and equiangular. Finally, since the straight lines FM, FN, FO, FP, FQ are cut proportionally at G, H, I, K, L — because FG, FH, FI, FK, FL, drawn from the centers, are equal; or indeed because FG, FH, FI, FK, FL are double GM, HN, IO, KP, LQ, by the corollary to Proposition 18 of Book 14 — [Margin: g — "2. sexti" (Elements VI.2)] GH, HI, IK, KL, LG will be parallel to MN, NO, OP, PQ, QM; [Margin: h — "10. vnde." (Elements XI.10)] and therefore the angles LGH, GHI, HIK, IKL, KLG will be equal to the equal angles QMN, MNO, NOP, OPQ, PQM, and hence equal to one another. [Margin: i — "15. vnde." (Elements XI.15)] Now since the planes drawn through GH, HI and through HI, IK are parallel to the plane of the pentagon MNOPQ drawn through MN, NO,

OP, and meet in the straight line HI, they will make one plane, by the scholium to Proposition 16 of Book 11. In the same way we shall show that the planes drawn through Ik, kL and through kL, LG, as well as through LG, GH, constitute the same plane with the plane drawn through GH, HI, Ik. Therefore GHIkL is an equilateral and equiangular pentagon, since it has both equal sides and equal angles.

And if by the same art the centers of the triangles are connected by straight lines in the remaining eleven pyramids of the icosahedron, equilateral and equiangular pentagons will likewise be described; and since these have their sides in common, they will be equal to one another. For this reason twelve pentagons of this kind will constitute a dodecahedron, which, by Definition 31 of Book 11, will be described in the icosahedron, since the twenty angles of the dodecahedron rest at the centers of the icosahedron's twenty bases. Therefore we have described a dodecahedron in the given icosahedron. Which was to be done.

Diagram. The same icosahedron figure that is fully described at fig-p597-1 below, printed again at the foot of this page: the pentagon ABCDE with its five triangles meeting at the central vertex F, the triangle-centers G, H, I, k, L, and the inner pentagon MNOPQ that forms one face of the inscribed dodecahedron. (Labels as in fig-p597-1.)

COROLLARY

Therefore, since all the straight lines from the center of the icosahedron to the centers of the bases — that is, to the angles of the dodecahedron inscribed in it — are equal (for, by the corollary to the first lemma of Proposition 10 of Book 14, they are perpendicular to the planes of the equal circles that circumscribe the bases of the icosahedron, and so their distances stand from the center of the sphere, or of the icosahedron; and they will be equal to one another, by the second lemma of the same Proposition 10 of Book 14) — the center of the icosahedron and of the dodecahedron inscribed in it will be one and the same.

Diagram. A plane projection of one pentagonal pyramid of the icosahedron seen from above its apex: the outer regular pentagon ABCDE with apex-vertex A at the top, the central point F (the projected apex of the pyramid), the five triangle-centers G, H, I, k, L around F, and the inner pentagon MNOPQ (with M, N, O, P, Q at the midpoints of the outer pentagon's sides) which is one face of the inscribed dodecahedron. The pentagon is filled with the connecting radii and diagonals. Readable labels:

- A (top apex of the outer pentagon)
- M (upper-left vertex, outer pentagon)

- Q (upper-right vertex, outer pentagon)
- B (left vertex, outer pentagon)
- E (right vertex, outer pentagon)
- C (bottom-left vertex, outer pentagon)
- O (bottom-center vertex, outer pentagon)
- D (bottom-right vertex, outer pentagon)
- F (center — projected pyramid apex)
- G (interior, upper-left — triangle center)
- L (interior, upper-right — triangle center)
- H (interior, lower-left — triangle center)
- k (interior, lower-right — triangle center)
- I (interior, lower-center — triangle center)
- N (lower-left interior — inner-pentagon vertex)
- P (lower-right interior — inner-pentagon vertex)

PROBL. 6. PROPOS. 6.

[Margin: vi.]

To describe a pyramid in a given octahedron.

Let the pyramid to be described be in the octahedron ABCDEF. In the upper pyramid of the octahedron, ABCDE, take G and H, the centers of the mutually opposite corresponding triangles AED, BEC; likewise in the lower pyramid ABCDF take I and k, the centers of the triangles CFD, AFB, which also correspond to one another oppositely. Let these centers be joined by the six straight lines GH, GI, Gk, HI, Hk, Ik, so that the pyramid HIkG is formed. Next, from A let the straight lines AL, AM be dropped through the centers G, k, cutting the opposite edges of the octahedron DE, BF in half at L and M, by the scholium to Proposition 12 of Book 13; and let the straight line LM be joined. [Margin: a — "33. primi" (Elements I.33)] This will be equal and parallel to BE, or to FD, since EL, BM, and likewise DL, FM, are equal and parallel straight lines — namely the halves of the sides DE, BF, which lie opposite in the square EF. Now since the straight lines AL, AM are cut proportionally at the points G and k — because AG, Ak are double GL, kM, by the corollary to Proposition 18 of Book 14 — [Margin: b — "2. sexti" (Elements VI.2)] Gk and LM will be parallel; and therefore, by the corollary to Proposition 4 of Book 6, the triangles ALM, AGk are similar. [Margin: c — "4. sexti" (Elements VI.4)] Hence, as AL is to LM, so is AG to Gk; and, alternately, as AL is to AG, so is LM to Gk. But AL is one and a half times AG, [Margin: d — "18. quartidec."]

(Elements XIV.18)] because GL is a third part of AL, and so AG is two thirds of the same AL. Therefore LM also — that is, its equal DF — will be one and a half times Gk.

By this same art we shall show that the remaining lines joining the centers G, H, I, k are one and a half times the edges of the octahedron; and accordingly that the straight lines composing the pyramid HIKG are equal to one another — that is, that equilateral and equal triangles are formed from them, and so a tetrahedron is constituted. And this, since it has all its angles at the centers of the four bases of the octahedron, will be described in the octahedron, by Definition 31 of Book 11. Therefore we have described a pyramid in the given octahedron. Which was to be done.

Diagram. A projection of the octahedron ABCDEF (drawn as the square ABCD with the apexes E and F shown among the interior points) with the pyramid — the inscribed tetrahedron HIKG whose vertices lie at the centers of four of the octahedron's faces. The square is crossed by the full set of face-diagonals and tetrahedron edges. Readable labels:

- A (top-left square corner)
- D (top-right square corner)
- B (bottom-left square corner)
- C (bottom-right square corner)
- G (upper-center interior — triangle center / tetrahedron vertex)
- L (right interior, upper — edge midpoint)
- E (right-center interior — octahedron apex)
- I (right-center interior, near E — triangle center)
- k (left interior — triangle center)
- F (center interior — octahedron apex)
- M (lower-left interior — edge midpoint)
- H (bottom-center interior — triangle center)

ALITER [Another way]

[Margin: e — Elements XV.4] Let a cube be inscribed in the given octahedron, [Margin: f — "1. quintidecim." (Elements XV.1)] and in the cube a pyramid, and what is proposed will have been accomplished. For since the angles of the cube rest at the centers of the octahedron's bases, and the angles of the pyramid are placed at the angles of the cube, it is evident that the angles of the pyramid touch

the bases of the octahedron at their centers; and therefore the pyramid is inscribed in the octahedron.

COROLLARIVM I.

(continuation — Corollary I to Proposition 6 of Book XV)

Since it has been shown that both GK and DF are parallel to LM [Margin: g — Elements XI.9], GK is therefore parallel to DF, and so also to BE. By the same reasoning KH is parallel to FC and to EA [Margin: h — Elements XI.15].

Consequently the plane GKH, drawn through GK and KH, is parallel to the plane DFC through DF and FC, and likewise to the plane BEA through BE and EA. In the same way the remaining triangular faces of the pyramid are parallel to the remaining triangular faces of the octahedron, each single face to two of them. It is therefore established that, if a tetrahedron is inscribed in an octahedron, the four faces of the tetrahedron are parallel to the eight faces of the octahedron — each single face parallel to two opposite ones.

COROLLARIVM II.

Moreover, since the octahedron circumscribes both the cube and the tetrahedron inscribed in the cube — because the tetrahedron's angles are set at the cube's angles, and the cube's angles at the centers of the octahedron's faces — the straight line joining the centers of the octahedron's opposite faces is the diameter of the cube; that is, the diameter of the sphere that circumscribes both the cube and the tetrahedron inscribed in it, as is clear from Prop. 4 of this book. Now the diameter of the sphere is one and a half times [*sesquialter*] the axis of the tetrahedron inscribed in that sphere, by Coroll. 1 of Prop. 31, Book 14, or by Coroll. 2 of Prop. 13, Book 13. It is therefore manifest that, if a tetrahedron is inscribed in an octahedron, the straight line joining the centers of the octahedron's opposite faces is one and a half times the axis of the tetrahedron — that is, of the perpendicular drawn from an angle of the tetrahedron to the opposite face.

PROBL. 7. PROPOS. 7. [Margin: o. vii.]

In a given dodecahedron to inscribe an icosahedron.

Let a half of the dodecahedron, in which the icosahedron is to be inscribed, be contained by the six pentagons ABLPK, PKIHO, OHGFN, NFEDM, MDCBL, LMNOP, whose centers are Q, R, S, T, V, X. Let each two neighbouring centers be joined by

the straight lines QR, RS, ST, TV, VQ, QX, RX, SX, TX, VX. From the angles K and D, which the straight lines AP and CM subtend, let the lines KY and DY be drawn through the centers Q and R; by Coroll. 2 of Prop. 10, Book 13, these will bisect the opposite side BL at right angles, and will therefore meet at the point Y. The same lines YK and YD also bisect the lines AP and CM at right angles, at α and β , by Coroll. 1 of the same proposition — and they likewise bisect the arcs AKP and CDM of the circles described about the pentagons [Margin: a — Elements III.28] (for the straight lines AK and PK, and likewise CD and MD, subtend equal arcs). Therefore $A\alpha$ and $C\beta$ are parallel to the line BY [Margin: b — Elements I.28], and so also parallel to each other [Margin: c — Elements XI.9]. They are moreover equal, being the halves of the lines AP and CM [Margin: d — Elements I.4], which are equal, since the sides KA, KP are equal to the sides DC, DM and contain equal angles. The straight lines AC and $\alpha\beta$ that connect them will therefore be equal and parallel [Margin: e — Elements I.33].

We shall show it no differently if, from the angles B and F, which the lines CL and EN subtend, the lines FZ and EZ are drawn through the centers R and S, and the lines CE and $\gamma\delta$ are connected: these CE and $\gamma\delta$ will be equal. Now AC and CE are equal to one another, since they contain equal angles enclosed by equal lines. (For both the dodecahedron's sides AB, BC and the sides CD, DE contain the angle of an equiangular pentagon, as is clear from any material dodecahedron. These angles, however, do not incline toward X, as the figure seems to show, but outward, as is evident from the same material dodecahedron.) Therefore $\alpha\beta$ and $\gamma\delta$ will also be equal.

Consequently, since the lines $Y\alpha$, $Y\beta$, $Z\gamma$, $Z\delta$ are equal [Margin: f — Elements I.4] — for YQ, YR, ZR, ZS, being perpendiculars, are the distances of the equal lines BL, DM from the centers Q, R, S of equal circles (which of course circumscribe equal pentagons), and are therefore equal [Margin: g — Elements III.14]; likewise $Q\alpha$, $R\beta$, $R\gamma$, $S\delta$ are the distances of the equal lines AP, CM, CL, EN from the centers of those same equal circles, and are therefore equal [Margin: h — Elements III.14]; and hence the whole lines $Y\alpha$, $Y\beta$, $Z\gamma$, $Z\delta$ will be equal — the angles $\alpha Y\beta$ and $\gamma Z\delta$ will also be equal [Margin: i — Elements I.8]. And therefore, since the lines YQ, YR, ZR, ZS are also equal, the lines QR and RS joining the centers Q, R, S will likewise be equal [Margin: k — Elements I.4]. By exactly the same method all the lines joining the centers of the pentagons will be shown equal. Hence the triangles QXR, RXS, SXT, TXV, VXQ, formed beneath the five solid angles L, M, N, O, P of the dodecahedron, will be equilateral and equal. And if in like manner triangles of the same sort are formed beneath the remaining fifteen solid angles of the dodecahedron (for the dodecahedron has twenty solid angles), triangles

which share their sides in common, then an icosahedron will have been inscribed within the dodecahedron, since the twelve solid angles of the icosahedron rest at the centers of the twelve faces of the dodecahedron. Thus in the given dodecahedron we have inscribed an icosahedron. Which was to be done.

Diagram. A dense plane projection of an icosahedron inscribed in a dodecahedron. The outer figure is a dodecahedral outline; a lattice of chords marks the inscribed icosahedron and the auxiliary construction lines of the proof. The labelling is very crowded and many interior letters overlap the ruled lines.

- A (top): apex vertex
- B (upper left): dodecahedron vertex
- K (upper right): dodecahedron vertex
- C (left): dodecahedron vertex
- D (lower left): dodecahedron vertex
- E (bottom left): dodecahedron vertex

- α (near top, right of Q): bisection point of AP
- β (center left, near R): bisection point of CM
- γ (center left): bisection point

- δ (center, near S): bisection point

[Several interior labels overlap the construction lines and cannot be resolved with confidence]

PROBL. 8. POPROS. 8. [Margin: o. viii.]

In a given dodecahedron to inscribe a cube.

Let four pentagons of the dodecahedron in which the cube is to be inscribed be set out — ABCDE, EFGHA, AHIKB, BKLMC — meeting at the side AB: two of them, ABCDE and ABKIH, along the same common side AB; the other two, AEFGH and BCMLK, along the angles EAH and CBK. In these pentagons let the straight lines EH, CK, CE, HK subtend the angles A, B, D, I, forming the quadrilateral EHKC, which will be equilateral. For since all the sides AE, AH, DE, DC, BC, BK, IH, IK are equal and contain equal angles, by hypothesis, the bases EH, HK, KC, CE will be equal [Margin: a — Elements I.4]. Now since the equal straight lines AE and BC cut off equal arcs from the circle circumscribing the pentagon ABCDE [Margin: b — Elements III.28], the lines AB and CE will be parallel, by the scholium to Prop. 27, Book 3. By the same reasoning AB and HK will be parallel. Therefore EC and HK will also be parallel to each other [Margin: c — Elements XI.9]; and consequently the lines EH and CK that join them will be parallel [Margin: d — Elements I.33], and lie in the same plane with them [Margin: e — Elements XI.7]. So EHKC will be a parallelogram, which we have shown to be equilateral.

And since the plane ECKH, produced, makes its common section with the sphere a circle — by Lemma 1 of Prop. 10, Book 14 — described about the quadrilateral EK, both the opposite angles E, K and the opposite angles C, H will be equal to two right angles [Margin: f — Elements III.22]. Therefore, since the opposite angles E and K are equal, and likewise the opposite C and H [Margin: g — Elements I.34], all four angles E, C, K, H will be right. Hence EK will be a square, placing its angles at four angles of the dodecahedron and its sides in the planes of four pentagons of the dodecahedron. If then in the remaining eight pentagons eight other straight lines are similarly drawn to subtend eight angles in the same order, a solid contained by six squares will be constituted. And since these squares are equal — because their sides, which subtend equal angles of the pentagons contained by equal straight lines, are equal [Margin: h — Elements I.4] — they will constitute a cube inscribed within the dodecahedron, since its twelve edges lie in the planes of twelve pentagons of the dodecahedron, and its eight angles

rest at eight angles of the dodecahedron. Thus in the given dodecahedron we have inscribed a cube. Which was to be done.

Diagram. A plane projection of a cube inscribed in a dodecahedron. The outer hexagonal outline represents the dodecahedron; the inner heavy square-faced figure is the inscribed cube EHKC with its further vertices.

- F (top left): dodecahedron vertex
- G (top right): dodecahedron vertex
- E (upper left): cube vertex
- H (upper right): cube vertex
- A (center, upper): cube vertex
- D (left): dodecahedron vertex
- B (center, lower): cube vertex
- C (lower left): cube vertex
- K (lower right): cube vertex
- I (right): dodecahedron vertex
- M (bottom left): dodecahedron vertex
- L (bottom right): dodecahedron vertex

COROLLARIUM.

From this it follows that the straight line subtending one angle of an equilateral and equiangular pentagon is parallel to the opposite side. For it has been shown that CE is parallel to AB.

PROBL. 9. PROPOS. 9. [Margin: o. ix.]

In a given dodecahedron to inscribe an octahedron.

In the dodecahedron in which the octahedron is to be inscribed, take those six edges that we said are opposite in Coroll. 3 of Prop. 17, Book 13 — namely AB, CD, EF, GH, IK, LM — and let them be bisected at N, O, P, Q, R, S. Then the straight lines NO, PQ, RS, which join the bisections of the opposite edges, will be equal, and will bisect one another at T, the center of the sphere, at right angles, by Coroll. 3 of Prop. 17, Book 13. Their halves NT, OT, PT, QT, RT, ST will therefore also be equal. Consequently the twelve straight lines that subtend the twelve right angles NTP, PTO, OTQ, QTN, NTR, RTP, PTS, STQ, QTR, RTO, OTS, STN — namely NP, PO, OQ, QN, NR, RP, PS, SQ, QR, RO, OS, SN — will be equal, since the said angles are contained by equal straight lines [Margin: a — Elements I.4]. Hence the

eight triangles NRP, PRO, ORQ, QRN, OSP, PSN, NSQ, QSO will be equilateral and equal, and will constitute an octahedron inscribed within the dodecahedron, since the six angles of the octahedron touch six opposite edges of the dodecahedron, by construction. Thus in the given dodecahedron we have inscribed an octahedron. Which was to be done.

Diagram. A plane projection of an octahedron inscribed in a dodecahedron. The octahedron NOPQRS has its center at T, with the six vertices resting on the midpoints of six opposite edges of the surrounding dodecahedron ABCDE...LM.

- A (top left), N (top center), B (top right): N is the top octahedron vertex
- E (left), R (upper interior): dodecahedron / octahedron vertices
- P (left interior): octahedron vertex
- I (right): dodecahedron vertex
- T (center): center of the octahedron/sphere
- M (center interior): octahedron vertex
- G (right), Q (right interior): Q is a side octahedron vertex
- F (lower left): dodecahedron vertex
- S (lower interior): octahedron vertex
- L (lower interior): dodecahedron vertex
- C (bottom left), O (bottom center), D (bottom right): O is the bottom octahedron vertex
- H (right): dodecahedron vertex

[A small interior label near the top (read as "k") could not be resolved; the octahedron/dodecahedron letters are otherwise legible]

PROBB. 10. PROPOS. 10. [Margin: o. x.]

In a given dodecahedron to inscribe a pyramid.

Let the dodecahedron be contained by the twelve pentagons ABCNL, CDEPN, EFGRP, GHITR, IKALT, MOQSV, BCDOM, DEFQO, FGHSQ, HIKVS, KABMV, LNPRT, in which a pyramid, or tetrahedron, is to be inscribed. Take the three pentagons ABCNL, LAKIT, TLNPR that make up the solid angle L, in which are the three angles C, R, K — of these, C is opposite the side AL common to the pentagons CAL and ALI; K is opposite the side LT common to the pentagons KLT and LTP; and finally R is opposite the side LN common to the pentagons RLN and LNB. Let these angles be connected by the straight lines CK, CR, KR; and from the points C, K, R let the straight lines CQ, KQ, RQ be drawn to the angle Q opposite L, so that the

pyramid CKRQ is constructed. Now let the three diameters of the dodecahedron, or of the sphere, CH, KE, RM be drawn, and let the straight lines KH, RH, RE, QE, QM, QH be connected. Since the dodecahedron is described in a sphere [Margin: a — Elements XIII.17], if the plane of the triangle CHK is extended, its common section with the sphere will be a circle, by Lemma 1 of Prop. 10, Book 14. And therefore the angle CKH, standing in a semicircle, will be right [Margin: b — Elements III.31]. We shall show in the same way that the angles CRH, KRE, KQE, RQM, CQH are right.

Consequently — since in every right-angled triangle the square on the side opposite the right angle is equal to the squares on the sides about the right angle [Margin: c — Elements I.47], and since the squares of the equal diameters CH, KE, RM are equal — the squares of the lines CK, KH will be equal to the squares of the lines CR, RH, and to the squares of the lines kR, RE, and to the squares of the lines kQ, QE, and to the squares of the lines RQ, QM, and also to the squares of the lines CQ, QH. Therefore, when the equal squares of the equal lines kH, RH, RE, QE, QM, QH are taken away (for these lines, since they subtend equal angles of the pentagons contained by equal straight lines, are equal [Margin: d — Elements I.4]), the squares of the lines Ck, CR, Rk, kQ, RQ, CQ will remain equal; and hence the lines themselves will be equal. Therefore the four triangles CkR, CkQ, kRQ, RCQ are equilateral and equal, and so make up the tetrahedron CkRQ; and since this has its four angles C, k, R, Q at four angles of the dodecahedron, it will be inscribed within the dodecahedron.

ALITER. In the proposed dodecahedron let a cube be inscribed [Margin: e — Elements XV.8]; and in this cube a pyramid [Margin: f — Elements XV.1]; and what is proposed will be accomplished. For since the angles of the pyramid rest at the angles of the cube, and the angles of the cube at the angles of the dodecahedron, it is evident that the angles of the pyramid have their seat at the angles of the dodecahedron. Therefore the pyramid will be inscribed in the dodecahedron. And so in the given dodecahedron we have inscribed a pyramid. Which was to be done.

Diagram. A very dense plane projection of a pyramid (tetrahedron) inscribed in a dodecahedron. The outer figure is the dodecahedral outline; a heavy web of chords marks the inscribed tetrahedron CkRQ together with the diameters CH, KE, RM and the numerous auxiliary connecting lines of the proof. Many interior labels overlap the ruled lines.

- A (top): dodecahedron vertex
- B (upper left): dodecahedron vertex

- K (upper right): tetrahedron vertex
- C (left): tetrahedron vertex
- D (lower left): dodecahedron vertex
- E (bottom, left of center): dodecahedron vertex
- F (bottom): dodecahedron vertex
- G (lower right): dodecahedron vertex
- H (right): dodecahedron vertex
- I (right): dodecahedron vertex
- T (upper right, interior): dodecahedron vertex
- S (right of center): dodecahedron vertex
- M (center, upper): interior label / pentagon center
- N (center left): interior label
- O (center): interior label
- P (center, lower): interior label
- L (center, upper): solid-angle vertex of the three chosen pentagons
- V (upper right, interior): interior label
- R (center, lower right): tetrahedron vertex
- Q (center, lower): tetrahedron vertex (opposite L)

[The interior of this figure is heavily overwritten by construction lines and several labels (M, N, O, P, L, V, R) cannot be fixed with confidence]

PROBB. 11. PROPOS. 11. [Margin: o. xi.]

In a given icosahedron to inscribe a cube.

In the given icosahedron let a dodecahedron be inscribed [Margin: a — Elements XV.5]; and in this dodecahedron a cube [Margin: b — Elements XV.8]; and what is proposed will be accomplished. For since the angles of the cube rest at the angles of the dodecahedron, and the angles of the dodecahedron are set at the centers of the faces of the icosahedron, the angles of the cube will touch those same centers of the icosahedron's faces. Therefore the cube will be inscribed in the icosahedron. Accordingly, in the given icosahedron we have inscribed a cube. Which was to be done.

PROBL. 12. PROPOS. 12. [Margin: o. xii.]

In a given icosahedron to inscribe a pyramid.

In the given icosahedron let a cube be inscribed [Margin: a — Elements XV.11], and in this cube a pyramid [Margin: b — Elements XV.1]; and what is proposed will be accomplished. For since the angles of the cube touch the centers of the icosahedron's faces [Margin: c — Elements XV.11], and the angles of the pyramid coincide with the angles of the cube, it is manifest that the angles of the pyramid reach the centers of those same faces of the icosahedron [Margin: d — Elements XV.1]; and consequently the pyramid is inscribed in the icosahedron. Thus in the given icosahedron we have inscribed a pyramid. Which was to be done.

THEOR. 13. PROPOS. 13.

In a given cube to inscribe a dodecahedron.

[Margin: Ducatur in figura recta HaC — "Let the straight line HaC be drawn in the figure"]

Let a dodecahedron be inscribed in the proposed cube AF. Let each of its edges be bisected at I, k, L, M, N, O, P, R, π , ξ , Z, Y. Draw the connecting straight lines IL, YZ, ξ O, M π , kP, NR, nowhere meeting one another, so that those drawn on opposite faces are parallel to one another, and from no one point are two lines drawn, but one only. Let these in turn be bisected at S, V, T, ς , Q, X, and let the straight lines ST, VX, ς Q be connected, which bisect one another at the center α , at right angles, as we taught in the corollary to Prop. 3 of this book; and, like the former six, they are equal to the edges of the cube. Now let the halves of the lines YZ and M π be cut in extreme and mean ratio at β , γ , θ , χ , so that the greater segments are Y β , Z γ , M θ , $\pi\chi$; and draw the straight lines Y ς , Y χ , $\beta\theta$, $\beta\chi$. Since, then, Y ς and YV are equal to half the edge of the cube [Margin: a — Elements XIII.4], and $\rho\chi$, βV , the lesser segments of the equal lines YV, $\rho\pi$, are likewise equal, the squares of the lines...

(Continuation of THEOR. 13. PROPOS. 13 — to describe a dodecahedron in a given cube AF. The demonstration begun in the previous pages continues without a break; the catchword there was "[re]ctarum.")

of the straight lines YV, βV — three times the square on the straight line Y ς . And the squares on the straight lines Y ρ , $\rho\kappa$ will likewise be three times the square on that same straight line Y β . Therefore [Margin: b — Elements I.47], since the square on the straight line Yk equals the squares on the straight lines Y ρ , $\rho\kappa$ [Margin: c — Elements I.29] — because the angle Y $\rho\kappa$ is right — the square on Yk will also be triple the square on Y β . Again, since VY is perpendicular to AY, Y ρ [Margin: d — Elements XI.4], and so stands at right angles to the plane AE drawn through the straight lines AY, Y ρ , the angle ς Yk will be right, by definition 3 of

Book 11. [Margin: e — *Elements* I.47] And for this reason the square on $\zeta\kappa$, being equal to the squares on $Y\kappa$, $Y\zeta$, will be four times the square on $Y\beta$.

(For the squares on $Y\kappa$, $Y\beta$ are likewise four times the square on $Y\zeta$, since the square on $Y\kappa$ was shown to be triple the square on $Y\beta$.) [Margin: f — *Elements* VI.20] And so, since squares stand in the doubled ratio of their sides, the straight line $\zeta\kappa$ will be double $Y\beta$. For a quadruple ratio is the double of a double ratio, as appears in the numbers 1, 2, 4. But $\theta\kappa$ is also double $\rho\kappa$, since the smaller segments $\theta\rho$, $\kappa\rho$ of the equal straight lines $M\rho$, $\pi\zeta$ are equal. [Margin: g — *Elements* V.15] Therefore, as $Y\beta$ is to $\rho\kappa$, so $\beta\kappa$ (double $Y\beta$) is to $\theta\kappa$ (double $\rho\kappa$). But $Y\beta$, the greater segment, is to $\rho\kappa$ — a straight line equal to the smaller segment $\beta\rho$ — as the whole to its greater segment. Hence $\beta\kappa$ too will be to $\theta\kappa$ as the whole to its greater segment; and consequently $\theta\kappa$ will be the greater segment of the straight line $\beta\kappa$ cut in extreme and mean ratio.

By the same reasoning we shall show that $\theta\kappa$ is the greater segment of the straight line $\beta\theta$ cut in extreme and mean ratio — provided the straight line $Y\theta$ is drawn. Hence $\zeta\theta$, $\beta\kappa$ will be equal, forming an isosceles triangle $\zeta\theta\kappa$ similar to the one Euclid constructed in proposition 10 of Book 4, as we shall demonstrate later. And accordingly $\theta\kappa$ will be the side of the pentagon described in the circle that circumscribes the triangle $\zeta\theta\kappa$, as is clear from proposition 11 of Book 4.

Now suppose the plane of the triangle $\beta\theta\kappa$ to be extended — the straight line $\beta\phi$ being drawn through β parallel to $M\pi$ — along the parallels $M\pi$, $\phi\theta$, so that the extended plane $\phi\pi$ meets the diameter AC of the square $ABCD$ at point 3, and the diameter AF of the cube at point 4. Through 3 let 37 be drawn parallel to $A\phi$, and let MS be joined [Margin: h — *Elements* I.33], which is parallel to both $A\phi$ and 73. Since, then, by the corollary to proposition 4 of Book 6 the triangle $A73$ is similar to triangle AMS [Margin: i — *Elements* VI.4], it follows that as AM is to MS , so $A7$ is to 73. But AM , MS are equal, being halves of the cube's edges; therefore $A7$, 73 are equal as well. By the same reasoning, as MA is to $A\phi$, so $M7$ is to 73. But $A\phi$ is the greater segment of the straight line MA divided in extreme and mean ratio [Margin: k — *Elements* I.34] (since $A\phi$, $Y\zeta$ are equal, and likewise MA , YV , the halves of the cube's edge). Therefore 73 — that is, 7A — will be the greater segment of the straight line $M7$ cut in extreme and mean ratio [Margin: l — *Elements* XIII.5]; and consequently the whole MA will be divided in extreme and mean ratio at 7, its greater segment being $M7$. [Margin: m — *Elements* VI.2] But as $M7$ is to 7A, so $S3$ is to 3A. Therefore SA too is cut in extreme and mean ratio at 3, its greater segment being $S3$. [Margin: n — *Elements* I.33] And since $S\alpha T$ is parallel to $M\pi$ — and since the straight line πT that is drawn is equal and parallel

to MS — if a plane parallel to plane $\varphi\pi$ (drawn through $M\pi$) is passed through $S\alpha T$ [Margin: o — *Elements* XI.17], the straight lines AS, $A\alpha$ will be cut in the same ratios at points 3 and 4: for plane $\varphi\pi$ cuts the straight lines AS, $A\alpha$ at 3 and 4, while the plane through $S\alpha T$, parallel to $\varphi\pi$, cuts them at S and α . And therefore, since AS is cut at 3 in extreme and mean ratio, $A\alpha$, the semidiameter of the cube, will be cut in the same way at 4, its greater segment being $\alpha 4$.

By the same arguments we shall show that, when the diameter HF of the cube — the diameter of square EFGH — and the diameter HC of the cube are drawn, the semidiameter of the cube is cut at point 9 in extreme and mean ratio by the plane $\varphi\pi$, as is evident if the cube is inverted, as appears in this second figure. For its lines are entirely similar to those of the first figure, even though the cube's bases have exchanged places, so that the square AC takes the position of square HF, and square HF the position of square AC, in this second figure. Yet this can also be proved in the first figure, without such inversion, in the following way. Let the diameter HC of the cube be drawn in that figure — it is missing from the figure, but anyone can draw it — and let the plane $\varphi\pi$ cut it at 9, near point H; and through the straight line AH conceive a plane parallel to plane $\varphi\pi$. Since, then, the straight lines $A\alpha$, $H\alpha$ meet at the center α and are cut by the parallel planes at the points A, H and 4, 9 — for the plane $\varphi\pi$ cuts them at 4 and 9, while the plane drawn through AH parallel to $\varphi\pi$ cuts them at A and H — [Margin: p — *Elements* XI.15] it follows that as $\alpha 4$ is to 4A, so $\alpha 9$ is to 9H. And since αA is cut at 4 in extreme and mean ratio, αH will likewise be so cut — a demonstration that holds also for the cube's inversion in the second figure. Let us now show that, if the straight lines $\theta 4$, $\beta 4$, $\beta 9$, $\kappa 9$ are joined, the rectilinear figure $\beta 4\theta\kappa 9$, lying in plane $\varphi\pi$, is an equilateral and equiangular pentagon.

Diagram. The first figure (*prima figura*) of the dodecahedron-in-cube construction: a cube drawn in oblique projection, its faces gridded and crossed by many diagonals, with the twelve dodecahedron pentagon-vertices and the extreme-and-mean-ratio division points marked by Greek minuscules and by numerals; the cube's center is α . The figure is extremely crowded and many of the small interior Greek-minuscule labels sit at the resolution floor. Labels I can read with confidence:

- Cube corners and principal points: A, B, G, F, E, D
- Upper/edge points: φ (a small dotted circle, top edge), I, N, H, M, P
- Interior construction/division points (read): Y, V, γ , θ , ς , S, K, π , α (center), δ , X, R, O
- Numerals used as points: 3, 4, 9, 10 (a 7 and an 8 also appear but are faint)

- Further interior labels (a μ -like, an Ω /Q-like, an ε -like, and additional Greek minuscules) are present but not securely resolvable at this resolution: [?]

Diagram. The second figure (*secunda figura*): the same cube-and-dodecahedron construction with the cube inverted (its bases exchanged), so that square AC and square HF swap places. Structure and label-set are those of the first figure; readable labels:

- Top edge: H, 10, ς [?], G
- Upper interior: Y, β , V, γ , Z
- Mid: A, ϕ , I, B; ρ [?], θ , α (center); P, μ [?], K
- Lower: κ [?], M, F, S; O, δ ; N, X, ς [?], R
- Bottom edge: D, L, G [?] (bottom-right corner, could be C)
- Numerals: 4, 8, 9

Let the cube again be inverted, so that the squares ADEH, ABGH — which of course contain the triangle $\beta\theta\kappa$, that is, the plane $\phi\pi$ — take the position shown in this third figure. Then in the plane $\phi\pi$ let the straight line joining $\theta 4$ be extended as far as the straight line $\phi 10$, to the point 13. Now since, when the straight line KP is drawn and the straight lines MK are joined [Margin: a — *Elements* XI.15], the plane MP is parallel to the plane AG — because the straight lines PK, KM are parallel to the straight lines GB, BA — [Margin: b — *Elements* XI.32] and it cuts the cube in half, and therefore passes through the center α (by what was shown in the scholium to proposition 39 of Book 11): if a plane is extended through the straight lines $\alpha 4$, A, $\theta 4$ 13 [Margin: c — *Elements* XI.16], then $\alpha\theta$, A13 become the common sections of the parallel planes MP, AG, and are therefore parallel. Consequently the triangles $\alpha\theta 4$ and $\alpha 34$ will be equiangular [Margin: d — *Elements* VI.4]; and as $\alpha 4$ is to 4A, so $\theta 4$ is to 413. Therefore, since αA is cut at 4 in extreme and mean ratio, as we showed, $\theta 13$ will be cut in the same way at 4. Again, let a plane pass through the center α parallel to plane NZ, and let another plane be drawn through the point 4 (by the scholium to proposition 15 of Book 11) [Margin: e — *Elements* XI.15], cutting $\phi\pi$ in the straight line 4·14. But the plane DB is parallel to that same plane NZ. [Margin: f — *Elements* XI.17] Therefore the straight lines αA , ρM will be cut in the same ratios at the points 4 and 14. Hence ρM too will be cut at 14 in extreme and mean ratio, and the segment 14M will be the smaller, and thus equal to the smaller segment $\rho\theta$ of Mp. Therefore, when from $\rho 14$ — the greater segment of ρM — the smaller segment $\rho\theta$ is taken away, then (as we demonstrated at proposition 5 of Book 13) $\rho 14$, divided at θ in extreme and mean ratio, will have $\rho\theta$ as its greater segment. Finally, when the straight line 13·15 is drawn through 13 parallel to 4·14 [Margin: g — *Elements*

VI.2], the straight lines $\theta 13$, $\theta 15$ will be cut proportionally; and hence $\theta 15$ too will be cut at 14 in extreme and mean ratio, its greater segment being $\theta 14$. [Margin: h — *Elements* XIV.2] Therefore, as $\rho\theta$, the greater segment, is to $\theta 14$, the smaller, so $\theta 14$, the greater, is to 14·15, the smaller; and as $\theta 14$ is to 14·15, so is the whole $\theta 15$ to $\theta 14$, the greater segment. Therefore, as $\rho\theta$ is to $\theta 14$, so $\theta 15$ is to that same $\theta 14$. And for this reason the straight lines $\rho\theta$ (or $\rho\kappa$) and $\theta 15$ will be equal.

Now since the plane NZ and the plane parallel to it drawn through 4·14 are both cut by the plane $\varphi\pi$ [Margin: i — *Elements* XI.16], the common sections $\beta\rho$, 4·14 will be parallel, and therefore 13·15 will also be parallel to $\beta\rho$ [Margin: k — *Elements* I.29], and the exterior angle $\beta\rho\kappa$ will be equal to the interior angle 13·15· θ . Since, then, the sides $\beta\rho$, $\rho\kappa$ are equal to the sides 13·15, 15· θ [Margin: l — *Elements* I.4], the straight lines $\beta\kappa$, 13· θ will also be equal. And accordingly their greater segments $\theta\kappa$, $\theta 4$ (for $\theta\kappa$ was shown to be the greater segment of $\beta\kappa$) will be equal. By the same technique $\zeta 4$ will be shown, in the first figure, to be equal to $\beta\gamma$, if an isosceles triangle is formed in a similar position on the base $\beta\gamma$, its vertex resting at the point that divides the straight line IS in extreme and mean ratio. And in the same way $\kappa 9$, $\zeta 9$ will be equal to those same $\theta\kappa$, $\zeta\gamma$. Therefore the pentagon $\beta 4\theta\kappa 9$ is equilateral, seeing that $\beta\gamma$, $\theta\kappa$ are equal straight lines — for since they are composed of the smaller segments of equal straight lines cut in extreme and mean ratio, the lines YV, ZV, $\pi\rho$, $M\rho$ are equal. But it is equiangular too, as we shall show presently. If, then, by this technique twelve triangles — two upon each of the straight lines $M\pi$, YZ, NR, IL, ξO , KP — are constructed similar and equal to $\beta\theta\kappa$ (for at $M\pi$ you see two such triangles, $\beta\theta\kappa$, $\delta\theta\kappa$), and if by their means twelve pentagons similar and equal to $\beta 4\theta\kappa 9$ are fabricated, then a Dodecahedron will be constituted. Its twelve angles lie on the six straight lines $M\pi$, YZ, NR, IL, ξO , KP — two on each — while the remaining eight rest on the eight semidiameters of the cube, namely at the points that divide them in extreme and mean ratio, such as the points 4 and 9 on the semidiameters $A\alpha$, $H\alpha$ of the second figure. And so such a Dodecahedron will be said to be in a certain manner inscribed in the cube — though not strictly, since not all its angles are set at the cube's angles, or on its edges, or finally in its faces, but twelve of them lie in six faces of the cube, while eight rest at the points that cut the eight semidiameters of the cube in extreme and mean ratio. Therefore we have described a Dodecahedron in a given cube. Which was to be done.

Diagram. The third figure (*tertia figura*): again the cube-and-dodecahedron construction, in the orientation described in the text (squares ADEH, ABGH containing the triangle $\beta\theta\kappa$). Densely lined; readable labels:

- Top edge: B, Z, G
- Upper interior: φ , 13, β , K, 10, P
- Mid: A, H; α (center); C, R
- Lower interior: M, 15, 14, θ , ς [?], κ [?], π
- Bottom edge: D, N, E
- Numerals as points: 4, 13, 14, 15, 10

LEMMA.

That the triangle $\beta\theta\kappa$ — whose base $\theta\kappa$ is the greater segment of each of the sides $\beta\theta$, $\beta\kappa$ divided in extreme and mean ratio — is similar to the one Euclid constructed in proposition 10 of Book 4, we shall demonstrate as follows.

About the isosceles triangle ABC, such as Euclid teaches how to construct in proposition 10 of Book 4, let the circle ADBCE be described; and when the angles ABC, ACB have been bisected by the straight lines BE, CD, let the equilateral and equiangular pentagon ADBCE be completed, as we set out in proposition 11 of Book 4; and let the straight lines AB, CD cut one another at F. [Margin: a — *Elements* XIII.8] Since, then, AB is cut at F in extreme and mean ratio, and its greater segment AF is equal to the side BC [Margin: b — *Elements* XIV.2], it will follow that, as the whole AB is to its greater segment BC, so the whole $\beta\theta$ is to its greater segment $\theta\kappa$ [the source here repeats "to its greater segment $\theta\kappa$ "; the doubled clause appears to be a compositor's dittography — [?]]. And in the same way, as the whole AC is to its greater segment CB, so the whole $\varsigma\kappa$ is to its greater segment $\kappa\theta$. But also, as AB is to AC, so $\beta\theta$ is to $\beta\kappa$, for in both cases the ratio is one of equality. Therefore the triangles $\beta\theta\kappa$, ABC, having their sides proportional, are equiangular; and the angles θ and B will be equal, likewise κ and C, and β and A; and for that reason each of the angles θ , κ will be double the angle β ; and the triangles $\beta\theta\kappa$, ABC are similar.

Diagram. Two figures side by side for the Lemma. On the left, a circle with an inscribed equilateral pentagon ADBCE and its diagonals forming a pentagram; vertices: A (top), D (upper left), E (upper right), B (lower left), C (lower right), with F marked at the interior intersection of the diagonals. On the right, a separate isosceles triangle $\beta\theta\kappa$ with apex β (top) and base endpoints θ (lower left) and κ (lower right). (Labels all read cleanly.)

That the pentagon $\beta\theta\kappa\varsigma\theta$ is equilateral, and also equiangular, we shall show by this reasoning. About the triangle $\beta\theta\kappa$ let the circle $\beta A\theta\kappa B$ be described. If it passes through the points 4 and 9, then it is clear — from what we taught at

proposition 16 of Book 4 — that the pentagon is equiangular. But if it does not pass through the points 4 and 9, let there be described in the said circle, following the doctrine of proposition 11 of Book 4, an equilateral and equiangular pentagon $\beta A \theta \kappa B$. Now since the straight lines $A\theta$, $A\varsigma$, as well as the straight lines 4θ , 4β , are equal to the straight line $\theta\kappa$ — because both $\beta 4 \theta \kappa 9$ and $\beta A \theta \kappa B$ are equilateral pentagons — the two straight lines θA , $\theta 4$ will then be equal, as will the two ςA , 4ς ; which was demonstrated to be impossible in proposition 7 of Book 1. Therefore the circle circumscribed about the triangle $\beta \theta \kappa$ passes through the points 4 and 9. And accordingly the pentagon $\beta 4 \theta \kappa 9$ is equiangular.

Diagram. A circle with an inscribed pentagon and its diagonals drawn from the apex. Vertices: β (top), A (upper left), B (upper right), θ (lower left), κ (lower right). The numerals 4 (left) and 9 (right) mark interior triangular cells formed by the diagonals from β . (Labels read cleanly.)

SCHOLIUM.

From these results the following propositions may be gathered.

I.

The diameter of the Dodecahedron is capable of two sides — namely of the Dodecahedron itself, and of the cube in which the Dodecahedron is described.

For, in the first figure, let the diameter of the Dodecahedron $\beta\epsilon$ be drawn, and let the straight line $\gamma\epsilon$ be understood to be joined [Margin: a — *Elements* I.33], which is equal and parallel to the cube's side VX (because $V\gamma$, $X\epsilon$ are equal and parallel). Since, then, the angle βVX is right [Margin: b — *Elements* I.29], the angle $\beta\gamma\epsilon$ constructed at γ will be right as well; [Margin: c — *Elements* I.47] and consequently the square on the diameter $\beta\epsilon$ will equal the squares on the sides $\varsigma\gamma$ [?: β/ς are confusable here — possibly $\beta\gamma$], $\gamma\epsilon$ — namely of the Dodecahedron and of the cube.

II.

If the side of the cube is cut in extreme and mean ratio, the smaller segment is the side of the Dodecahedron described in the cube; but the greater segment is the side of the cube described in this dodecahedron.

For, in the same first figure [Margin: d — *Elements* V.15], since as YX is to βV , so YZ (double YV) is to $\beta\gamma$ (double ςV); and let ςV be the smaller segment of YV cut in extreme and mean ratio: then $\varsigma\gamma$ too will be the smaller segment of the cube's

side YZ cut in extreme and mean ratio, while the segment composed of $Y\beta$, γZ — that is, the straight line $\zeta\kappa$ (which was shown to be double $Y\zeta$, and therefore equal to the sum of $Y\zeta$, γZ) — will be the greater segment. But it is established from the construction that $\zeta\gamma$ is the side of the Dodecahedron [Margin: e — *Elements* XV.8], and that $\zeta\kappa$ (or $\zeta\theta$) is the side of the cube described in the said Dodecahedron, since it subtends the angle of the pentagon $\beta 9\kappa$, or $\beta 4\theta$.

III.

The side of the cube is equal to two sides — namely of the Dodecahedron described in it, and of the Dodecahedron described about the same cube.

For, in the first figure again, the side of the cube YZ is composed of the side of the Dodecahedron $\beta\gamma$ described in it, and of the straight line composed of $Y\beta$, γZ , which is established to be the side of the Dodecahedron circumscribed about the same cube. For since YZ , the cube's side, subtends the angle of a pentagon of the Dodecahedron described about the cube, as is clear from proposition 8 of this book [Margin: f — *Elements* XIII.8], and since the side of that pentagon is the greater segment of the side YZ cut in extreme and mean ratio: then $\beta\theta$, being likewise the greater segment of that same side YZ and equal to the two $Y\beta$, γZ together (as we have already demonstrated), will be the side of the Dodecahedron circumscribed about the cube of side YZ .

IV.

The straight line joining the two angles of the pentagons of the Dodecahedron that lie opposite the common side is equal to the side of the cube in which the Dodecahedron is inscribed.

For, in the first figure, the straight line joining the points β , δ — at which are constituted the two angles of the pentagons opposite the common side $\theta\kappa$ [Margin: g — *Elements* I.33] — is equal to the straight line VX (because βV , δX are equal and parallel), that is, to the side of the cube in which the Dodecahedron is described.

Diagram. The first figure of the construction, reproduced here to serve the Scholium (the same cube-and-dodecahedron figure as fig-p601-1). Readable labels: H, 10, ζ [?], G (top edge); Y, β , V, γ , Z (upper); A, ϕ , I, B; κ [?], ρ [?], θ , α (center); P, μ [?], K; M, F, S; O, δ ; N, X, ζ [?], R (lower); D, L, G [?] (bottom edge). Numerals 4, 8, 9.

PROBL. 14. PROPOS. 14.

To inscribe an icosahedron in a given cube.

Let AB be the given cube in which the icosahedron is to be inscribed. Through the centres C, D, E, F, G, H of its faces, draw straight lines parallel to the edges of the cube, none of them meeting one another; and cut the halves of these lines in extreme and mean ratio, so that the greater segments — those near the centres — end at the points I, K; L, M; N, O; P, Q; R, S; T, V. Join each of these points to its four nearest neighbours: L to I, K, T, and R; R to L, M, I, and N; and so on. In this way twenty triangles are formed: IKL, IKQ, LMR, LMT, NOM, NOP, PQV, PQS, RSI, RSN; TVR, TVO, ILR, ISQ, KTL, KQV, OPV, OTM, NSP, NMR. The first twelve of these lie under the eleven [recte: twelve] edges of the cube, while the latter eight are set beneath its eight corners.

Now join the straight lines XC, XI, XK. Since the sides XC, CI of triangle XCI are equal to the sides XC, CK of triangle XCK, and [Margin: a — *Elements* I.29] the angles they contain are right — because XC is parallel to AY — [Margin: b — *Elements* I.4] the bases XI, XK will also be equal. Next, since the line LX is perpendicular to the plane AZ (by definition 4 of Book XI), it is also perpendicular to the lines XI, XK. Therefore, since the sides LX, XI of triangle LXI are equal to the sides LX, XK of triangle L XK, and the angles they contain are right, [Margin: c — *Elements* I.4] the bases LI, LK will be equal.

Again, [Margin: d — *Elements* I.47] the square on LI equals the squares on LX and XI; the square on LX equals the square on IY; and the square on XL equals the squares on XC and CI. Hence the square on LI equals the three squares on XC, CI, and IY. But the squares on XC and CY are also equal, because their sides are halves of the cube's edges. Therefore the square on LI equals the three squares on CY, CI, and IY. Now these three squares are quadruple the square on CI. [Margin: e — *Elements* XIII.4] For the squares on CY and IY — on the whole line and on the lesser segment — are triple the square on CI, the greater segment; and when the square on CI is added to those two, the three squares on CY, CI, IY become quadruple that same square on CI. So the square on LI too is quadruple the square on CI. And since the square on KI is quadruple the same square on CI (by the scholium to proposition 4 of Book 2), the squares on LI and IK are equal, and hence the lines themselves are equal. Therefore triangle IKL, laid under the cube's face AG, is equilateral.

In just the same way we shall show that the remaining eleven triangles, placed under the eleven remaining edges of the cube, are equilateral; and moreover that

they are equal to one another, since their sides IK, LM, NO, PQ, RS, TV are equal. Now the sides of the remaining eight triangles, set beneath the cube's eight corners, are shared with the twelve triangles already named — for instance, in triangle KTL the side KL is common to triangle IKL, the side KT to triangle TVK, and the side TL to triangle LMT. It is therefore clear that these too are equal both to one another and to the twelve triangles already named. So all twenty such triangles compose an icosahedron inscribed in the cube, since its twelve vertices all rest on the six faces of the cube, two on each. Thus we have inscribed an icosahedron in the given cube. Which was to be done.

Diagram. A large three-dimensional cube shown in oblique projection with an icosahedron inscribed inside it; a dense web of interior lines joins the construction points on the cube's faces. The cube's diagonal is AB. The six face-centres are C, D, E, F, G, H, and the icosahedron's twelve vertices (I, K, L, M, N, O, P, Q, R, S, T, V) are marked as golden-section points on the segments through the face-centres, with additional auxiliary points X, Y, Z, and the cube's centre α [Greek: ἄλφα (alpha)]. Readable labels, by approximate position :

- A (top-left rear corner)
- Y (top edge)
- C (upper region, near top face)
- K (upper right)
- X (upper left)
- L (left)
- B (upper-right region) [?]
- "2" (right-hand face) [?] — a construction point marked with a numeral, or a compositor artifact
- Z (right; printed as a reversed N)
- R (left-middle)
- G (middle) [?]
- S (middle)
- α [Greek: alpha] (centre of the cube)
- D (left, lower)
- F (right-middle)
- T (lower centre)
- H (lower centre-right)
- V (lower right)
- P (lower right)

- M (lower left)
- N (bottom left)
- E (bottom)
- O (bottom)
- B (bottom-right corner, opposite end of the diagonal AB)

Several of the small interior labels are crowded and abraded; the readings marked [?] are uncertain.

SCHOLIVM.

We gather from this the following propositions.

I.

The diameter of the icosahedron is equal in square [potest — Greek δύναται, "is equal in power/square to"] to both the side of the icosahedron and the side of the cube that surrounds the icosahedron.

For draw the straight line LQ, [Margin: f — *Elements* I.33] which is parallel and equal to the cube's edge DF, since DL and FQ are parallel and equal. [Margin: g — *Elements* I.47] Then it is clear that the square on the diameter QM equals the squares on the lines LM, the side of the icosahedron, and LQ, the side of the cube in which the icosahedron is inscribed, [Margin: h — *Elements* I.29] since the angle MLQ is right — because the angle LDF is also right.

II.

The bisection points of six opposite sides of the icosahedron are joined by three equal straight lines, which cut one another in half at the centre of the icosahedron, and also at right angles.

For three such lines — namely DF, CE, GH — since they join the centres of opposite faces of the cube, are equal to the edges of the cube; and by the corollary to proposition 3 of this book they cut one another in half, and at right angles, at the centre of the cube, which is the point α [Greek: ἄλφα (alpha)]. That this point is also the centre of the icosahedron is shown as follows. Draw the line αP . Since the sides αF , FQ of triangle αFQ are equal to the sides αF , FP of triangle αFP , and they contain right angles, [Margin: i — *Elements* I.4] the lines αQ , αP will be equal. By the same reasoning all the lines drawn from α to the vertices of the icosahedron will be equal. Therefore α is the centre of the icosahedron.

III.

If the edge of the cube is cut in extreme and mean ratio, the greater segment is the side of the icosahedron inscribed in the said cube.

For since CI is the greater segment of the line CY, [Margin: k — *Elements* V.15] and as CI is to CY, so KI — double CI — is to βY [Greek: $\beta\eta\tau\alpha$ (beta)], double CY, [Margin: l — *Elements* XIV.2] then KI, the side of the icosahedron, will also be the greater segment of βY , the side of the cube. For if some straight line other than KI were the greater segment of the line βY , then βY would be to that line as CY is to CI — that is, as βY is to KI — making it different from that line: which is absurd.

IV.

In the icosahedron both the sides and the opposite triangular faces are parallel to one another.

For if the extreme points of any two opposite sides are connected by two diameters, two triangles are formed that are equal to one another and have their alternate angles equal (by proposition 4 of Book 1); and these diameters meet at the centre. Therefore any opposite sides will be parallel. [Margin: m — *Elements* XI.15] And for that reason the planes of the triangles as well, drawn through the parallel sides themselves, will be parallel to one another.

PROBL. 15. PROPOS. 15.

To inscribe an octahedron in a given icosahedron.

Let there be set out the six opposite sides AB, CD, EF, GH, IK, LM of the given icosahedron in which the octahedron is to be inscribed, whose bisection points N, O, P, Q, R, S are joined by three equal straight lines NO, PQ, RS, cutting one another in half at the centre T and at right angles — as was shown in the scholium to the preceding proposition. Draw the lines NP, NR, NS, NQ; OP, OR, OS, OQ; PR, PS; QR, QS, forming the eight triangles SNP, SPO, SOQ, SQN; RNP, RPO, ROQ, RQN. Now since the sides TN, TS of triangle TNS are equal to the sides TN, TP of triangle TNP — being halves of equal lines — and they contain right angles, as was said, [Margin: a — *Elements* I.4] the bases NS, NP will be equal. In the same way all the remaining lines will be equal both to these two and to one another. Therefore the eight named triangles are equilateral and equal to one another, and so constitute an octahedron. This octahedron is inscribed in the icosahedron, since its vertices rest on the bisection points of the six opposite sides of the icosahedron. Thus we have inscribed an octahedron in the given icosahedron. Which was to be done.

Diagram. A rhombus-shaped figure representing an icosahedron seen in projection, with an octahedron inscribed. Six "diameters" of the icosahedron — AB, CD, EF, GH, IK, LM — are drawn; their midpoints N, O, P, Q, R, S are the vertices of the inscribed octahedron, whose faces are traced by the interior lines meeting at the centre T. Readable labels, by position :

- A, N, B (top horizontal line; N is the midpoint of AB)
- K (interior, just below N)
- E (upper left end), F (lower left end) — endpoints of the left "diameter"
- G (upper right end), H (lower right end) — endpoints of the right "diameter"
- P (left-centre; midpoint of EF)
- Q (right-centre; midpoint of GH)
- R (upper-left interior), I (interior left), T (centre), M (interior right)
- S (lower-centre interior)
- L (interior, just below S)
- C, O, D (bottom horizontal line; O is the midpoint of CD)

All labels read cleanly.

COROLLARIVM.

It follows from this that the icosahedron and the octahedron inscribed in it have the same centre. For the lines NO, PQ, RS, passing through T, the centre of the icosahedron, are the diameters of the octahedron NPOQRS inscribed in it. Therefore T, the centre of the icosahedron where they intersect, is also the centre of the octahedron.

PROBL. 16. PROPOS. 16.

To inscribe an icosahedron in a given octahedron.

Let ABCDEF be the given octahedron in which the icosahedron is to be inscribed. Since four edges issue from each vertex, take from each vertex two that are not adjacent but lie opposite one another — that is, the ones which fall at the opposite corners of the octahedron's square sections. Always take the two beside opposite corners of the same square: thus BA, BC and DA, DC beside the opposite corners B, D of the square ABCD; AF, AE and CE, CF beside the opposite corners A, C of the square AECF (for only two edges are to be taken from each vertex, whereas the edges AB, AD and CB, CD of the square ABCD, beside the same corners A and C, have already been taken); and EB, ED and FD, FB beside the opposite corners E, F

of the square EBFD (for the edges EA, EC and FC, FA of the square AECF, beside the same corners E and F, have already been taken). Let all of these be cut in extreme and mean ratio, under this rule: that the greater segments lie near the corners from which they issue, at the twelve points G, H, I, K, L, M, N, O, P, Q, R, S. From each of these draw five straight lines to the five nearest section-points — for example, from R the lines RQ, RI, RL, RO, RK; and from I the lines IQ, IR, IM, IL, IG; and so with the rest — although not

Diagram. A rhombus-shaped figure of the octahedron ABCDEF drawn in projection, with the icosahedron inscribed; a dense web of interior lines joins the twelve golden-section points on the octahedron's edges. (The same figure is repeated at the top of the following page.) The octahedron's four "equatorial" vertices are A (top), B (left), C (bottom), D (right); E and F are the remaining opposite pair, shown at the interior; X marks the centre. Readable labels, by position :

- A (top vertex), C (bottom vertex), B (left vertex), D (right vertex)
- G (upper-left edge), I (upper-right edge), H (lower-left edge), K (lower-right edge)
- E (upper-interior apex), F (lower-interior apex)
- Y (near top interior), M, L (upper interior), P (left interior), S (lower-left interior)
- X (centre), T, V (right of centre), Q (right interior)
- R (right-of-centre interior), N (lower interior), O, Z (lower interior)

Most labels read cleanly; Q (printed as a rounded form) and Z are the least certain.

all are drawn in the figure, so as to avoid a confusion of lines. Which these five nearest points are, the solid octahedron shows beautifully. Three of them lie on the three remaining edges which, together with the edge on which the point was taken, form a pyramid [tetrahedron]; the other two lie on two edges of two octahedron-faces that share the edge on which the point was taken. For instance, since the point taken is R, on the edge DF — which, with the three edges DE, DA, DC, forms a pyramid at the vertex D — this edge DF is common to the octahedron's triangles DFA and DFC; and so from R five straight lines are drawn to the five points of these five edges; and likewise for the rest.

After this, draw the three diameters of the octahedron AC, BD, EF, cutting one another in half and at right angles at the centre X (by the corollary to proposition 14 of Book 13); of these, AC and BD cut the lines GI and RQ at Y and V. Join the line

IV, and draw IT parallel to YX. Now since the sides DQ, DI of triangle DQI are equal to the sides DR, DI of triangle DRI (for DQ and DR are the lesser segments of the equal lines DE, DF), and they contain equal angles — namely those of the octahedron's triangles ADE, ADF — [Margin: a — *Elements* I.4] the bases IQ, IR will be equal. Next, since [Margin: b — *Elements* XIV.2] as BG is to GA, so DI is to IA, [Margin: c — *Elements* VI.2] GI will be parallel to the line BD. By the same reasoning QR is parallel to EF; [Margin: d — *Elements* VI.4] and consequently, as DI is to IA, so XY is to YA. Therefore the line XA is cut at Y in extreme and mean ratio.

Again, since as AX is to XD, so AY is to YI (because triangle AYI is similar to triangle AXD, by the corollary to proposition 4 of Book 6), and AX is equal to XD, AY too will be equal to YI. Therefore YI is the lesser segment of the line XA. In just the same way we shall show that AY is equal to YG, and hence that GI is cut in half at Y, and likewise QR at V.

Now since the sides AG, AI of triangle AGI are equal to the sides DQ, DR of triangle DQR (being, of course, lesser segments of the lesser segments of equal lines), and they contain right angles — namely those of the squares ABCD, DEBF — [Margin: e — *Elements* I.4] the bases GI, QR will be equal. By the same reasoning the lines HK, PS, MN, LO will be shown equal to these — the lines which subtend the remaining corners of the squares ABCD, DEBF, AECF (at each square, two opposite corners) and which embrace two lesser segments of the sides.

Next, since YI, the lesser segment of XA, has been shown to be greater than the greater segment of the greater segment XY when XY is divided in extreme and mean ratio (as we demonstrated at proposition 5 of Book 13); and since XY equals XV, [Margin: f — *Elements* I.34] and YI equals XT (both being the greater segments of the equal lines XA, XD); XT will be the greater segment of XV, and therefore TV the lesser segment of that same XV. Hence the squares on XV — the whole, that is, on IT itself, [Margin: g — *Elements* I.34] since IT is equal to XY — and on TV, the lesser segment, [Margin: h — *Elements* XIII.4] are triple the square on XT, the greater segment. And so the square on IV, [Margin: i — *Elements* I.47] being equal to the squares on IT and VT, is triple that same square on XT — that is, on RV, which is equal to XT, or to YI, from what has been shown, since RV and YI are halves of the equal lines RQ, GI. Therefore, adding the square on RV to the square on IV, the squares on IV and VR will be quadruple the square on RV. [Margin: k — *Elements* I.47] But the square on IR is equal to the squares on IV and VR, [Margin: l — *Elements* I.8] because the angles IVR, IVQ — contained by the equal sides IV, VR and IV, VQ, and subtended by the equal bases IR, IQ — are equal, and

therefore right. So the square on IR is quadruple the same square on VR; and the square on QR is likewise quadruple it (by the scholium to proposition 4 of Book 2). The squares on IR and QR will therefore be equal, and hence the lines themselves equal. But IQ was equal to IR. Therefore triangle IQR is equilateral.

In the same way we shall show that the triangles similarly situated to IQR — namely KQR; GIL, GIM; GPS; HPS, NHK, OHK; RLO, SLO; PMN, QMN — are equilateral and equal to triangle IQR, since the sides of all of them are equal to one another. This we shall also demonstrate by the following reasoning. In each of these triangles one side subtends the right angle of a square and is contained by two lesser segments of the octahedron's edges; while the other two sides subtend two equal angles of the equilateral triangles, each contained by two segments of the octahedron's edges, a greater and a lesser. Therefore the sides of any one triangle are equal to the sides of the others, and consequently the triangles themselves are equal (by the corollary to proposition 8 of Book 1). For example, in the triangles IQR, GIL, the sides RQ, GI — which subtend the right angles QDR, GAI of the squares DEBF, ABCD, contained by the lesser segments DQ, DR and AG, AI — are equal. In the same way the sides IQ, IL will be equal, since they subtend the equal angles IDQ, IAL of the equilateral triangles ADE, ADF; the former angle is contained by the octahedron's edge-segments DI, DQ, a greater and a lesser, the latter by the segments AL, AI, likewise a greater and a lesser. In the same way IR, GL will be equal. Therefore the triangles IQR, GIL are equal (by the corollary to proposition 8 of Book 1). But IQR has been shown to be equilateral; therefore GIL is equilateral too. And the same reasoning holds for the rest. These twelve triangles, then, are set beneath the six vertices of the octahedron, two at each. From this it follows that the remaining eight triangles, set upon the eight faces of the octahedron, namely

Diagram. The same rhombus-shaped figure of the octahedron ABCDEF with inscribed icosahedron that appears at the foot of the preceding page, here repeated at the top of this page beside the demonstration. The octahedron's vertices are A (top), B (left), C (bottom), D (right), with E and F the remaining opposite pair shown in the interior; X is the centre; the twelve icosahedron points G, H, I, K, L, M, N, O, P, Q, R, S lie at golden-section points on the edges, with auxiliary points Y, T, V, Z. Readable labels, by position :

- A (top vertex), C (bottom vertex), B (left vertex), D (right vertex)
- G (upper-left edge), I (upper-right edge), H (lower-left edge), K (lower-right edge)
- E (upper-interior apex), F (lower-interior apex)

- Y, M, L (upper interior), P (left interior), S (lower-left interior)
- X (centre), T, V (right of centre), Q (right interior)
- R (right-of-centre interior), N (lower interior), O, Z (lower interior)

The interior labels agree with those of fig-p605-2; Q and Z are the least certain readings.

namely GMP in AEB, HNP in BEC, KNQ in CED, IMQ in AED, GLS in AFB, HOS in BFC, KOR in CFD, and ILR in AFD — are likewise equilateral and equal to the aforesaid triangles, since their sides are shared with the sides of those. Therefore these twenty triangles — five of which meet at each section-point of the octahedron's edges to form a solid angle (as you see in the five RQI, RIL, RLO, ROK, RKQ, which compose the solid angle R) — make up an icosahedron inscribed in the octahedron, since the icosahedron's twelve vertices occupy the twelve section-points of the octahedron's edges. Therefore in a given octahedron, and so on. Which was to be done.

COROLLARIVM I. [Corollary I]

It is gathered from what has been demonstrated that, if two sides of an equilateral triangle are cut in extreme and mean ratio in such a way that the greater segment of the one and the lesser segment of the other lie next to the angle they contain, then the square on the straight line joining these two section-points is double the square on the lesser segment. For in the equilateral triangle ADE, let DI be the greater segment of side AD, and DQ the lesser segment of side DE; and let the straight line IQ be drawn. It was shown to be equal to GI, the square on which is double the square on the lesser segment AI [Margin: l 47.primi (Elements I.47)], since the square on GI equals the two equal squares on the equal straight lines AG and AI. It is therefore evident that the square on IQ also is double the square on the same lesser segment AI.

COROLLARIVM II. [Corollary II]

Again, when eight bases of the icosahedron have been placed on eight bases of the octahedron, [it follows] that the center of a base of the octahedron and of the icosahedron is one and the same. For take the triangle AED of the upper part of the octahedron, in which the icosahedron's triangle IMQ has been placed, and let C be the center of triangle AED, from which the straight lines CA, CE, CD and CI, CM, CQ are drawn. Now the sides CA, AM of triangle CAM are equal to the sides CE, EQ of triangle CEQ (because these sides run from the center, and are the greater segments of equal straight lines) and contain equal angles — namely

halves of the angles of an equilateral triangle, as we showed in the scholium of prop. 12, book 13. The bases CM, CQ will therefore be equal. In the same way we shall demonstrate that CI is equal to the lines CM, CQ. Therefore C will be the center of triangle IMQ.

Diagram. An equilateral triangle AED with an inscribed smaller triangle IMQ and a common center C, illustrating Corollary II. Labels read on the leaf:

- A (apex, top)
- E (bottom-left vertex)
- D (bottom-right vertex)
- Q (bottom, center of base ED)
- M (left, on side AE)
- I (upper right, on side AD)
- C (center, joined by lines to A, E, D and to I, M, Q)

COROLLARIUM III. [Corollary III]

Finally, it is not difficult to gather from what has been said that the center of the octahedron and that of the icosahedron inscribed in it are the same. For draw from X, the center of the octahedron, two straight lines to any two vertices of the icosahedron — namely the straight lines XG, XO to the vertices G and O. The sides XA, AG of triangle XAG are equal to the sides XF, FO of triangle XFO (for XA and XF are semidiameters of the octahedron, while AG and FO are the lesser segments of the equal edges of the octahedron cut in extreme and mean ratio), and they contain equal angles, namely half-right angles — since AC, EF are the diagonals of the squares ABCD, EAFC, and hence, by what was demonstrated in the scholium of prop. 34, book 1, they bisect the angles of the squares. The bases XG, XO will therefore be equal [Margin: m 4.primi (Elements I.4)]. By the same argument all the other straight lines drawn from X to the vertices of the icosahedron will be shown equal. Therefore X, the center of the octahedron, is also the center of the icosahedron.

PROBL. 17. PROPOS. 17. [Problem 17, Proposition 17]

To inscribe a dodecahedron in a given octahedron.

Inscribe an icosahedron in the given octahedron [Margin: a 18[?].quintidec. (Elements XV.18[?]; referent is the icosahedron-in-octahedron construction, prop. 16 of this book)], and in this icosahedron a dodecahedron [Margin: b 5.quintidecim (Elements XV.5[?])], and what is required will be done. For since

the vertices of the dodecahedron are set at the centers of the icosahedron's bases, eight of which are concentric with the bases of the octahedron (by cor. 2 of prop. 16 of this book), it is manifest that eight vertices of the dodecahedron rest in those same centers of the eight bases of the octahedron, while the remaining twelve rest in the centers of the twelve bases of the icosahedron, of which pairs lie under each of the six vertices of the octahedron. For this reason the dodecahedron will be said to be inscribed in the octahedron — though not properly so, as can be seen from def. 31, book 11. We have therefore described a dodecahedron in a given octahedron. Which was to be done.

PROBL. 18. PROPOS. 18. [Problem 18, Proposition 18]

To inscribe a cube in a given pyramid [tetrahedron].

Let there be given a pyramid ABCD in which a cube is to be described, and let its center be E. Through E draw from the four vertices of the pyramid the straight lines AEF, BEG, CEH, DEI, which fall on the centers F, G, H, I of the opposite bases and are perpendicular to those same bases BCD, ACD, ABD, ABC [Margin: a 13[?].quartidec. (Elements XIV.13[?])]. Then through these centers draw from the vertices A, B, C the straight lines AHK, AGL, AIT, BFL, BHS, CIM, CFK, CGS, cutting the opposite bases BD, CD, AB, AD, BC in half and at right angles (by the scholium of prop. 12, book 13) at the points K, L, M, S, T. Let the straight lines AF, BG, CH, DI, dropped from the solid angles through the center E, also be bisected at the points N, O, P, Q, each of which is joined to its three nearest

centers (by the centers, I mean, the line itself of the base on which the point lies, standing around it, so that there remains the center of that base on which the perpendicular falls) by straight lines: thus N with G, H, I; O with F, H, I; P with F, G, I; and Q with F, G, H. I say that the solid NF, contained by the quadrilaterals NO, NP, NQ, FG, FH, FI, is a cube. For the sides AF, FK of triangle AFK are equal to the sides AF, FL of triangle AFL (because FK, FL, being drawn perpendicular from the center F to BD, CD, show equal distances of the equal straight lines BD, CD from the center F) [Margin: b 4.primi (Elements I.4)], and they contain right angles, by def. 3, book 11. The bases AK, AL will therefore be equal, and the angles KAF, LAF. Again, since the sides AN, AH of triangle ANH are equal to the sides AN, AG of triangle ANG (for AH, AG are semidiameters of the equal equilateral triangles ABD, ACD) [Margin: c 4.primi (Elements I.4)], and they likewise contain equal angles, as we have demonstrated, the bases NH, NG will be equal. In just the same way it will be shown that the straight lines QG, QH are equal, if the straight lines DG, DH are drawn — and likewise all the rest, since they all subtend equal angles contained by equal sides, as is evident. For if the

straight line FT be drawn, since the sides AF, FT are equal to the sides AF, FK (for FT, FK are the distances of the equal straight lines BC, BD from the center) and the contained angles are right (by def. 3, book 11), the angles TAF, KAF will be equal. And accordingly, since the sides AN, AI are equal to the sides AN, AH (for AI, AH are semidiameters of the equal equilateral triangles ABC, ABD) and they contain equal angles [Margin: d 4.prim. (Elements I.4)], the bases NI, NH will be equal, and so on. Therefore the six quadrilaterals mentioned are equilateral. Let us now show that they are plane and rectangular, so that we may at last conclude that they are squares and thus compose the cube NF.

Take the quadrilateral NQ, and draw the straight lines GH, NQ. Since in the pyramid the sides BC, AD are opposite — that is, not meeting at any point — if their midpoints S and T are joined by the straight line ST, this will be the diameter of the octahedron described in the pyramid, as is clear from the figure of prop. 2 of this book. For the point S of this figure corresponds to the point H of that one, and the point T to the point F, since in that figure too BC, AD are opposite, or non-meeting, sides. Therefore, since the pyramid and the octahedron described in it have the same center (as we shall soon demonstrate), T will pass through E, the center of the pyramid, and ES, ET will be equal, namely the semidiameters of the octahedron [Margin: e 18.quartidec. (Elements XIV.18)]. Next, since BS, CS are perpendicular to AD (by the scholium of prop. 12, book 13), HS, GS, from the centers H and G, will be third parts of the perpendiculars BS, CS. Hence the sides BS, CS of triangle BSC are cut proportionally [Margin: f 2.sexti (Elements VI.2)], and therefore HG is parallel to the side BC, and cuts the sides TS, CS of triangle TSC (which is indeed a part of triangle BSC) proportionally; and so RS too is a third part of ST, and accordingly two thirds [of it are] the half SE.

Again, since DI is perpendicular to triangle ABC [Margin: g 15.quartidec. (Elements XIV.15)], EI will be a third part of the semidiameter DE (by cor. 2 of prop. 13, book 13); that is, of whatever parts DE is reckoned as 3, EI will be 1, and accordingly the straight line DI will be 4 of the same, and so its half DQ will be 2 of those parts. For this reason the remainder EQ will be 1 of those parts, and therefore EQ will be a third part of DE. By the same reasoning EN will be a third part of AE. Accordingly, since the sides DE, AE of triangle AED are cut proportionally [Margin: h 2.sexti (Elements VI.2)], the straight line NQ will be parallel to the side AD, and will cut the sides ES, ED of triangle DES (which is indeed a part of triangle AED) proportionally; and so, since EQ is a third part of DE, ER will be a third part of SE, and accordingly SR will be two thirds of the same SE. Since therefore each of HG, NQ has taken from SE two thirds, at the same point R, SE will be cut by the straight lines HG, NQ [Margin: i 2.vndec. (Elements

XI.2)]; and therefore HG, NQ will intersect one another at the same point. Hence they lie in the same plane, and for that reason the straight lines HQ, QG, GN, NH also lie in the same plane with them. The quadrilateral NQ is therefore plane; and the same reasoning holds for the other five. Let us now demonstrate that it is also rectangular.

Since HG has been shown parallel to BC, and hence triangle SHG similar to triangle SBC (by the corollary of prop. 4, book 6) [Margin: k 4.sexti (Elements VI.4, cor.)], it will follow that as SH is to HG, so SB is to BC; and, by alternation, as SH is to SB, so HG is to BC. But SH is a third part of SB; therefore HG too will be a third part of the side BC. In just the same way we shall show NQ to be a third part of the side AD. Since, then, the sides BC, AD are equal, their third parts HG, NQ will also be equal. And accordingly, since they are subtended by the equal sides HN, GN; GQ, HQ; NG, QG; NH, QH [Margin: l 8.primi (Elements I.8)], the four angles HNG, NGQ, GQH, QHN will be equal. Since therefore these are together equal to four right angles, as we showed at prop. 32, book 1, they will be right angles, and so NQ will be a square. By the same reasoning the remaining quadrilaterals will be squares; and for this reason they will constitute a cube, which will therefore be said to be inscribed in the pyramid — though improperly — because four of its vertices F, G, H, I rest in the centers of the four bases of the pyramid, while the remaining four N, O, P, Q rest at the bisection points of the perpendiculars drawn from the vertices of the pyramid to its bases, as is clear.

Alternatively. In the given pyramid let an octahedron be described, and in this octahedron a cube; and what is required will be done. For since the eight vertices of the cube are set at the centers of the eight bases of the octahedron, four of which lie in the four bases of the pyramid (as is clear from prop. 2 of this book) and have the same centers as they (as we shall soon show), it comes about that four vertices of the cube rest in the centers of the four bases of the pyramid, just as in the previous

Diagram. A large, densely ruled triangular pyramid (tetrahedron) ABCD with an inscribed cube and its many auxiliary lines, illustrating Proposition 18. It is one of the crowded three-dimensional figures of Book XV; the interior labels are cramped and foxed. Labels read on the leaf (positions as visible; roles as defined in the text):

- A (apex, top)
- B (bottom-left vertex)
- C (right vertex)
- D (front vertex, lowest point of base)

- M (upper-left, on edge AB)
- N (upper-center, a cube vertex — midpoint of AF)
- S (just below N, center — midpoint of edge BC)
- H (mid-left, base-center / cube vertex)
- G (mid-right, base-center / cube vertex)
- R (center)
- E (center, just below R — center of the pyramid)
- O (left of center, cube vertex)
- P (right of center, cube vertex)
- T (lower-center — midpoint of edge AD)
- Q (just right of T, cube vertex)
- K (bottom, between B and F)
- F (bottom-center, base-center / cube vertex)
- L (bottom-right)
- I [?] (cube vertex / base-center per text; not confidently locatable among the interior lines)

previous demonstration it was stated. Again, since the remaining four bases of the octahedron are parallel to the bases of the pyramid, as is clear from the figure of prop. 2 of this book (for since the straight lines EG, EH are parallel to the straight lines BC, BD [Margin: m 2.sexti (Elements VI.2)], the triangles EGH, BCD drawn through those lines will also be parallel to one another [Margin: n 15.vnde. (Elements XI.15)], and so with the rest) — it comes about that the perpendiculars dropped from the vertices of the pyramid to the opposite bases are also perpendicular to those four remaining bases of the octahedron, by the scholium of prop. 14, book 11. Hence, since the aforesaid bases cut off from the pyramid smaller pyramids similar to the whole, those perpendiculars will fall on the centers of the said bases, just as they fall on the centers of the bases of the whole pyramid [Margin: o 17.vnde. (Elements XI.17)]. And since the said four bases of the octahedron divide those perpendiculars proportionally with the sides of the pyramid — that is, in half — it is brought about that the remaining four vertices of the cube are set at the midpoints of the four perpendiculars, just as the earlier demonstration taught. It is therefore established that the cube is described in the pyramid, as before. And so we have described a cube in a given pyramid. Which was to be done.

COROLLARIVM I. [Corollary I]

It is established from these things that the center of the pyramid and of the cube described in it is the same. For the diagonals of the cube NF, OG, PH, QI, since they are the halves of the perpendiculars dropped from the vertices of the pyramid through its center to the bases, pass through E, the center of the pyramid.

COROLLARIVM II. [Corollary II]

It is also inferred that the straight line joining the bisection points of the opposite edges of the pyramid passes through the center of the pyramid, and is triple the side of the cube described in the pyramid. For since ER, drawn from E, the center of the cube, to R, the center of the base GNHQ, is half the side of the cube (as is clear), the straight line RS will be equal to the side of the cube. Since therefore RS was shown to be a third part of ST, it is evident that the straight line ST, joining S and T, the bisection points of the opposite edges AD, BC of the pyramid, passes through the center of the pyramid, and is triple the cube's side RS.

LEMMA.

(The Lemma is set entirely in italic type in the source.)

But we shall demonstrate as follows that the center of the pyramid and of the octahedron described in it is one and the same, and that the center of a base of the pyramid and of a base of the octahedron described in it is likewise the same.

Let there first be a pyramid ABCD, all six of whose edges are bisected at E, F, G, H, I, K; and from L, the center of the pyramid, let perpendiculars LM, LN be dropped to the bases ABD, BCD, which will fall on the centers of the circles circumscribing the said bases, by the corollary of lemma 1 of prop. 10, book 14. Now, having joined the straight lines LE, EM, LF, FN: since the sides LM, ME of triangle LME are equal to the sides LN, NF of triangle LNF (for since the circles circumscribing the bases ABD, BCD are equal, they are equidistant from the center L, by lemma 2 of prop. 10, book 14, and therefore their distances LM, LN will be equal; likewise ME, NF, the distances of the equal straight lines AB, BD from the centers M and N of the equal circles, will be equal), and they contain right angles by def. 3, book 11 [Margin: p 4.primi (Elements I.4)]: the straight lines LE, LF will be equal. By the same reasoning the straight lines LG, LH, LI, LK will be equal to these and to one another. Hence, since the vertices of the octahedron described in the pyramid are

set at the points E, F, G, H, I, K (as is clear from prop. 2[?] of this book), L will be the center of the octahedron, since all the lines falling from it to its vertices are equal. Since therefore L is also the center of the pyramid, the center of the pyramid and of the octahedron described in it will be the same.

Diagram. A triangular pyramid ABCD with edge-midpoints and the inscribed octahedron's centers, illustrating the first part of the Lemma. Labels read on the leaf:

- A (apex, top)
- E (left, on edge AB)
- H (upper right, on edge AC)
- L (center, the center of the pyramid)
- I (right of L)
- M (left of L)
- K (center-low)
- N (right of K)
- B (bottom-left vertex)
- C (right vertex)
- F (bottom-center)
- G (bottom-right)
- D (bottom, front vertex)

Next, let the base DEF of the octahedron lie in the base ABC of the pyramid, cutting the sides of that base in half, as is evident from prop. 2 of this book; and let G be the center of triangle ABC, from which straight lines are drawn to the vertices of each base. Now the sides AG, AD are equal to the sides BG, BF, and they contain equal angles — namely halves of the equal angles of an equilateral triangle [Margin: q 4.sexiti (Elements VI.4)]; the bases GD, GF will therefore be equal. By the same reasoning GE will be equal to each of GD, GF. Therefore G is the center of triangle DEF. Which was proposed.

Diagram. An equilateral triangle ABC with the inscribed triangle DEF and common center G, the interior lines forming a star, illustrating the second part of the Lemma. Labels read on the leaf:

- A (apex, top)
- D (upper-left, on side AB)
- E (upper-right, on side AC)
- G (center)

- B (bottom-left vertex)
- F (bottom-center, on side BC)
- C (bottom-right vertex)

PROBL. 19. PROPOS. 19. [Problem 19, Proposition 19]

To inscribe an icosahedron in a given pyramid.

In the given pyramid ABCD let an octahedron EFGHIK be inscribed [Margin: a 2.quartidecim (Elements XIV.2)], all twelve edges of which are cut in extreme and mean ratio, on this condition: that from each edge two corresponding points be taken — that is, points falling toward the opposite vertices of the octahedron's squares, as we stated in prop. 16 of this book. Such are EG, EK, HK, HG; KF, KI; GI, GF; FH, FE; IE, IH, [cut] at the points L, M, N, O, P, Q, R, S, T, V, X, Y. For if we join each of these points to its five nearest by straight lines — as M with V, L, X, P, and Q, and so on — an icosahedron will be described in the said

This batch completes Book XV of the *Elements* (with Propositions 20–21 and the concluding Scholium), reaches the end of Euclid's *Elements* (FINIS ELEMENTI QVINTIDECIMI), and opens **Book XVI** — the treatise added by François de Foix, Count of Candale (*Franciscus Flussas Candalla*), on how the regular solids inscribe one within another — through its preface and first two theorems.

[Euclid, Book XV — continuation of PROBL. 19 / PROPOS. 19: to inscribe an icosahedron in a given pyramid]

Diagram. A triangular projection of the pyramid (tetrahedron) ABCD with an inscribed icosahedron built upon an inscribed octahedron.

- A (top apex): a vertex of the pyramid
- B (bottom-left corner): a vertex of the pyramid [reads as a B with a long descender]
- C (bottom-right corner): a vertex of the pyramid
- D (interior center): the fourth vertex of the pyramid
- E (upper center): octahedron vertex (on edge AD)
- F (left): octahedron vertex (on edge AB)
- G (lower left): octahedron vertex (on edge BD)
- H (bottom center): octahedron vertex (on edge BC)
- I (right): octahedron vertex (on edge CD)
- K (upper right): octahedron vertex (on edge AC)

- V, M, P, X, S, L, N, T, R, O, Y: the extreme-and-mean section points on the octahedron's edges, joined to form the icosahedron
- [one further interior minuscule label, to the right of N near I, is not resolvable — possibly q [?]]

in the said octahedron, as is clear from Prop. 16 of this book, since it has all twelve of its angles in the twelve aforementioned sections of the twelve edges of the octahedron. Since, then, these very edges of the octahedron have been drawn in the planes of the pyramid's bases, it is evident that the twelve angles of the icosahedron are established in the planes of the pyramid's bases — three in each, inasmuch as three edges of the octahedron lie in each base of the pyramid. For in the base ABC lie the edges FH, HK, KF; in ABD, the edges EF, FG, GE; in BDC, the edges GH, HI, IG; and in ADC, finally, the edges IK, KE, EI. Therefore the said icosahedron will have been inscribed in the pyramid, by Def. 31 of Book XI — its four bases MXQ, ROY, LSV, NPT lying in the four bases of the pyramid, as is evident. And so we have inscribed an icosahedron in the given pyramid. Which was to be done.

PROBL. 20. PROPOS. 20.

To inscribe a dodecahedron in a given pyramid.

In the given pyramid inscribe an icosahedron [Margin: a. *Elements* XV.19], and in this icosahedron a dodecahedron [Margin: b. *Elements* XV.5] having its twenty angles at the centers of the twenty bases of the icosahedron; and what is required will have been done. For since four bases of the icosahedron lie in the four bases of the pyramid, as we said in the preceding proposition, four angles of the dodecahedron inscribed in that icosahedron will fall in the four bases of the pyramid — namely at their centers. For those four bases of the icosahedron are concentric with the four bases of the pyramid, as is clear from the second corollary of Prop. 16 of this book.

Next, since the cube inscribed in the dodecahedron places its eight angles at the eight angles of the dodecahedron [Margin: c. *Elements* XV.8]; and likewise the cube inscribed in the pyramid sets four of its angles at the centers of the pyramid's bases (of which we have already spoken), and its remaining four at the bisection-points of the perpendiculars dropped from the pyramid's angles onto the bases [Margin: d. *Elements* XV.18] — the four corresponding angles of the cube will be placed at those same bisection-points of the said perpendiculars. There remain, moreover, twelve angles of the dodecahedron, of which pairs will be assigned to the several edges of the pyramid. And thus the said dodecahedron

will be said to have been inscribed in the proposed pyramid, even if not in the strict sense. For which reason we have inscribed a dodecahedron in the given pyramid. Which was to be done.

PROBL. 21. PROPOS. 21.

To inscribe a sphere in a given regular solid.

From the center of the sphere enclosing the given solid let perpendiculars be dropped onto the several bases. By the corollary of Lemma 1 of Prop. 10 of Book XIV, these will fall at the centers of the circles circumscribing the bases, and will therefore be equal — since those circles, being equal, are equally distant from the center, by Lemma 2 of the same proposition. Consequently a sphere whose radii are the aforesaid equal perpendiculars will have been inscribed in the solid, for its convex surface will touch each of the bases at their centers.

SCHOLIVM.

Since, then, each of the five regular solids is inscribed in the four remaining ones, so that there are twenty inscriptions in all, only the dodecahedron alone is inscribed improperly — in the cube, the octahedron, and the pyramid, as is plain from Props. 13, 17, and 20 of this book. Likewise the cube alone is inscribed not properly in the pyramid, as is manifest from Prop. 19 of this book. For, that some solid be said to be inscribed in a solid in the proper sense, it is necessary that all the angles of the inscribed solid be established either at the angles, or on the edges, or finally in the planes (that is, the bases) of the solid in which it is inscribed — as we set forth in Def. 31 of Book XI. And this condition does not hold for the dodecahedron if it be inscribed in the cube, the octahedron, and the pyramid; nor yet for the cube, if it be inscribed in the pyramid.

Furthermore, among all five regular solids, one — the octahedron — receives the remaining four mutually inscribed within itself. [Margin: a. Elements XV.16] For in the octahedron an icosahedron is inscribed, setting its twelve angles at the twelve points at which the twelve edges of the octahedron are cut in extreme and mean ratio. Next, [Margin: b. Elements XV.5] upon the icosahedron is set a dodecahedron, which is inscribed in that same octahedron, as is clear from Prop. 17 of this book. After this, [Margin: c. Elements XV.8] in the dodecahedron a cube is inscribed, whose eight angles, coinciding with the eight angles of the dodecahedron, occupy the centers of the octahedron's bases; and for that reason the cube itself too is inscribed in the octahedron. [Margin: d. Elements XV.1] Finally, a pyramid is enclosed in the cube, which will therefore be said to be inscribed in the octahedron,

because its four angles, coinciding with four angles of the cube, rest at the centers of four bases of the octahedron. And that this privilege is denied to the remaining regular solids is plain from what has been said.

Nor, indeed, is it to be passed over that a dodecahedron, the cube inscribed within it, and the pyramid inscribed within that cube are all comprehended by the same sphere. [Margin: e. Elements XV.1] For since the four angles of the pyramid occupy four of the eight angles of the cube, [Margin: f. Elements XV.8] and since all the angles of the cube coincide with eight angles of the dodecahedron, it is clearly established that the sphere circumscribed about the dodecahedron encloses also the cube and the pyramid, since the surface of that sphere passes through the angles of these solids.

By the same reasoning it is manifest from what has been said that the dodecahedron, the cube, and the pyramid are likewise inscribed in the icosahedron, the octahedron, and the pyramid. For their angles are established at the centers of the bases of these, as has been demonstrated: at the centers, indeed, of the bases of the icosahedron, by Props. 5, 11, and 12; at the centers of the bases of the octahedron, by Props. 17, 4, and 6; and finally at the centers of the bases of the pyramid, by Props. 20 and 18 of this book.

In the twenty preceding propositions of this book, moreover, we have completed all the delineations, that is inscriptions, of the five regular solids one within another, as many as can be devised, since in each one we have marked out the remaining four. Namely: in the pyramid, the octahedron, cube, icosahedron, and dodecahedron, by Props. 2, 18, 19, 20; in the octahedron, the pyramid, cube, icosahedron, and dodecahedron, by Props. 6, 4, 16, 17; next, in the cube, the pyramid, octahedron, icosahedron, and dodecahedron, by Props. 5, 1, 3, 14, 13 [?]; in the icosahedron, the pyramid, octahedron, cube, and dodecahedron, by Props. 12, 15, 11 [?]; and finally, in the dodecahedron, the pyramid, octahedron, cube, and icosahedron, by Props. 10, 9, 8, 7 — these we have described. And in the last, single proposition we have taught by what art a sphere may be drawn in any given regular solid.

FINIS ELEMENTI QVINTIDECIMI. [End of the Fifteenth Element — and of Euclid's *Elements*.]

ELEMENTVM SEXTVMDECIMVM.

In which the various comparisons of the regular solids mutually inscribed one within another, and of their edges, are explained — added by François de Foix,

Count of Candale [Franciscus Flussas Candalla] — together with matter concerning the five bodies.

LIBER TERTIVS.

Just as in Book 14 there were handed down very many comparisons of the regular figures and of their edges described within the same sphere — whose description Euclid set forth in Book 13 — so also Franciscus Flussas Candalla, in this Book 16, compares those same regular figures inscribed one within another, and likewise their edges, the inscription of which we ourselves handed down in the preceding Book 15. And so this Book 16 bears to the preceding Book 15 the same connection that the fourteenth bore to the thirteenth, so that the treatment of these five regular bodies might in some way appear incomplete were this sixteenth book not appended.

THEOR. 1. PROPOS. 1.

If in a dodecahedron a cube be inscribed, and in this cube another dodecahedron, then the ratio of the outer dodecahedron to the inner dodecahedron will be the triplicate of the ratio which the greater segment of a straight line divided in extreme and mean ratio has to the lesser.

Let the edge of the cube inscribed in the dodecahedron whose edge is C be AB, and let the edge of the dodecahedron inscribed in the cube of edge AB be D; and let AB, the edge of the cube, be divided at E in extreme and mean ratio. I say that the dodecahedron of edge C has to the dodecahedron of edge D the triplicate of the ratio which AB — the greater segment — has to EB — the lesser.

For since, as we showed in the scholium to the last proposition of Book 15, the dodecahedron and the cube inscribed in it are comprehended by the same sphere; and since, when the edge of the cube is divided in extreme and mean ratio, the greater segment is the edge of the dodecahedron described in the same sphere as the cube, by the first corollary of Prop. 17 of Book 13 — AE, the greater segment of the cube's edge, will be equal to the edge C of the dodecahedron described in the same sphere and about that cube. Again, since it has been demonstrated in the scholium to Prop. 13 of Book 15 that, if the edge of the cube be divided in extreme and mean ratio, the lesser segment is the edge of the dodecahedron inscribed in that cube — EB, the lesser segment of the cube's edge, will be equal to the edge D of the dodecahedron which is inscribed in that cube. And therefore C, the edge of the dodecahedron circumscribed about the cube, is to D, the edge of the dodecahedron inscribed in the same cube, as AE, the greater

segment, is to EB, the lesser. But the dodecahedron of edge C has to the dodecahedron of edge D the triplicate of the ratio of edge C to edge D, by the corollary of Prop. 17 of Book 12. Therefore the same dodecahedron of edge C also has to the dodecahedron of edge D the triplicate of the ratio of the greater segment AE to the lesser segment EB. And so, if in a dodecahedron a cube be inscribed, etc. Which was to be demonstrated.

Diagram. A simple lettered line-figure.

- A — E — B: a straight segment AB with the division-point E marking its section in extreme and mean ratio (E lies toward B, so AE is the greater segment)
- C: a shorter reference segment (drawn below, at the left; the edge of the outer dodecahedron)
- D: a still shorter reference segment (drawn below, at the right; the edge of the inner dodecahedron)

THEOR. 2. PROPOS. 2.

A perpendicular dropped from any angle of an equilateral and equiangular pentagon onto the opposite side is cut, by the straight line subtending that angle, in extreme and mean ratio.

Opera Mathematica, Tomus I — Book XVI (Candalla's treatise on the regular solids)

(This batch covers global source- i.e. printed pages 611–613. It completes the demonstration of Theorem 2 / Proposition 2 and continues through Candalla's propositions on the mutual inscriptions of the five regular solids, Theorems 3–11.)

Demonstration of THEOR. 2. PROPOS. 2. (conclusion)

(Enunciation given in the preceding batch: "A perpendicular dropped from any angle of an equilateral and equiangular pentagon onto the opposite side is cut, by the straight line subtending that angle, in extreme and mean ratio.")

In the equilateral and equiangular pentagon ABCDE, let a perpendicular AF be dropped from angle A onto the opposite side CD. I say that AF is cut at G in extreme and mean ratio [ratio extrema ac media] by the straight line BE, which subtends angle A. For draw the straight line AD, and let it cut BE at H. Since BE is parallel to the side CD (by the scholium to Prop. 8, Book 13), the straight lines AF

and AD will be cut proportionally [Margin: a — 2.sex. = *Elements* VI.2]. But AD is cut at H in extreme and mean ratio, and DH is the greater segment [Margin: b — 18[?].tertiidecimi = *Elements* XIII.8 (printed "18"; the sense requires XIII.8)]. Therefore AF too will be cut in the same way at G. And so the perpendicular from any angle, etc. Which was to be demonstrated.

Diagram. An equilateral, equiangular pentagon with apex A at top, "shoulders" B (left) and E (right), and lower vertices C (left) and D (right). A horizontal chord BE runs across the figure and subtends angle A. From A a perpendicular AF drops to the midpoint F of the base CD. The diagonal AD is drawn from A to the lower-right vertex D. The chord BE is met by the perpendicular AF at G and by the diagonal AD at H.

- A (top apex): vertex of the pentagon from which the perpendicular AF and the diagonal AD are drawn
- B (upper-left vertex): left endpoint of the subtending chord BE
- E (upper-right vertex): right endpoint of the subtending chord BE
- G (on BE, left of center): point where the perpendicular AF crosses BE — the point of extreme-and-mean-ratio division on AF
- H (on BE, right of center): point where the diagonal AD crosses BE
- C (lower-left vertex)
- F (midpoint of base CD): foot of the perpendicular from A
- D (lower-right vertex)

THEOR. 3. PROPOS. 3.

If from the angles of the triangular face of a tetrahedron [pyramis] straight lines are drawn cutting the opposite sides in extreme and mean ratio, in such a way that near each angle there is the greater segment of one side and the lesser segment of the other, then these lines, by their own intersections, will produce in the middle the base of the icosahedron inscribed in that tetrahedron. This base is itself inscribed in another equilateral triangle, whose angles cut the sides of the tetrahedron's triangle in extreme and mean ratio, and whose sides are themselves bisected by the angles of the base of the icosahedron.

Let the triangular face of the tetrahedron be ABC, whose sides are bisected at D, E, F; and joining the straight lines DE, EF, FD, let these in turn be cut in extreme and mean ratio at G, H, I. Joining GH, HI, IG then forms GHI, the triangle of the icosahedron inscribed in that tetrahedron, as is established from Prop. 19, Book 15. Next, let the sides of triangle ABC be cut in extreme and mean ratio at K, L, M,

and join BK, CL, AM. I say that these straight lines, by their sections, produce the triangle GHI of the icosahedron — that is, that BK passes through the points G, I; CL through the points H, I; and AM through the points G, H.

For, drawing through H the straight line NO parallel to BC, the triangle FHO will be similar to triangle FEC (by the corollary to Prop. 4, Book 6), and therefore also equilateral, since FEC too is equilateral — being similar to triangle ABC by the same corollary. Hence HO, a straight line equal to FH, is equal to the greater segment of FE (that is, of DF). (For DEF too is an equilateral triangle, since its sides subtend equal angles of the equilateral triangle, contained by equal — namely half — of the sides of that same triangle; and therefore they are equal [Margin: a — 4.pri. = *Elements* I.4].) Also NH is equal to the whole of DF, in the parallelogram DH [Margin: b — 34.pri. = *Elements* I.34], because FH and DF are parallel to AB and BC (that is, to NO) [Margin: c — 2.sexti = *Elements* VI.2].

Therefore the straight line NO, composed of NH (the whole) and HO (the greater segment), will be cut at H in extreme and mean ratio [Margin: d — 5.tertiidecimi = *Elements* XIII.5]. And accordingly, since the three parallels BC, NO, DF are similarly cut at M, H, G — namely in extreme and mean ratio — and since the straight line AM cuts them similarly (from what we demonstrated at Prop. 4, Book 6), it clearly follows that AM passes through the points G, H. In just the same way we shall show that BK passes through the points G, I, and CL through the points H, I, if through G and I straight lines are drawn parallel to the sides AC and AB. And therefore the straight lines BK, CL, AM, by their sections, produce the triangle GHI of the icosahedron.

Now let PQ be drawn through G parallel to CL. Since therefore AF is equal to DF (that is, to FE), whose greater segment was FH — that is FO, equal to it — FO will also be the greater segment of AF [Margin: e — 5.tertiidecimi = *Elements* XIII.5]; and accordingly the whole AO is cut at F in extreme and mean ratio. Now, as AF is to FO, so is AG to GH (because of triangle AHO); and as AG is to GH, so is AQ to QC, and AP to PL (because of the triangles AHC, AHL) [Margin: f — 2.sexti = *Elements* VI.2]. Therefore the straight lines AH, AC, AL are cut at G, Q, P in extreme and mean ratio, and AG, AQ, AP are the greater segments. Therefore AQ and AL — the greater segments of the equal straight lines AC, AB — will be equal. And since, as AQ, the greater segment, is to QC, the lesser, so is AL, the whole, to AP, the greater segment [Margin: g — 2.quartidecimi = *Elements* XIV.2]; and AQ is equal to AL: then QC too will be equal to AP. Therefore AP too will be the lesser segment of the side AB, and the remainder BP the greater; and consequently the straight line PQ will cut the sides BA, AC in extreme and mean ratio. By the same reasoning the

straight line PR, which is drawn through I parallel to AM, will cut the sides CB, BA in extreme and mean ratio, and therefore will fall on the point P. Not otherwise, the straight line RQ, drawn through H parallel to BK, will cut the sides AC, CB in extreme and mean ratio, and so will fall on the points R, Q.

And since the individual sides of triangle PQR — subtending equal angles of the equilateral triangle, contained by equal lines, namely each by the greater and the lesser segment — are equal to one another [Margin: h — 4.pri. = *Elements* I.4], the triangle PQR composed of them will be equilateral, and its sides are indeed bisected by the angles of the triangle GHI of the icosahedron. (For since in triangle ACL the straight line PQ is parallel to the side CL, PQ and LC will be cut in the same ratios, from what we demonstrated at Prop. 4, Book 6. Now CL is bisected at H, on account of triangle ACL, in which FH is parallel to the side AL, cutting the sides CA, CL proportionally [Margin: i — 2.sexti = *Elements* VI.2]. Therefore PQ too is bisected at G. And the same reasoning holds for the remaining ones, QR, RP.) And therefore the triangle GHI of the icosahedron is inscribed

Diagram. A large equilateral triangle ABC (apex A, base BC) subdivided by a dense network of interior lines into the construction of the inscribed icosahedron triangle. Down the left edge from A to B lie the points P, D, L, N; down the right edge from A to C lie K, F, Q, O; along the base from B to C lie R, E, M, S. Interior points are G (upper center), I (center-left), H (lower center), and T (center-right). The central triangle PQR encloses the smaller icosahedron triangle GHI.

- A (top apex): vertex of the tetrahedron's triangular face
- B (lower-left vertex); C (lower-right vertex)
- P (left edge, upper): angle of the inscribed equilateral triangle PQR
- K (right edge, upper)
- D (left edge, midpoint of AB); F (right edge, midpoint of AC); E (base, midpoint of BC): bisection points of the three sides
- L (left edge, lower); Q (right edge, lower)
- N (left edge, near B); O (right edge, near C): endpoints of the parallel NO drawn through H
- R, M, S (base points): sections of the base
- G (upper center); H (lower center); I (center-left): vertices of the icosahedron triangle GHI
- T (center-right): point on the parallel NO

(continuation of Prop. 3) ...in the equilateral triangle PQR, whose angles divide the sides of the base of the tetrahedron in extreme and mean ratio, and whose sides are themselves bisected at G, H, I by the angles of the base GHI of the icosahedron. Therefore, if from the angles of the triangular face of a tetrahedron, etc. Which was to be shown.

COROLLARIVM.

From these things it can easily be gathered that the side of the icosahedron inscribed in an octahedron is the greater segment of a straight line divided in extreme and mean ratio — the line which, drawn from one angle of the base of the octahedron, cuts the opposite side likewise in extreme and mean ratio. For since, as is established from Prop. 16, Book 15, GHI is the triangle of the icosahedron inscribed in the octahedron, whose base is DEF: let there be drawn from angle F, of triangle FEC — which is equal to triangle DEF — the straight line FS parallel to AM, cutting MC and HO at S and T. Since therefore MC is bisected at S, on account of triangle AMC [Margin: k — 2.sex. = *Elements* VI.2], and MS is equal to GF, on account of the parallelogram GS [Margin: l — 34.pri. = *Elements* I.34], SC too will be equal to that same GF, the lesser segment of DF. And consequently, since the wholes DF, EC are equal, the remainder ES too will be equal to the remainder DG, the greater segment. Therefore EC is cut at S in extreme and mean ratio. Then, since FE and FS are cut similarly [Margin: m — 2.sex. = *Elements* VI.2], and FE is cut in extreme and mean ratio, FS too will be cut at T in extreme and mean ratio; and the greater segment will be FT, a straight line equal to the side GH of the icosahedron, on account of the parallelogram GT [Margin: n — 34.pri. = *Elements* I.34]. Therefore FT, the side of the icosahedron inscribed in the octahedron, is the greater segment of the straight line FS — which divides EC, the side of the octahedron, in extreme and mean ratio, being dropped from the angle F. Which was proposed.

Diagram. The same large subdivided equilateral triangle ABC as on the preceding page, reprinted here for the corollary. Apex A; left edge A→B carries P, D, L, N; right edge A→C carries K, F, Q, O; base B→C carries R, E, M, S. Interior points G (upper center), I (center-left), H (lower center), T (center-right).

- A (apex); B (lower-left); C (lower-right)
- P, D, L, N (left edge, top to bottom)
- K, F, Q, O (right edge, top to bottom)
- R, E, M, S (base, left to right)
- G (upper center); H (lower center); I (center-left): icosahedron triangle GHI

- T (center-right)

THEOR. 4. PROPOS. 4.

The lesser segment of the side of a tetrahedron cut in extreme and mean ratio is, in square [potential], double the side of the icosahedron inscribed in that tetrahedron.

Let the base of the tetrahedron be ABC, whose sides are cut in extreme and mean ratio at K, L, M. Drawing the straight lines BK, CL, AM, which produce GHI, the base of the icosahedron inscribed in that tetrahedron, inscribed in turn in the equilateral triangle PQR — whose angles cut the sides of triangle ABC in extreme and mean ratio at P, Q, R, and whose sides PQ, QR, RP are bisected at G, H, I, as was demonstrated in the preceding proposition. I say that AP, the lesser segment of the side of the tetrahedron, is in square double the side HI of the icosahedron. For since PQ is in square double the lesser segment AP (by Corollary 1 to Prop. 16, Book 15), but quadruple the square of HI (by the scholium to Prop. 4, Book 2 — because the straight line PQ is double PG, that is, double HI equal to it, on account of the parallelogram PH): PQ will be, in square, 4; AP, 2; and HI, 1. For which reason AP will be in square double HI. Therefore the lesser segment of the side, etc. Which was to be demonstrated.

Diagram. A smaller equilateral triangle ABC (apex A, base BC) with the inscribed construction. Down from A on the left: P then L; near the top center G; on the right near the top K; interior center-left I, center H; right side Q; base points R and M.

- A (apex); B (lower-left); C (lower-right)
- P (left, upper); G (center, upper); K (right, upper)
- L (left, lower); I (interior, center-left); H (interior, center); Q (right, lower)
- R, M (base points between B and C)

COROLLARIVM.

It follows from these things that the side of the icosahedron inscribed in the tetrahedron is an apotome [*apotome*, from Greek ἀποτομή — a species of irrational straight line]. For since the diameter of the sphere is, in square, one-and-a-half times [sesquialtera] the side of the tetrahedron [Margin: a — 13.tertiidecimi = *Elements* XIII.13]: if the diameter is set as rational, the side of the tetrahedron too will be rational, since it is commensurable in square with the diameter [Margin: b — 6.dec. = *Elements* X.6]. Therefore the lesser segment of the side of the tetrahedron cut in extreme and mean ratio will be an apotome

[Margin: c — 6.tertiidecimi = *Elements* XIII.6]. And accordingly, since the side of the icosahedron is commensurable in square with the lesser segment of the side of the tetrahedron [Margin: d — 6.dec. = *Elements* X.6] — for we showed that the lesser segment is, in square, double the side of the icosahedron — the side of the icosahedron too will be an apotome, by the scholium to Prop. 104, Book 10.

THEOR. 5. PROPOS. 5.

The side of a cube is, in square, half the side of the tetrahedron inscribed in it. The side of the tetrahedron, in turn, is double, in length, the side of the octahedron inscribed in it. And finally, the side of the cube is, in square, double the side of the octahedron inscribed in it.

For since the side of the tetrahedron inscribed in a cube is the diameter of a face of the cube, as is established from Prop. 1, Book 15; and since the square of this diameter is double a face of the cube — that is, double the square of the side of the cube — by the scholium to Prop. 47, Book 1: it is manifest that the side of the cube is, in square, half the side of the tetrahedron inscribed in that cube. Again, since the straight lines joining the bisection-points of the sides of the tetrahedron constitute the octahedron inscribed in the tetrahedron, as is clear from Prop. 2, Book 15; and since the side of an equilateral triangle is double the straight line joining the bisections of its sides — that line being equal to half the side of the triangle, as is established from the corollary to Prop. 4, Book 6 (for since it is parallel to the third side, it cuts off an equilateral triangle, etc.) [Margin: a — 2.sex. = *Elements* VI.2]: it is evident that the side of the tetrahedron is double, in length, the side of the octahedron inscribed in it. Finally, since the diameter of the sphere, or of the octahedron, is, in square, double the side of the octahedron [Margin: b — 14.tertiidecimi = *Elements* XIII.14]; and since the side of the cube is equal to the diameter of the octahedron inscribed in it — because the diameter of the octahedron joins the centers of opposite faces, as

(*continuation of Prop. 5*) ...we said in the corollary to Prop. 3, Book 15: it is clear that the side of the cube is, in square, double the side of the octahedron inscribed in it. And therefore the side of the cube is, in square, half the side of the tetrahedron, etc. Which was to be shown.

THEOR. 6. PROPOS. 6.

The side of a dodecahedron is the greater segment of a straight line which is, in square, half the side of the tetrahedron inscribed in it.

For since the tetrahedron inscribed in the cube is also inscribed in the dodecahedron in which that cube is inscribed, as we taught at Prop. 10, Book 15; and since the side of the dodecahedron is the greater segment of the side of the cube inscribed in it (by Corollary 1 to Prop. 17, Book 13); and finally, since the side of the cube is, in square, half the side of the tetrahedron inscribed in it [Margin: $a — 5.\text{sextidecimi} = \textit{Elements XVI.5}$, i.e. Prop. 5 of this book]: it is plainly gathered that the side of the dodecahedron is the greater segment of a straight line which is, in square, half the side of the tetrahedron inscribed in it. Which was to be demonstrated.

THEOR. 7. PROPOS. 7.

If both an icosahedron and a dodecahedron are inscribed in a cube, the side of the icosahedron will be the mean proportional between the side of the cube and the side of the dodecahedron.

Let the side of the cube be A, the side of the icosahedron inscribed in it B, and finally the side of the dodecahedron inscribed in the same cube C. I say that B, the side of the icosahedron, is in the mean position, proportional between A, the side of the cube, and C, the side of the dodecahedron. For since, from what was demonstrated at Prop. 14, Book 15, B, the side of the icosahedron, is the greater segment of the side of the cube A; and C, the side of the dodecahedron, is the lesser segment of that same side of the cube, by what we showed in the scholium to Prop. 13 of the same book: it becomes plain that A, the whole, is to B, the greater segment, as B, the greater segment, is to C, the lesser. Therefore, if both an icosahedron and a dodecahedron are inscribed in a cube, etc. Which was to be shown.

Diagram. Three horizontal straight-line segments drawn one above another, decreasing in length, illustrating the mean-proportional relation $A : B :: B : C$.

- A: the longest segment (side of the cube)
- B: the middle segment (side of the icosahedron — the mean proportional)
- C: the shortest segment (side of the dodecahedron)

THEOR. 8. PROPOS. 8.

The side of a tetrahedron is, in square, eighteen times [octodecuplum] the side of the cube inscribed in it.

For since, by what was demonstrated at Prop. 18, Book 15, the side of the tetrahedron is triple, in length, the diameter of a face of the cube inscribed in it —

for it was shown there that GH, the diameter of the face of the inscribed cube, is a third part of the side BC of the tetrahedron — and since squares have the duplicate ratio of their sides [Margin: a — 20.sex. = *Elements* VI.20]: the square of the side of the tetrahedron will be nine times the square of the diameter of the cube's face inscribed in it, since the ninefold ratio is the duplicate of the triple, as appears in these numbers 1, 3, 9. Therefore, since the square of the diameter of the cube's face is double the face of the cube itself (by the scholium to Prop. 47, Book 1), it comes about that, if the face of the cube — that is, the square of the side of the cube — is set as 1, the square of the diameter of that face is 2, and the square of the side of the tetrahedron is 18. For which reason the side of the tetrahedron is, in square, eighteen times the side of the cube inscribed in it. Which was to be shown.

THEOR. 9. PROPOS. 9.

The side of a tetrahedron is, in square, eighteen times a straight line cut in extreme and mean ratio, whose greater segment is the side of the dodecahedron inscribed in the tetrahedron.

For since the cube inscribed in the dodecahedron is also inscribed in the tetrahedron in which that dodecahedron is inscribed, as we taught in the scholium to the last proposition of Book 15: the side of the tetrahedron will be, in square, eighteen times the side of the cube inscribed both in it and in the dodecahedron [Margin: a — 8.sex tidecimi = *Elements* XVI.8, i.e. Prop. 8 of this book]. Now the greater segment of this side of the cube, cut in extreme and mean ratio, is (by Corollary 1 to Prop. 17, Book 13) the side of the dodecahedron inscribed in the tetrahedron, in which of course the cube is inscribed. Therefore the side of the tetrahedron is, in square, eighteen times a straight line cut in extreme and mean ratio, whose greater segment is the side of the dodecahedron inscribed in the tetrahedron. Which was to be demonstrated.

THEOR. 10. PROPOS. 10.

If an icosahedron is inscribed in an octahedron, the side of the icosahedron will be, in square, double the lesser segment of the side of the octahedron divided in extreme and mean ratio.

For, as is established from Prop. 16, Book 15, the straight line joining the two sections — those near the lesser segments — of two sides of the octahedron that contain a right angle (such as was there the straight line GI, subtending the right angle GAI, contained by the lesser segments AG, AI) is the side of the icosahedron inscribed in the octahedron. Therefore, since this very side of the icosahedron is,

in square, equal to those two equal lesser segments, it will be, in square, double one lesser segment [Margin: a — 47.pri. = *Elements* I.47]. Therefore, if an icosahedron is inscribed in an octahedron, etc. Which was to be demonstrated.

THEOR. 11. PROPOS. 11.

The side of an octahedron is, in square, four-and-a-half times [quadruplum sesquialterum] the side of the cube inscribed in it.

Let ABCDE be one of the pyramids of the octahedron [vna ex(?) pyramidum octaedri — printed "vna lex"], whose base is the square ABCD, and whose triangular faces at the vertex E are ABE, EBC, CED, DEA; and let the centers of these triangles be F, G, H, I, through which the straight lines kL, LM, MN, Nk are drawn...

(Continuation of Book XVI, Proposition 11: the side of an octahedron is, in square, four-and-a-half times the side of the cube inscribed in it. The demonstration begun in the prior pages continues.)

MN and Nk are parallel to the straight lines AB, BC, CD, DA. And if the straight lines FG, GH, HI, IF are joined, FGHI will be the square of the cube inscribed in the octahedron, as we demonstrated in proposition 4 of book 15. Now when the straight line EHO is drawn, it is one-and-a-half times [sesquialterate] the straight line EH, by the corollary to proposition 18 of book 14; so that if EO is set at 3 such parts, EH will be 2 of them. [Margin: a — *Elements* VI.2 ("2. sexti")] But as EO is to EH, so is EB to EL. Therefore, of whatever parts EB contains 3, EL — or LM, which equals it — will be 2.

And so the square on the octahedron's side EB will be 9 parts, while the square on the straight line LM — namely kLMN — will be 4 parts; and hence also the square on the cube's side GH — that is, FGHI — will be 2 such parts, since the square LN is double the square GI inscribed in it, by what we demonstrated in the scholium to proposition 47 of book 1. For LN is the square described on the diagonal of the square HI, [Margin: b — *Elements* I.33 ("33. pri.")] since GI, the diagonal (if it be drawn), equals the side LM. Therefore the octahedron's side EB is, in square, four-and-a-half times [quadruple-sesquialterate] the cube's side GH, since their squares have the ratio of 9 to 2. Therefore the side of an octahedron is, in square, four-and-a-half times the side of the cube inscribed in it. Q.E.D.

Diagram. The octahedral pyramid figure for Proposition 11, drawn as a square with an inscribed cross-hatched figure. The outer square has A at the top-left corner and D at the top-right; B at the bottom-left and C at the bottom-right, with

O marked at the middle of the base BC. Within it are the diagonals and the inscribed square FGHI.

- A (top-left corner)
- D (top-right corner)
- B (bottom-left corner)
- C (bottom-right corner)
- O (midpoint of the base BC)
- K (upper-left interior)
- F (upper-center interior)
- N (upper-right interior)
- E (center)
- G (left interior, mid-height)
- I (right interior, mid-height)
- L (lower-left interior)
- H (bottom-center interior)
- M (lower-center-right interior)

COROLLARY

Since the cube's side, divided in extreme and mean ratio, makes its greater segment the side of the dodecahedron in which the cube is inscribed, by the second corollary to proposition 13 of book 15, and since both the dodecahedron and the cube inscribed in it are inscribed in the same octahedron, as we taught in the scholium to the last proposition of book 15, it becomes clear that the octahedron's side is, in square, four-and-a-half times that straight line — divided in extreme and mean ratio — whose greater segment is the side of the dodecahedron inscribed in the octahedron. For such a straight line is the side of the cube inscribed in the same octahedron, of which we showed the octahedron's side to be, in square, four-and-a-half times.

THEOR. 12. PROPOS. 12.

The side of an icosahedron is the greater segment of that straight line — cut in extreme and mean ratio — which is, in square, double the side of the octahedron inscribed in the icosahedron.

Since the six opposite sides of the icosahedron inscribed in a cube are set upon the six faces of the cube, and three straight lines equal to the cube's side join their bisection points, as is clear from proposition 14 of book 15 and its scholium; and

since the six vertices of the octahedron inscribed in the icosahedron lie at the bisection points of those six sides of the icosahedron, by proposition 15 of the same book 15; it follows that the diameter of the octahedron inscribed in the said icosahedron equals the side of the cube in which the icosahedron is inscribed.

Therefore, since by what we showed at proposition 14 of book 15 the icosahedron's side is the greater segment of the aforesaid cube's side when it is divided in extreme and mean ratio, the same icosahedron's side will also be the greater segment of the diameter of the octahedron inscribed in that icosahedron. [Margin: a — *Elements* XIII.14 ("14. tertijdec.")] But the diameter of the sphere — that is, of the octahedron — is, in square, double the octahedron's side. Therefore the icosahedron's side is the greater segment of that straight line, cut in extreme and mean ratio, which is, in square, double the side of the octahedron inscribed in the icosahedron. Q.E.D.

THEOR. 13. PROPOS. 13.

The side of a cube has to the side of the dodecahedron inscribed in it the duplicate ratio of that which the greater segment has to the lesser of a straight line divided in extreme and mean ratio. But the side of the dodecahedron has to the side of the cube inscribed in it the ratio which the lesser segment has to the greater of the same straight line.

It was shown in the scholium to proposition 13 of book 15 that the lesser segment of the cube's side, cut in extreme and mean ratio, is the side of the dodecahedron inscribed in that cube. Since, then, the whole line divided in extreme and mean ratio has to the lesser segment the duplicate of the ratio of the whole line to the greater segment (or of the greater segment to the lesser) — because the whole line, the greater segment, and the lesser are three straight lines in continued proportion — it is clearly established that the ratio of the cube's side to the side of the dodecahedron inscribed in it is likewise the duplicate of the ratio of the greater segment to the lesser.

Moreover, since it is established from the first corollary to proposition 17 of book 13 that the greater segment of the cube's side, divided in extreme and mean ratio, is the side of the dodecahedron in which the cube is inscribed, it is evident that, as the side of the dodecahedron — that is, the greater segment — is to the side of the cube inscribed in it — that is, to the whole line cut in extreme and mean ratio — so is the lesser segment to the greater. For since, as the whole line is to the greater segment, so the greater segment is to the lesser, it will also be, by conversion, that as the greater segment is to the whole line, so the lesser segment

is to the greater. Therefore the side of the cube to the side of the dodecahedron, and so forth. Q.E.D.

THEOR. 14. PROPOS. 14.

The side of an octahedron is one-and-a-half times [sesquialterate] the side of the tetrahedron inscribed in it.

Let ABCDE be one of the six pyramids of the octahedron, whose base is the square ABCD and whose triangles at the apex E are ABE, EBC, CED, DEA; and let the centers of these triangles be F, G, H, I, which are joined by the straight lines FG, GH, HI, IF, forming the square of the cube inscribed in the octahedron, as we taught in proposition 4 of book 15. Now since the tetrahedron inscribed in the cube is also inscribed in the octahedron on which the cube is set — as we explained in the scholium to the last proposition of book 15 — and since the side of the tetrahedron inscribed in the cube is the diagonal of the cube's face, as is clear from proposition 1 of book 15, the diagonal GI, when drawn, will be the side of the tetrahedron inscribed in the said octahedron. I say, then, that the octahedron's side BC is one-and-a-half times the tetrahedron's side GI.

For when the straight lines EGK, EIL are drawn, the sides AB, CD are bisected at K, L, by the scholium to proposition 12 of book 13, and EK, EL themselves will be one-and-a-half times the straight lines EG, EI, by the corollary to proposition 18 of book 14. [Margin: a — *Elements* VI.2 ("2. sex."); the text itself cites the corollary to VI.4] And therefore GI will be parallel to the straight line KL, cutting off — by the corollary to proposition 4 of book 6 — the triangle EGI similar to the triangle EKL. Hence, as EK is to KL, so EG is to GI; and alternately, as EK is to EG, so KL is to GI. And so, since EK is one-and-a-half times EG, KL too will be one-and-a-half times GI. [Margin: b — *Elements* I.33 ("33. pri.")] Since, then, BC equals KL — because BK and CL are equal and parallel — BC, the octahedron's side, will be one-and-a-half times GI, the side of the tetrahedron inscribed in it. Q.E.D.

Diagram. The octahedral pyramid ABCDE for Proposition 14, drawn in oblique view with apex E uppermost and the square base ABCD below, with the inscribed square GI–KL of face-centers.

- E (apex, top)
- F (just below the apex, a face-center)
- A (upper-left base corner)
- D (upper-right base corner)
- G (left interior face-center)

- I (right interior face-center)
- K (lower-left, midpoint of AB)
- L (lower-right, midpoint of CD)
- H (bottom-center interior)
- B (bottom-left base corner)
- C (bottom-right base corner)

THEOR. 15. PROPOS. 15.

If from the square on the icosahedron's diameter there is taken away three times the square on the side of the cube inscribed in it, there remains a square that is four-thirds [sesquitercian] of the square on the icosahedron's side.

Let there be an icosahedron ABCDEFGH, whose diameter is BE and whose center is I; and let BCG, EFH be opposite and parallel triangles, by the fourth corollary to proposition 14 of book 13, whose centers are K, L. From the center I let a perpendicular IK be drawn to the plane BCG, which — by the corollary to lemma 1 of proposition 10 of book 14 — falls upon the center K. KI produced will therefore also be perpendicular to the plane EFH, which is parallel to the plane BCG, by the scholium to proposition 14 of book 11, and will accordingly fall upon the center L, by the corollary to the aforesaid lemma. For this reason, since the cube inscribed in the icosahedron sets its vertices at the centers of the icosahedron's faces, as is clear from proposition 11 of book 15 — and hence its opposite vertices at the centers of opposite faces — KL will be the diameter of the cube inscribed in the icosahedron, passing through I, the icosahedron's center.

Since, then, by the same reasoning the remaining diameters of the cube pass through the same center I, I will also be the center of the inscribed cube, and therefore the half-diameters IK, IL are equal. Now if KB — the radius of the circle circumscribing the triangle BCG — is joined, the angle BKI will be a right angle, by definition 3 of book 11. [Margin: a — *Elements* I.47 ("47. pri.")] And accordingly the square on the straight line BI equals the squares on the straight lines BK, KI. Therefore the square on the diameter BE also — being four times the square on the half-diameter BI, as we showed in the scholium to proposition 4 of book 2 — will equal the squares on two straight lines, namely on the diameter of the circle circumscribing the triangle BCG, and on KL. For these squares too, by the same scholium, are four times the squares described on the half-diameters BK, KI. So when the square on the cube's diameter KL — [Margin: b — *Elements* XIII.15 ("15. tertijdec.")] which is three times the square on the cube's side — is taken away

from the square on the icosahedron's diameter BE, there remains the square on the diameter of the circle circumscribing the triangle BCG.

This, I say, is four-thirds of the square on the icosahedron's side BC. For let a circle be described about the equilateral triangle BCG from the center K, and let Bk be extended to M — cutting CG at N — and let the straight line CM also be drawn. Now since BN, drawn through the center k, is perpendicular to CG, by what we showed in the scholium to proposition 12 of book 13, [Margin: c — *Elements* XIV.12 ("12. quartidec.")] the straight line BC will be, in square, four-thirds of the straight line BN; and as BC is to BN, so is BM to BC, since BC is the mean proportional between BM and BN, by the corollary to proposition 8 of book 6, [Margin: d — *Elements* III.31 ("31. ter.")] the angle BCM being right, standing in a semicircle. Therefore the straight line BM too is, in square, four-thirds of the straight line BC; and so the square on the diameter BM is four-thirds of the square on the side BC. Wherefore, if from the square on the icosahedron's diameter, and so forth. Q.E.D.

Diagram. The icosahedron figure for Proposition 15, drawn as a hexagonal projection ABCDEFGH with interior points and the two parallel triangles BCG and EFH.

- A (top-left)
- B (top-right)
- F (far left)
- G (upper-center interior)
- K (right, between B and C)
- I (center)
- L (left-center interior)
- H (lower-center interior)
- C (right)
- E (bottom-left)
- D (bottom-center)

Diagram. The circle figure for the latter part of Proposition 15: a circle circumscribing the equilateral triangle BCG, with the diameter BM drawn vertically through the center K, and CG cut at N.

- B (top of circle)
- K (center)
- C (left, on the circle)

- G (right, on the circle)
- N (on CG, below center, where BM meets CG)
- M (bottom of circle, opposite B)

COROLLARY

From this it follows that the icosahedron's diameter is, in square, [equal to the sum of] two straight lines: namely the diameter of the cube inscribed in it, and the diameter of the circle surrounding the icosahedron's triangle. For it was shown that the square on the icosahedron's diameter BE equals the squares on the cube's diameter kL and on the diameter of the circle circumscribing the triangle BCG.

THEOR. 16. PROPOS. 16.

The side of a dodecahedron is the lesser segment of a straight line divided in extreme and mean ratio, which is, in square, double the side of the octahedron inscribed in the dodecahedron.

Since the diameter of the octahedron inscribed in the dodecahedron — being, in square, double the octahedron's side — [Margin: a — *Elements* XIII.14 ("14. tertijdec.")] joins the bisection points of opposite sides of the dodecahedron, as is evident from proposition 9 of book 15; and since the side of the dodecahedron is the lesser segment of the straight line joining those bisection points when it is divided in extreme and mean ratio, by the fourth corollary to proposition 17 of book 13; it is clear that the side of the dodecahedron is the lesser segment of that straight line — divided in extreme and mean ratio — which is, in square, double the side of the octahedron inscribed in it. For such a straight line joins the bisection points of opposite sides of the dodecahedron, and its lesser segment is indeed the side of the dodecahedron, by the aforesaid corollary. And so the side of the dodecahedron is the lesser segment of a straight line [divided] in extreme and mean ratio, and so forth. Q.E.D.

THEOR. 17. PROPOS. 17.

The diameter of an icosahedron is, in square, both four-thirds of its own side and one-and-a-half times the side of the tetrahedron inscribed in it.

Since the cube and the tetrahedron inscribed in it are inscribed in the same icosahedron, as we taught in the scholium to the last proposition of book 15, and are contained by the same sphere, the diameter of the cube and the diameter of the sphere surrounding the tetrahedron will be the same. [Margin: a — *Elements*

XIII.13 ("13. tertijdec.")] Now the sphere's diameter is, in square, one-and-a-half times the tetrahedron's side. Therefore the diameter of the cube inscribed in the icosahedron — in which the tetrahedron too is inscribed — will also be, in square, one-and-a-half times the side of the tetrahedron inscribed in that cube and in the icosahedron. But the diameter of the circle circumscribing the icosahedron's face is, in square, four-thirds of the icosahedron's side, as we demonstrated in the proof of proposition 15 of this book. Therefore the icosahedron's diameter — which is, in square, [equal to the sum of] both the diameter of the cube inscribed in it and the diameter of the circle surrounding the icosahedron's face, by the corollary to proposition 15 of this book — is also, in square, both four-thirds of its own side (namely the diameter of the circle described about the icosahedron's face) and one-and-a-half times the side of the tetrahedron inscribed in it (namely the diameter of the cube). Q.E.D.

THEOR. 18. PROPOS. 18.

The side of a dodecahedron is to the side of the icosahedron inscribed in it as the lesser segment of the perpendicular line — drawn from one vertex of a pentagon to the opposite side and divided in extreme and mean ratio — is to that part of the same line lying between the pentagon's center and its side.

Let there be half a dodecahedron contained by six pentagons ABMLK, LKIHP, PHGFO, OFEDN, NDCBM, LMNOP, whose centers Q, R, S, T, V, X (each two neighboring ones, that is) are joined by the straight lines QR, RS, ST, TV, VQ, QX, RX, SX, TX, VX. Thus there are formed five triangles of the icosahedron inscribed in the dodecahedron, composing the solid angle X at the center of the pentagon LMNOP, as was shown in the proof of proposition 7 of book 15. From the two pentagon-vertices D, K, let straight lines DY, KY be dropped to the common base BM through the centers R, Q; and since these cut the side BM in half and at right angles, by the second corollary to proposition 10 of book 13, they will meet at the point Y. And if the straight line AL is drawn subtending the angle K, the perpendicular KY will be cut at Z in extreme and mean ratio. [Margin: a — *Elements* XVI.2 ("2. sextidec.")] I say that the dodecahedron's side LM is to the side QR of the icosahedron inscribed in it as KZ — the lesser segment of the perpendicular KY — is to the straight line QY intercepted between the center Q and the side BM.

For the straight line DK, drawn as a subtense — which, by what was demonstrated in the scholium to proposition 13 of book 15, is the side of the cube in which the given dodecahedron is inscribed — makes LM, the dodecahedron's

side, the lesser segment of DK, if DK is cut in extreme and mean ratio, by the same scholium to proposition 13 of book 15. Now since the sides YD, YK of the triangle YDK are cut proportionally at R and Q — for RD, QK are equal, being radii of equal circles, and likewise YR, YQ, being the distances of the straight line BM from the centers R and Q of those same equal circles — [Margin: b — *Elements* VI.2 ("2. sex.")] QR will be parallel to DK; and therefore the triangle YRQ is similar to the triangle YDK, by the corollary to proposition 4 of book 6. [Margin: c — *Elements* VI.4 ("4. sex.")] For this reason, as DK is to KY, so QR will be to QY; [Margin: d — *Elements* XIV.2 ("2. quartidec.")] but as the whole DK is to the whole KY, so is LM, the lesser segment, to the lesser [segment] KZ. Therefore, as LM is to KZ, so will QR be to QY; and alternately, as LM, the dodecahedron's side, is to QR, the side of the icosahedron inscribed in it, so is KZ, the lesser segment of the perpendicular KY, to QY, the part set between the center Q and the side BM. Therefore the side of the dodecahedron to the side of the icosahedron inscribed in it, and so forth. Q.E.D.

Diagram. The projection of half a dodecahedron with its inscribed icosahedron, for Proposition 18. The outer boundary is a ten-vertex figure (the six pentagons seen in plane), with a central pentagon LMNOP (center X) surrounded by the pentagon-centers Q, R, S, T, V that form the vertices of the inscribed icosahedron. This is a dense figure; positions are read from the plate as follows.

- A (top outer vertex)
- B (upper-left outer, below A)
- C (left outer)
- D (lower-left outer)
- E (bottom-left outer)
- F (bottom outer)
- G (bottom-right outer)
- H (right outer, lower)
- I (right outer)
- K (upper-right outer)
- L (central pentagon, upper-right)
- M (central pentagon, upper-left)
- N (central pentagon, lower-left)
- O (central pentagon, bottom)
- P (central pentagon, lower-right)
- Q (center of the top pentagon ABMLK; upper-center interior)

- R (center of a pentagon; left-center interior)
- S (center of a pentagon; lower-left-center interior)
- T (center of a pentagon; lower-right-center interior)
- V (center of a pentagon; right-center interior)
- X (center of the whole figure; center of pentagon LMNOP)
- Y (constructed point, upper-center, near Q)
- Z (constructed point on KY, near Q) [?]

THEOR. 19. PROPOS. 19.

If half the side of an icosahedron is cut in extreme and mean ratio, and its lesser segment is taken away from the whole side of the icosahedron, and from the remaining straight line a third part is again subtracted: there will be left the side of the dodecahedron inscribed in the icosahedron.

About the pentagon ABCDE, composed of five sides of the icosahedron, let a circle be described, whose center is F; and upon the five sides of the pentagon let five equilateral triangles be raised, forming the solid angle G of the icosahedron, by what was demonstrated in proposition 16 of book 13. Then in the said circle let an equilateral triangle AHI be inscribed. Now since the arcs ABC, AED are equal — each containing two-fifths of the whole circumference — and likewise the two arcs ABH, AEI, since they are thirds of the same circumference, the remaining arcs HC, ID will be equal; and therefore the straight lines HI, CD are parallel, by the scholium to proposition 27 of book 3. To these let a perpendicular FKL be drawn from the center F, [Margin: a — *Elements* III.3 ("3. ter.")] cutting the straight lines HI, CD in half at K and L; and let the straight lines FC, FD be joined. Let there further be taken the centers N and O of the equilateral triangles GBC, GCD, through which let the straight lines GNP, GOL be drawn, which — by the scholium to proposition 12 of book 13 — divide the opposite sides BC, CD in half and at right angles. And so the straight line GO will fall upon the point L, at which CD is bisected. Now let the centers N, O be joined by the straight line NO, which — as is established from what was demonstrated in proposition 5 of book 15 — will be the side of the dodeca

(Conclusion of the demonstration of Proposition 19: the side of the dodecahedron inscribed in the icosahedron.)

the dodecahedron inscribed in the icosahedron. Finally, let BP — half the side of the icosahedron — be cut at Q in extreme and mean ratio; and when the lesser segment BQ has been removed from the whole side BC, let a third part CR be

subtracted from the remainder CQ. I say that the remainder QR is equal to NO, the side of the dodecahedron.

For FL, the perpendicular from the side HI of the equilateral triangle, is cut at K in extreme and mean ratio — since FL cut in this way makes the greater segment equal to the perpendicular FK, by the corollary of proposition 2 of book 14. And KM is set equal to the greater segment FK, by the corollary of proposition 12 of book 13. It follows, from what we demonstrated at proposition 5 of book 13, that the greater segment KM is likewise cut at L, in extreme and mean ratio, by the lesser segment KL. Therefore the line FM exceeds the line FL by the segment LM, which is less than half of FM — that is, by a segment less than the line KM, as we showed.

Now PL, when joined, is the side of the equilateral and equiangular pentagon inscribed within the pentagon ABCDE, having the same center F, by the last scholium of book 4; and so it is similar to ABCDE. Hence the triangles FCD and FPL — if FP were drawn — will be similar, by the scholium of proposition 20 of book 6. Therefore, as FC is to CD, so FL is to LP; and, alternately, as FC is to FL, so CD is to LP. But FC — that is, FM, which is equal to it — exceeds the line FL by a segment less than half of FM, namely by a segment less than KM, as we showed. Therefore the line CD, or BC which is equal to it, will also exceed the line LP by a segment less than half of BC — namely by a segment less than the line BP, which was BQ; and consequently the remainder CQ will be equal to the line PL.

Again, since GP and GL are cut proportionally at the centers N, O — because GN and GO are double NP and OL respectively, by the corollary of proposition 18 of book 14 — [Margin: b — Elements VI.2] PL and NO will be parallel, and consequently the triangle GNO is similar to GPL, by the corollary of proposition 4 of book 6. [Margin: c — Elements VI.4] Therefore, as GP is to PL, so GN is to NO; and, alternately, as GP is to GN, so PL is to NO. But GP is one-and-a-half times GN, by the corollary of proposition 18 of book 14. Therefore PL — that is, CQ, which is equal to it — will also be one-and-a-half times NO. And since CQ is likewise one-and-a-half times the line QR — for of whatever parts CQ is 3, CR is 2, by construction, and therefore QR is 2 of those same parts — QR will be equal to NO, the side of the dodecahedron inscribed in the icosahedron. So then, if half the side of the icosahedron has been cut in extreme and mean ratio, and so on. Which was to be demonstrated.

THEOR. 20. POPROS. 20.

(Heading printed "POPROS." — evidently a compositor error for "PROPOS." — see the anomalies note.)

The cube is triple the pyramid inscribed in it.

Let the pyramid ACEG be inscribed in the cube AF. I say that the cube is triple the pyramid. For the inscribed equilateral pyramid is surrounded by four pyramids, founded upon its four faces and having as their apexes the remaining four angles of the cube — those in which the four angles of the inscribed equilateral pyramid do not sit. (For upon the base ACE is founded the pyramid ACED; upon the base AEG, the pyramid AEGH; upon the base CEG, the pyramid CEGF; and upon the base ACG, the pyramid ACGB. These four pyramids are equal, by definition 10 of book 11, since they are contained by planes similar and equal both in number and in magnitude. For each consists of three equal and similar triangles — namely halves of the squares of the cube, as is clear — together with one triangle of the inscribed equilateral pyramid.)

Now let the cube be six times any one of these pyramids. (For example, the pyramid ABCG, having ABC as its base — half of BD, the base of the cube — and

the same height as the cube, namely the line BG, is a third part, by corollary 1 of proposition 7 of book 12, of the prism that has the same base and height. [Margin: a — Elements XI.32] Since, then, the cube is double this prism — because the base of the cube is double the base of the prism — it is manifest that the pyramid ABCG is a sixth part of the cube, and consequently that the cube is six times that pyramid.) It follows that the four surrounding pyramids are four sixth-parts, that is, two-thirds of the cube; and consequently that the remaining equilateral pyramid ACEG, inscribed in the cube, is a third part of the same cube. Therefore the cube is triple the pyramid inscribed in it. Which was to be demonstrated.

ANOTHER PROOF. Since the cube and the pyramid described within it are comprehended by the same sphere — as we taught in the scholium of the last proposition of book 15 — [Margin: b — Elements XIV.32] and since the cube is triple the pyramid described in the same sphere, as has been demonstrated, it is clearly gathered that the cube is triple the pyramid inscribed in it, seeing that this pyramid is contained in the same sphere as the cube.

THEOR. 21. PROPOS. 21.

The pyramid is double the octahedron inscribed in it.

In the pyramid ABCD let the octahedron EIKGHF be described. I say that the pyramid is double the octahedron. For the octahedron is surrounded by four pyramids similar to the pyramid ABCD — as was demonstrated at proposition 3 of book 15 — founded upon the four faces of the octahedron EGH, EFI, FGK, HIK, namely the pyramids EGHA, EFIB, FGKC, HIKD. (These are equal to one another, by definition 10 of book 11, since they are contained by triangles similar, and equal in number and in magnitude — being indeed similar to the bases of the

equilateral pyramid ABCD, by the corollary of proposition 4 of book 6, and having equal sides, namely the halves of the equal sides of the same pyramid ABCD, by construction —

and having the triplicate ratio of homologous sides, by proposition 2 of book 15. [Margin: a — Elements XII.8] Since, then, similar pyramids have the triplicate ratio of their homologous sides, the pyramid ABCD will be eight times any one of those four pyramids set around the octahedron — since an eightfold ratio is the duplicate of a double ratio, such as the sides of the pyramid ABCD have to the sides of the said four pyramids when tripled, as is plainly seen in these numbers 1. 2. 4. 8. That is, each of those four pyramids will be an eighth part of the pyramid ABCD; and therefore all four of the said pyramids will make four eighths, that is, half of the pyramid ABCD. Hence the remaining octahedron EIKGHF will be the other half of the same pyramid ABCD.) Therefore the pyramid is double the octahedron inscribed in it. Which was to be demonstrated.

THEOR. 22. PROPOS. 22.

The cube is six times the octahedron inscribed in it.

Since, if a pyramid be described in a cube, and an octahedron in the pyramid, the octahedron is likewise inscribed in the cube — as is clear from the second demonstration of proposition 3 of book 15 — and since the cube is triple the pyramid described in it [Margin: a — Elements XVI.20] while the pyramid is double the octahedron inscribed in it, [Margin: b — Elements XVI.21] it comes about that, of whatever parts the cube is 6, the pyramid is 2 and the octahedron 1;

and thus the cube is six times the octahedron. Therefore the cube is six times the octahedron inscribed in it. Which was to be demonstrated.

THEOR. 23. PROPOS. 23.

The octahedron is four-and-a-half times the cube inscribed in it.

In the octahedron $ABCDEF$ let the cube $GHikLMNO$ be described, setting its angles at the centers of the faces of the octahedron. I say that the octahedron is four-and-a-half times the cube. For, taking the pyramid $BEDFA$ of the octahedron, let there be drawn through G, k, I, H — the centers of the four faces of the octahedron — the lines PQ, QR, RS, SP , parallel to the sides BE, ED, DF, FB , forming the parallelogram-square $PQRS$, as was demonstrated at proposition 4 of book 15.

[Margin: a] This square will be parallel to the square $BEDF$. Let there also be drawn the diameter AC of the octahedron, perpendicular to the square $BEDF$, at the center T , by what we showed in corollary 1 of proposition 14 of book 13; and hence it is perpendicular to the faces GI, MO of the cube, at the points V, X , by the scholium of proposition 14 of book 11. Now V is the center of the square $PQRS$; [Margin: b] (for since the parallel planes $BEDF, PQRS$ cut the equal lines AB, AE, AD, AF proportionally, AP, AQ, AR, AS will also be equal. Let the lines VP, VQ, VR, VS be understood as drawn. [Margin: c] Then, since the equal squares of the equal lines AP, AQ are equal to the squares of the lines AV, VP and of AV, VQ — because the angles AVP, AVQ are right, by definition 3 of book 11 — the common square of the line AV being taken away, the squares of the lines VP, VQ will be equal, and therefore the lines VP, VQ themselves equal. In no other way we shall show that VR, VS are equal, and that these are equal to one another. Therefore V is the center of the square $PQRS$.) So then V will be the center of the square $GHik$ described in that plane, by the last scholium of book 4; for the sides PQ, QR, RS, SP are bisected at G, k, I, H , as is clear from what was demonstrated at proposition 4 of book 15.

By the same argument we shall conclude that X is the center of the base $LMNO$; and likewise that the other diameters drawn, BD and EF , pass through Y, Z, α, β , the centers of the remaining faces. Now, the line $A\beta$ having been drawn through G , the center of the equilateral triangle ABE , AG will be double $G\beta$, by the corollary of proposition 18 of book 14. [Margin: d] Since, then, the parallel planes PR and BD cut the lines $A\beta, AT$ proportionally, AV will also be double VT . In the same way it will be proved that CX is double XT ; and hence, since AT, CT are equal, so likewise are VT, XT . Therefore the line VX , joining the centers of the opposite faces of the cube, is bisected at T . And so, since in the same way YZ and $\alpha\beta$ are bisected at T , T will be the center of the cube, by corollary 1 of proposition

15 of book 13 — for the lines joining the centers of the opposite faces of the cube bisect one another at the center. Now since VX is double VT , and AV was likewise double VT — that is, of the height of the cube — the pyramid $GHkA$, when the lines AI , Ak , AH have been drawn, is (since the base GI is common to both and the height of $PQRSA$ is double that of the pyramid $GHkA$, and the base $PQRS$ is double the base GHk) double the pyramid $GHkA$, by corollary 1 of proposition 7 of book 12. [Margin: e] And the pyramid $PQRSA$ contains two-thirds of the cube GO . But since the pyramids $BEDFA$, $PQRSA$ are similar — by definition 9 of book 11, their triangles being similar, by the corollary of proposition 4 of book 6 — [Margin: f] they have the triplicate ratio of their homologous sides. [Margin: g] And the side AB is one-and-a-half times the side AP , because the line $A\beta$, cut proportionally, is one-and-a-half times AG .

Therefore the pyramid $BEDFA$ will be to the pyramid $PQRSA$ as 27 to 8; for this triplicate ratio is one-and-a-half — as appears in these numbers 8. 12. 18. 27. And consequently the whole octahedron $ABCDEF$, being double the pyramid $BEDFA$, will have to the same pyramid $PQRSA$ the ratio of 54 to 8. But it has already been demonstrated that, of whatever parts the pyramid $PQRSA$ is 8, the cube GO is 12 (for the number 8 contains two-thirds of the number 12). Therefore the octahedron $ABCDEF$ has to the cube GO the ratio of 54 to 12 — that is, in the least numbers, found by proposition 35 of book 7, the ratio of 9 to 2, which is the quadruple-plus-one-half ratio. And so the octahedron is four-and-a-half times the cube inscribed in it. Which was to be shown.

Diagram. The figure for Proposition 23: the octahedron $ABCDEF$ (drawn as a large rhombus, apexes A above, C below, B left, D right, with E and F the front/back apexes) enclosing the inscribed cube $GHkLMNO$, together with the auxiliary square $PQRS$ and the centers/diameters. The interior is very densely lettered and foxed; several labels cannot be placed with confidence. — more than two interior labels flagged [?].**

COROLLARIVM I.

Therefore the octahedron and the cube inscribed in it have the same center; for we showed that T is the center of both.

COROLLARIVM II.

From this too we shall plainly infer that the octahedron has to the cube inscribed in it the same ratio that the squares of their sides have. [Margin: h — Elements XVI.11] For the squares of their sides have the quadruple-plus-one-half ratio, which is precisely the ratio we demonstrated the octahedron to have to the cube inscribed in it.

THEOR. 24. PROPOS. 24.

The octahedron is thirteen-and-a-half times the pyramid inscribed in it.

Since, as we showed at the end of book 15, a cube and a pyramid inscribed in it are described within the same octahedron, and since the octahedron is four-and-a-half times the cube described in it [Margin: a — Elements XVI.23] while the cube is triple the pyramid inscribed in it, and hence in the octahedron, [Margin: b — Elements XVI.20] it follows that, of whatever parts the pyramid is set as 2, the cube will be 6 and the octahedron 27. For 27 has to 6 the quadruple-plus-one-half ratio, and 6 to 2 the triple ratio. Therefore the octahedron has to the pyramid inscribed in it the ratio of 27 to 2 — that is, thirteen-and-a-half. And so the octahedron is thirteen-and-a-half times the pyramid inscribed in it, and so on. Which was to be shown.

THEOR. 25. PROPOS. 25.

The pyramid is nine times the cube inscribed in it.

In the pyramid ABCD let a cube be understood as described. I say that the pyramid is nine times the cube. For let G, H be taken, the centers of the two faces ACD, ABD; and to the common opposite side AD let the lines CGS, BHS be drawn, dividing the side AD in half and at right angles, by the scholium of proposition 12 of book 13, and therefore meeting at the midpoint S. Now the line GH having been joined — since BH, CG are double the lines HS, GS, by the corollary of proposition 18 of book 14, and are therefore cut proportionally at BS, CS — [Margin: a — Elements VI.2] BC and GS will be parallel, and, by the corollary of proposition 4 of book 6, the triangle HGS is similar to the triangle BCS. Therefore, as BC is to CS, so HG is to GS; and, alternately, as BC is to HG, so CS is to GS. [Margin: b — Elements VI.4] But CS is triple GS. Therefore BC will also be triple HG. [Margin: c — Elements XIV.18]

Now since the side of the pyramid described in the cube is the diameter of the base of the cube — as was demonstrated at proposition 1 of book 15 — while the line joining the two centers of the faces of the pyramid that have a common side is the diameter of the base of the cube described in the pyramid, as is clear from what was demonstrated at proposition 18 of book 15 (for there the line GH, joining the centers G, H of the bases ACD, ABD which have the common side AD, was the diameter of GNHQ, the base of the cube described in the pyramid): the side of the pyramid BC will be the diameter of the base of the cube circumscribing the pyramid ABCD, and GH the diameter of the base of the cube described in the same pyramid. Since, then, the diameters of the squares have the same ratio to one another as their sides — (for as the diameter of one square is to its side, so is the diameter of the other square to its side, because each ratio is a duplicate in power; alternately, then, as diameter is to diameter, so side is to side. Or thus: the square of the diameter of one square is to that square as the square of the diameter of the other is to that square, since in both the ratio is double. [Margin: d — Elements VI.22] Therefore diameter will also be to side as diameter to side; and so, alternately, as diameter to diameter, so side to side) — and since BC, the diameter of the base of the circumscribed cube, has to GH, the diameter of the base of the inscribed cube, a triple ratio, as we showed, the side of the circumscribed cube will likewise have to the side of the inscribed cube a triple ratio.

But cubes, being similar parallelepipeds, have the triplicate ratio of their homologous sides. [Margin: e — Elements XI.33] Therefore the circumscribed cube has to the cube inscribed in the pyramid ABDC the ratio of 27 to 1; for this triplicate ratio is the triplicate of a triple ratio, as may be seen here: 1. 3. 9. 27. For which reason, since the cube has to the inscribed pyramid the ratio of 27 to 9 —

that is, triple — [Margin: f — Elements XVI.20] the pyramid ABDC will have to the cube inscribed in it the ratio of 9 to 1, that is, ninefold; and so the pyramid is nine times the cube inscribed in it. Which was to be demonstrated.

Diagram. The figure for Proposition 25: the equilateral pyramid (tetrahedron) with apex B and base A, D, C, showing the inscribed cube and the auxiliary lines CGS, BHS meeting at S.

- B (top apex): pyramid vertex
- A (bottom left): pyramid vertex
- D (bottom right): pyramid vertex
- C (right): pyramid vertex
- H (mid-left, interior): center of face ABD
- G (center-low, interior): center of face ACD
- S (bottom center, on AD): midpoint of AD, meeting-point of CGS and BHS

COROLLARIVM.

Therefore the cube has to the cube described in the pyramid — the one that is described in the prior cube — the ratio of 27 to 1. For this was demonstrated from proposition 33 of book 11 in the demonstration of the present proposition.

THEOR. 26. PROPOS. 26.

The octahedron has to the icosahedron inscribed in it the ratio that two bases of the octahedron have to five bases of the icosahedron.

In the octahedron ABCDEF imagine an icosahedron described. I say that the octahedron is to the icosahedron as two bases of the octahedron are to five bases of the icosahedron. For, as is clear from what was demonstrated in (Elements XV.16), the eight bases of the icosahedron are set upon the eight bases of the octahedron. Let two bases of the icosahedron, GHI and kLM, lie on two opposite bases of the octahedron, ADE and BCF. From N, the center of the octahedron — which is also the center of the icosahedron, since the center of both is the same, by (XV.16 coroll. 3) — let a perpendicular NO be drawn to the base ADE, falling on the center O of the triangle ADE, that is, of the circle circumscribing it, by (XIV.10 lemma 1 coroll.). This O is also the center of the triangle GHI, by (XV.16 coroll. 2).

Now since the opposite planes ADE and BCF are parallel, by (XIII.14 coroll. 4), the straight line ON, produced, will likewise be perpendicular to the plane BCF, by the scholium of (XI.14), and will therefore fall on its center P, which is also

common to the triangle kLM . Hence OP is the true altitude both of the octahedron and of the icosahedron inscribed in it.

Since the octahedron is divided into eight equal pyramids by straight lines drawn from the center N to all the vertices of the octahedron — pyramids whose altitude is NO , half the altitude of the octahedron — and likewise the icosahedron into 20 equal pyramids of the same altitude NO ; and since a prism is triple a pyramid having the same base and altitude as itself, by (XII.7 coroll. 1): the prism whose base is ADE and altitude ON will be equal to three pyramids of the octahedron. But a prism whose base is the same ADE , but whose altitude is OP , double the altitude ON , is double the prism whose base is likewise ADE but altitude ON , by what we showed in the scholium of (XII.14). Therefore the prism whose base is ADE and altitude OP is equal to six pyramids of the octahedron.

Consequently, to the remaining two pyramids of the octahedron, which make up a third part of those six, will be equal a third part of the prism set upon the base ADE and under the altitude OP ; namely the prism whose base is a third part of the triangle ADE and whose altitude is the same OP . For this prism is a third part of the prism upon the base ADE and under the altitude OP , since — by what we taught at (XII.7) — prisms of the same altitude are to one another as their bases. Therefore two prisms, one having base ADE and altitude OP , the other having as base a third part of the base ADE and the same altitude OP , are together equal to the octahedron $ABCDEF$.

In just the same way we shall demonstrate that the prism whose base is GHI and altitude OP is equal to six pyramids of the icosahedron, and therefore that triple this prism — namely the prism whose base is triple the base GHI and whose altitude is the same OP — is equal to 18 pyramids of the icosahedron. To the remaining two pyramids of the icosahedron, which make up a third part of six pyramids of that same icosahedron, will therefore be equal a third part of the prism set upon the base GHI and under the altitude OP , whose base is a third part of the triangle GHI and whose altitude is the same OP . And accordingly two prisms — one whose base is triple the triangle GHI and altitude OP , the other whose base is a third part of the base GHI and the same altitude OP — will together be equal to the icosahedron described in the said octahedron.

Now, since those two prisms equal to the octahedron are to these two prisms equal to the icosahedron — by what we showed at (XII.7) — as the bases of the prisms equal to the octahedron, containing four thirds of the triangle ADE (since one has for base ADE , that is, three thirds of ADE , and the other has for base a third part of ADE), are to the bases of the prisms equal to the icosahedron,

comprehending ten thirds of the triangle GHI (since one has as base triple the triangle GHI, namely nine thirds of GHI, and the other a third part of GHI): let it be that, as four thirds of the triangle ADE are [Margin: a — Elements V.15] to two thirds of ADE (namely half of the four thirds) so are five thirds of GHI to half of the ten thirds. And as two thirds of ADE are to five thirds of GHI, so also, by what we demonstrated in the scholium of (V.22), let six thirds of ADE (that is, two bases of the octahedron, making up triple the two thirds of one base) be to six thirds of GHI [recte: fifteen thirds of GHI] (that is, five bases of the icosahedron, comprehending triple the five thirds of one base, since they comprehend fifteen thirds). Then those two prisms equal to the octahedron — that is, the octahedron itself — will be to these two prisms equal to the icosahedron — namely to the icosahedron itself — as two bases of the octahedron are to five bases of the icosahedron. Therefore the octahedron has to the icosahedron inscribed in it the ratio that two bases of the octahedron have to five bases of the icosahedron. Which was to be demonstrated.

THEOR. 27. PROPOS. 27.

The icosahedron has to the dodecahedron inscribed in it a ratio compounded of the ratio of the edge of the icosahedron to the edge of the

cube described in the same sphere as the icosahedron, and of the triplicate ratio of that which the diameter of the icosahedron has to the straight line joining the centers of the opposite bases of the icosahedron.

Let the icosahedron ABC be presented, in which the straight line DE joins the centers of the opposite bases, and let its diameter be AC; let F be the edge of the icosahedron, and G the edge of the cube described in the same sphere as the icosahedron. I say that the ratio of the icosahedron ABC to the dodecahedron inscribed in it is compounded of the ratio of F, the edge of the icosahedron, to G, the edge of the cube, and of the triplicate ratio of the diameter AC to the straight line DE.

For since, by what was demonstrated at (XV.5), the dodecahedron described in the icosahedron sets its vertices at the centers of the bases of the icosahedron, and hence its opposite vertices at the centers of the opposite bases, DE will be the diameter of the dodecahedron described in the icosahedron ABC, since it joins its opposite vertices residing at D and E, the centers of the opposite bases of the icosahedron.

Now that three magnitudes have been posited — namely the icosahedron ABC; the dodecahedron of diameter AC, that is, described in the same sphere in which the icosahedron ABC is described (since the diameter of both is the same); and the dodecahedron of diameter DE, constructed within the icosahedron ABC — the ratio of the first magnitude, namely the icosahedron ABC, to the third, namely the dodecahedron of diameter DE inscribed in it, will be compounded of the ratios of the first to the second and of the second to the third, by what we have demonstrated on (Elements VI, def. 5); that is, of the ratios of the icosahedron ABC to the dodecahedron of diameter AC described in the same sphere as it, and of the dodecahedron of that same diameter AC to the dodecahedron of diameter DE described in the icosahedron ABC.

Since, then, the icosahedron ABC is to the dodecahedron of diameter AC comprehended in the same sphere as F, the edge of the icosahedron, is to G, the edge of the cube — [Margin: a — Elements XIV.11] (for the dodecahedron of diameter AC is to the icosahedron ABC of the same diameter as G, the edge of the cube, is to F, the edge of the icosahedron; therefore by inversion the icosahedron ABC will be to the dodecahedron of diameter AC as F, the edge of the icosahedron, is to G, the edge of the cube) — and since the dodecahedron of that same diameter AC has to the dodecahedron of diameter DE, described in the icosahedron ABC, a ratio triplicate of that of diameter AC to diameter DE, that is, to the straight line joining the centers of the opposite bases of the icosahedron, by (XII.17 coroll.): it

is manifest that the ratio of the icosahedron ABC to the dodecahedron of diameter DE inscribed in it is likewise compounded of the ratio of F, the edge of the icosahedron, to G, the edge of the cube, and of the triplicate of the ratio of diameter AC to the straight line DE. Therefore the icosahedron has to the dodecahedron inscribed in it a compounded ratio, and so on. Which was to be demonstrated.

Diagram. A hexagonal projection of the icosahedron ABC with the inscribed dodecahedron, drawn with internal chords, accompanied to its right by two vertical reference segments marked F and G (the edge of the icosahedron and the edge of the cube).

- A (top, right of B): vertex
- D (interior, upper-left): center of one base (endpoint of the dodecahedron diameter)
- E (interior, lower-right): center of the opposite base (other endpoint of the diameter)
- Q (bottom-left corner): vertex
- F (right, vertical segment): the edge of the icosahedron
- G (right, vertical segment): the edge of the cube

THEOR. 28. PROPOS. 28.

The dodecahedron exceeds the cube inscribed in it by a parallelepiped, whose base falls short of the square of the cube by a rectangle contained by the edge of the cube and the third part of the minor segment of the same edge of the cube; but whose altitude falls short of the altitude — that is, of the edge of the cube — by the minor segment of that line which is the minor segment of the halved edge of the cube.

Since, by what was demonstrated at (XV.8), the four sides of the base of the cube described in the dodecahedron subtend four angles of four bases of the dodecahedron that meet at one edge: let there be pentagons of this kind — ABCDE, EFGHA, AHIKB, BKLMC — meeting at the edge AB; two of them, ABCDE and AHIKB, along that same common edge AB, and the other two, AEFGH and BCMLK, along the angles EAH and CBK. In these pentagons let there be inscribed the square ECKH of the cube, upon which stands a part of the dodecahedron that circumscribes the cube — namely the solid CBKHAE, consisting of five planes: CBK, EAH, ABCE, ABKH, and ECKH. Of these, the two triangles CBK and EAH [Margin: a — Elements I.4] are equal, since the sides BC, BK of the pentagon are

equal to the sides AE, AH of the pentagon, and they contain equal angles of the pentagons EAH and CBK. The two trapezia ABCE and ABKH are likewise equal: for since the pentagons ABCDE and ABKIH are equal by hypothesis, and the triangles CDE and HIK cut off from them are [Margin: b — Elements I.4] equal, the remaining trapezia ABCE and ABKH will also be equal. The fifth plane, finally, is ECKH, the base of the inscribed cube. In the same way five other solids like and equal to this — by (XI def. 10) — will be found upon the remaining five bases of the cube, so that the dodecahedron exceeds the cube inscribed in it by six such solids.

I say, then, that this whole excess, made up of those six solids standing around the inscribed cube, is equal to a parallelepiped whose base falls short of CEHK, the base of the cube, by a rectangle contained by the edge of the cube CK and the third part of the minor segment of the same edge of the cube; while its altitude falls short of the altitude — that is, of the edge of the cube — by the minor segment of that line which is the minor segment of the halved edge of the cube.

For, the sides EH and CK being bisected at N and O, and the straight line NO being joined — which is parallel to the side AB of the pentagon, and onto which fall the perpendiculars AP, BQ dropped into the plane EK, as is clear from what was demonstrated at (XIII.17) (for the lines NO, AB, AP, BQ of this figure express the lines LN, VX, VR, XS of the figure of XIII.17) — each of AB and NO will be the major segment of the edge of the cube [recte: NO or HK will be the major segment], and each of AP, BQ will be equal to half the side AB of the pentagon, that is, half the major segment of the edge of the cube, as is clear from the same (XIII.17). And therefore, if through P and Q straight lines RS, TV be drawn parallel to the lines EH, CK, then RT and SV will also be the major segments of the sides EC, HK; and thus ER, CT together, and HS, KV together, are the minor segments of those same sides. Then, straight lines AR, AS, BT, BV being drawn, let two pyramids ERS^{HA} and CTV^{KB} be constructed, which by (XII.6 coroll.) will be equal to one another, since their bases ERS^H, TCK^V and their altitudes PA, QB are equal; and they will stand outside the solid ABTVSR.

Now since AS is equal and parallel to BV, and AR to BT [Margin: c — Elements I.33] — since they join the equal and parallel straight lines AB, SV, RT — the planes of the triangles ARS, BTV will be parallel [Margin: d — Elements XI.15], and thus equal to one another, by (I.8 coroll.), since the sides of one are equal to the sides of the other. Therefore the solid ABTVSR, contained by two opposite equal, similar, and parallel triangles ARS, BTV, and by three parallelograms RV, AT, AV, is a prism, by definition.

Now, since it has been shown that the straight lines HS, KV make up the minor segment of the side HK, let VX be made equal to them — namely double each of HS and KV — and let VY contain two thirds of VX, the minor segment of the side HK, while XY is its third part; and let XZ, Y α be drawn parallel to the line TV. Since, then, the pyramids ERS α HA, CTVKB have been shown to be equal, and the pyramid set upon the base TX and under the same altitude PA (or QB) is double each of them [Margin: e — Elements XII.6], because the base TX is [Margin: f — Elements VI.1] double the base CV (or RH), the pyramid TVXZB will be equal to both pyramids ERS α HA, CTVKB together. But the pyramid TVXZB contains two thirds of the prism whose base is the same TX, whose altitude is the same QB, but whose vertex is a straight line — namely the part of the straight line AB equal to VX — as we demonstrated in the scholium of (XII.7). Likewise, of that same prism whose base is TX, altitude QB, and vertex the part of AB equal to VX, the prism whose base is TY and altitude the same QB, with vertex the part of AB equal to VY, contains two thirds, by the scholium of (XI.25) [Margin: g — Elements VI.1], because the base TY comprehends two thirds of the base TX.

Therefore the prism whose base is TY and altitude QB, with vertex the part of AB equal to VY, will be equal to both pyramids ERS α HA, CTVKB. And accordingly this prism, added to the prism ABTVSR, will make a prism equal to the solid CB α HAE, having as base the rectangle contained by the edge of the cube TV and by the straight line composed of VY (comprehending two thirds of the minor segment VX) and VS (the major segment); and therefore falling short of the base of the cube by the rectangle α X, contained by the edge of the cube α Y and by XY, the third part of the minor segment VX. By a not dissimilar procedure we shall investigate five other prisms, similar and equal to the one just named, and to the remaining five solids set upon the remaining five bases of the cube. Six such prisms, then, will be equal to those six solids — that is, to the excess of the dodecahedron over the cube inscribed in it.

But since any two prisms of that kind, fitted to one another, compose a parallelepiped of the same altitude, from those six prisms three parallelepipeds will be constructed under the same altitude QB — which is equal to half the side AB of the pentagon, that is, half the major segment of the edge of the cube — and upon bases each falling short of the base of the cube by a rectangle contained by the edge of the cube and by the third part of the minor segment of that same edge of the cube. And accordingly, from these three parallelepipeds composed together, there will arise a parallelepiped equal to the same excess of the dodecahedron over the cube inscribed in it, whose base falls short of the base of the cube by a rectangle contained by the edge of the cube and by the third part of

the minor segment of that same edge of the cube, and whose altitude is equal to the three altitudes of the aforesaid three parallelepipeds — that is, to the altitude QB, which was equal to half the major segment of the edge of the cube, taken three times.

I say, then, that this altitude falls short of the altitude — that is, of the edge of the cube — by the minor segment of that line which is the minor segment of the halved edge of the cube. For let Ck, the edge of the cube, be divided in extreme and mean ratio at β ; likewise let C β , the major segment, and β k, the minor, be bisected at γ and δ ; and from β k let $\beta\epsilon$ be cut off equal to $\beta\gamma$ (or C γ), so that C γ (or $\gamma\beta$, or $\beta\epsilon$), half the major segment C β , is equal to QB, and C ϵ to the whole altitude of the aforesaid parallelepiped. Now a straight line equal to C γ , half the major segment, can be cut off from the minor segment β k, because β k is greater than half the major segment C β . For since Ck is to C β as C β is to β k, and Ck is less than double C β (because C β is its major segment), C β will also be less than double β k — that is, β k will be greater than half of C β .

Since, then, as the whole Ck is to the major segment C β , so is the major segment C β to the minor β k, it will also be [Margin: h — Elements V.15] that as CO, half of Ck, is to C γ (or $\beta\epsilon$), so is $\beta\delta$ [recte: $\beta\epsilon$ to $\beta\delta$, half of β k]. And accordingly, if CO be cut in extreme and mean ratio, its major segment will be C γ (or $\beta\epsilon$) and its minor $\beta\delta$. Therefore $\beta\delta$ too is the minor segment in extreme and mean ratio, as we demonstrated at (XIII.5); and the major segment will be $\beta\delta$, the minor $\delta\epsilon$. And therefore again the minor segment $\delta\epsilon$ will cut the straight line δ k in extreme and mean ratio, its major segment being $\beta\delta$ [recte: the major segment $\delta\epsilon$ equal to $\beta\delta$], and its minor segment ϵ k. Therefore C ϵ , the altitude of the aforesaid parallelepiped, falls short of the altitude — that is, of the edge of the cube Ck — by the minor segment ϵ k of the straight line δ k (or of the straight line $\beta\delta$ equal to it), which was shown to be the minor segment of the halved edge of the cube.

It is established, therefore, that the base of the parallelepiped by which the dodecahedron exceeds the cube inscribed in it falls short of the base of the cube by a rectangle contained by the edge of the cube and the third part of the minor segment of the same edge of the cube; while its altitude falls short of the altitude of the cube by the minor segment of that line which is the minor segment of the halved edge of the cube. Therefore the dodecahedron exceeds the cube inscribed in it by a parallelepiped, and so on. Which was to be demonstrated.

Diagram. A large hexagonal figure showing the cube ECKH inscribed in the dodecahedron, with the construction lines, pyramids, and the extreme-and-mean-

ratio division points of Prop. 28. The same figure is repeated at the top of the following page.

- F (top-left) and G (top-right): upper vertices of the outer hexagon
- D (far left) and I (far right): side vertices of the outer hexagon
- M (bottom-left) and L (bottom-right): lower vertices of the outer hexagon
- E, H (upper corners) and C, K (lower corners): the four corners of the inscribed cube-face ECKH
- N (midpoint of EH) and O (midpoint of CK): bisection points
- A (upper apex, below N) and B (lower apex): pyramid apices
- P (center, below A) and Q (below B): feet of the perpendiculars AP, BQ
- R (left) and S (right): points on line RS through P
- T (lower-left) and V (lower-right): points on line TV through Q
- X (right, below S) and Y (right, below X): construction points on the right
- Z (left) and α (left, below Z): construction points (endpoints of XZ, $Y\alpha$)
- γ , O, β , δ , ϵ (along the bottom side CK): division points of the edge Ck in extreme and mean ratio

COROLLARIVM.

From this it is elicited that the dodecahedron falls short of double the inscribed cube by two parallelepipeds. Of one, the length is equal to the edge of the cube, the breadth is a third part of the minor segment of that same edge of the cube, and finally the altitude falls short of the edge of the cube by the minor segment of that line which is the minor segment of the halved edge of the cube. Of the other, both the length and the breadth are equal to the edge of the cube, while the altitude is the minor segment of that line which is the minor segment of the halved edge of the cube — so that the two altitudes together are equal to the altitude, that is, to the edge of the cube. For if the first parallelepiped be added to that parallelepiped by which we showed the cube to be surpassed by the dodecahedron, there will be made up a parallelepiped whose length and breadth are equal to the edge of the cube — having, indeed, the same base as the cube — while its altitude falls short of the edge of the cube by the minor segment of that line which is the minor segment of the halved [edge of the cube].

Diagram. A repetition of the large cube-in-dodecahedron construction figure from the previous page, printed again at the head of this page for reference while the demonstration and corollary continue. Same labeling as fig-p621-2.

- Outer hexagon: F, G (top), D, I (sides), M, L (bottom)

- Inscribed cube-face: E, H (upper), C, K (lower)
- Interior construction: N, A, R, P, S, Z, α , X, Y, B, T, V, Q, and the Greek division points γ , O, β , δ , ε along CK

is less than the edge of the cube by the [minor] segment — that is, by the height of the latter parallelepiped. Therefore, if to the parallelepiped now completed the latter parallelepiped is joined, the composite will be a parallelepiped exactly equal to the cube described within the dodecahedron, since both the base and the height of the parallelepiped are equal to the base and the height of the cube. And accordingly, in order that the dodecahedron may turn out to be double its inscribed cube, the two aforesaid parallelepipeds are lacking; and when these are added to the excess of the dodecahedron over the inscribed cube, a parallelepiped is constituted equal to the inscribed cube — indeed, a second cube — as has been demonstrated.

THEOR. 29. PROPOS. 29.

The dodecahedron has to the icosahedron inscribed in it a ratio compounded of the triplicate of the ratio which the diameter of the dodecahedron has to the straight line joining the centres of opposite bases of the dodecahedron, and of the ratio of the edge of the cube to the edge of the icosahedron described in the same sphere with the cube.

In the dodecahedron ABC let the diameter be AC, and let DE be the straight line joining the centres of the opposite bases; and let F be the edge of the cube, and G the edge of the icosahedron described in the same sphere with the cube. I say that the ratio of the dodecahedron ABC to the icosahedron inscribed in it is compounded of the triplicate of the ratio of the diameter AC to the straight line DE, and of the ratio of F, the edge of the cube, to G, the edge of the icosahedron. For since the angles of the icosahedron described in the dodecahedron are set at the centres of the bases of the dodecahedron — and hence the opposite angles at the centres of the opposite bases — the straight line DE joining the centres of the opposite bases of the dodecahedron will be the diameter of the inscribed icosahedron. And on that account a dodecahedron whose diameter is DE will be described in the same sphere with the icosahedron placed within the dodecahedron ABC, since they have the same diameter DE.

Now that the three magnitudes are grasped — namely the dodecahedron ABC; the dodecahedron of diameter DE; and the icosahedron of the same diameter DE described within the dodecahedron ABC — the ratio of the dodecahedron ABC, the first magnitude, to the icosahedron inscribed in it, the third magnitude, will

be compounded (by what we demonstrated at Definition 5 of Book 6) out of the ratios: of the dodecahedron ABC, the first magnitude, to the dodecahedron of diameter DE, the second magnitude; and of the dodecahedron described from the diameter DE, the second magnitude, to the icosahedron described within the dodecahedron ABC, the third magnitude. Since, then, the dodecahedron ABC has to the dodecahedron of diameter DE the triplicate ratio of the diameter AC to the diameter DE, by the corollary of Prop. 17 of Book 12 [Margin: a 11.quartidec.]; and since the dodecahedron of diameter DE has to the icosahedron of the same diameter DE — which is of course described within the dodecahedron ABC — the ratio which F, the edge of the cube, has to G, the edge of the icosahedron: it is plainly established that the ratio of the dodecahedron ABC to the icosahedron inscribed in it, whose diameter is DE, is likewise compounded of the triplicate of the ratio of the diameter AC to the diameter DE — namely the straight line joining the centres of the opposite bases of the dodecahedron — and of the ratio of F, the edge of the cube, to G, the edge of the icosahedron described in the same sphere with the cube. The dodecahedron, therefore, has to the icosahedron inscribed in it a compounded ratio, etc. Which was to be demonstrated.

Diagram. A roughly hexagonal outline representing the dodecahedron ABC seen along its axis, with an inner pentagon and radiating edges (the projection of the solid). To the right of it stand two separate short vertical parallel line-segments, representing the edge of the cube and the edge of the icosahedron.

- A (top): a vertex of the dodecahedron
- B (upper left): a vertex
- D (right): a vertex
- E (left): a vertex
- C (bottom): a vertex
- F (right, left-hand vertical segment): the edge of the cube
- G (right, right-hand vertical segment): the edge of the icosahedron

THEOR. 30. PROPOS. 30.

The dodecahedron contains two ninth parts of the pyramid [tetrahedron] in which it is described, less two parallelepipeds — of which the length of the one is equal to the edge of the cube described in the same pyramid, its breadth is equal to the third part of the minor segment of the edge of the same cube, and finally its height falls short of the edge of the same cube by the minor segment of that line which is the minor segment of the half-edge of the same cube; while of the other, both the length and the

breadth are equal to the edge of the aforesaid cube, but the height is the minor segment of that line which is the minor segment of the half-edge of the same cube — so that the heights of both together are equal to the height, or the edge, of the same cube.

Since, if a cube is described in the dodecahedron inscribed in the pyramid, this same cube is described in the same pyramid, as we set forth at the end of Book 15; and since the cube is a ninth part of the pyramid in which it is described [Margin: a 25.sextidecim.], the pyramid being ninefold its inscribed cube: it comes about that the doubled magnitude of the said cube contains two ninth parts of the pyramid surrounding the dodecahedron, or the cube. Therefore, since the dodecahedron is double its inscribed cube — by the corollary of Prop. 28 of this book — less those two parallelepipeds mentioned in the words of this proposition, it is not obscurely gathered that the dodecahedron inscribed in the pyramid contains two ninth parts of the pyramid itself, less the said two parallelepipeds; so that, if the said two parallelepipeds are added to the dodecahedron, then at last the magnitude arises that embraces two ninth parts of the pyramid. Wherefore the dodecahedron contains two ninth parts of the pyramid in which it is described, less two parallelepipeds — of which the length of the one is equal to the edge of the cube described in the same pyramid, etc. Which was to be demonstrated.

THEOR. 31. PROPOS. 31.

The octahedron exceeds the icosahedron inscribed in it by a parallelepiped whose base is the square of the edge of the icosahedron, and whose height is the greater segment of the semidiameter of the octahedron cut in extreme and mean ratio.

Let the octahedron in which the icosahedron is inscribed be ABCDEF — the figure of Prop. 16 of Book 15 being repeated, where it was demonstrated that the twenty triangles composing the inscribed icosahedron are IQR, KQR, GIL, GIM, GPS, HPS, NHK, OHK, RLO, SLO, PMN, QMN, GMP, HNP, KNQ, IMQ, GLS, HOS, KOR, ILR, of which the last eight are set upon the eight faces of the octahedron, cutting namely all its edges in extreme and mean ratio; and likewise that the straight line IT, perpendicular to BD, is equal to the greater segment XY of the semidiameter AX. I say that the octahedron ABCDEF exceeds the icosahedron inscribed in it by a parallelepiped whose base is the square of the edge QR of the icosahedron, and whose height is IT, the greater segment of the semidiameter AX.

For since upon the four faces of the octahedron DEA, DFA, DEC, DFC — those constituting the solid angle D of the octahedron — are set the four bases of the icosahedron IMQ, ILR, KNQ, KOR, there will remain, next to the solid angle D, in those same four faces of the octahedron, four triangles IQD, IRD, KQD, KRD; and if to these are added the two triangles of the icosahedron QIR, KQR, together with the common triangle DQR, there will be constituted two pyramids upon the common base DQR — namely IDQR, KDQR — equal to each other, by the corollary of Prop. 5 of Book 12, since their height is the same straight line IT, namely the greater segment of the semidiameter of the octahedron. (For just as AX is cut by the straight line GI at Y in extreme and mean ratio, so too is CX cut by the straight line HK at Z. Therefore, if from K a perpendicular is drawn to BD [Margin: a 34.prim.] — the height, namely, of the pyramid KDQR — it will be equal to the straight line ZX, the greater segment of the semidiameter CX, that is, to IT itself. These pyramids, indeed, stand outside the icosahedron described in the octahedron.) In like manner, near almost each of the remaining five angles of the octahedron, two pyramids are constituted, equal both to each other and to the two just described, outside the aforesaid icosahedron, so that the octahedron exceeds the icosahedron inscribed in it by those twelve equal pyramids.

Now since the triangle DQR is half of the square of the edge DQ — for DQ, DR are equal straight lines, namely the minor segments of the edges of the octahedron, and contain a right angle — the straight line QR will be the diagonal of that square; and accordingly the square of QR will be double the square of the edge DQ, and therefore quadruple the triangle DQR. Therefore the prism, or parallelepiped, whose base is the square of the straight line QR and whose height is IT, will likewise be quadruple the prism whose base is the triangle DQR and whose height is the same IT, by what we demonstrated at Prop. 7 of Book 12. But the prism whose base is DQR and whose height is IT, being triple the pyramid IDQR — by the first corollary of Prop. 7 of Book 12 — is equal to three of those twelve pyramids which we said stand around the icosahedron. Therefore the prism, or parallelepiped, whose base is the square of the straight line QR and whose height is IT, is likewise quadruple those three pyramids. Wherefore, since all twelve pyramids together surrounding the icosahedron are quadruple those same three pyramids, the prism, or parallelepiped, whose base is the square of the straight line QR — namely the edge of the icosahedron — and whose height is IT, the greater segment of the semidiameter AX, will also be equal to those twelve pyramids, that is, to the excess of the octahedron over the icosahedron inscribed in it. And accordingly the octahedron will exceed the icosahedron by the said prism, or parallelepiped. Therefore the octahedron exceeds the icosahedron

inscribed in it by a parallelepiped whose base is the square of the edge of the icosahedron, etc. Which was to be shown.

Diagram. A large octahedron drawn as a rhombus — with vertices B (left), D (right), A (top apex) and C (bottom apex), together with the two mid-plane vertices — inside which the inscribed icosahedron and its construction lines are drawn (the figure of Prop. 16 of Book 15, repeated). The interior is very densely lettered with the icosahedron's vertices and the division points; several of these small labels are crowded and foxed.

- A (top apex): vertex of the octahedron
- B (left): vertex of the octahedron
- D (right): vertex of the octahedron
- C [?] (bottom apex): vertex of the octahedron (the drawn glyph resembles "G"; read as C from the text, where CX is a semidiameter)
- G (upper-left, on edge BA): construction / icosahedron point
- I (upper-right): icosahedron vertex
- Y (upper-middle, on axis AX): division point (extreme-and-mean section of AX)
- M (middle, below Y): icosahedron vertex
- L (centre-left): icosahedron vertex
- E (centre): mid-plane vertex of the octahedron
- P (left of L): icosahedron vertex
- O (right, toward D): icosahedron vertex
- X (centre): centre of the octahedron
- T (centre-right): foot of the perpendicular IT
- N (below centre): icosahedron vertex [?]
- S (lower-left): icosahedron vertex
- F (lower-middle): mid-plane vertex of the octahedron
- R (lower-right): icosahedron vertex
- H (lower-left, toward B): icosahedron vertex
- K (lower-right): icosahedron vertex
- Z (bottom-middle): division point (extreme-and-mean section of CX)
- V [?] (near R): crowded — not securely read

COROLLARIUM

Hence it is inferred that the pyramid exceeds double the icosahedron inscribed in it by a parallelepiped whose base is the square of the edge of the icosahedron,

and whose height is the straight line joining the bisection-points of opposite edges of the icosahedron. For since it is established from what was demonstrated in Prop. 19 of Book 15 that, if the octahedron is inscribed in the pyramid and the icosahedron in this octahedron [Margin: b 31.sexidec.], and the octahedron exceeds the icosahedron inscribed in it by a parallelepiped whose base is the square of the edge of the icosahedron — namely of the straight line QR — and whose height is the greater segment of the semidiameter of the octahedron, namely the straight line IT, or YX: it comes about that the octahedron taken twice — namely the pyramid, in which it is inscribed [Margin: c 21.sexidec.] (since the pyramid is double the octahedron inscribed in it) — exceeds double the icosahedron in the octahedron, and hence also [double the icosahedron] described in the pyramid, by double that parallelepiped: namely by a parallelepiped whose base is the same square of the edge of the icosahedron, and whose height is the straight line YZ joining the bisection-points of the opposite edges GI, HK of the icosahedron. For this parallelepiped is double the former, by what we demonstrated in the scholium of Prop. 14 of Book 12, since the heights have a double ratio. Wherefore by this same parallelepiped — whose base is the square of the edge of the icosahedron, and whose height is the straight line joining the bisection-points of opposite edges of the icosahedron — the pyramid exceeds double the icosahedron inscribed in it.

ON THE DESCRIPTION OF THE FIVE REGULAR SOLIDS IN A GIVEN SPHERE, FROM PAPPUS OF ALEXANDRIA

Since Euclid in Book 13 constructed the five regular solids separately, outside a sphere, and then confirmed by a new demonstration that these same solids are comprehended by a sphere, it will not be beside the point to teach in what way Pappus of Alexandria describes those same five solids in a given sphere — especially since his method appears much clearer and easier than that construction prescribed by Euclid. But first, from the same Pappus, certain lemmas must be set out beforehand — some of which, even though they are demonstrated

by means of the spherical elements of Theodosius, yet not on that account can we be judged to pervert the order of Euclid, since the propositions of the spherical elements which we need here depend only on the first 19 propositions of Book 11 of Euclid, so that they can conveniently be understood before Book 12, and much more so before this construction of the regular solids. But in citing the propositions of Theodosius we shall follow the order of our own commentaries,

which we wrote upon those same elements. Let us therefore make our beginning here.

LEMMA I.

Given two parallel circles in a sphere, and a straight line given in one of them, to draw in the other a diameter parallel to this given straight line.

In a sphere let there be two parallel circles ABCD, EFG; and first, in ABCD, let the diameter AD be given, to which a parallel diameter is to be drawn in EFG. Let there be drawn — as we taught in the scholium of Prop. 18 of Book 11 — through the diameter AD a plane perpendicular to the circle ABCD [Margin: a 1.Theod.], making on the surface of the sphere the circle AEGD. Since, then, the circle AEGD cuts the circle ABCD in two and at right angles, the circle AEGD will be a great circle, and it will pass through the poles of the circle ABCD, by the scholium of Prop. 15 of Book 1 of Theodosius; and accordingly also through the poles of the circle EFG [Margin: b 1.2.Theod.], since parallel circles have the same poles [Margin: c 15.1.Theod.]; and therefore it will cut it in two. Hence the common section EG will be its diameter [Margin: d 16.vnde.]; and since this is parallel to AD, the proposition is evident.

Next, in the circle ABCD let the given straight line BC not be its diameter, to which a parallel diameter is to be drawn in the circle EFG. [Margin: e 31.primi.] Let there be drawn parallel to BC, through the centre of the circle ABCD, the diameter AD; to which, in the circle EFG, let the diameter EG be drawn parallel, as we have just shown. Since, then, each of BC, EG is parallel to the same AD, by construction [Margin: f 9.vndeci.], BC and EG will also be parallel to each other. Which was proposed.

By the same reasoning a straight line HI will be drawn in the circle EFG parallel to BC and distinct from the diameter EG, equal to BC — provided only that BC is not greater than the diameter EG. For if in the circle EFG there is drawn HI parallel and equal to BG [recte: BC?], as we set forth at Prop. 1 of Book 4, what is required will have been done.

Diagram. A circle representing the sphere in outline, containing two horizontal lens-shapes — the two parallel circles ABCD and EFG seen nearly edge-on.

- A (upper lens, left) and D (upper lens, right): endpoints of the diameter AD
- B (upper lens, inner left) and C (upper lens, inner right): endpoints of the chord BC
- E (lower lens, left) and G (lower lens, right): endpoints of the diameter EG

- H (lower lens, inner left) and I (lower lens, inner right): endpoints of the chord HI
- F (bottom of the circle): point on the outline

LEMMA II.

If in parallel planes two circles are described, in which two parallel straight lines cut off similar arcs, then the two straight lines joining the extremities of the one straight line with the centre will be parallel to the two straight lines which join the extremities of the other straight line with the centre.

In parallel planes AB, CD let two circles be described, in which let the straight lines EF, GH be first parallel, toward the same parts of the centres I, K; and let there be cut off the similar arcs EF, GH; and finally let there be joined to the centres the straight lines EI, FI, GK, HK. I say that both EI, GK and FI, HK are parallel. For since the arcs EF, GH are similar, the angles I, K will be equal, by the scholium of Prop. 22 of Book 3 [Margin: a 32.prim.]. Therefore the remaining angles E, F will be equal to the remaining angles G, H [Margin: b 5.primi.]. Since, then, both those and these are equal to each other, the angle E will be equal to the angle G, and the angle F to the angle H. Since, therefore, in parallel planes the straight lines EF, GH are parallel, and the straight lines EI, GK, drawn toward the same parts of the plane through EF, GH, make with them equal angles E, G, it will follow — from what we demonstrated in the scholium of Prop. 16 of Book 11 — that EI, GK are parallel; and by the same reasoning FI, HK will be parallel.

Next, let EF [printed DF] and GH be parallel, but not toward the same parts of the centres I, K. I say that both EI, HK and FI, GK are parallel. For, GK and HK being produced, let the straight line LM be joined. And since the sides GK, HK are equal to the sides LK, MK [Margin: c 14.prim.], and contain equal vertical angles at K [Margin: d 4.primi.], the bases GH, LM will be equal, and the angles H, L equal, and the angles G, M [Margin: e 28.tertij.]. Therefore the arcs GH, LM are equal [Margin: f 27.prim.], and the straight lines GH, LM parallel to each other; and accordingly, since each of EF, LM is parallel to GH [Margin: g 9.vndec.], EF and LM will also be parallel to each other. Since, then, EF, LM are parallel, cutting off toward the same parts of the centres the similar arcs EF, LM — for since the arc GH is similar to the arc EF, the arc LM also, which is equal to the arc GH, will be similar to the same arc EF — both EI, LK (that is, EI, HK) and FI, MK (that is, FI, GK) will be parallel. Which was proposed.

Diagram. Two stacked rectangles representing the two parallel planes, each containing lens-shaped circles with their radii drawn to the centre.

- A (upper rectangle, top-left corner) and B (upper rectangle, bottom-right corner): the plane AB
- Upper rectangle, left ellipse: E (left), F (right), with I at the centre (radii EI, FI drawn)
- Upper rectangle, right ellipse: E (left), F (right), with I at the centre
- C (lower rectangle, top-left corner) and D (lower rectangle, bottom-right corner): the plane CD
- Lower rectangle, left ellipse: G (left), H (right), with K at the centre (radii GK, HK drawn)
- Lower rectangle, right ellipse: L (top-left), M (top-right), G (bottom-left), H (bottom-right), with K at the centre (the crossing radii of the second construction)

LEMMA III.

If in a sphere there are two parallel and equal circles, in which are drawn two parallel and equal straight lines toward the same parts of the centres, then the straight lines joining the extreme points of these parallels toward the same parts are also equal and parallel, and perpendicular to the planes of the circles.

In a sphere let there be two parallel and equal circles AB, CD, in which let there be two equal and parallel straight lines AB, CD, toward the same parts of the centres, whose extremities are joined toward the same parts by the straight lines AC, BD. I say that the straight lines AC, BD are also equal, and parallel, and perpendicular to the planes of the circles. For since AB, CD are parallel [Margin: a 7.vnde.], AC, BD will be in the same plane with them. Wherefore, since AB, CD are also equal [Margin: b 33.primi.], AC, BD will likewise be equal and parallel — which is the first [part].

(This page concludes the demonstration of the preceding lemma — that in a sphere two equal parallel circles AB, CD, whose equal parallel chords AB, CD lie toward the same side of the centers, are joined at their ends by AC, BD, which are equal, parallel, and perpendicular to the planes of the circles.)

Diagram. A sphere (large circle) enclosing a rectangular box. The top face carries the chord/diameter AB, with A at the upper left and B at the upper right, and its center E marked just below the middle of that face. The lower face carries the

chord/diameter CD, with C at the lower left and D at the lower right, and its center F marked at the bottom. AC and BD join the corresponding ends; E and F are the centers of the two parallel equal circles.

- A (upper left): end of the upper chord AB
- B (upper right): end of the upper chord AB
- E (upper center): center of the upper circle
- C (lower left): end of the lower chord CD
- D (lower right): end of the lower chord CD
- F (bottom center): center of the lower circle

Next, from the centers E and F draw the lines EA, EB, FC, FD, and join the line EF. Then AE and CF, and likewise BE and DF, are parallel (by the second lemma), and they are also equal because the circles are equal. [Margin c: Elements I.33] Therefore AC and EF, and BD and EF, are parallel and equal. [Margin d: Theodosius, *Sphaerica* I.2 [?]] Now since the circles AB, CD are parallel about the same poles, [Margin e: Theodosius, *Sphaerica* I.10 [?]] the line drawn through their poles will pass through their centers and through the center of the sphere, and will stand perpendicular to their planes. Consequently the line EF, which joins their centers, will run through their poles and through the center of the sphere — otherwise two distinct straight lines would be said to pass through their centers, namely EF and the line extended through their poles, which is absurd, for then those two lines would have the segment EF in common. [Margin f: Theodosius, *Sphaerica* I.10 [?]] Therefore EF is perpendicular to the planes of the circles AB, CD; [Margin g: Elements XI.8] and for that reason each of AC, BD, being parallel to EF, will also be perpendicular to those same planes. This is the second point.

This demonstration also holds when the parallels AB, CD are diameters of the circles; but in that case EA, EB, FC, FD will be parts of the diameters, as is plain.

LEMMA IV.

If in a sphere there are two parallel and equal circles in which two parallel and equal straight lines are drawn, not toward the same sides of the centers, then: the straight lines that join the end points of these parallels **not** toward the same sides intersect at the center of the sphere, and are therefore diameters of the sphere and equal to one another. But the straight lines that connect the end points of the same parallels toward the same sides are both equal and parallel to one another, and make right angles with the parallels.

Let there be in a sphere two parallel and equal circles AB, CD, and in them two parallel and equal straight lines AB, CD, not toward the same sides of the centers. First let their end points be joined **not** toward the same sides, by the lines AD, BC. I say that AD, BC intersect at the center of the sphere, and are therefore diameters of the sphere and equal to one another.

Diagram. A sphere (circle) containing two parallel chords: the upper chord AB (with center E) near the top and the lower chord CD (with center F) near the bottom. The lines AD and BC are drawn as an X crossing at the point G in the middle, which is the center of the sphere. Radii and connecting lines EA, EG, FD, FG appear about the axis E–G–F.

- A (top left): end of upper chord
- E (top center): center of the upper circle
- B (top right): end of upper chord
- G (center): intersection of AD and BC, the center of the sphere
- C (bottom left): end of lower chord
- F (bottom center): center of the lower circle
- D (bottom right): end of lower chord

Since AB, CD are parallel, [Margin a: Elements XI.7] the lines AD, BC lie in the same plane with them; they will therefore cut one another, at the point H [recte: G] — which I say is the center of the sphere. For let the centers E, F of the circles be connected by the lines EA, EG and FD, FG. [Margin b: Elements I.15] Since the vertical angles AGB, CGD are equal, [Margin c: Elements I.29] and likewise both the alternate angles BAD, CDA and the alternate angles ABC, DCB are equal, the triangles ABG, CDG are equiangular. [Margin d: Elements VI.4 [?]] Therefore AB is to BG as DC is to CG, and likewise AB is to AG as DC is to DG. And since AB, CD are supposed equal, [Margin e: Elements V.14 [?]] both BG, CG and AG, DG are equal to one another. Again, since AE, DF, the semidiameters of equal circles, are equal, and are also parallel (by the second lemma), [Margin f: Elements I.29] the alternate angles EAD, FDA are equal; hence the two sides EA, AG equal the two sides FD, DG, and they contain equal angles. [Margin g: Elements I.4] Therefore the bases EG, FG, and the angles AGE, DGF, are equal. [Margin h: Elements XI.7] And since AD lies in the same plane in which the parallels AE, DF lie, [Margin i: Elements XI.2] EG and FG are set in one straight and continuous line, on account of the equal angles AGE, DGF, as we showed from Proclus on Proposition 15 of Book I. Hence the line EF, which joins the centers of the parallel circles, will pass through the center of the sphere, [Margin k: Theodosius, *Sphaerica* I.10] and will be perpendicular to their planes. Since EG, FG have been shown equal, G will be

the center of the sphere, [Margin l: Theodosius, *Sphaerica* I.6] because the equal circles AB, CD are equally distant from the center of the sphere; whereas they would be unequally distant if some point on the line EF other than G were said to be the center of the sphere. Therefore AD, BC are diameters of the sphere, and for that reason equal to one another. This is the first point.

But now let the end points of the equal parallels AB, CD be joined toward the same sides, by the lines AC, BD. I say that AC, BD are both equal and parallel to one another, and that the angles CAB, ABD, BDC, DCA are right angles.

Diagram. A sphere (circle) enclosing a rectangular figure. The upper chord AB has A at the upper left and B at the upper right; the lower chord CD has C at the lower left and D at the lower right. The perpendiculars CE, DF rise from C, D, with E and F marked in the middle band, and EF, AE, BF are joined, forming the right-angled figure.

- A (upper left): end of upper chord
- B (upper right): end of upper chord
- E (middle left): foot of the perpendicular from C's line
- F (middle right): foot of the perpendicular from D's line
- C (lower left): end of lower chord
- D (lower right): end of lower chord

That they are parallel and equal [Margin m: Elements I.33] is clear, since they join the end points of equal parallels. That they are also perpendicular to AB, CD is shown thus. In the circle CD, erect on the line CD the perpendiculars CE, DF, and join EF, AE, BF. Since the angles ECD, FDC are right, the arcs ECD, FDC are semicircles (by the scholium to Elements III.31), and consequently the remaining arcs EFD, CEF are also semicircles, [Margin n: Elements III.31] and the angles EFD, CEF are right. Hence in the right-angled parallelogram DE the lines CD, EF are equal, [Margin o: Elements XI.9] and therefore AB, EF are also parallel and equal. Therefore, by the third lemma, AE, BF are perpendicular to the planes of the circles, and consequently, by Elements XI, definition 3, the angles AEC, BFD are right. The line EF is therefore perpendicular to both EC and EA, and hence [Margin p: Elements XI.4] perpendicular to the plane of the triangle AEC drawn through EC, EA, and to the plane of the triangle BFD drawn through FD, FB; [Margin q: Elements XI.8] and for that reason CD, AB too, being parallel to EF, are perpendicular to those same planes of the triangles. Therefore, by Elements XI, definition 3, the angles CAB, ABD, BDC, DCA are right. This is the second point.

LEMMA V.

(printed "LEMA V." — single M)

If in a sphere there are two parallel straight lines, the straight lines joining their end points toward the same sides will be equal to one another. And if the parallels are equal, the joining lines will be not only equal but also parallel, and will make right angles with them.

Let there be in a sphere two parallels AB, CD, whose end points are connected toward the same sides by the lines AC, BD. I say that AC, BD are equal. For since AB, CD are parallel, [Margin a: Elements XI.7] the lines AC, BD lie in the same plane with them. Therefore, passing a plane through them, [Margin b: Theodosius, *Sphaerica* I.1] let there be made in the sphere the circle ABDC; and since AB, CD are parallel in it, the arcs AC, BD are equal (by the scholium to Elements III.27), [Margin c: Elements III.29] and therefore the lines AC, BD are equal as well. But if the parallels AB, CD are equal — so that the quadrilateral ABCD has in the circle two opposite sides AB, CD that are parallel and equal — then, by the scholium to Elements III.31, ABDC will be a right-angled parallelogram, and consequently the angles A, B, D, C will be right. This is what was proposed.

Diagram. Two circles side by side, illustrating the two cases. In the left circle an inscribed quadrilateral ABDC with A upper left, B upper right, C lower left, D lower right, forming a trapezium (the parallels unequal). In the right circle the same lettering A, B, C, D forms a rectangle/square (the parallels equal).

- Left circle — A (upper left), B (upper right), C (lower left), D (lower right): quadrilateral with parallel sides AB, CD
- Right circle — A (upper left), B (upper right), C (lower left), D (lower right): right-angled parallelogram

LEMMA VI.

In a given sphere, to describe two equal and parallel circles such that the diameter of the sphere is, in square, sesquialter to the diameter of each — that is, such that the square on the sphere's diameter is one-and-a-half times (the ratio 3 : 2) the square on each circle's diameter.

Let A be the center of the sphere, through which let a plane be drawn making the great circle BCDE, whose diameter is BD (by the corollary to Theodosius, *Sphaerica* I.1). [Margin: corollary, propos. 1, lib. 1, Theod.] Let BD be cut at F so that BF is double FD; then BD will be, of such parts as BF is 2, equal to 3, and

therefore BD is sesquialter to BF. Draw also FC perpendicular to BD, join the lines BC, DC, draw DE parallel to BC, and connect the line BE. [Margin a: Elements I.29] Since the two angles BCD, EDC together, and likewise the two BED, CBE together, equal two right angles, [Margin b: Elements III.31] and since each of BCD and BED is right, both EDC and CBE will also be right. Therefore, by the scholium to Elements I.34, the right-angled quadrilateral BCDE is a parallelogram, [Margin c: Elements I.34] and hence the lines BC, DE are equal. Now, the arc BC having been bisected at G, the arc EGD will likewise be bisected at G — since, by the scholium to Elements III.27, the arcs BE, CD are equal. Then, with pole G and radii GB, GE, let circles be described on the surface of the sphere passing through C, D, on account of the equality both of the arcs GB, GC and of the arcs GE, GD; [Margin d: Theodosius, *Sphaerica* II.2 [?]] and these circles will be parallel, since they have the same poles. [Margin e: Theodosius, *Sphaerica* I.15] And because the great circle BCDE cuts the circles BC, ED through their poles, bisecting them — and their diameters, having been shown equal, make the circles BC, ED equal as well. I say that the diameter of the sphere BD is, in square, sesquialter to each of the diameters BC, DE. For since, by the corollary to Elements VI.8, the three lines DB, BC, BF are continually proportional, then, by the corollary to Elements VI.20, as BD is to BF, so is the square on BD to the square on BC. But BD is sesquialter to BF, as was shown. Therefore the square on BD is sesquialter to the square on BC, and hence also to the square on DE. Accordingly the diameter of the sphere BD is, in square, sesquialter to each of the diameters BC, DE. This is what was proposed.

Diagram. The great circle BCDE, with C at the top, B at the left, D at the right, and E at the bottom. A is the center of the sphere, marked near the middle; F lies on the diameter BD just below A. G is marked at the upper left (the pole). The chords BC, CD, DE, EB form the inscribed quadrilateral, with the perpendicular FC and the lines BE, DC drawn.

- C (top): point on the great circle
- B (left): end of the diameter BD
- D (right): end of the diameter BD
- E (bottom): point on the great circle
- A (center): center of the sphere
- F (below center, on BD): point where BD is cut (BF double FD)
- G (upper left): pole of the described circles

PROBL. 1. PROPOS. 1.

In a given sphere, to describe a pyramid [tetrahedron].

By the sixth lemma, describe in the given sphere two equal and parallel circles AD, BC, the square of whose diameters is sesquialter to [is two-thirds of the square on] the sphere's diameter; and through their poles draw the great circle ABCD, [Margin a: Theodosius, *Sphaerica* I.15] which will cut them at right angles and bisect them, so that its common sections with them are the diameters AD, BC. In the circle AD draw another diameter EF, cutting AD at right angles at the center, and draw the lines EB, EC, FB, FC. I say that EBCF is a pyramid — that is, that the four triangles EBC, BCF, CFE, EFB are equilateral and equal.

For, joining the lines AE, ED, DF, FA, AB, CD, CA: AC will be a diameter of the sphere (by the fourth lemma); AB, DC will be equal and perpendicular to the planes of the circles (by the third lemma); and AEDF will be a square inscribed in the circle AD, as is established by Elements IV.6. Now, since by construction the square on the sphere's diameter AC is sesquialter to the square on AD, the diameter of the circle, then, setting the square on AC equal to 3, the square on AD will be 2. And since the square on AC [Margin b: Elements I.47] equals the squares on AD, DC (because the angle ADC is right, by Elements XI, definition 3), the square on DC will be 1; and consequently the square on AD is double the square on DF (by the scholium to Elements I.47). Therefore the squares on DC, DF are equal; [Margin c: Elements I.47] and since the square on CF equals them (because the angle CDF is right, by Elements XI, definition 3), the square on CF is likewise double the square on DF, and therefore equal to the square on AD. Hence the line CF equals the line AD — that is, equals the line BC; and similarly it will be shown that BF equals that same BC. Therefore the triangle BCF is equilateral.

Diagram. A circle with an inscribed pentagon-and-tetrahedron figure. E is at the top, A at the left, D at the right; F is marked at the center just below E; B is at the lower left and C at the lower right. The chords EA, ED, AD, and the lines EB, EC, FB, FC, BC (and AB, CD) are drawn, giving the four triangular faces of the tetrahedron EBCF.

- E (top): apex vertex of the tetrahedron
- A (left): point of the circle AD (end of diameter AD)
- D (right): end of diameter AD
- F (center, below E): center of the circle / point of diameter EF
- B (lower left): vertex of the tetrahedron
- C (lower right): vertex of the tetrahedron

Diagram. The same tetrahedron figure repeated at the head of the page for the continuation of the demonstration: a circle with E at the top, A at the left, D at the

right, F at the center below E, B at the lower left, and C at the lower right, with the edges of the tetrahedron EBCF drawn.

- E (top): apex vertex
- A (left): end of diameter AD
- D (right): end of diameter AD
- F (center, below E): center of the circle
- B (lower left): vertex
- C (lower right): vertex

Again, since the square on AD was shown to be double the square on DC, [Margin d: Elements I.47] and since (by the scholium to Elements I.47) it is also double the square on DE, the squares on DC, DE will be equal. And since the square on CE equals them (because the angle CDE is right, by Elements XI, definition 3), the square on CE will likewise be double the square on DE. Therefore the squares on CE, AD are equal, and for that reason the line CE equals the line AD — that is, equals the line BC, EF — and so also equals the line CF, which was shown equal to BC. The triangle CEF is therefore equilateral as well, and equal to BCF because of the equality of their sides. In the same way we shall demonstrate that the triangle BEF is equilateral and equal to BCF and FCE. From this it follows that the triangle BCE is also equilateral and equal to the other three, since its sides BE, CE were shown equal to BC. Therefore EBCF is a pyramid, by Elements XI, definition 26, and it is described in the given sphere, since its solid angles E, B, C, F lie on the surface of the sphere. This is what was proposed.

COROLLARIUM

From this it follows that the diameter of the sphere is, in square, sesquialter to the edge of the pyramid described in that sphere. For the edge of the pyramid equals the diameter AD, as we showed, and by construction the diameter of the sphere is, in square, sesquialter to the diameter AD.

PROBL. 2. PROPOS. 2.

In a given sphere, to describe an octahedron.

By the sixth lemma, describe in the given sphere two equal and parallel circles ABC, DEF, such that the sphere's diameter is, in square, sesquialter to the diameter of either of them. [Margin a: Elements IV.2] Then, an equilateral triangle ABC having been described in the circle ABC, draw (by the first lemma) in the circle DEF the line DE, parallel and equal to AB, toward the opposite sides of the centers; DE will also be a side of the equilateral triangle described in the

circle DEF, because the circles are equal. Therefore, having completed the equilateral triangle DEF, its several sides will be equal and parallel to the several sides of the triangle ABC — equal, on account of the equality of AB, DE; and parallel, by the scholium to Elements XI.16. For since AB, DE are parallel and the angles ABC, DEF are equal, then, producing the lines DE, FE to G, H, the angles ABC, GEH will also be equal. And since AB, GE are parallel, and BC, EH lie toward the same sides of the plane drawn through AB, GE, then BC, HE — that is, BC, EF — will also be parallel, by that scholium to Elements XI.16. By the same reasoning DF will be parallel to AC. Finally, connect AE, EC, CD, DB, BF, FA, as in the figure.

I say that AD is an octahedron — that is, that the eight triangles ABC, CAE, ECD, DCB, BFA, AFE, EFD, DFB are equilateral and equal. For since in the parallel and equal circles of the sphere the lines AB, DE are equal and parallel toward opposite sides of the centers, then, by the fourth lemma, the joined lines AD, BE (which, however, we have not drawn, to avoid confusion) are diameters of the sphere, and the lines AE, BD will also be equal and perpendicular to AB, DE themselves. [Margin b: Elements I.47] Therefore the square on BE equals the two squares on BD, DE. Now, setting the square on the sphere's diameter BE equal to 6 (for, since by construction the sphere's diameter is, in square, sesquialter to the diameter of the circle DEF, then, setting the square on BE equal to 6, the square on the diameter of the circle DEF will be 4; and, the square on the diameter of the circle DEF being 4, the square on DE, the side of the equilateral triangle, is 3 — because, by the corollary 1 to Elements XIII.12, the diameter of the circle is, in square, sesquitertian to [is four-thirds of the square on] the side of the equilateral triangle): therefore the square on BD is also 3; and consequently the squares on DE, BD are equal, and the lines DE, BD themselves are equal. But DE equals AB (by construction), and BD equals AE (by the fourth lemma). Therefore the four lines AB, BD, DE, EA are equal, and they constitute the square ABDE, since the angles at A, B, D, E are right, by the same fourth lemma.

Again, since BC, EF are parallel and equal toward opposite sides of the centers, then the joined lines BE, CF (not toward the same sides) will be diameters of the sphere, by the fourth lemma, and the lines BF, CE will be equal to one another and perpendicular to BC, EF; and again, as before, BCEF will be a square. In no other way we shall show that ACDF is a square, since the joined lines AD, CF are likewise diameters of the sphere by the fourth lemma, and so forth. Since then the three squares AD, BE, CF are constructed upon the equal sides AB, BC, CA — namely upon the sides of the equilateral triangle, AB being the side of the square AD, BC of the square BE, and CA of the square CF — all eight triangles ABC, CAE, ECD, DCB, BFA, AFE, EFD, DFB will be equilateral and equal to one another.

Therefore AD is an octahedron, by Elements XI, definition 27, and it is described in the given sphere, since its solid angles A, B, D, E, C, F touch the surface of the sphere. This is what was proposed.

Diagram. A circle enclosing an octahedron. A is at the upper left, B at the upper right, C in the upper-middle; D is at the lower right, E at the lower left, and F near the center-right. G and H are marked at the far left beside E (the points to which DE and FE are produced). The connecting lines AE, EC, CD, DB, BF, FA and the diagonals are drawn, giving the eight triangular faces.

- A (upper left): vertex of the octahedron
- B (upper right): vertex
- C (upper middle): vertex
- D (lower right): vertex
- E (lower left): vertex
- F (center right): vertex
- G (far left, above H): point to which DE is produced
- H (far left, below G): point to which FE is produced

COROLLARIVM

It is gathered from these things that the diameter of the sphere is, in square, double the edge of the octahedron described in that sphere. For it was demonstrated that the square on BE, the diameter of the sphere, is double the square on DE, the edge of the octahedron.

PROBL. 3. PROPOS. 3.

In a given sphere, to describe a cube.

BOOK XVI

(Continuation of the demonstration of PROBL. 3 / PROPOS. 3 — to describe a cube in a given sphere.)

By Lemma 6, let two equal and parallel circles ABCD and EFGH be described in the given sphere, the squares on whose diameters are in sesquialter ratio [3:2] to the square on the diameter of the sphere. [Margin: a — Elements IV.6] Now, with the square ABCD described in circle ABCD, let the straight line AD be drawn (by Lemma 1) in circle EFGH, parallel to EH and equal to it on the same side of the centers; because the circles are equal, this too will be the side of the square described in circle EFGH. When, therefore, the square EFGH has been completed,

its individual sides will be equal and parallel to the individual sides of square ABCD — equal because the sides AD and EH are equal, and parallel by the scholium to Elements XI.16. For since AD and EH are parallel, and the angles ADC and EHG are equal (both being right angles), DC and HG will likewise be parallel, since they are drawn toward the same parts of the plane through AD and EH; and so with the rest. Finally, let the straight lines AE, BF, CG, DH be joined toward the same parts of the centers; by Lemma 3 these will be perpendicular to the planes of the circles and parallel to one another.

I say that AG is a cube — that is, that the six quadrilaterals ABCD, EFGH, ADHE, BCGF, ABFE, CDHG are squares and equal to one another. For when the straight lines BH and BD are drawn, BH will (by Lemma 4) be the diameter of the sphere, while BD is the diameter of circle ABCD, being the diameter of the square inscribed in the circle. Since, then, by the construction, the square on BH is sesquialter to the square on BD, while the square on BD is double the square on BC (by the scholium to Elements I.47), [Margin: b — Elements I.47] if the square on BH is set at 3, the square on BD will be 2 and the square on DC will be 1; and so the square on BH will be triple the square on DC. Again, since the square on BH is 3 and the square on BD is 2, and since the square on BH is equal to the squares on BD and DH together (because the angle BDH is right, by Elements XI, def. 3), the square on DH will be 1. Therefore the square on BH is triple the square on DH. But the same square on BH was also triple the square on DC. Hence the squares on DC and DH are equal, and therefore the straight lines DC and DH are equal.

Since, then, these are equal to the opposite sides GH and CG, all four sides of the parallelogram CH will be equal; and since its angles are also right (by Elements XI, def. 3), CH will be a square. By the same reasoning BE, AH, and BG will be shown to be squares; and AC and EC are squares by construction. Therefore all six quadrilaterals are squares, and equal to one another because their sides are equal. So AG is a cube (by Elements XI, def. 25), described in the given sphere, since its solid angles A, B, C, D, E, F, G, H touch the surface of the sphere. Which was what was proposed.

Diagram. A cube inscribed in a circle (representing the sphere), drawn in oblique projection. The top face is bounded by the upper vertices and the bottom face by the lower vertices; the diagonals BD (of the top square) and BH (the sphere's diameter) are drawn.

- A (top-left): upper-back vertex
- D (top-right): upper-back vertex
- B (upper-left): upper-front vertex

- C (upper-right): upper-front vertex
- E (mid-left): lower-back vertex
- H (mid-right): lower-back vertex
- F (bottom-left): lower-front vertex
- G (bottom-right): lower-front vertex

COROLLARY

It is established from these results that the diameter of the sphere is triple in square [potentia tripla] to the side of the cube described in that sphere. For it has been demonstrated that the square on the diameter of the sphere BH is triple the square on the side of the cube DC, or DH, or AD, etc.

It is likewise manifest that one and the same circle contains both the square of the cube and the triangle of the octahedron described in the same sphere: namely, circle ABCD of the present figure is equal to circle ABC of the preceding proposition. This too was demonstrated in Elements XIV.21.

Diagram. An octahedron inscribed in a circle (the sphere), with its edges and internal diagonals drawn; carried over from the preceding proposition for the comparison stated in the corollary. The letters G and H are set close together at the left, marking one endpoint of a diameter/axis.

- A (upper-left): vertex
- B (upper-right): vertex
- C (upper-center): vertex
- E (lower-left): vertex
- F (lower-center): vertex
- D (lower-right): vertex
- G (left, upper of the pair): axis/diameter point
- H (left, lower of the pair): axis/diameter point

PROBL. 4. PROPOS. 4.

In a given sphere, to describe an icosahedron.

Let a straight line be found [Margin: a — Elements VI.12] to which the diameter of the given sphere has the same ratio as the side of a pentagon has to the side of a hexagon described in the same circle with the pentagon. And by the corollary to Elements X.6, let it be brought about that, as the number 3 is to 1, so the square on the straight line found is to the square on some other line; and about an interval equal to this other line, taken as a radius, let a circle be described in the

given sphere. This will be done easily, as follows. In the given sphere let a great circle be described, and in it [Margin: b — Elements V.1 [?] ("1.quinti"); context suggests IV.1] let a straight line be fitted that is double the radius found — for this straight line is less than the diameter of the sphere, or of that great circle, as will be proved below. For if through this straight line a plane is drawn at right angles to that great circle, it will make [Margin: c — Theodosius I.1] the circle ABC in the sphere, whose radius, by the construction, is subtriple in square to the straight line found at the outset.

Next, let another straight line be found [Margin: d — Elements VI.12] to which the diameter of the given sphere has the same ratio as the side of a pentagon has to the side of a decagon described in the same circle with the pentagon; and, by the corollary to Elements X.6, let it be brought about that, as 3 is to 1, so the square on the straight line found is to the square on another line; and about an interval equal to this let another circle be described in the sphere, parallel to the former circle ABC. This will come about if in that same great circle a straight line is fitted equal to double the radius found and parallel to the diameter of the former circle — from what we demonstrated at Elements IV.1 — and if through that straight line a plane is extended parallel to the former circle: that is,

that is, at right angles to the said great circle, from the scholium to Elements XI.18. For by the same scholium this plane will be parallel to circle ABC, and will make [Margin: e — Theodosius I.1] in the sphere a circle DEF, whose radius is equal to the radius found. On the other side of the center of the sphere let two other circles GHI and KLM be described, equal and parallel to these two; this will easily be done if straight lines equal and parallel to their diameters are drawn in that same great circle, etc. [Margin: f — Elements IV.2]

Now, with an equilateral triangle DEF described in circle DEF, let a straight line AB be drawn (by the first lemma) in the parallel circle ABC, on the other side of the center, parallel to the side EF and equal to one side of the equilateral triangle described in circle ABC. Likewise, parallel and equal to this AB, let KL be drawn on the other side of the center in circle KLM. And finally let HI be drawn, in circle GHI, on the other side of the center, parallel to this KL and equal to EF — that is, to the side of the equilateral triangle described in circle GHI. When, therefore, the equilateral triangles ABC, KLM, GHI have been completed, their individual sides will be parallel to the individual sides of triangle DEF — namely AC, ML, GH to DF, and BC, MK, GI to DE — as will be proved from the scholium to Elements XI.16, just as in the second problem we showed that BC and EF, drawn toward different parts of the centers, are parallel. In the figure we have not drawn those

triangles in circles ABC and KLM, lest the multitude of lines cause confusion, but have marked only the endpoints of their sides.

Finally, from each of the 12 points of the four equilateral triangles, let five straight lines be drawn to the five nearest points — namely, from point D the lines DE, DA, DM, DB, DF; from G the lines GH, GK, GC, GL, GI; and so on, as appears in the figure. For you see that from each point five straight lines are sent out. I say that DG is an icosahedron — that is, that the twenty triangles DEF, DEA, DAM, DMB, DFB, etc. are equilateral and equal. To demonstrate this, it must first be shown that the icosahedron described in the sphere (that an icosahedron can be described in a given sphere, Euclid taught at Elements XIII.16) sets its 12 angles in the four parallel circles which we described — namely three angles in each circle, and in that same position in which we marked the points.

Diagram. An icosahedron inscribed in a circle (the sphere), redrawn from the foot of the preceding page, densely crossed by the edges and the internal chords joining each vertex to its five neighbors. The twelve vertices named in the text are D, E, A, K, H, G, I, L, B, F, M, C. Legible label positions: D (top), a point at upper-left [K or E, ?], a point at upper-right [F or B, ?], A (left), B (right), C (center-left), M (center), a point at lower-left [?], L (lower-right), H (bottom-left), I (bottom-right), G (bottom). Several peripheral labels cannot be resolved with certainty against the crossing lines and foxing.**

Let there be, then, an icosahedron DG described in the sphere, setting its twelve angles at the points D, E, A, K, H, G, I, L, B, F, M, C. And since the five straight lines DE, DA, DM, DB, DF are equal, being sides of equal equilateral triangles, if from the pole D through E a circle is described in the sphere, it will pass through the remaining points A, M, B, F; and therefore the pentagon E, A, M, B, F will lie in one plane — namely in the plane of that circle. Since its sides are equal, being sides of the icosahedron, that pentagon will also be equiangular, from what we demonstrated at the end of Elements Book IV.

By the same reasoning the pentagon AKCFD will be equilateral and equiangular, because of the five equal straight lines EA, EK, EC, EF, ED; and KHMDE, because of the five equal sides of the icosahedron AK, AH, AM, AD, AE; and HGCEA, because of the five equal sides of the icosahedron KH, KG, KC, KE, KA; and GIMAK, because of the five equal sides of the icosahedron HG, HI, HM, HA, HK; and ILCKH, because of the five equal straight lines GI, GL, GC, GK, GH; and LBMHG, because of the five equal straight lines IL, IB, IM, IH, IG; and BFCGI, because of the five equal straight lines LB, LF, LC, LG, LI; and FDMIL, because of the five equal straight lines BF, BD, BM, BI, BL; and DECLB, because of the five equal straight

lines FD, FE, FC, FL, FB; and DAHIB, because of the five equal sides of the icosahedron MD, MA, MH, MI, MB; and finally GLFEK, because of the five equal sides of the icosahedron CG, CL, CF, CE, CK — so that 12 equilateral and equiangular pentagons, equal to one another, are constituted.

Now, since a straight line subtending an angle of an equilateral and equiangular pentagon is equidistant from [i.e., parallel to] the opposite side — as we demonstrated in the scholium to Elements XIII.8 — the line AB joined will be parallel to EF in the pentagon EAMBF; and AC joined will be parallel to DF in the pentagon AKCFD; and BC joined will be parallel to DE in the pentagon DECLB. [Margin: g — Elements XI.15] Therefore the planes drawn through the straight lines DE, EF and through CB, BA are parallel, [Margin: h — Theodosius I.1] and they make parallel circles in the sphere, DEF and ABC. In the same way KL joined will be parallel to HI in the pentagon ILCKH; and KM joined to GI in the pentagon GIMAK; and LM joined to GH in the pentagon LBMHG. Not otherwise, AB joined will be parallel to HI in the pentagon DAHIB, and KL joined to EF in the pentagon GLFEK. [Margin: i — Elements XI.9] Therefore EF and HI, since each is parallel to the same joined line AB or KL, are parallel to each other. And by the same reasoning DE and GI, since each is parallel to the same joined line BC or KM; and because of this the planes of the circles DEF and GHI, drawn through the straight lines DE, EF and HI, GI, will be parallel. Therefore all four circles in the sphere — DEF, GHI, ABC, KLM — are parallel to one another; and the circles DEF and GHI are equal to each other, because of the equal equilateral triangles described in them, just as the circles ABC and KLM are also equal to each other, because of the equal equilateral triangles in them, which are constituted from the joined lines AB, BC, CA and KL, LM, MK — since these sides are straight lines subtending the angles of equal pentagons.

Now, since the joined straight line KB — which connects the endpoints k and B of the parallels kL and AB (drawn, in parallel circles, not toward the same parts, and not toward the same parts of the centers) — is a diameter of the sphere, and the angle BAK is right (by Lemma 4, because kA connects the endpoints k and A of those same parallels toward the same parts), [Margin: k — Elements I.47] the square on the diameter kB will be equal to the two squares on AB and Ak together. Again, since in the pentagon EAMBF the joined straight line AB subtends the angle AMB — and since a straight line subtending an angle of a pentagon has to the side of the pentagon the same ratio as the side of a hexagon has to the side of a decagon described in the same circle, by the scholium to Elements XIII.2 [Margin: l — Elements XIII.10] — AB joined will be to EF (or to Ak, which equals EF) as the side of a hexagon is to the side of a decagon. And therefore, since the

side of a pentagon has the power of both the side of a hexagon and the side of a decagon described in the same circle, the diameter of the sphere kB (which has the power of both AB and Ak together) will be the side of a pentagon in the circle in which AB is the side of a hexagon and Ak , or EF , the side of a decagon. Hence the sphere's diameter has to the side of a pentagon the ratio that the side of a pentagon has to the side of a hexagon, but to EF the ratio that the side of a pentagon has to the side of a decagon. [Margin: m — Elements XIII.12] And accordingly, since AB — the side of the equilateral triangle in circle DEF — is triple in square to the radius of its own circle, the circles DEF , ABC , and therefore also GHI and kLM (which are equal to them), will be those which we described at the beginning of the proposition. From this it is clear that the straight line which is double the radius found at the outset is less than the diameter of the sphere, as we said above.

Having demonstrated these things, we shall easily conclude that the solid figure DG described by us is an icosahedron. For, taking the icosahedron described in the sphere whose base is the triangle DEF , all its solid angles fall on the three-point sets of the other three parallel circles from which we drew the sides of the triangles; and accordingly the individual sides of these coincide with the individual sides of that icosahedron.

COROLLARY I

It is established from these results that the diameter of the sphere has to the side of the icosahedron described in it the ratio that

the side of a pentagon has to the side of a decagon described in the same circle; so that, if the diameter of the sphere is the side of a pentagon in some circle, the side of the icosahedron will be the side of a decagon in that same circle. For, with the icosahedron DG described in the sphere, it was shown that the diameter of the sphere KB is to EF , the side of the icosahedron, as the side of a pentagon is to the side of a decagon.

From this it follows that the side of the icosahedron is greater than the radius of the sphere — just as the side of a decagon is greater than half the side of a pentagon, since two sides of a decagon together with one side of a pentagon constitute an isosceles triangle, [Margin: n — Elements I.20] and therefore two sides of a decagon are greater than the side of a pentagon, and hence one side of a decagon is greater than half the side of a pentagon.

COROLLARY

It is also gathered from what has been demonstrated that the diameter of the sphere is triple in square to the side of the pentagon described in circle ABC. For since, as the side of a pentagon is to the side of a hexagon described in the same circle ABC, so is the diameter of the sphere KB to AB joined, by the construction, it will be, alternately, as the side of a pentagon is to the diameter of the sphere, so the side of a hexagon to AB joined. [Margin: o — Elements XIII.12] But the side of a hexagon in circle ABC (that is, the radius) is subtriple in square to the joined straight line AB, because AB is the side of an equilateral triangle. Therefore the side of a pentagon in the same circle ABC is likewise subtriple in square to the diameter of the sphere — that is, the diameter of the sphere is triple in square to the side of the pentagon described in circle ABC.

PROBL. 5. PROPOS. 5.

In a given sphere, to describe a dodecahedron.

In the given sphere let four parallel circles be described, as in the preceding proposition — ABCDE, FGHIK, LMNOP, QRSTV — such that the radii of the circles ABCDE and QRSTV are subtriple in square to two straight lines to which the diameter of the sphere has the same ratio as the side of a pentagon has to the side of a decagon; while the radii of the circles FGHIK and LMNOP are subtriple in square to two straight lines to which the diameter of the sphere has the same ratio as the side of a pentagon has to the side of a hexagon. Now, with the equilateral and equiangular pentagon ABCDE described in circle ABCDE, let a line HI be drawn parallel to its side CD, toward the same parts of the centers, in circle FGHIK, equal to the side of the pentagon of that same circle, by the first lemma. In the same way let the straight line HI be drawn parallel toward the different parts of the centers as LP, in circle LMNOP; and finally let QV be drawn parallel to this LP, toward the same parts of the centers, in circle QRSTV. When the pentagons in these three circles have been completed (whose sides, however, we have not drawn, to avoid confusion, but have marked only their endpoints), their individual sides will be parallel to the individual sides of the pentagon ABCDE, in the same order in which the parallels to side CD were drawn — as will be demonstrated, just as in Problem 2 we showed BC and EF to be parallel; namely, the joined sides HG, PO, TV will be parallel to BC, and so on. Finally, from each of the 20 points of the four pentagons, let three straight lines be drawn to the three nearest points, as appears in the figure. For from each point you see three straight lines sent out.

I say that AS is a dodecahedron — that is, that the twelve pentagons ABCDE, DEKOI, OINST, STVQR, QRMGL, GLFAB, AFPKE, KPVTO, RSNHM, FLQVP, CDINH, BCHMG are equilateral, equiangular, and equal. To show this, it must first be demonstrated that the dodecahedron described in the sphere (that a dodecahedron can be described in a given sphere, Euclid taught at Elements XIII.17) sets its 20 angles in the four parallel circles which we described — five in each circle — and in that same position in which we marked the 20 points.

Let there be, then, a dodecahedron AS described in the sphere, setting its twenty angles at the points A, B, C, D, E, F, G, H, I, K, L, M, N, O, P, Q, R, S, T, V. [Margin: a — Elements XI.13 [?] ("13.unde.")] And since a straight line subtending an angle of an equilateral and equiangular pentagon is equidistant from [parallel to] the opposite side — as we demonstrated in the scholium to Elements XIII.8 — GH joined will be parallel to the side BC in the pentagon BCHMG; and HI joined to the side CD in the pentagon CDINH; and Ik to the side DE in the pentagon DEKOI; and kF to AE in the pentagon AEkPF; and FG to AB in the pentagon ABGLF; and so with the rest.

Since, then, the straight lines AB, AE are parallel to the straight lines FG, FK, [Margin: c — Elements [reference illegible, ?]] the plane drawn through FG, FK will also be parallel to the plane of the pentagon ABCDE drawn through AB, AE. By the same reasoning the plane drawn through FG, GH will be parallel to that same plane of the pentagon, because these lines are parallel to the lines AB, BC. Therefore, by the scholium to Elements XI.16, the planes drawn through FG, FK and through FG, GH are parallel to each other, since they are parallel to the same plane of the pentagon ABCDE; and accordingly, by the same scholium, since they meet in the straight line FG, they will make one plane. In just the same way we shall show that the plane through FK, KI and the plane through IH, HG make one plane with the plane drawn through FK, FG. Therefore the planes drawn through the points A, B, C, D, E and through the points F, G, H, I, K will make [Margin: d — Theodosius I.1] two parallel circles in the sphere, ABCDE and FGHIK. And in the same way the planes drawn through the points Q, R, S, T, V and through the points L, M, N, O, P will make parallel circles QRSTV and LMNOP; [Margin: e — Elements I.4] and both the two circles ABCDE, QRSTV and the two FGHIK, LMNOP will be equal to one another, because of the equal pentagons ABCDE, QRSTV, and because of the straight lines FG, GH, HI, IK, KF; LM, MN, NO, OP, PL, which are all equal, since they subtend equal angles in equal pentagons.

Next, since by the scholium to Elements XIII.8 the joined straight lines ND, MB are parallel to the side CH in the pentagons CHNID and BGMHC, [Margin: f —

Elements XI.9] the joined lines ND, MB will themselves also be parallel; and they are also equal, because they subtend equal angles in equal pentagons. [Margin: g — Elements I.33] Therefore the joined lines NM, BD will also be equal and parallel. In the same way the joined lines NO, CE will be equal and parallel, since they connect the two lines NC, OE, which are equal and parallel because each is parallel to the side DI. [Margin: h — Elements XI.15] Therefore circle LMNOP is parallel to circle ABCDE, since the former is drawn through the straight lines NM, NO, and the latter through the straight lines BD, CE, to which those have been shown parallel. Not otherwise will the circles QRSTV, FGHIK be shown parallel. Therefore all four circles are parallel.

Diagram. A dodecahedron inscribed in a sphere, drawn in oblique projection with the sphere's outline and the four parallel circles indicated; the twenty vertices are named A–V and connected by the edges and chords of the twelve pentagonal faces. Legible label positions:

- B (top-left), A (top-center), E (top-right)
- C (upper-left), D (upper-right)
- G (left), F (center), K (right)
- H (below G, left), I (below K, right)
- L (lower-left), P (lower-right)
- M (lower-left), O (lower-right)
- N (bottom-center, upper)
- Q (bottom-left), V (bottom-center)
- R (bottom-left, lowest), S (bottom-center, lowest), T (bottom-right, lowest)

(continuation of PROBL. 5 / PROPOS. 5 — inscribing a dodecahedron in a given sphere; conclusion of the demonstration)

Again, since the joined lines EF and OV, being (by the scholium of prop. 8 of book 13) equidistant from the side PK in the pentagons AEKPF and TVPKO, are parallel [Margin: a — Elements XI.9], and are moreover equal to one another — because they subtend equal angles in equal pentagons — the joined lines EO and FV will likewise be parallel and equal [Margin: b — Elements I.33]. Therefore the quadrilateral EFVO lies in one plane [Margin: c — Elements XI.7], since EF and OV are in the same plane as the parallels EO and FV. It also lies in a circle [Margin: d — Theodosius, *Sphaerica* I.1], because the plane in which it lies produces a circle in the sphere. Therefore, from what we demonstrated on prop. 31 of book 3, since the opposite sides of this quadrilateral are equal, the quadrilateral EFVO is a

rectangle; and consequently, since all its sides are equal — subtending equal angles in equal pentagons — it will be a square.

So, drawing its diagonal FO, the square on FO is double the square on the side FE (by the scholium of prop. 47 of book 1) — that is, double the square on the joined line FG, since FG and FE are equal, subtending angles of equal pentagons. And so, taking the square on FG to be 1 of some parts, the square on FO will be 2 of those parts, and both squares together 3 of the same parts. Now the square on the joined line OG — which is the diameter of the sphere — is equal to these [Margin: e — Elements I.47]. (For since the joined lines FG and ON are equal, subtending equal angles of the pentagons, and are parallel to one another — being parallel to the two parallels AB, ST, by the scholium of prop. 8 of book 13 — it follows, by lemma 4, that the joined line OF is perpendicular to FG, and that OG is the diameter of the sphere.) Hence the square on the diameter of the sphere is also 3 of the parts of which the square on FG is 1; that is, the square on the sphere's diameter is triple the square on FG.

But the square on the side of an equilateral triangle is likewise triple the square on the radius — that is, on the side of the hexagon [Margin: f — Elements XIII.12]. Therefore, as the square on the diameter of the sphere is to the square on FG, so is the square on the side of the triangle to the square on the side of the hexagon; and hence, as the diameter of the sphere is to FG, so is the side of the equilateral triangle to the side of the hexagon [Margin: g — Elements VI.22]. But as FG is to the side of the triangle in the same circle FGHIK, so is the side of the pentagon of that circle to the side of the triangle — since FG is the side of the pentagon. Therefore, by perturbed proportion, as the diameter of the sphere is to the side of the equilateral triangle in circle FGHIK, so is the side of the pentagon to the side of the hexagon, as appears in the adjoining scheme:

Diameter of the sphere	Side of the pentagon
Line FG	Side of the triangle
Side of the triangle	Side of the hexagon

Since, then, in the figure of the preceding proposition it is likewise the case that, as the diameter of the sphere is to the side of the triangle — that is, to the joined line AB in that figure — so is the side of the pentagon to the side of the hexagon, each of the circles ABC and KLM of that figure will be equal to each of the circles FGHIK and LMNOP of this figure.

Furthermore, since by the scholium of prop. 2 of book 14 it holds that, as the joined line FG (subtending the angle of the pentagon ABGLF) is to AB, the side of

the pentagon, so is the side of the hexagon to the side of the decagon; and as FG, the side of the pentagon in circle FGHIK, is to AB, the side of the pentagon in circle ABCDE, so is the side of the triangle in circle FGHIK to the side of the triangle in circle BCDE [recte: ABCDE?] — it will follow that, as the side of the triangle in circle FGHIK is to the side of the triangle in circle ABCDE, so is the side of the hexagon to the side of the decagon described in the same circle with the hexagon. But as the diameter of the sphere is to the side of the triangle in circle FGHIK, so is the side of the pentagon to the side of the hexagon described in the same circle with the pentagon, as was just demonstrated. Therefore, *ex aequali*, as the diameter of the sphere is to the side of the triangle in circle ABCDE, so is the side of the pentagon to the side of the decagon described in the same circle with the pentagon, as appears in this second scheme:

Diameter of the sphere	Side of the pentagon
Side of the triangle in circle FGHIK	Side of the hexagon
Side of the triangle in circle ABCDE	Side of the decagon

Since, then, in the figure of the preceding proposition it likewise holds that, as the diameter of the sphere is to EF, the side of the triangle in circle DEF, so is the side of the pentagon to the side of the decagon, each of the circles DEF and GHI of the preceding figure will be equal to each of the circles ABCDE and QRSTV of this figure. And so the circles ABCDE, FGHIK, LMNOP, QRSTV are those which we described in the preceding proposition and in this one.

With these things demonstrated, we shall prove without difficulty that the solid figure AS, which we have described, is a dodecahedron. For, once a dodecahedron has been described in the sphere with the pentagon ABCDE as its base, all its solid angles fall on the five points of each of the other three parallel circles, from which we drew out the sides of the pentagons; and consequently each of these sides coincides with each side of that dodecahedron.

COROLLARIUM.

It is clearly gathered from these results that one and the same circle encompasses both the triangle of the icosahedron and the pentagon of the dodecahedron, when they are described in the same sphere — namely, because the circle DEF of the preceding proposition's figure is equal to the circle ABCDE of this proposition's figure. This too has been demonstrated in book 14, prop. 5.

It is also manifest that the very same circles support both the solid angles of the icosahedron and the solid angles of the dodecahedron.

SCHOLIUM.

From what we have demonstrated here, and in books 13 and 14, we shall also easily show that, if all five regular solids are described in one and the same sphere, the greatest of all is the dodecahedron; next, the icosahedron is greater than the remaining three; third, the cube is greater than the remaining two; and finally the octahedron is greater than the tetrahedron. From this it will be established that Euclid constructed these five solids in the correct order, since after the tetrahedron he set down the octahedron immediately, and not the cube — for in this way he always advanced from the smaller to the greater. But first some other things must be demonstrated. Let us therefore begin with these.

I.

If a square and an equilateral triangle have equal sides, then twenty triangles together will be greater than eight squares together.

Diagram. A schematic proportion figure for the theorem. At the left stand two reference figures: a square labelled **A**, and an equilateral triangle labelled **B** with its altitude drawn from the apex to the base. To the right are two long horizontal rectangles, stacked one above the other:

- **A** — the square (side equal to the side of triangle **B**).
- **B** — the equilateral triangle, with an internal altitude.
- **C** — lower-left corner of the upper rectangle (rectangle **CE**).
- **D** — lower-right corner of the upper rectangle; **CD** is the base (eight times the side of square **A**).
- **E** — upper-right corner of the upper rectangle; **DE** is its height (equal to the side of square **A**).
- **F** — lower-left corner of the lower rectangle (rectangle **FH**).
- **G** — lower-right corner of the lower rectangle; **FG** is its base (ten times the side of triangle **B**).
- **H** — upper-right corner of the lower rectangle; **GH** is its height (equal to the altitude of triangle **B**).
- **I** — upper-left corner of the lower rectangle.
- **K** — a point on the right edge between **H** and **G**; the line **KI** is drawn parallel to the base **FG**.

Let there be a square **A** and an equilateral triangle **B** with equal sides. I say that twenty triangles are greater than eight squares. For let there be a rectangle **CE**, one side of which, **CD**, is eight times the side of the square **A**, and the side **DE**

equal to the side of the same square. Then the rectangle CE will be eight times the square A [Margin: h — Elements VI.1], since, on account of their equal height, as CD is to the side of the square A, so is the rectangle CE to the square A. Let there also be a rectangle FH, one side of which, FG, is ten times the side of the triangle B, and the side GH equal to the perpendicular dropped from one angle of the triangle to its base — that is,

— that is, equal to the altitude of the triangle B. And since a right-angled triangle, one side of which is twenty times the side of the triangle B, and the other side equal to GH itself (that is, to the altitude of the triangle B), is twenty times the triangle B [Margin: a — Elements VI.1]; and since the rectangle FH is equal to that right-angled triangle (by the scholium of prop. 41 of book 1), inasmuch as the base FG is half the base of that triangle; the rectangle FH will also be twenty times the triangle B. It must therefore be proved that the rectangle FH is greater than the rectangle CE [Margin: b — Elements XIV.12].

Since the side of the triangle B — that is, the side DE — is, in square [*potential*], four-thirds [*sesquitertium*] of its perpendicular, that is, of the side GH; while the side FG has to the side CD, in square, the ratio of 25 to 16 (since FG is 10 and CD is 8, that is, FG is 5 and CD is 4): the ratio of FG to CD will be greater than the ratio of DE to GH. For the ratio 25 to 16 — a ratio of one plus nine-sixteenths [*supernonupartiens sedecimas*] — is greater than 4 to 3, the sesquitertian ratio, since the fraction $9/16$ is greater than $1/3$. Let it be arranged that, as FG is to CD, so is DE to HK [Margin: c — Elements VI.12]; then the ratio of DE to HK will also be greater than that of DE to GH; and consequently GH will be greater than HK [Margin: d — Elements V.10]. So, drawing KI parallel to FG, it will hold that, as IK (equal to FG) is to CD, so is DE to HK. Therefore the rectangle IH will be equal to the rectangle CE [Margin: e — Elements VI.14 or VI.16]; and so EH [recte: FH?] is greater than CE. Which is what was proposed.

II.

Eight squares described on the radius of a sphere are equal to the surface of a cube described in that sphere.

Since two squares described on the diameter of a sphere are equal to the surface of a cube described in that sphere [Margin: f — Elements XIV.20]; and since these same two squares are equal to eight squares described on the radius of the sphere — because the square on the diameter is quadruple the square on the radius — it follows, by the scholium of prop. 4 of book 2, that eight squares on the

radius of the sphere are likewise equal to the surface of the cube of the same sphere. Which is what was proposed.

III.

If an octahedron, a cube, and an icosahedron are described in the same sphere, then the perpendicular drawn from the center of the sphere to one face of the icosahedron will be greater than the perpendicular drawn from the same center of the sphere to one face of the octahedron and of the cube.

For, since the edge of the octahedron is greater than the edge of the icosahedron in the same sphere [Margin: g — Elements XIII.18], one triangle of the octahedron will also be greater than one triangle of the icosahedron. Therefore, if both solids are so set within the sphere that a triangle of the one is parallel to a triangle of the other, the icosahedron's triangle will lie farther from the center than the octahedron's triangle, since each touches the surface of the sphere with its three angles. And consequently the perpendicular drawn from the center of the sphere to a face of the icosahedron will be greater than the perpendicular from the same center to a face of the octahedron. Since, then, the perpendicular of the octahedron is equal to the perpendicular of the cube — because the face of the cube and the face of the octahedron are circumscribed by the same circle, and so are equally distant from the center [Margin: h — Elements XIV.21] — the perpendicular of the icosahedron will also be greater than the perpendicular of the cube. Which is what was proposed.

IV.

If a cube and an icosahedron are described in the same sphere, the surface of the icosahedron is greater than the surface of the cube.

Since twenty equilateral triangles [constructed] on the radius of the sphere are greater than eight squares described on the radius of the same sphere, as we demonstrated in theorem 1; and since the twenty triangles of the icosahedron are greater than twenty equilateral triangles constructed on the radius of the sphere — because the edge of the icosahedron is greater than the radius of the sphere, by corollary 1 of the fourth problem above — the twenty triangles of the icosahedron are therefore much greater than eight squares described on the radius of the sphere. For this reason, since the twenty triangles of the icosahedron make up the whole surface of the icosahedron, and since eight squares described on the radius of the sphere are equal to the surface of the cube

(by theorem 2, demonstrated just above), the surface of the icosahedron will also be greater than the surface of the cube. Which is what was proposed.

DE COMPARATIONE SOLIDITATVM QVINQVE CORPORVM Regularium in eadem sphaera descriptorum.

(On the comparison of the solidities of the five regular bodies described in the same sphere.)

With these premises laid down, let us now demonstrate that the dodecahedron is greater than the icosahedron, the icosahedron greater than the cube, the cube greater than the octahedron, and finally the octahedron greater than the tetrahedron — which will be done as follows.

I.

DODECAEDRVM Icosaedro maius est.

The dodecahedron is greater than the icosahedron.

Since, as the edge of the cube is to the edge of the icosahedron, so is the dodecahedron to the icosahedron [Margin: i — Elements XIV.11]; and since the edge of the cube is greater than the edge of the icosahedron [Margin: k — Elements XIII.18]; the dodecahedron will also be greater than the icosahedron. Which is what was proposed.

II.

ICOSAEDRVM cubo maius est.

The icosahedron is greater than the cube.

Since the perpendicular falling from the center of the sphere onto one face of the icosahedron is greater than the perpendicular dropped from the same center onto one face of the cube (as was shown in the third theorem above); and likewise, by the fourth theorem, the surface of the icosahedron is also greater than the surface of the cube: the solid contained by the perpendicular falling from the center of the sphere onto one face of the icosahedron and by a third part of the surface of the icosahedron will be greater than the solid contained by the perpendicular falling from the same center of the sphere onto one face of the cube and by a third part of the surface of the cube. Since, then — as we demonstrated in the scholium of prop. 20 of book 14 — the former solid is equal to the icosahedron and the latter to the cube, the icosahedron will also be greater than the cube. Which is what was proposed.

III.

CVBVS Octaedro maius est.

The cube is greater than the octahedron.

Since, as the edge of the cube is to the radius of the sphere, so is the cube to the octahedron [Margin: a — Elements XIV.27]; and since the edge of the cube is greater than the radius of the sphere — (for, since the edge of the cube is greater than the edge of the icosahedron [Margin: b — Elements XIII.18], and the edge of the icosahedron, by corollary 1 of the fourth problem above, is greater than the radius of the sphere, the edge of the cube will be much greater than the radius of the sphere) — the cube will therefore also be greater than the octahedron. Which is what was proposed.

IV.

OCTAEDRVM Tetraedro maius est.

The octahedron is greater than the tetrahedron.

Since the face of the octahedron is smaller than the face of the tetrahedron — because the face of the tetrahedron has to the face of the octahedron the sesquitercian ratio [4:3] [Margin: a — Elements XIV.14] — the perpendicular dropped from the center of the sphere to one face of the octahedron will be greater than the perpendicular falling from the same center to one face of the tetrahedron; which will be proved in no other way than we showed above, in theorem 3, that the perpendicular in the icosahedron is greater than the perpendicular in the octahedron and in the cube. Moreover, the surface of the octahedron is also greater than the surface of the tetrahedron, since the former is one-and-a-half times [*sesquialtera*] the latter [Margin: b — Elements XIV.14]. Therefore the solid contained by the perpendicular falling from the center of the sphere onto one face of the octahedron and by a third part of the surface of the octahedron is greater than the solid contained by the perpendicular drawn from the same center of the sphere onto one face of the tetrahedron and by a third part of the surface of the tetrahedron. Wherefore, since — by the scholium of prop. 20 of book 14 — the former solid is equal to the octahedron and the latter to the tetrahedron, the octahedron will also be greater than the tetrahedron. Which is what was proposed.

ALITER. (*Otherwise.*) Since, as the edge of the octahedron is to the edge of the tetrahedron, so is the octahedron to triple the tetrahedron [Margin: c — Elements XIV.22]; and since, as the edge of the tetrahedron is to its third part, so is triple the tetrahedron to a third part of it — that is, to the tetrahedron itself: therefore,

ex aequali, it will also hold that, as the edge of the octahedron is to the third part of the edge of the tetrahedron, so is the octahedron to the tetrahedron. Since, then, the edge of the octahedron is greater than the third part of the edge of the tetrahedron — (for, because the square on the edge of the tetrahedron is four-thirds of the square on the edge of the octahedron [Margin: d — Elements XIII.18], the edge of the tetrahedron will have to the edge of the octahedron a ratio less than sesquitercian [4:3], and therefore much less than triple; and consequently the third part of the edge of the tetrahedron will be less than the edge of the octahedron [Margin: e — Elements V.10]) — the octahedron will also be greater than the tetrahedron. Which is what was proposed.

ALITER. (*Otherwise.*) Since the tetrahedron is to the octahedron as the rectangle — contained by a line whose square is $27/64$ of the square on the edge of the tetrahedron, and by a line containing [numeral: ?] of the edge of the tetrahedron [Margin: f — Elements XIV.17] — is to the square on the diameter of the sphere; and since that rectangle is less than the square on the diameter of the sphere, inasmuch as each of its lines is less than the edge of the tetrahedron (which is itself less than the diameter of the sphere): therefore the tetrahedron will also be less than the octahedron — that is, the octahedron will be greater than the tetrahedron. Which is what was proposed.

ALITER. (*Otherwise.*) Since the cube is triple the tetrahedron, but less than triple the octahedron [Margin: g — Elements XIV.32] — (for the cube is to the octahedron as the edge of the cube is to the radius of the sphere; and the edge of the cube is less than triple the radius of the sphere [Margin: h — Elements XIV.27], because even the whole diameter, which is greater than the edge of the cube, has to the radius a ratio less than triple) — the octahedron will be greater than the tetrahedron. Which is what was proposed.

In exactly the same order the convex surfaces of these same regular bodies exceed one another: that is, the convex surface of the dodecahedron is greater than the convex surface of the icosahedron; the convex surface of the icosahedron is greater than the convex surface of the cube; the convex surface of the cube is greater than that of the octahedron; and finally the convex surface of the octahedron is greater than the convex surface of the tetrahedron.

For since the surface of the dodecahedron is to the surface of the icosahedron as the edge of the cube is to the edge of the icosahedron [Margin: i — Elements XIV.9], and since the edge of the cube is greater than that of the icosahedron [Margin: k — Elements XIII.18] (as was demonstrated above), the surface of the dodecahedron will also be greater than the surface of the icosahedron. That the

surface of the icosahedron is greater than the surface of the cube was demonstrated a little earlier, in the fourth theorem before the comparison of the solidities of the five regular bodies. Next, since the surface of the cube is to the surface of the octahedron as the edge of the cube is to the radius of the sphere [Margin: l — Elements XIV.27], and since the edge of the cube is greater than the radius of the sphere (as was demonstrated in the third theorem, in which we showed the cube to be greater than the octahedron), the surface of the cube will also be greater than the surface of the octahedron. Finally, since the surface of the octahedron is one-and-a-half times the surface of the tetrahedron [Margin: m — Elements XIV.14], it is plain that the surface of the octahedron is greater than the surface of the tetrahedron.

You see, then, that the surfaces and solidities of the regular bodies correspond to their edges in the opposite order: so that the larger a body is, the greater indeed is its surface, but the smaller its edge. For, as was demonstrated above, the edge of the tetrahedron is the largest of all [Margin: n — Elements XIII.18], whereas its surface and solidity, as we have demonstrated here, are the smallest of all; likewise the edge of the dodecahedron is the smallest of all, whereas its convex surface and solidity are the greatest of all. Finally, just as — if the tetrahedron, octahedron, cube, icosahedron, and dodecahedron are described in the same sphere — their edges exceed one another in the order in which they have been set out and described by Euclid [Margin: o — Elements XIII.18] (as was shown above), so, in the opposite order, their convex surfaces and their solidities exceed one another, as we have demonstrated here.

For the rest, we must not pass over here what Pappus demonstrated in book 4 of the *Mathematical Collections*: namely that the solidities of the five regular bodies, if they are isoperimetric — and therefore not constructed in the same sphere — stand in a far different relation than the one we have demonstrated. For a body that has more faces is always greater than a body with fewer faces: so that the icosahedron exceeds the dodecahedron, the dodecahedron is greater than the octahedron, the octahedron exceeds the cube, and finally the cube is greater than the tetrahedron.

INVENTIO ANGVLI INCLINATIONIS DVARVM basium cuiuscunque solidi regularis, vnus ad alteram, ex Isidoro Hypsiclis praeceptore.

(The finding of the angle of inclination of two faces of any regular solid, of one to the other, from Isidore [Isidorus], the teacher of Hypsicles [Hypsicles of Alexandria].)

I.

To find the angle of inclination of the two faces of a pyramid [tetrahedron], of one to the other.

Let there be a pyramid ABCD. Its edge BD being bisected at E, from the angles A and C — which are opposite to the side BD — let the straight lines AE and CE be drawn. Since these are perpendicular to BD, the common section of the planes ABD and CBD in which they lie — (for in the triangles AEB and AED the angles at E are equal, and so on [Margin: a — Elements I.8]) — they will contain the angle of inclination AEC of the faces ABD and CBD, by definition 6 of book 11. We shall therefore display an angle equal to this in any plane, in the following way. Let FGH be taken: an equilateral triangle constructed on the straight line FG, equal to the edge of the pyramid, and therefore a triangle

[an equilateral triangle FGH] equal to any face of the proposed pyramid — namely to ABD — in which HI has been drawn perpendicular to FG. On FG let there be constructed the triangle FGK, having each of its sides FK, GK equal to the perpendicular HI — that is, equal to each of the perpendiculars AE, CE — since the perpendiculars HI, AE, CE are equal, lying as they do in equal triangles. I say that the angle FKG equals the inclination angle AEC of the faces ABD, CBD. For since the sides KF, KG equal the sides EA, EC, and the base FG equals the base AC, [Margin: a — Elements I.8] the angles FKG, AEC will be equal.

I say further that the inclination angle ACE is acute. [Margin: b — Elements XIV.12] For since the side AD, or its equal AC, is such that the square on it is one and a third [sesquitercian, 4:3] of the square on each of the perpendiculars AE, CE: of such parts as the square on the straight line AC is taken to be 4, the square on each of the straight lines AE, CE will be 3; and therefore both squares on the straight lines AE, CE together will be 6 of the same parts. Since then in triangle ABC [recte: AEC?] the square on the side AC is less than the squares on the sides AE, CE together, the angle AEC will be acute, as we demonstrated in the scholium to Proposition 13 of Book 2.

COROLLARIUM [Corollary]

We shall easily gather from this that all the inclinations of the faces of a pyramid are equal to one another. For since each of the inclination angles is contained by two perpendiculars drawn from the angles of the triangles to the opposite bases — such as AE, CE — and these are subtended by the edges of the pyramid, such as AC was, all the angles will be equal to one another, because all those

perpendiculars that contain them are equal, and likewise the edges of the pyramid that subtend the same angles are equal.

II.

To find the angle of inclination of two faces of an octahedron, one to the other.

Let there be exhibited an octahedron ABCDEF, whose diameter is BD. From the angles B and D let straight lines BG, DG be drawn to the side AE — common to the triangles ABE, ADE and bisected at G. Since these are perpendicular to AE, the common section of the planes ABE, ADE in which they lie, [Margin: c — Elements I.8[?]] (because in the triangles BGA, BGE the angles at G are equal, and so on), they will contain the angle BGD, the inclination angle of the faces ABE, ADE, by Definition 6 of Book 11.

To this angle, therefore, we shall in any plane whatever exhibit an equal one, in this way. Take HIK, an equilateral triangle built upon the straight line HI equal to the edge of the octahedron — that is, equal to any triangle of the proposed octahedron, namely to ABE — in which the straight line KL is drawn perpendicular to HI. Upon a straight line MN equal to the diameter BD of the octahedron (that is, equal to the diameter of the square ABCD described on AB, the side of the octahedron) construct the triangle OMN, having each of its sides

MO, NO equal to the perpendicular KL — that is, equal to each of the perpendiculars BG, DG — since the perpendiculars KL, BG, DG are equal in equal triangles. I say that the angle MON equals the inclination angle BGD of the faces ABE, ADE. For since the sides OM, ON equal the sides GB, GD, and the base MN equals the base BD, [Margin: d — Elements I.8] the angles MON, BGD will be equal.

I say moreover that the inclination angle BGD is obtuse. [Margin: e — Elements XIII.14] For since the square on the diameter BD of the octahedron is double the square on the side AB, [Margin: f — Elements XIV.12[?]] while the square on the side AB is one and a third [sesquitertian, 4:3] of the square on the straight line BG: of such parts as the square on the diameter BD is taken to be 8, the square on the side AB will be 4, and the square on the straight line BG will be 3 of the same; and therefore both squares on the straight lines BG, DG together will be 6 of those parts. Hence the square on the side BD, in triangle GBD, is greater than the squares on the sides GB, GD together; and for that reason the angle BGD will be obtuse, as we showed in the scholium to Proposition 12 of Book 2.

- N (lower right): base vertex

COROLLARIVM [Corollary]

Hence it follows that all the inclinations of the faces of an octahedron are equal. For since each of the inclination angles is contained by two perpendiculars drawn from the angles of the triangles to the opposite bases — such as BG, DG — and these are subtended by the diameters of the octahedron, such as BD is, [Margin: g — Elements I.8] all will be equal to one another, because all those perpendiculars that contain them are equal, and likewise the diameters of the octahedron that subtend the same angles are equal.

III.

To find the angle of inclination of two faces of a cube, one to the other.

Let there be a cube ABCDEFGH, in which the side DE is bisected at I, and likewise the sides opposite it — in the squares AE, EC, which have that side DE in common — are bisected at the points K, L. Then let the straight lines IK, IL be drawn. [Margin: h — Elements I.33] Since these are equal and parallel to the sides EF, EH (because both KF, IE are equal and parallel to one another, and likewise IE, LH are equal and parallel to one another), [Margin: i — Elements I.29] they therefore make right angles with the side DE, and so will contain the angle KIL, the inclination angle of the faces AE, EC, by Definition 6 of Book 11. And since the straight lines IK, IL, being parallel to the straight lines EF, EH but not in the same plane with them, [Margin: k — Elements XI.10] make the angle KIL e-

---equal to the right angle FEH, the inclination angle of the faces of the cube will be a right angle. Therefore, in order that an angle equal to the inclination angle of the faces of the cube may be exhibited in some plane, a right angle must be constructed. For this, as we have just demonstrated, will be equal to the inclination angle of the faces of the cube.

COROLLARIUM. I. [Corollary I]

Since by the same argument it can be demonstrated that the inclination angle of any two faces of a cube is a right angle, it is plainly concluded that all the inclinations of the faces of a cube are equal to one another.

IV.

To find the angle of inclination of two faces of an icosahedron, one to the other.

Let there be a pyramid ABCDEF, one of the 12 pyramids of the icosahedron, whose base is the pentagon ABCDE — composed of five edges of the icosahedron — and whose vertex is F. So, with the edge AF bisected at G, let straight lines BG, EG be drawn from the angles B and E (opposite to the side AF) of the triangles ABF, AEF, which have the side AF in common. Since, as follows from what was demonstrated in the second problem of this scholium, these are perpendicular to AF — the common section of the planes ABF, AEF in which they are drawn — they will contain the angle BGE, the inclination angle of the faces ABF, AEF, by Definition 6 of Book 11.

To this angle we shall in any plane whatever exhibit an equal one, in this way. Take an equilateral triangle HIK built upon the straight line HI equal to the edge of the icosahedron — that is, equal to any triangle of the icosahedron, namely to ABF itself — in which the straight line KL is drawn perpendicular to HI. Upon a straight line MN equal to the straight line BE (which subtends the angle A of the pentagon) construct the triangle OMN, having each of its sides MO, NO equal to the perpendicular KL — that is, equal to each of the perpendiculars BG, EG — since the perpendiculars KL, BG, EG are equal in equal triangles. I say that the angle MON equals the angle BGE, the inclination angle of the faces ABF, AEF. For since the sides OM, ON equal the sides GB, GE, and the base MN equals the base BE, [Margin: a — Elements I.8] the angles MON, BGE will be equal.

I say too that this inclination angle BGE is obtuse. For since BG makes the right angle AGB, [Margin: b — Elements I.19] the straight line AB will be greater than the straight line BG; and in the same way AE will be greater than EG. Therefore

the straight lines AB, AE will also be greater than the straight lines OM, ON, since these last were set equal to GB, GE. So if the straight line BE be supposed placed upon a straight line MN equal to it, the angle A will fall outside the triangle MON, in such a way that the straight lines AB, AE entirely enclose the straight lines OM, ON. [Margin: c — Elements I.21] The angle O, therefore, will be greater than the angle BAE. But this last is obtuse — for since the five angles of the pentagon equal six right angles, by what we demonstrated in the scholium to Proposition 32 of Book 1, each of them will comprise one right angle and, over and above, one fifth part of a right angle; being greater than a right angle, it is therefore obtuse. Much more, then, will the angle MON — that is, its equal BGE — be obtuse.

- N (lower right): base vertex

COROLLARIVM [Corollary]

It also follows, not obscurely, from these things that all the inclinations of the faces of an icosahedron are equal to one another. For since each of the inclination angles is contained by two perpendiculars drawn from the angles of the triangles to the opposite bases — such as BG, EG — and these are subtended by the straight lines that subtend the angles of the pentagons, such as BE is: [Margin: d —

Elements I.8] all will be equal to one another, because all those perpendiculars that contain them are equal, and likewise all those straight lines that subtend the angles of the pentagons are equal, [Margin: e — Elements I.4] being comprised by equal straight lines equal to equal ones; [Margin: e — Elements I.4] and so they will be equal.

V.

To find the angle of inclination of two faces of a dodecahedron, one to the other.

Since, by what we showed in Proposition 8 of Book 15, the four edges of the cube described in the dodecahedron subtend four angles of four faces of the dodecahedron meeting at one edge: let there be pentagons of this kind — ABCDE, EFGHA, AHIKB, BKLMC — meeting at the edge AB; two of them, namely ABCDE, AHIKB, along the same common edge AB; and the other two, AEF GH, BCMLK, along the angles EAH, CBK. In these pentagons, moreover, let there be inscribed the square ECKH of the cube, whose four edges subtend four angles of the pentagons, namely D, B, I, A. Now, with the edge AB bisected at N, let perpendiculars NO, NP be drawn from N, in the planes of the pentagons ABCDE, ABKIH, to AB, cutting the sides EC, HK at O and P at right angles as well — since the straight lines EC, HK are parallel to AB itself, by the scholium to Proposition 8 of Book 13. Therefore NO, NP contain the angle ONP, the inclination angle of the faces ABCDE, ABKIH.

To this angle we shall in any plane construct an equal one, in this way. Upon a straight line QR equal to the edge AB of the dodecahedron, let there be constructed an equilateral and equiangular pentagon QRSTV — that is, equal to any pentagon of the dodecahedron, namely to ABCDE itself — whose angle T is subtended by the straight line VS, [Margin: f — Elements I.4] which is equal to the straight line EC,

---since the sides TV, TS equal the sides DC, DE and contain equal angles. Then, with the straight line QR bisected at X, let a perpendicular XY be drawn from the point X to QR; and this will also be perpendicular to VS, since VS is parallel to QR itself, by the scholium to Proposition 8 of Book 13. Finally, upon the straight line VS let a triangle VZS be built, having each of its sides ZV, ZS equal to the perpendicular XY.

I say that the angle VZS equals the inclination angle ONP. For when the straight lines NE, NH, VX have been drawn: since the sides EA, AN equal the sides HA, AN, and likewise the sides VQ, QX, and they contain equal angles, [Margin: a — Elements I.4] the bases NE, NH, VX will be equal, and so too the angles ANE, ANH, QXV; and consequently the remaining angles made with the perpendiculars — namely ENO, HNP, VXY — will be equal. Since, then, the angles ENO, EON of triangle ENO equal the angles HNP, HPN of triangle HNP, and also the angles VXY, VYX of triangle VXY (for EON, HPN, VYX have been shown to be right angles), and the side NE has been demonstrated equal to the sides NH, VX, [Margin: b — Elements I.26] the remaining sides NO, OE will be equal to the remaining sides

NP, PH and likewise to the sides XY, YV. Therefore the straight lines ZV, ZS, being equal to XY, will be equal to the straight lines NO, NP.

Now, since OE, PH are equal and parallel, [Margin: c — Elements I.33] the joining straight line OP will also be equal and parallel to EH, and therefore equal to EC — that is, to the straight line VS. For this reason, since the sides ZV, ZS equal the sides NO, NP, and the base VS equals the base OP, [Margin: d — Elements I.8] the angle VZS will be equal to the inclination angle ONP.

I say also that this inclination angle ONP is obtuse. For, a straight line $B\alpha$ having been drawn parallel to NO — since NB is likewise parallel to $O\alpha$, by the scholium to Proposition 8 of Book 13 — the figure $NO\alpha B$ will be a parallelogram, [Margin: e — Elements I.34] and therefore the straight line $B\alpha$ will be equal to NO. But since BC, the side of the pentagon opposite the angle $C\alpha B$ [Margin: f — Elements I.29] (which is equal, indeed, to the interior angle CON), is greater than the side $B\alpha$ — that is, than the straight line NO, or than each of ZV, ZS, which were shown to be equal to NO — the two straight lines TV, TS will be greater than the two straight lines ZV, ZS. Therefore the point Z falls inside the triangle TVS, in such a way that the straight lines TV, TS entirely enclose the straight lines ZV, ZS. And accordingly the angle VZS — and so its equal ONP — is greater than the angle T of the pentagon. But this last, being an angle of the pentagon, was shown a little before (when I was treating of the inclination of the faces of the icosahedron) to be greater than a right angle. Much more, then, will the inclination angle ONP be greater than a right angle, and so obtuse.

COROLLARIUM [Corollary]

It is therefore clear from these things that all the inclinations of the faces of a dodecahedron are equal to one another. For since each of the inclination angles is contained by two perpendiculars [Margin: g — Elements I.8] drawn from the midpoint of an edge of the dodecahedron to two edges of the cube described in the dodecahedron — such as NO, NP — and these are subtended by straight lines equal to the edges of the inscribed cube, or at any rate equal to the straight lines subtending the angles of the pentagons (of which sort is the straight line OP, equal to EH, the edge of the inscribed cube, which subtends the angle EAH of the pentagon): all will be equal to one another, since all those perpendiculars that contain them are equal, and likewise all those straight lines that subtend the same angles — namely the edges of the cube — are also equal to one another.

ELEMENTI DECIMISEXTI FINIS. [The End of the Sixteenth Element.]

QVID IN SINGVLIS XV. LIBRIS AGAT EVCLIDES. [What Euclid Treats in Each of the Fifteen Books]

EX FEDERICO COMMANDINO. [From Federico Commandino]

In the first book he discusses rectilinear figures — namely triangles and parallelograms. First he sets out the generation and properties of triangles, comparing them both with respect to their angles and with respect to their sides. Then, interposing the properties of parallels, he passes to parallelograms and explains their generation, and demonstrates the attributes belonging to them. Afterward he shows the mutual relation of triangles and parallelograms, and by

what means a parallelogram may be made equal to a triangle. Finally, concerning the squares described on the sides of right-angled triangles, he shows what proportion the square described on the side subtending the right angle has to those made on the sides comprising it.

In the second book the rectangular parallelogram and the gnomon are defined. Then the proportions of rectangular parallelograms and squares that arise from the sections of straight lines are set forth. Afterward, concerning the squares described on the sides of obtuse-angled and acute-angled triangles, he shows what proportion those made on the sides subtending the obtuse and the acute angle have to those described on the sides comprising them. Finally, by what method a square equal to a given rectilinear figure may be constructed.

In

(Commandino's synopsis, continued — "What Euclid treats in each of the fifteen books," from Federico Commandino. The previous portion summarized Books I–II; the account resumes here with Book III.)

In the **third** book he treats of the things that belong to circles, and of the straight lines drawn within a circle or to a circle; likewise of the angles that stand at the centers of circles or at their circumferences.

In the **fourth** book, of the inscription and circumscription of plane figures.

In the **fifth**, of proportions [analogiae].

In the **sixth**, of the proportions of figures to one another; of similar and reciprocal figures; of proportional straight lines; of the application of parallelograms to straight lines, such that they either fall short of the similar parallelograms or exceed them; how a given finite straight line may be cut in extreme and mean ratio; and of the proportions of arcs, of angles, and likewise of sectors, in equal circles.

In the **seventh** he treats of prime and composite numbers, and by what method the greatest common measure of numbers that are not prime is found; of a part and of parts of numbers; of multiple numbers; of proportionals; and whatever was demonstrated generally of magnitudes in the fifth book is here demonstrated in particular, and almost in the same way, of numbers.

In the **eighth**, of numbers continuously proportional; of plane numbers; of squares; of cubes and of solid numbers; of similar plane and similar solid numbers.

In the **ninth**, likewise of similar plane numbers; of cubes and solids; and of numbers continuously proportional, whether from unity or without qualification; of prime numbers; of even numbers; of odd; of even-times-even, of even-times-odd, and of odd-times-odd; and of perfect numbers.

In the **tenth**, of commensurable and incommensurable magnitudes, and likewise of rational and irrational ones.

In the **eleventh** he treats first of straight lines insofar as they bear on solid bodies: namely, when they lie in one plane; when they are erect, that is, perpendicular to a plane; when they are parallel; and how, from a given point set on high, a perpendicular is drawn to a plane. Then he discusses planes taken together, and next solid angles. Finally, of solid parallelepipeds, and some things about prisms.

In the **twelfth**, of pyramids and prisms; then of cones and cylinders; and lastly of spheres.

In the **thirteenth**, of the construction of the five cosmic figures, which they call the regular solids: namely the tetrahedron (or pyramid), the hexahedron (or cube), the octahedron, the dodecahedron, and the icosahedron. To make these clear he sets out first some things about what belongs to a straight line cut in extreme and mean ratio; about the equilateral pentagon; about the sides of the hexagon and the decagon; and about the equilateral triangle.

In the **fourteenth**, of the comparison of the dodecahedron and the icosahedron described in the same sphere.

In the **fifteenth** and last, of the inscription of the five figures already named, and of their sides and angles.

This figure was omitted at Book One, Proposition 24, Number 2.

Diagram. Two triangles standing side by side on a common base line, illustrating Euclid *Elements* I.24 (of two triangles with two sides respectively equal, the one with the greater included angle has the greater base). The left triangle is narrow and steep; the right triangle is broader, with an internal line drawn from its apex down to the base.

- A (apex of the left triangle)
- B (left foot of the left triangle's base)
- C (right foot of the left triangle's base)
- D (apex of the right triangle)

- E (left foot of the right triangle's base, adjacent to C)
- G (right foot of the right triangle's base)

[The right triangle has an internal segment descending from its apex D toward a point on the base near G; a further label at that lower point is too faint on the foxed sheet to resolve with certainty [?].]

THEODOSII TRIPOLITAE SPHAERICORVM LIBRI III

(Beginning of Clavius's commentary on Theodosius's Spherics — display title page of the Theodosius section.)

**THEODOSIUS OF TRIPOLI [Theodosius Tripolites] THE THREE BOOKS
OF THE SPHERICS [*Sphaericorum Libri III*]**

by

**CHRISTOPHER CLAVIUS [Christophorus Clavius] of Bamberg, of the
Society of Jesus,**

illustrated with lucid demonstrations and scholia.

And by the same author corrected and enlarged in this second edition.

MAINZ [Moguntiae], At the expense of **Antonius Hierat**; printed by
Reinhard Eltz [Reinhardus Eltz]. With the grace and privilege of His
Sacred Imperial Majesty.

In the year **1611 [M.DC.XI.]**

[Margin: two handwritten ownership inscriptions across the title page, in an old hand — at left "Monasterij [?]" ("of the monastery of..."), at right an inscription too cursive to resolve [?]. Not part of the printed text.]

(Verso of the Theodosius title page — blank. The leaf carries no printed text; only faint mirror-image show-through of the title-page setting and the IHS device is visible through the foxed parchment.)

[This page is blank.]

THEODOSIUS OF TRIPOLI, *SPHERICS*, IN THREE BOOKS

[Printed page number: 3.]

PREFACE

That there is a city named Tripolis both in Phoenicia and in Africa is attested by geographers and historians alike; but the sources give us no certain word as to which of these two cities was Theodosius's homeland. Neither is there sufficient agreement among them about the period in which he flourished. Still, it is no slight conjecture that he lived around the time of Pompey the Great [Pompeius Magnus], since Strabo writes that he flourished in Bithynia together with the physician Asclepiades [Asclepiades] — who, if we may believe Pliny [Pliny the Elder], flourished in Pompey the Great's day.

He wrote a number of mathematical treatises — *On Habitations* [*De Habitationibus*], *On Nights and Days* [*De Noctibus et Diebus*], and also these three books of *Spherics*, packed with the greatest learning. In them he demonstrates various properties of the sphere, knowledge of which is exceedingly necessary for mastering the doctrine of the heavenly bodies. Indeed, without these results astronomy has no way at all of maintaining its own dignity; and gnomonics too — the science of laying out sundials [horologia Solaria] — depends on them above all. Add to this that they are of no small importance for rightly understanding geography and perspective [optics] as well — and this is to pass over in silence, for now, the other uses of the elements of the sphere.

Now, since two versions of Theodosius's *Spherics* are in circulation — the one genuine and faithful, that of Joannes Pena [Jean Pena], corresponding word for word to the Greek exemplar; the other that of Francesco Maurolico [Francesco Maurolico], Abbot of Messina, from the tradition of the Arabs — we have followed the former, which is completed in fifty-nine propositions. We have inserted various scholia in which we demonstrate many theorems, necessary and pleasant to know, that Theodosius indeed omitted but the Arabs added. In the demonstrations, however, we have not followed the wording of the Greek codex but its sense, so that the demonstrations themselves might come out clearer. Here and there we have also added certain corollaries and scholia, as well as lemmas,

[Printed page number: 4.]

so that we may use them whenever the matter requires. In the margin, moreover, we have added numbers indicating the sequence of the propositions according to Maurolico's version, so that anyone may easily locate the propositions of Theodosius that some cite according to the order of the Arabs. As for the figures found in the Greek exemplar, we have for the most part passed them over, because those that Maurolico drew are more convenient, and much easier for grasping matters of the sphere. Finally, so that the flow of the demonstrations should not be interrupted, we have cited the propositions of Euclid and of these books in the margin — a practice we have observed in the following works as well. The citations are to be understood in the following way.

The table below pairs each marginal abbreviation (verbatim) with its full expansion.

Marginal form	Full expansion (Latin, verbatim)	Meaning
1. primi.	Prima propositio lib. 1. Euclid.	First proposition, Book 1 of Euclid
18. vndec.	Decimaoctaua propositio lib. 11. Euclid.	Eighteenth proposition, Book 11 of Euclid
Coroll. 16. tertij.	Corollarium propositionis sextædecimæ lib. 3. Euclid.	Corollary of the sixteenth proposition, Book 3 of Euclid
Coroll. 2. 33. sexti.	Corollarium secundum propositionis trigesimætertiae sexti libr. Euclid.	Second corollary of the thirty-third proposition, Book 6 of Euclid
Schol. 1. 2. octauu.	Scholium primum propositionis secundæ lib. 8. Euclid.	First scholium of the second proposition, Book 8 of Euclid
4. huius.	Propositio quarta huius lib.	Fourth proposition of this book
12. 2. huius.	Propositio duodecima libr. 2. huius operis.	Twelfth proposition, Book 2 of this work
Coroll. 10. huius.	Corollarium propositionis decimæ huius lib.	Corollary of the tenth proposition of this book
Coroll. 1. 1. huius.	Corollarium propositionis primæ lib. 1. huius operis.	Corollary of the first proposition, Book 1 of this

		work
Schol. 15. huius.	Scholium propositionis quintædecimæ huius lib.	Scholium of the fifteenth proposition of this book
Schol. 15. 1. huius.	Scholium propositionis quintædecimæ lib. 1. huius operis.	Scholium of the fifteenth proposition, Book 1 of this work
20. 1. Theod.	Propositio vigesima lib. 1. Theod.	Twentieth proposition, Book 1 of Theodosius
Coroll. 16. 1. Theod.	Corollarium propositionis sextædecimæ lib. 1. Theodosii.	Corollary of the sixteenth proposition, Book 1 of Theodosius
Schol. 19. 1. Theod.	Scholium propositionis decimænonæ lib. 1. Theodosii.	Scholium of the nineteenth proposition, Book 1 of Theodosius

From these the other citations will be readily understood, since in all of them the principle is the same.

THEODOSIUS, *SPHERICS*, BOOK ONE

[Printed page number: 5.]

DEFINITIONS

I.

A sphere is a solid figure contained by a single surface, such that all straight lines drawn to it from one of the points that lie within the figure are equal to one another.

II.

That point, moreover, is the center of the sphere.

III.

The axis of the sphere is a certain straight line drawn through the center and terminated at both ends on the surface of the sphere, about which — remaining at rest — the sphere revolves.

IV.

The poles of the sphere are the end points of that axis.

V.

The pole of a circle on the sphere is a point on the surface of the sphere from which all straight lines running to the circumference of the circle are equal to one another.

SCHOLIUM

In the Greek exemplar there is added yet another definition, by which it is explained what it is for one plane to be similarly inclined to another plane, and one thing to another. But since the inclination of a plane to a plane has been explained by Euclid in Book 11, definition 6; and since what it is for one plane to be said similarly inclined to another plane, and one thing to another, has been set out in the same book, definition 7 — I have decided to omit that definition altogether in this place, and to put in its stead the next one, which is not unlike Euclid Book 3, definition 4, so that it occupies the sixth place.

VI.

Circles are said to be equally distant from the center of the sphere when the perpendiculars drawn from the center of the sphere to their planes are equal. And that circle is said to be farther off onto whose plane the greater perpendicular falls.

THEOREM 1. PROPOSITION 1.

If a spherical surface is cut by some plane, the line that is formed on the surface of the sphere is the circumference of a circle.

[Margin: 1.]

Let the spherical surface ABC be cut, its center being D, by some plane producing on the surface of the sphere the line BEFCG. I say that BEFCG is the circumference of a circle. For let the cutting plane first pass through the center D of the sphere, so that D lies in the cutting plane; and in that plane let there be drawn from D, to the line BEFCG that has been formed, any number of straight lines DE, DF, DG. Since, then, all these lines that have been drawn — however many there be — are equal to one another (because they fall from the center of the sphere to its surface), the line BEFCG will, by Euclid, Book 1, definition 15, be the circumference of a circle whose center D is the same as the center of the sphere.

[Margin: 15. primi — *Elements* I, def. 15]

Diagram. The first of two figures for Proposition 1: the case in which the cutting plane passes through the center. A circle (the outline of the sphere) with a great circle drawn through it as a lens/almond shape. Labelled points, read off the scan under magnification:

- A (top of the sphere's outline)
- B (left extremity, where the section-circle meets the outline)
- C (right extremity, where the section-circle meets the outline)
- G (upper point of the section-circle, above the center)
- D (center of the sphere and of the circle)
- E (lower-left point of the section-circle)
- F (lower-right point of the section-circle)

The straight lines DE, DF, DG are drawn from center D to the section curve; B–D–C runs across as a diameter of the section. The section line is lettered BEFCG.

Diagram. The second figure for Proposition 1: the case in which the cutting plane does *not* pass through the center. A full circle (the sphere's outline) with a small circle drawn near the bottom, and a perpendicular dropped from the center to that plane. Labelled points, read off the scan under magnification:

- A (top of the sphere's outline)
- D (the center, from which the construction lines descend)
- B (lower-left, on the sphere's outline where the small circle meets it)
- E (lower point on the small circle, left of center)
- H (foot of the perpendicular from D, at the center of the small circle)
- F (lower point on the small circle, right of center)
- G (right point of the small circle, above C)
- C (lower-right, on the sphere's outline)

Lines run from D down to the rim of the small circle (B–E–H–F–G–C), forming a cone-like figure with apex D and the perpendicular D–H to the center of the section.

(Continuation of the demonstration of Proposition 1 — that a plane section of a sphere is a circle — begun on the preceding page. This second case treats the plane that does not pass through the center.)

Next, let the cutting plane not pass through the center of the sphere. [Margin: a. Elements XI.11] From D, the center of the sphere, drop a perpendicular DH to the cutting plane, and from H draw any lines HE, HF to the line BEFCG, and join DE, DF. Since the angles DHE, DHF are right angles (by Elements XI, def. 3), [Margin: b. Elements I.47] the square on DE equals the squares on DH, HE together, and the square on DF equals the squares on DH, HF together. But the squares on DE, DF are equal to one another, because the lines DE, DF, falling from the center of the sphere onto its surface, are equal. Therefore the squares on DH, HE together equal the squares on DH, HF together. Take away the common square on DH, and the remaining squares on HE, HF are equal to one another; and therefore the lines HE, HF are equal. By the same argument we shall show that all the lines drawn from H to the line BEFCG are equal both to one another and to the two lines HE, HF already named. Therefore the line BEFCG is the circumference of a circle (by Elements I, def. 15), whose center is the point H, on which the perpendicular DH falls. Therefore, if a spherical surface be cut by any plane, and so on. Which was to be demonstrated.

Diagram. Two panels illustrating Proposition 1. The **left panel** shows a sphere (outer circle) with a section taken through the center: A at the top, B at the left, C at the right, G between A and the center, D at the center, and E, F at the lower rim of the section — the plane through the center yields a great circle.

- A (top): pole of the sphere
- B (left) / C (right): ends of the horizontal section
- G (upper middle): point on the section
- D (center): center of the sphere and of the great circle
- E (lower left) / F (lower right): rim points of the section

The **right panel** shows the cone-like figure for the off-center section: a sphere with A at the top, D as the apex within, and the base rim of the section carrying B, E, H, F, C (with H at the base center) and G to the right. Lines DE, DF and the perpendicular DH are drawn from D.

- A (top): pole of the sphere
- D (apex): center of the sphere
- H (base center): foot of the perpendicular DH, center of the section
- B (left) / C (right): ends of the section rim
- E, F (base, either side of H): points on the rim to which HE, HF are drawn
- G (right of H): point on the rim

COROLLARIVM.

Thus, if the cutting plane passes through the center of the sphere, the circle produced has the same center as the sphere. But if it does not pass through the center, the circle produced has a center different from the sphere's — namely, the point on which the perpendicular drawn from the center of the sphere to the cutting plane falls. For it will always be demonstrated that the straight lines falling from this point to the circumference of the circle are equal.

HOC EST.

That is: the center of the sphere and the center of a circle drawn through the center of the sphere are the same. And the perpendicular drawn from the center of the sphere onto the plane of a circle not drawn through the center of the sphere falls on the center of the circle — for the point H, on which the perpendicular DH falls, has been demonstrated to be the center of the circle.

PROBL. 1. PROPOS. 2.

[Margin: ij.]

To find the center of a given sphere.

Let the center of the sphere ABCD be sought. Let its surface be cut by some plane, producing in it the line BDE, [Margin: a. Sphaerica I.1 (this book)] which will be the circumference of a circle. [Margin: b. Elements III.1] Let the center of this circle be F. If, then, the circle BDE passes through the center of the sphere, [Margin: c. Corollary 1 of this book] the point F will also be the center of the sphere. But if it does not pass through the center of the sphere, [Margin: d. Elements XI.12] erect from F a perpendicular FG to the plane of the circle BDE; and this, produced both ways to the surface of the sphere at the points A, C, let it be bisected at G. I say that G is the center of the sphere. For if it is not, let the center, if it be possible, be H, bisecting all the diameters — which point will indeed not lie on the line AC (since AC is bisected only at the point G), but outside it. [Margin: e. Elements XI.11] From H, the supposed center of the sphere, drop a perpendicular HI to the plane of the circle BDE, [Margin: f. Elements XI.6] which will be parallel to the line FG; and therefore it will not fall on the point F, for then the two parallels HI, GF would meet at F — which cannot happen. Now since a perpendicular dropped from the center of the sphere onto the plane of the circle BDE [Margin: g. Corollary 1 of this book] falls on its center, I will be the center of the circle BDE. But F also, by construction, is the center of the same circle. This is

absurd, for the same circle must have only one center. Therefore no point other than G will be the center of the sphere. Thus we have found the center of the given sphere. Which was to be done.

Diagram. A sphere (outer circle) ABCD with a vertical diameter A–C and a horizontal section BDE shown as a flattened ellipse. On the vertical axis lie G and H (the true and the hypothetical center); on the section lie F (its center) and I (the foot of the perpendicular HI).

- A (top): upper end of the axis AC
- C (bottom): lower end of the axis AC
- B (left): left end of the section
- right end of the section [?] (label formed like a reversed C; on geometric grounds the point D of the section BDE)
- E (front, left of center): point on the section
- F (center of section): center of the circle BDE
- G (on axis, center): the center of the sphere
- H (on axis, beside G): the hypothetical alternative center
- I (beside F): foot of the perpendicular HI

COROLLARIVM.

Hence it is clear that, if there is in a sphere a circle not drawn through the center of the sphere, and from its center a perpendicular is raised to its plane, the center of the sphere lies on that perpendicular. For it has been shown that the point G, which bisects the perpendicular AC, is the center of the sphere.

THEOR. 2. PROPOS. 3.

[Margin: iij.]

A sphere does not touch a plane, by which it is not cut, in more than one point.

For if it be possible, let a sphere touch a plane, by which it is not cut, in more than one point — say at A and B. [Margin: a. Prop. 2 of this book] Having found C, the center of the sphere, draw the lines CA, CB; and through CA, CB pass a plane, which produces on the surface of the sphere [Margin: b. Prop. 1 of this book] the circumference of a circle ABD, and in the tangent plane [Margin: c. Elements XI.3] the straight line EABF. Now since the tangent plane, in which the line EABF lies, does not cut the sphere — and therefore does not cut the circle ABD lying on the

sphere's surface either — it follows that the line EABF does not cut the circle ABD. Therefore the straight line AB falls wholly outside the circle. But since the two points A, B are taken on the circumference of the circle ABD, [Margin: d. Elements III.2] the same straight line AB, drawn from point A to point B, falls wholly inside the circle ABD. Which is absurd. Therefore a sphere does not touch a plane, by which it is not cut, in more than one point. Which was to be demonstrated.

Diagram. A circle (the great circle ABD of the sphere) with D at the top and C at the center. A horizontal line EABF runs across the bottom, tangent to the plane; A and B are the two supposed points of contact on the circle, with the lines CA, CB drawn from the center to form a triangle.

- D (top): point on the circle
- C (center): center of the sphere
- E (far left) / F (far right): ends of the line EABF in the tangent plane
- A (left of center) / B (right of center): the two supposed contact points on the circle

COROLLARIUM.

Hence it follows that, if two points are marked on the surface of a sphere, the straight line joining them falls within the sphere — [Margin: e. Elements III.2] namely because it falls within the circle whose circumference lies on the surface of the sphere.

THEOR. 3. PROPOS. 4.

[Margin: iv.]

If a sphere touch a plane which does not cut it, the straight line drawn from the center of the sphere to the point of contact will be perpendicular to the plane.

Let a sphere touch a plane, which does not cut it, at the point A. [Margin: a. Prop. 2 of this book] Having found B, the center of the sphere, draw from it the line BA to the point of contact A. I say that the line BA is perpendicular to the said plane. For through the line AB draw any two planes cutting one another, which produce on the surface of the sphere [Margin: b. Prop. 1 of this book] the circumferences of the circles ACDE, AFDG, and in the tangent plane [Margin: c. Elements XI.3] the straight lines HAI, KAL. Now since each circle ACDE, AFDG passes through B, the center of the sphere, [Margin: d. Corollary 1 of this book] B will also be the center of both. Again, since the tangent plane does not cut the sphere, it follows that the

lines HAI, KAL lying in it do not cut it either — and therefore neither do they cut the circles ACDE, AFDG lying on the sphere's surface. Therefore the line HAI touches the circle ACDE at the point A, and the line KAL touches the circle AFDG at the same point A. [Margin: e. Elements III.18] Therefore the line BA is perpendicular both to the line HAI and to the line KAL. [Margin: f. Elements XI.4] Hence the same line BA will be perpendicular to the tangent plane, which is drawn through the lines HAI, KAL. Therefore, if a sphere touch a plane which does not cut it, and so on. Which was to be shown.

Diagram. A sphere (outer circle) with D at the top and A at the bottom as poles, B at the center. Two great circles are drawn as vertical ellipses through the poles D and A, carrying C, F on the left and G, E on the right. At the bottom, in the tangent plane at A, run the two straight lines HAI (H left, A center, I right) and KAL (K lower-left, L at the base).

- D (top) / A (bottom): poles; A is the point of contact
- B (center): center of the sphere and of both circles
- C, F (left) / G, E (right): points on the two circles ACDE, AFDG
- H (left) / I (right): ends of the tangent line HAI
- K (lower left) / L (base): ends of the tangent line KAL

THEOR. 4. PROPOS. 5.

[Margin: v.]

If a sphere touch a plane which does not cut it, and from the point of contact a straight line be raised at right angles to that plane, the center of the sphere will lie on the line so raised.

Let the sphere ABCD touch the plane EF, which does not cut it, at the point C; and from the point C [Margin: a. Elements XI.12] let a perpendicular CA be raised to the plane EF. I say that the center of the sphere lies on AC. For if it does not, let G be the center of the sphere, outside the line AC, if that be possible, and from G to C draw the line GC, [Margin: b. Prop. 4 of this book] which will be perpendicular to the plane EF. But AC too was perpendicular to the same plane. Therefore from the same point C two perpendiculars are drawn to the same plane EF. Which is absurd; for [Margin: c. Elements XI.13] from a given point in a given plane two straight lines cannot be raised at right angles to it. Therefore, if a sphere touch a plane which does not cut it, and so on. Which was to be shown.

Diagram. A sphere (circle) ABCD resting on a plane (drawn as a parallelogram) which it touches at C below. A vertical line runs A (top) through the center G down to C (contact); the plane EF extends to either side.

- A (top): upper end of the axis AC
- B (left) / D (right): points on the sphere
- G (center, marked by a dot): supposed center of the sphere
- C (bottom): point of contact with the plane
- E (left) / F (right): ends of the tangent plane EF

THEOR. 5. PROPOS. 6.

[Margin: vj.] [Margin: vij.]

Of the circles that are in a sphere, the greatest are those drawn through the center of the sphere; of the rest, those are equal to one another which are equally distant from the center, while those farther from the center are smaller. And the greatest circles in a sphere pass through the center of the sphere; of the rest, the equal ones are equally distant from the center, while the smaller ones are farther from the center.

In the sphere ABCDEF, whose center is G, let the circle AD pass through the center G, and let others, BC, FE, not pass through the center. I say that the circle AD is the greatest of all, and so on. [Margin: a. Elements XI.11] From the center G draw perpendiculars GH, GI to the planes of the circles BC, FE, [Margin: b. Corollary 1 of this book] which will fall on their centers, so that H, I are the centers of the circles BC, FE. [Margin: c. Corollary 1 of this book] Now G, the center of the sphere, is also the center of the circle AD, which is drawn through the center of the sphere. If, then, from G, H, I the lines GD, HC, IE be drawn to the surface of the sphere, these will be the radii of the circles AD, BC, FE. Let the lines GC, GE be joined. Now since in the triangle GHC the angle H is a right angle (by Elements XI, def. 3), [Margin: d. Elements I.47] the square on GC equals the squares on GH, HC. Taking away the square on GH, the square on GC is greater than the square on HC; and therefore the line GC — that is, its equal GD (for GC, GD are drawn from the center of the sphere to the surface) — is greater than the line HC. Hence the circle AD, having a greater radius than the circle BC, is greater than the circle BC. In the same way we shall show that the circle AD is greater than any other that does not pass through the center G. Therefore the circle AD is the greatest.

Diagram. A sphere (outer circle) ABCDEF with center G. The circle AD is drawn vertically through the center (A at the top, D at the bottom); two off-center circles

BC and FE are drawn to the left and right (B upper-left, C lower-left; F upper-right, E lower-right). The perpendiculars GH (to the plane of BC, H being its center) and GI (to the plane of FE, I being its center) are drawn, together with the radii GC, GE, GD, HC, IE.

- A (top) / D (bottom): ends of the great circle AD through the center
- G (center): center of the sphere
- B (left) / F (right): upper points of the off-center circles
- C (lower left) / E (lower right): lower points of the off-center circles
- H (inner left): center of circle BC
- I (inner right): center of circle FE

(The demonstration of Proposition 6 continues.)

Now let the circles BC, FE be equally distant from the center G — that is, let the perpendiculars GH, GI be equal (by definition 6 of this book). I say that the circles BC, FE are equal. For since the lines GC, GE, falling from the center of the sphere onto its surface, are equal, their squares too are equal; [Margin: e. Elements I.47] and since the square on GC equals the squares on GH, HC, and the square on GE equals the squares on GI, IE, the squares on GH, HC together will equal the squares on GI, IE together. Taking away the equal squares on GH, GI (for these lines are assumed equal), the remaining squares on HC, IE will be equal, and therefore the lines HC, IE will be equal; and since these are the radii of the circles BC, FE, the circles BC, FE themselves will be equal.

But if one of these circles, namely BC, be supposed to be farther from the center G than the other, FE — that is, the perpendicular GH be supposed greater than the perpendicular GI — we shall show in almost the same way that the circle BC is smaller than the circle FE. For since the squares on GH, HC have been demonstrated equal to the squares on GI, IE, if the unequal squares on the unequal lines GH, GI be taken away — of which the former is the greater (since the line GH is supposed greater than the line GI) — the remaining square on HC will be less than the remaining square on IE; and therefore the line HC will be less than the line IE. Therefore the circle BC will also be smaller than the circle FE.

Now let AD be the greatest circle of all. I say that it passes through G, the center of the sphere. For if it did not pass through the center, there would be some other circle, passing through the center G, greater than the circle AD not passing through the center, as has been demonstrated in this proposition. Hence AD

would not be the greatest circle. Which is absurd, for it is assumed to be the greatest. Therefore it passes through G, the center of the sphere.

Next, let the circles BC, FE be equal. I say that they are equally distant from the center G. For, the figure being constructed as before, the radii HC, IE will be equal. And since the squares on GH, HC are equal to the squares on GI, IE, [Margin: f. Elements I.47] as has been demonstrated, then, on taking away the equal squares on the equal lines HC, IE, the remaining squares on the lines GH, GI will be equal; and therefore the lines GH, GI will be equal. Since these are, by construction, perpendicular to the planes of the circles BC, FE, the circles BC, FE will be equally distant from the center G (by definition 6 of this book).

But if one of the circles BC, FE — namely the circle BC — be supposed smaller than the other circle FE, we shall show in almost the same way that the perpendicular GH is greater than the perpendicular GI. For since the squares on GH, HC have been shown equal to the squares on GI, IE, and since the square on HC is less than the square on IE (because the radius HC of the smaller circle is less than the radius IE of the larger circle), the remaining square on the line GH will be greater than the remaining square on the line GI; and therefore the line GH will be greater than GI. Hence, since GH, GI are by construction perpendicular to the planes of the circles, the smaller circle BC will be farther from the center G (by definition 6 of this book) than the larger circle FE. And so, of the circles that are in a sphere, the greatest are those drawn through the center of the sphere, and so on. Which was to be demonstrated.

Diagram. A repetition of the figure for Proposition 6 (identical to fig-p647-3). A sphere ABCDEF with center G: the great circle AD is drawn vertically through the center (A top, D bottom); the off-center circles BC and FE lie to the left and right (B upper-left, C lower-left; F upper-right, E lower-right). The perpendiculars GH, GI and the radii GC, GE, GD, HC, IE are drawn.

- A (top) / D (bottom): ends of the great circle AD
- G (center): center of the sphere
- B (left) / F (right): upper points of the off-center circles
- C (lower left) / E (lower right): lower points of the off-center circles
- H (inner left): center of circle BC
- I (inner right): center of circle FE

THEOR. 6. PROPOS. 7.

[Margin: viij.]

If there be a circle in a sphere, and a straight line be joined from the center of the sphere to the center of the circle, the joining line will be perpendicular to the plane of the circle.

In the sphere ABC, whose center is D, let there be a circle BFCG, whose center is E; and let the line DE join the two centers D, E. I say that DE is perpendicular to the plane of the circle BFCG. For, drawing any two diameters BC, FG in the circle, draw from their extremities to D, the center of the sphere, the lines BD, CD, FD, GD, which will all be equal to one another, since they fall from the center of the sphere to its surface. But BE, CE, FE, GE, the radii of the circle BFCG, are also equal. Therefore the two triangles DEB, DEC have the two sides DE, EB equal to the two sides DE, EC, and the base DB equal to the base DC; from which it follows [Margin: a. Elements I.8] that the angles DEB, DEC are equal, and therefore right angles. Therefore the line DE stands at right angles to the line BC. In the same way we shall show that the line DE stands at right angles to the line FG. [Margin: b. Elements XI.4] Therefore it also stands at right angles to the plane of the circle BFCG, drawn through the lines BC, FG. If, then, there be a circle in a sphere, and so on. Which was to be shown.

Diagram. A sphere (circle) ABC with center D, containing a circle BFCG with center E, shown as an inscribed flattened figure. From D and E the lines BD, CD, FD, GD and the joining line DE are drawn to the base rim.

- A (top): point on the sphere
- D (upper center): center of the sphere
- E (center): center of the circle BFCG
- B (left) / C (right): ends of the diameter BC
- F (bottom) / G (inner): ends of the diameter FG

THEOR. 7. PROPOS. 8.

[Margin: ix.]

If there be a circle in a sphere, and from the center of the sphere a perpendicular be drawn to the circle and produced both ways, it will fall on the poles of that circle.

In the sphere ABCD, whose center is E, let there be a circle BGDH, [Margin: a. Elements XI.11] to whose plane, from the center of the sphere E, let a perpendicular EF be drawn; and let this, produced both ways, fall on the surface of the sphere at the points A, C. I say that A, C are the poles of the circle BGDH. For the perpendicular EF will fall on the center of the circle BGDH, and therefore F

will be the center of the circle. But if the circle BGDH be drawn through the center of the sphere, [Margin: b. Corollary 1 of this book] it will be the very center...

Diagram. Two panels for Proposition 8. In each, a sphere (outer circle) ABCD with center E contains a circle BGDH shown in perspective; the polar axis runs from A (top) through E (center) and F to C (bottom).

Left panel:

- A (top) / C (bottom): the poles
- E (center): center of the sphere
- F (below E): foot of the perpendicular / center of the circle BGDH
- B (left) / D (right): ends of a diameter of the circle
- H (upper inner) / G (lower inner): points on the circle

Right panel (same construction, more fully drawn):

- A (top) / C (bottom): the poles
- E (center): center of the sphere
- F (below E): center of the circle BGDH
- B (left) / D (right): ends of a diameter
- H (upper inner) / G (lower inner): points on the circle

the center of the sphere, E, is the same point as F, the center of the circle, from which the perpendicular AC has been raised to the plane of the circle [Margin: c — *Elements* XI.12].

So let the diameters BD and GH be drawn in any way, and from their endpoints let straight lines be drawn to the points A and C. Since AF is perpendicular to the plane of the circle BGDH, all the angles it makes at F are right angles, by *Elements* XI, def. 3. The two triangles AFB and AFH therefore have two sides, AF and FB, equal to the two sides AF and FH, and these contain equal angles — namely right angles. [Margin: d — *Elements* I.4] So the bases AB and AH will be equal. In the same way we shall show that AD, AG, and all other lines drawn from A to the circumference of the circle BGDH are equal both to one another and to the lines AB, AH. Therefore the point A is the pole of the circle BGDH, by def. 5 of this book. In just the same way we shall prove that C too is a pole of the same circle. So, if in a sphere there is a circle, and from its center, and so on. Which was to be shown.

Diagram. The left of a pair of sphere figures illustrating Proposition 8. The great outer circle is the sphere; the inner ellipse is the circle BGDH seen edge-on.

Straight lines run from the apex A and the lowest point C to the endpoints of the diameters and to the inner points.

- A (top apex): pole of the circle BGDH
- C (bottom): the other pole of the circle BGDH
- B (left): endpoint of a diameter of the circle
- D (right): endpoint of a diameter of the circle
- E (center, marked with a dot): center of the sphere
- F (just below E): center of the circle BGDH
- G (lower, toward C): point on the circle
- H (upper left): point on the circle

Diagram. The right of the pair — the same configuration redrawn with a fuller set of connecting lines, again illustrating Proposition 8.

- A (top apex): pole of the circle BGDH
- C (bottom): the other pole
- B (left): endpoint of a diameter
- D (right): endpoint of a diameter
- E (center): center of the sphere
- F (below E): center of the circle BGDH
- G (lower): point on the circle
- H (upper left): point on the circle

SCHOLIVM

In Maurolico's [Maurolico] version the following two theorems are added, which the Arabs appended.

I.

[Margin: x.]

If in a sphere there is a circle, and from its center a perpendicular is drawn to the plane of the circle, and this is produced in both directions, it will fall on both poles of the circle.

In the same figure, from F, the center of the circle BGDH, [Margin: a — Elements XI.12] let the straight line FA be erected perpendicular to the plane of the circle, meeting the surface of the sphere at the points A and C. I say that A and C are the poles of the circle BGDH. For once again, by Elements XI, def. 3, all the angles that

the line AF makes at F will be right angles. [Margin: b — Elements I.4] Hence, as before, the lines AB, AD, AG, AH, and so on, will be equal to one another, and so forth.

ANOTHER PROOF. [Margin: c — Coroll. 2 of this book] Since the perpendicular FA passes through E, the center of the sphere, the straight line EF, drawn from E, the center of the sphere, to the plane of the circle BGDH, will be perpendicular. [Margin: d — Sphaerica I.8] Therefore, as has been demonstrated, it falls on the poles of that same circle. Which is what was proposed.

II.

[Margin: xj.]

If in a sphere there is a circle, and from one of its poles a straight line is drawn through its center, this line will be perpendicular to the plane of the circle, and produced it will fall on the remaining pole.

Still in the same figure, from A, a pole of the circle BGDH, through its center F, let the straight line AF be dropped, meeting the surface of the sphere at C. I say that the line AF is perpendicular to the plane of the circle BGDH, and that C is the other pole of the same circle. For the two triangles AFB and AFD have two sides, AF and FB, equal to the two sides AF and FD, and the base AB equal to the base AD, by the definition of pole; [Margin: a — Elements I.8] so they will also have the two angles AFB and AFD equal, and hence right angles. Therefore AF stands at right angles on the straight line BD. In the same way we shall show that this same AF stands at right angles on the straight line GH. [Margin: b — Elements XI.4] So this same line AF will also stand at right angles on the plane of the circle BGDH, which passes through the straight lines BD and GH. Which is the first point proposed. Since, then, AF is at right angles to the plane of the circle BGDH — being perpendicular from the center of the circle, F, to the plane of the circle — therefore, as has just been demonstrated in this scholium, when produced in both directions it will fall on both poles of the circle; and consequently C will be the remaining pole of the circle BGDH. Which is the second point proposed.

THEOR. 8. PROPOS. 9.

[Margin: xij.]

If in a sphere there is a circle, and from one of its poles a perpendicular straight line is drawn to it, this line will fall on the center of the circle, and produced from there it will fall on the remaining pole of that circle.

In the sphere ABCD let there be a circle BFDG, [Margin: a — *Elements* XI.11] and from its pole A let a perpendicular AE be drawn to its plane, meeting the surface of the sphere at C. I say that E is the center of the circle BFDG, and C the other pole. For let two straight lines BD and FG be drawn through E in any way, and let their endpoints be joined to the pole A by the straight lines AB, AD, AF, AG, which will all be equal to one another, by the definition of pole. Likewise all the angles that the line AE makes at E are right angles, by *Elements* XI, def. 3. [Margin: b — *Elements* I.47] The square on AB will therefore equal the squares on AE and EB together, and the square on AG will equal the squares on AE and EG together. And since the squares on the equal lines AB and AG are equal, the squares on AE and EB together will equal the squares on AE and GE together. So, removing the common square on the line AE, the remaining squares on EB and EG will be equal, and consequently the lines EB and EG themselves will be equal. In the same way we shall show that the lines EG and ED are equal. [Margin: c — *Elements* III.9] Therefore E is the center of the circle BFDG — which is what was proposed. Now since the perpendicular EA has been drawn from E, the center of the circle BFDG, to its plane, [Margin: d — Coroll. 2 of this book] it will pass through H, the center of the sphere; and so this same line HE, drawn from H, the center of the sphere, will be perpendicular to the plane of the circle BFDG. [Margin: e — *Sphaerica* I.8] Therefore HE, produced in both directions, will fall on the poles of that same circle; and consequently C will be the remaining pole of the circle BFDG. So, if in a sphere there is a circle, and from one of its poles, and so on. Which was to be shown.

Diagram. A sphere figure for Proposition 9. The outer circle is the sphere; an inner ellipse is the circle BFDG seen edge-on, with its horizontal diameter BD. Straight lines run from the apex A down to B, D, and to the inner points E, F, G, H, and the vertical line AEC (through the center) reaches the lowest point C.

- A (top apex): pole of the circle BFDG
- G (inner, left of center): point on the circle
- H (inner, middle): point on the circle
- B (left): endpoint of the diameter BD
- D (right): endpoint of the diameter BD
- E (center): center of the circle BFDG
- F (below E, near bottom): point on the circle
- C (bottom): the other pole of the circle BFDG

THEOR. 9. PROPOS. 10.

[Margin: xiiij.]

If in a sphere there is a circle, a straight line drawn through its poles is perpendicular to the circle, and passes through the center of the circle and of the sphere.

In the sphere ABCD let there be a circle BFDG, and through its poles A and C let the straight line AC be drawn, meeting the plane of the circle at E. I say that the line AC is perpendicular to the plane of the circle, and passes through its center (that is, that E is its center), as well as through the center of the sphere. For let two straight lines BD and FG be drawn through E in any way, and let their endpoints be joined to the poles A and C by straight lines, as in the figure. Then AB, AG, AF, AD will be equal to one another, and likewise CB, CG, CF, CD to one another, by the definition of pole. Therefore the two triangles ABC and ADC have two sides, AB and AC, equal to the two sides AD and AC, and the base BC equal to the base DC. [Margin: a — *Elements* I.8] So they will also have the angles BAC and DAC equal. And since the two triangles ABE and ADE have two sides, AB and AE, equal to the two sides AD and AE, and the angles contained by them, BAE and DAE, equal (as has just been demonstrated), [Margin: b — *Elements* I.4] the angles AEB and AED will also be equal, and therefore right angles. In just the same way we shall show that the angles AEG and AEF are right angles. So the line AE stands at right angles on the two straight lines BD and FG. [Margin: c — *Elements* XI.4] It will therefore be perpendicular to the plane of the circle BFDG, which is drawn through the straight lines BD and FG. Which is the first point proposed. Now since the perpendicular AE has been drawn from A, a pole of the circle BFDG, to its plane, [Margin: d — *Sphaerica* I.9] AE will fall on its center. So E is the center of the circle BFDG. Again, since the perpendicular EA has been drawn from E, the center of the circle BFDG, to its plane, [Margin: e — Coroll. 2 of this book] this line will also pass through the center of the sphere. Therefore the line AC is perpendicular to the plane of the circle BFDG, and passes through its center and through the center of the sphere. Which is what was proposed. So, if in a sphere there is a circle, and a straight line is drawn through its poles, and so on. Which was to be demonstrated.

Diagram. A sphere figure for Proposition 10. The outer circle is the sphere; the inner ellipse is the circle BFDG seen edge-on. Straight lines connect the apex A and the lowest point C to the endpoints B and D of the diameter and to the inner points, and the vertical line AC passes through the center E.

- A (top apex): pole of the circle
- G (inner, upper left): point on the circle
- E (center): center of the circle BFDG / where AC meets the plane
- B (left): endpoint of the diameter
- D (right): endpoint of the diameter
- F (lower, inner): point on the circle
- C (bottom): the other pole

SCHOLIUM

Two further theorems of this kind are added here.

I.

[Margin: xiv.]

If in a sphere there is a circle, and from one of its poles a straight line is drawn through the center of the sphere, this line will be perpendicular to the plane of the circle, and produced it will fall on its center and on the remaining pole.

In the sphere ABCD, whose center is E, let there be a circle BGDH; and from its pole A, through E, the center of the sphere, let the straight line AE be drawn, meeting the plane of the circle at F and the surface of the sphere at C. I say that AE is perpendicular to the plane of the circle, and passes through its center as it does to the remaining pole — that is, that F is its center and C the remaining pole. For let two straight lines BD and GH be drawn through F in any way, and let their endpoints be joined to the points A and E, as in the figure. Then AB, AH, AD, AG will be equal to one another, by the definition of pole; and likewise EB, EH, ED, EG, the radii of the sphere, will be equal to one another. Since, then, the two triangles ABE and ADE have two sides, AB and AE, equal to the two sides AD and AE, and the base EB equal to the base ED, [Margin: a — Elements I.8] the angles BAE and DAE will be equal. And so the two triangles ABF and ADF have two sides, AB and AF, equal to the two sides AD and AF, and the angles contained by them, BAF and DAF, equal, as was just shown. [Margin: b — Elements I.4] So the angles AFB and AFD will be equal, and hence right angles. In the same way we shall demonstrate that the angles AFH and AFG are right angles. Therefore the line AF stands at right angles on the two straight lines BD and GH. [Margin: c — Elements XI.4] So it will be perpendicular to the plane of the circle BGDH, which is drawn through the straight lines BD and GH. [Margin: d — Sphaerica I.9] And so, produced, it will fall on both the center of the circle and the remaining pole; and consequently F will be the center

of the circle, and C the remaining pole. Which is what was proposed. So, if in a sphere there is a circle, and so on. Which was to be shown.

Diagram. A sphere figure for the added Scholium theorem. The outer circle is the sphere; an inner ellipse is the circle BGDH seen edge-on, with center F. Lines run from the apex A to B, D and the inner points, and the vertical line AC passes through E (center of the sphere) and F.

- A (top apex): pole of the circle BGDH
- E (center, upper): center of the sphere
- H (inner, left of center): point on the circle
- B (left): endpoint of the diameter BD
- D (right): endpoint of the diameter BD
- F (lower, inner): center of the circle BGDH
- G (bottom, inner near C): point on the circle
- C (bottom): the other pole

COROLLARIVM

From this it follows that a great circle which passes through one of the poles of any circle in the sphere also passes through the other pole. For if from one pole, through the center of the sphere, the diameter of the great circle passing through that pole is drawn, it will fall on the other pole, as has been demonstrated. So the same great circle will pass through the remaining pole.

And since the diameter of a great circle is also a diameter of the sphere, it is clear that the two poles of any circle in the sphere are diametrically opposite; and so a semicircle of a great circle lies between them.

II.

[Margin: xv.]

If in a sphere there is a circle, and from the center of the sphere a straight line is drawn through the center of the circle, it will fall on both poles of the circle.

In the same figure, through E, the center of the sphere, and F, the center of the circle BGDH, let the straight line EF be drawn in both directions. I say that EF falls on both poles of the circle BGDH. For since the straight line EF, joining the center of the sphere and the center of the circle BGDH, [Margin: e — Sphaerica I.7] is perpendicular to the plane of that same circle, [Margin: f — Sphaerica I.8] this same

line EF, produced in both directions, will fall on both poles of that same circle. Which is what was proposed.

COROLLARIVM

From all of this it is established that in a sphere these four points — namely the two poles of any circle, its center, and the center of the sphere — always lie on one straight line, namely a diameter of the sphere; and that this diameter is perpendicular to the plane of that same circle. So a straight line drawn through any two of these points passes through the remaining two, and is perpendicular to the plane of the circle; and a straight line drawn through any one of them perpendicular to the plane of the circle also passes through the other three points.

THEOR. 10. PROPOS. 11.

[Margin: xvj.]

In a sphere, great circles bisect each other.

In the sphere ABCD let two great circles AC and BD cut each other at the points E and F. I say that they bisect each other. [Margin: a — *Sphaerica* I.6] Since great circles in a sphere pass through the center of the sphere, the circles AC and BD will pass through the center of the sphere, which let be G. [Margin: b — Corollary 1 of this book] And since the center of the sphere and the center of a circle carried through the center of the sphere are the same, the point G — which is taken to be the center of the sphere — will also be the center of each circle AC and BD, so that it lies in the same plane of each of the circles AC and BD. But the points E and F also lie in each of the same planes. Therefore the three points E, G, F lie in each plane of the circles AC and BD, and so they will lie on the common section of the two, since only their common section lies in both planes. [Margin: c — *Elements* XI.3] Now their common section is a straight line. So the three points E, G, F lie on a straight line drawn from E through G to F; and since this line passes through G, the center of each circle and of the sphere, as has been shown, it will be a diameter both of the sphere and of each circle, and will bisect each of them — so that EAF, FCE, EBF, FDE are semicircles. Therefore in a sphere great circles bisect each other. Which was to be demonstrated.

Diagram. A sphere figure for Proposition 11. Within the great outer circle (the sphere) two great circles AC and BD are drawn, crossing to form a star-like pattern; the diameters AC and BD meet at the center G.

- A (upper left): endpoint of the great circle AC
- D (upper right): endpoint of the great circle BD
- E (left, on the line EF): intersection point of the two great circles
- G (center, marked with a dot): center of the sphere
- F (right, on the line EF): intersection point of the two great circles
- B (lower left): endpoint of the great circle BD
- C (lower right): endpoint of the great circle AC

THEOR. 11. PROPOS. 12.

[Margin: 17.]

In a sphere, circles that bisect each other are great circles.

In the sphere ABCD let the circles AE [recte: AC] and BD bisect each other at the points E and F. I say that the circles AC and BD are great circles. For since they bisect each other at E and F, the line EF, when drawn, will be a diameter of each — since only a diameter divides any circle in half. And so, when the line EF is itself divided in half at G, G will be the center of each circle; and this, I say, is also the center of the sphere, and hence each circle is drawn through the center of the sphere. For suppose G is said not to be the center of the sphere, and so the circles AC and BD not to be drawn through the center of the sphere; by this very supposition we shall show that G is the center of the sphere, and therefore that each circle is drawn through the center of the sphere. [Margin: a — *Elements* XI.12] For from G let the perpendicular GH be erected to the plane of the circle AC, and likewise GI perpendicular to the plane of the circle BD. Now since the circles AC and BD are supposed not to pass through the center of the sphere, [Margin: b — Coroll. 2 of this book] each perpendicular GH and GI will pass through the center of the sphere. So the point G, where they meet, will be the center of the sphere — otherwise the center would not lie in both. And consequently each circle will be carried through the center of the sphere. [Margin: c — *Sphaerica* I.6] Therefore the circles AC and BD, carried through the center of the sphere, are great circles. So in a sphere, circles that bisect each other are great circles. Which was to be shown.

Diagram. A sphere figure for Proposition 12. Within the outer circle (the sphere) two circles AC and BD cross in a star-like pattern; their common line EF passes through the center G, with the perpendiculars meeting at the inner points I and H above G.

- A (upper left): endpoint of a circle

- D (upper right): endpoint of a circle
- I (inner, upper left of center): foot of a perpendicular / point on a circle
- H (inner, upper right of center): foot of a perpendicular / point on a circle
- E (left): intersection point of the two circles
- F (right): intersection point of the two circles
- G (center): common center of the two circles / center of the sphere
- B (lower left): endpoint of a circle
- C (lower right): endpoint of a circle

SCHOLIVM

Here you see a truly remarkable manner of argument. For from the fact that G is said *not* to be the center of the sphere, it is proved — by an affirmative demonstration — that G *is* the center of the sphere. Euclid [Euclid] also used this manner of argument in Book 9, Prop. 12, and Cardano [Cardano] in Book 5 of *De Proportionibus*, Prop. 201, as we noted in the scholium to that same proposition.

THEOR. 12. PROPOS. 13.

[Margin: 18.]

If in a sphere a great circle cuts some circle at right angles, it also cuts it in half and through the poles.

In a sphere let the great circle ABCD cut the circle BED at the points B and D at right angles — that is, let the plane of the circle ABCD be at right angles to the plane of the circle BED, and let their common section be the straight line BD. I say that the circle ABCD cuts the circle BED both in half and through the poles.

[Margin: a — *Elements* III.1] For let F be taken as the center of the great circle ABCD, which [Margin: b — *Sphaerica* I.6] will also be the center of the sphere [Margin: c — Coroll. 1 of this book] (for since a great circle is drawn through the center of the sphere, its center is the same as that of the sphere). [Margin: d — *Elements* XI.11] From F let the perpendicular FG be drawn to the plane of the circle BED, [Margin: e — *Elements* XI.38] which will fall on BD, their common section. Let it fall on the point G. [Margin: f — Coroll. 1 of this book] And since this same perpendicular also falls on the center of the circle BED, G will be the center of the circle BED; and so BD, drawn through G, is a diameter of that circle. Since this diameter divides the circle BED in half, the great circle ABCD, drawn through the straight line BD, will also divide the same circle in half. Which is the first point proposed. Now since the line FG lies in the plane of the circle ABCD, when produced it will fall on the circumference at the points A and C, which lie on the

surface of the sphere. [Margin: g — *Sphaerica* I.8] But it also falls on each pole of the circle BED, since the perpendicular is drawn from F, the center of the sphere, to the plane of the circle. Therefore A and C are the poles of the circle BED; and consequently the great circle ABCD passes through the poles of the circle BED — which is the second point that was proposed for demonstration. So, if in a sphere a great circle cuts some circle, and so on. Which was to be demonstrated.

Diagram. A sphere figure for Proposition 13. The outer circle is the great circle ABCD (the sphere); the vertical diameter AC passes through F, marked with a dot. A smaller circle BED is drawn low in the figure, with its diameter BD horizontal and its center G on the line AC; E lies to the left.

- A (top): pole of the circle BED / endpoint of the vertical diameter
- F (center, marked with a dot): center of the great circle ABCD and of the sphere
- E (lower left, inner): point on the small circle BED
- B (left): endpoint of the diameter BD of the small circle
- G (center, below F): center of the small circle BED
- D (right): endpoint of the diameter BD
- C (bottom): the other pole of the circle BED

SCHOLIVM

Moreover, this proposition, together with 8, 9, 10 and their scholia, is also to be understood of the case where the circle BD is a great circle and passes through the center of the sphere. For the demonstration is nearly always the same, as is evident.

THEOR. 13. PROPOS. 14.

[Margin: 19.]

If in a sphere a great circle bisects a circle that is not a great circle, it cuts it at right angles and through the poles.

(Continuation of the demonstration of THEOR. 13 / PROPOS. 14, whose enunciation stood at the end of the previous section: "If in a sphere a great circle bisects a circle that is not a great circle, it cuts it at right angles and through the poles.")

Diagram. A sphere shown as the great circle ABCD (the outer circle), with a lens-shaped small circle BED across its upper part.

- A (top of the sphere): pole

- B (upper left, on the small circle): one end of the common section
- D (upper right, on the small circle): other end of the common section
- F (on the chord BD, below A): center of small circle BED
- E (just below F, on the near/far arc of the small circle): point of the small circle's circumference
- G (center of the sphere, marked with a dot): center of the sphere and of the great circle ABCD
- C (bottom of the sphere): pole

In the sphere let the great circle ABCD bisect the circle BED, which is not a great circle, at the points B and D, and let their common section be the straight line BD. I say that the circle ABCD cuts the circle BED at right angles and through its poles. For since the circle BED is bisected at B and D — that is, into semicircles — BD, their common section, will be its diameter. So when BD has been bisected at F, F will be the center of circle BED.[Margin: a. 2. huius (*Sphaerica* I.2)] Now let G be taken as the center of the sphere, which will also be the center of the great circle ABCD, and from G to F let the straight line FG be drawn; it will be perpendicular to the plane of circle BED.[Margin: b. 7. huius (*Sphaerica* I.7)] Therefore the plane of the great circle ABCD, drawn through the straight line FG onto that same plane of circle BED, will also be at right angles to it.[Margin: c. 18. unde. (*Elements* XI.18)] Hence the great circle ABCD cuts the circle BED, which is not a great circle, at right angles — which was the first thing proposed.

And since it has been shown that the straight line FG, drawn from the sphere's center G to the plane of circle BED, is perpendicular to it, FG produced in both directions will fall on the poles of circle BED.[Margin: d. 8. huius (*Sphaerica* I.8)] Therefore, since GF, lying in the plane of circle ABCD, when produced falls upon that circle's circumference at the points A and C, which also lie on the surface of the sphere, A and C will be the poles of circle BED. And so the great circle ABCD will cut the circle BED, which is not a great circle, through the poles A and C — which was the second thing proposed. If, therefore, in a sphere a great circle cuts a circle that is not a great circle, and so on. Which was to be shown.

THEOR. 14. PROPOS. 15. [Margin: 20.]

If in a sphere a great circle cuts through the poles any one of the circles that are in the sphere, it cuts it both in half and at right angles.

Diagram. A sphere shown as the great circle ABCD, with a lens-shaped small circle BED across its lower part.

- A (top): pole
- B (lower left, on the small circle): one end of the common section
- D (lower right, on the small circle): other end of the common section
- F (on chord BD): meeting point of AC with the plane of the small circle
- E (just above F): point of the small circle's circumference
- C (bottom): pole (the vertical line AC is the axis through both poles)

In the sphere let the great circle ABCD cut the circle BED through the poles A and C. I say that the circle ABCD cuts the circle BED both in half and at right angles. For let the straight line AC join the poles A and C, meeting the plane of circle BED at the point F.[Margin: a. 10. huius (*Sphaerica* I.10)] Now since the straight line AC is perpendicular to the plane of circle BED, and passes through the center of the sphere and of circle BED, F will be the center of circle BED. Therefore, since the great circle ABCD, cutting circle BED, passes through the straight line AC and hence through the center F, the common section BFD will be a diameter of circle BED. So circle BED is bisected. I say also that it is cut at right angles. For since the straight line AC has been shown to be perpendicular to the plane of circle BED, [Margin: b. 18. unde. (*Elements* XI.18)] the plane of the great circle ABCD, drawn through the straight line AC onto that same plane of circle BED, will also be at right angles to it. Therefore, if in a sphere a great circle, and so on. Which was to be demonstrated.

SCHOLIVM.

Four other theorems are added at this place in another version, in this order.

I. [Margin: 21.]

If in a sphere a great circle passes through the poles of some other great circle, this latter in turn passes through the poles of the former.

Diagram. A sphere shown as two intersecting great circles.

- A (top): pole
- B (left): one intersection point / end of common section BD
- D (right): other intersection point / end of common section BD
- G (bottom): pole

In the sphere let the great circle ABCD pass through A and C, the poles of the great circle BD. I say that the great circle BD also passes through the poles of the great circle ABCD. For since the great circle ABCD cuts the circle BD through its poles, it will cut it at right angles.[Margin: a. 15. huius (*Sphaerica* I.15)] Therefore, in turn,

the great circle BD will cut the circle ABCD at right angles,[Margin: b. 13. huius (*Sphaerica* I.13)] and so it will cut it through its poles. Which is what was proposed.

II. [Margin: 22.]

If in a sphere a circle cuts another circle through its poles, it is a great circle, and it cuts it both in half and at right angles.

Diagram. A sphere with a vertical diameter and a circle BD across the middle.

- A (top): pole
- B (left): one end of the diameter of circle BD
- D (right): other end of the diameter of circle BD
- C (bottom): pole (the vertical line AC passes through the two poles and the center)

In the sphere let the circle ABCD cut the circle BD through the poles A and C. I say that it is a great circle, and that it cuts the circle BD both in half and at right angles. For let the straight line AC join the poles A and C; it will necessarily lie in the plane of circle ABCD, since that circle's circumference is assumed to pass through the same poles A and C. Now since the straight line AC, drawn through A and C, the poles of circle BD, passes through the center of the sphere,[Margin: a. 10. huius (*Sphaerica* I.10)] the circle ABCD (since it is drawn through the straight line AC) will also pass through the center of the sphere,[Margin: b. 6. huius (*Sphaerica* I.6)] and so it will be a great circle. Therefore, since it is assumed to pass through A and C, the poles of circle BD, it will cut it both in half and at right angles.[Margin: c. 15. huius (*Sphaerica* I.15)] Which is what was proposed.

III. [Margin: 23.]

If in a sphere a circle cuts another circle both in half and at right angles, it is a great circle, and it cuts it through the poles.

(Continuation of the demonstration of Scholium theorem III.)

In the sphere let the circle ABCD cut the circle BD both in half and at right angles. I say that it is a great circle, and that it passes through the poles of circle BD. Let the straight line BD be the common section of the circles. Since, then, the circle ABCD cuts the circle BD in half, the straight line BD — namely the common section of the circles — will be a diameter of circle BD; and so, when the straight line BD has been bisected at E, E will be the center of that circle. In the plane of circle ABCD let the straight line EA be drawn perpendicular to the straight line

BD. And since the circle ABCD is assumed to cut the circle BD at right angles, EA will, by *Elements* XI, definition 4, be at right angles to the plane of circle BD; and hence, since it is drawn from E, the center of that circle, it falls on each of its poles.[Margin: h. schol. 8. huius (Scholium on *Sphaerica* I.8)] But it falls on the circumference of circle ABCD, lying on the surface of the sphere, at the points A and C. Therefore A and C are the poles of circle BD; and so the circle ABCD cuts circle BD through the poles A and C. Hence, by the preceding theorem, it is a great circle. And it has been proved that it also cuts circle BD through the poles. So what was proposed is established.

I V. [Margin: xxiv.]

If in a sphere there is a circle, and a straight line falling from one of its poles onto its plane at right angles is equal to its radius, the circle is a great circle.

Diagram. A sphere with a vertical diameter AC and a horizontal chord BD meeting at the center E.

- A (top): pole
- B (left): endpoint of the chord
- D (right): endpoint of the chord
- C (bottom): pole
- E (center): center of the sphere / meeting point

In the sphere let there be a circle AB, and from one of its poles C let the perpendicular straight line CD, falling onto its plane, be equal to its radius. I say that AB is a great circle. For since CD is perpendicular to circle AB, it will fall on the circle's center,[Margin: i. 9. huius (*Sphaerica* I.9)] and when produced it will fall on the other pole, which let be E. Therefore D is the center of circle AB, [Margin: k. coroll. 2. huius (Corollary 2, *Sphaerica*)] and so the perpendicular CD passes through the center of the sphere. Through the straight line CE let a plane be drawn in the sphere in any way whatever,[Margin: l. 1. huius (*Sphaerica* I.1)] making in the sphere the circle AEBC; since this passes through the center of the sphere, it will be a great circle,[Margin: m. 6. huius (*Sphaerica* I.6)] and it cuts the circle AB at the points A and B. Let the radius DB be joined, to which, by hypothesis, CD is equal. Now since CD is assumed perpendicular to circle AB, the angle CDB will, by *Elements* XI, definition 3, be a right angle.[Margin: n. schol. 13. sexti (Scholium on *Elements* VI.13)] Therefore BD is the mean proportional between CD and DE — that is, as CD is to BD, so BD is to DE. But CD is equal to BD. Therefore DE too will be equal to that same BD; and so CD and DE will be equal to

each other. Since, then, CE has been shown to pass through the center of the sphere, and passes through the center of circle AB, D will be the center of the sphere. But it was also the center of circle AB. Therefore the center of the sphere and of circle AB is the same,[Margin: o. 6. huius (*Sphaerica* I.6)] and hence the circle AB is a great circle. Which is what was proposed.

THEOR. 15. PROPOS. 16. [Margin: xxv.]

If in a sphere there is a great circle, a straight line drawn from a pole of that circle to its circumference is equal to the side of a square inscribed in a great circle.

Diagram. A sphere with vertical diameter CD (through the poles) and horizontal diameter AB, meeting at the center E; a great circle ADBC is shown.

- C (top): pole
- A (left): endpoint of diameter AB
- B (right): endpoint of diameter AB
- D (bottom): other pole
- E (center): center of the sphere / meeting of the diameters

In the sphere let there be a great circle AB, and from its pole C let the straight line CB be drawn to its circumference. I say that CB is equal to the side of a square inscribed in circle AB, or in any other great circle.[Margin: a. 11. undec. (*Elements* XI.11)] From C let the perpendicular CE be drawn to circle AB;[Margin: b. 9. huius (*Sphaerica* I.9)] it will fall on the circle's center, which let be E, and produced it will fall on the remaining pole, which let be D. Now through the straight lines CB and CD let a plane be drawn,[Margin: c. 1. huius (*Sphaerica* I.1)] making in the sphere the circle ADBC; since this passes through E, the center of the sphere (for E, the center of the great circle AB, is the same as the center of the sphere, because AB passes through the sphere's center),[Margin: d. coroll. 1. huius (Corollary 1, *Sphaerica*)] it will be a great circle,[Margin: e. 6. huius (*Sphaerica* I.6)] and so it will bisect the great circle AB.[Margin: f. 11. huius (*Sphaerica* I.11)] This is also clear from the fact that it passes through its poles;[Margin: g. 15. huius (*Sphaerica* I.15)] for from this it follows that it bisects it. Let the common section, then, be the diameter BEA. And since the perpendicular CE has been drawn to circle AB, it will be the same perpendicular to the straight line AB, by *Elements* XI, definition 3. Therefore the two diameters AB and CD, in the great circle ADBC, cut each other at right angles;[Margin: h. 6. quart. (*Elements* IV.6)] and on that account, as is demonstrated in *Elements* IV, CB is the side of a square inscribed in the great circle ADBC, and so also in the great circle AB. If, therefore, in a sphere

there is a great circle, and a straight line is drawn, and so on. Which was to be demonstrated.

COROLLARIVM.

Now since the four right angles at the center E are equal, and hence the four arcs BC, CA, AD, DB, on which they stand, are equal — namely quadrants — it is clear that in a sphere the pole of a great circle is distant from the circumference of a great circle by a quadrant of a great circle. For C, the pole of the great circle AB, is distant from that circle's circumference by the quadrant CB, and the same holds of the rest.[Margin: i. 26. tertij (*Elements* III.26)] For a straight line drawn from the circumference of a great circle to its pole is always equal to the side of a square inscribed in a great circle,[Margin: k. 16. huius (*Sphaerica* I.16)] and so it subtends a quadrant in a great circle.

SCHOLIVM.

The converse of this is also demonstrated in another version, in this theorem.

If in a sphere there is a circle, and a straight line drawn from its pole to the circumference is equal to the side of a square inscribed in it, the circle itself is a great circle.

(Continuation of the converse-theorem demonstration.)

In the same figure, from C, the pole, let a straight line CB be drawn to the circumference of circle AB, equal to the side of a square inscribed in circle AB. I say that AB is a great circle. For from C let the perpendicular CE be drawn to circle AB;[Margin: l. 11. undec. (*Elements* XI.11)] it will fall on its center, which let be E.[Margin: m. 9. huius (*Sphaerica* I.9)] Now when the radius EB has been drawn, the angle E will, by *Elements* XI, definition 3, be a right angle.[Margin: n. 47. pri. (*Elements* I.47)] Therefore the square on CB — that is, the square inscribed in circle AB — is equal to the squares on BE and CE. But the square on the radius BE is half the square inscribed in circle AB, as we shall show presently. Therefore the square on CE too will be half of that same square inscribed in circle AB; and so the squares on BE and CE will be equal to each other, and consequently the lines BE and CE will also be equal. Therefore, since CE has been drawn from C, the pole of circle AB, perpendicular to that circle, and has been shown to be equal to the radius BE, the circle AB will be a great circle.[Margin: o. schol. 15. huius (Scholium on *Sphaerica* I.15)]

LEMMA.

In every circle the square on the radius is half the square inscribed in that circle.

Diagram. A circle with a square ABCD inscribed in it, its two diameters AC and BD drawn through the center E.

- A (top): vertex of the inscribed square
- B (left): vertex of the inscribed square
- D (right): vertex of the inscribed square
- C (bottom): vertex of the inscribed square
- E (center): center of the circle (intersection of the diameters)

In a circle whose center is E, let two diameters AC and BD be drawn, cutting each other at right angles at the center E. When, therefore, the straight lines AB, BC, CD, DA have been joined, ABCD will be a square inscribed in the circle, as is established from *Elements* IV.6. Now since the squares on the equal radii EA and EB, being equal to each other, [Margin: p. 47. pri. (*Elements* I.47)] are together equal to the square on AB, the square on the radius EA will be half the square on AB, which is inscribed in the circle. Which is what was proposed. From this it is established that, in the upper figure, the square on the radius BE is half the square on CB, which is assumed equal to the one inscribed in circle AB.

THEOR. 16. PROPOS. 17. [Margin: xxvij.]

If in a sphere there is a circle, and a straight line drawn from its pole to its circumference is equal to the side of a square inscribed in a great circle, that circle will be a great circle.

Diagram. A sphere with a great circle ACB inscribed, and lines drawn from C to A and B.

- C (top): pole of circle AB
- A (left): endpoint of the diameter AB
- B (right): endpoint of the diameter AB
- (center, marked with a dot): center of the sphere

In the sphere let there be a circle AB, and from its pole C let the straight line CA be drawn to its circumference, equal to the side of a square inscribed in a great circle of the sphere. I say that the circle AB is a great circle. For through the straight line AC and the center of the sphere let a plane be drawn, [Margin: a. 1.

huius (*Sphaerica* I.1)] making in the sphere the circle ACB,[Margin: b. 6. huius (*Sphaerica* I.6)] which will be a great circle, since it is drawn through the sphere's center. Also from C let the straight line CB be drawn to B, the point where the great circle ACB cuts the circle AB; and, by the definition of the pole, the straight line CB will be equal to the straight line CA. Since, then, AC is assumed to be the side of a square inscribed in the great circle ACB, CB too will be the side of the same square; and so the two arcs AC and CB will be quadrants making up the semicircle ACB, since the four equal sides of the square[Margin: c. 28. ter. (*Elements* III.28)] subtend four equal arcs of the circle. Therefore the straight line AB, the common section of the circles, will be a diameter of the great circle ACB, and hence of the sphere. Now since the great circle ACB, cutting the circle AB through the poles, bisects it,[Margin: d. 15. huius (*Sphaerica* I.15)] AB too will be the common section, a diameter of circle AB; and hence, since it is also a diameter of the sphere, AB will be a great circle. If, therefore, in a sphere there is a circle, from whose pole, and so on. Which was to be demonstrated.

PROBL. 2. PROPOS. 18. [Margin: xxvii.]

To describe a straight line equal to the diameter of any given circle in a sphere.

Diagram. Two figures side by side. On the left, a circle ABCD with the inscribed triangle ABD, the diameter AC, and the chord DC. On the right, a kite-shaped quadrilateral EFGH.

- A (top of circle): point taken on the circumference
- B (left of circle): point taken on the circumference
- D (right of circle): point taken on the circumference
- C (bottom of circle): opposite end of diameter AC
- (center of circle, marked with a dot): center
- E (top of the kite): apex, corresponding to A
- F (left of the kite): foot of perpendicular, corresponding to B
- G (right of the kite): corresponding to D
- H (bottom of the kite): meeting point of the perpendiculars FH and GH

In the sphere let there be any given circle ABCD, a straight line equal to whose diameter is to be described. Taking any three points A, B, D on the circle's circumference, and joining the straight lines AB, AD, BD,[Margin: a. schol. 22. primi (Scholium on *Elements* I.22)] let there be constructed a triangle EFG equal to the triangle ABD, in such a way that the side EF is equal to AB, EG to AD, and

FG to BD. For the three intervals AB, AD, BD, taken with a compass on the surface of the sphere, can be transferred onto a plane, and thus a triangle can be constructed whose three sides are equal to those three distances. Then from G and F let the perpendiculars FH and GH be drawn to the straight lines EF and EG, meeting at H, and let the straight line EH be joined. I say that EH is equal to the diameter of circle ABCD. For when the diameter AC has been drawn, let the straight line DC be joined.[Margin: b. schol. 32. primi (Scholium on *Elements* I.32)] Now since the four angles of the quadrilateral EFHG are equal to four right angles, and the angles EFH and EGH are right angles, the angles FEG and FHG will be equal to two right angles; and so in the quadrilateral EFHG any two opposite angles will be equal to two right angles.[Margin: c. schol. 22. tertij (Scholium on *Elements* III.22)] Therefore a circle can be described about it;[Margin: d. 27. tert. (*Elements* III.27)] and when it has been described, the angles EFG and EHG will stand on the same segment, whose chord is EG, insist-

(The demonstration of Prop. 18 breaks off mid-word at the foot of the page and continues onto the following page.)

PROBL. 2. PROPOS. 18 (continued)

[Continuation of the demonstration begun in the previous proposition — construct a straight line equal to the diameter of a given circle.]

standing [on equal arcs], are equal. ^e Now the angle EFG is equal to the angle ABD, because the two sides EF, FG are equal to the two sides AB, BD, and the base EG to the base AD, by construction; ^f and the angle ABD is equal to the angle ACD. Therefore the angle EHG too will be equal to the angle ACD. Moreover the right angle EGH is equal to the angle ADC, ^g since this angle too is a right angle, standing in the semicircle ADC. Therefore the triangles EHG and ACD have two angles equal to two angles, and also the side EG equal to the side AD, which subtends one of the equal angles. ^h Hence the side EH too will be equal to the side AC. Therefore we have constructed the straight line EH equal to the diameter AC of the circle ABCD. Which was to be done.

[Margin: e — *Elements* I.8 (8. primi)] [Margin: f — *Elements* III.27 (27. tertij)]

[Margin: g — *Elements* III.31 (31. tertij)] [Margin: h — *Elements* I.26 (26. pri.)]

Diagram. The figure for Proposition 18. On the left, a circle with a vertical diameter and interior lines; on the right, a kite-shaped quadrilateral.

- A (top of circle): endpoint of the diameter
- B (left of circle): vertex

- D (upper right, on circle): vertex, with chords to A and C
- C (bottom of circle): lower endpoint of the diameter
- E (apex, right figure): vertex; EH is the long axis
- F (left, right figure): vertex
- G (right, right figure): vertex
- H (bottom, right figure): vertex where the perpendiculars meet

PROBL. 3. PROPOS. 19.

[Margin: xxix.]

To construct a straight line equal to the diameter of a given sphere.

In the given sphere let two points A, B be taken at random, and from A as pole, with radius AB, ^a let a circle BD be described. ^b Let a straight line FG be drawn equal to the diameter of this circle, and on FG let a triangle EFG be built, having each of its remaining sides EF, EG equal to the drawn line AB — that is, by taking the interval AB with the compass, and so on. Then from F and G let perpendiculars FH, GH be drawn to EF, EG, meeting at H; and let the straight line EH be joined. I say that EH is equal to the diameter of the given sphere.

For let the diameter AC of the sphere be drawn, and through the straight lines AB, AC let a plane be passed, ^c making in the sphere the circle ABCD, ^d which will be a great circle, since it is drawn through the diameter of the sphere and hence through its center. Therefore this same plane, passing through A, the pole of the circle BD, ^e will bisect the circle BD; and consequently the common section BD will be a diameter of the circle BD. Now when the straight lines AD, DC are joined, the two sides AB, BD will be equal to the two sides EF, FG, and likewise the bases AD, EG will be equal. For FG is equal to the diameter BD by construction, and each of EF, EG is equal to AB, or to AD. ^f Therefore the angles ABD, EFG will be equal. ^g Now the angle ACD is equal to the angle ABD, and the angle EHG to the angle EFG, as was demonstrated in the preceding proposition. Therefore the angles ACD, EHG are also equal. But the right angles ADC, EGH are equal too, and the side AD, which is opposite one of the equal angles, is equal to the side EG. ^h Therefore the straight line EH too will be equal to the straight line AC. So we have constructed the straight line EH equal to the diameter AC of the given sphere. Which was to be done.

- A (top of circle): endpoint of the sphere's diameter AC
- B (left of circle): point on the circle BD
- D (right, on circle): endpoint of the diameter BD of circle BD
- C (bottom of circle): lower endpoint of the diameter AC
- E (apex, right figure): vertex; EH is the constructed line equal to the diameter
- F (left, right figure): vertex, with perpendicular FH
- G (right, right figure): vertex, with perpendicular GH
- H (bottom, right figure): meeting point of the perpendiculars

SCHOLIVM.

[Margin: xxx.]

In another version the following theorem is added.

A straight line drawn from the pole of any circle in a sphere to the surface of the sphere, being equal to the straight line drawn from the same pole to the circumference of the circle, falls upon the circumference of the circle.

In the sphere, from A, the pole of the circle BC, let a straight line AD be drawn at random to its circumference. This line will be less than the diameter of the sphere, and hence less than the diameter of a great circle in the sphere, since the diameter of the sphere is the greatest of all straight lines drawn in the sphere. Now from the same pole A let a straight line AE be drawn to the surface of the sphere, equal to AD. I say that the straight line AE falls upon the circumference of the circle BC. For if this is not so, suppose it does not fall on that circumference. Through the straight line AE and the center of the sphere let a plane be passed,ⁱ making in the sphere the circle ABC,^k which will be a great circle, since it passes through the center of the sphere. Let the circle ABC cut the circle BC at the points B, C. Then the straight line AE does not fall on the points B, C, since it is supposed not to fall on the circumference of the circle BC. So when the straight line AB is drawn, it will, by the definition of the pole, be equal to AD, and hence to AE. And

since each of AB, AE is less than the diameter of the great circle ABC, as has been said, ¹ the arcs AB, AE — being segments less than a semicircle — will be equal, the part and the whole. Which is absurd. Therefore the straight line AE falls upon the circumference of the circle BC. Which was the thing proposed.

[Margin: i — Prop. 1 of this book (1. huius)] [Margin: k — Prop. 6 of this book (6. huius)] [Margin: l — *Elements* III.28 (28. tertij)]

- A (top): the pole of the circle BC
- F (left, on the arc): point on the circumference
- B (left): point where the arc meets the great circle
- E (lower left): point on the sphere's surface
- D (upper middle, on the arc): point on the circumference of circle BC
- C (right): point on the circumference

PROBL. 4. PROPOS. 20.

[Margin: xxxj.]

Through two given points on a spherical surface to describe a great circle.

On the given spherical surface let there be two points A, B, through which a great circle is to be described. Now if the points A, B are diametrically opposite on the sphere, it is certain that infinitely many great circles can be drawn through them, namely by passing infinitely many planes through the diameter of the sphere that joins those points. But if the points A, B are not on a diameter of the sphere, then from A as pole, with an interval equal to the side of the square inscribed in a great circle,

let a circle CD be described, ^a which will be a great circle, since the straight line drawn from A, the pole, to its circumference is equal to the side of the square inscribed in a great circle, on account of the interval by which the circle CD was described. And this interval is found as follows. When the diameter of the sphere, or of a great circle, has been found — as was shown in the preceding proposition — the side of the square inscribed in the circle of that diameter will be the interval sought, as is plain. Similarly, from B as pole and with the same interval as before, let a circle EF be described, ^b which again will be a great circle. Let this

cut the former in the point G, and from G let the straight lines GA, GB be drawn to the poles A, B; each of these, by construction, will be equal to the side of the square inscribed in a great circle, for the circles CD, EF were described from the poles A, B with just such an interval. Therefore GA, GB are equal. Now from G as pole and with radius GA let a circle AEDFCB be described, ^c which will be a great circle, since the straight line GA, drawn from G, the pole, to its circumference, is equal to the side of the square inscribed in a great circle, as has been demonstrated. And since the straight line GB, equal to GA, drawn to the surface of the sphere, ^d falls on the circumference of the circle AEDFCB, the described great circle AEDFCB will therefore pass through the two given points A, B on the surface of the sphere. So through the two given points on the spherical surface we have described a great circle. Which was to be done.

[Margin: a — Prop. 17 of this book (17. huius)] [Margin: b — Prop. 17 of this book (17. huius)] [Margin: c — Prop. 17 of this book (17. huius)] [Margin: d — Scholium on Prop. 19 of this book (schol. 19. huius)]

Diagram. The figure for Proposition 20 : a circle within which two great circles cross, meeting at the central point G.

- B (top right, on circle): a given point / pole
- E (left, on circle): point on the circumference
- C (right, on circle): point on the circumference
- G (center): intersection of the two described circles
- D (lower left, on circle): point on the circumference
- F (lower right, on circle): point on the circumference

PROBL. 5. PROPOS. 21.

[Margin: xxxij.]

To find the pole of any given circle in a sphere.

Let the pole of the circle AB, given in a sphere, be sought, and let the circle AB first be not a great circle. Taking two points C, D at random on the circumference, ^a let each of the arcs CAD, CBD be bisected at the points A and B, ^b through which let a great circle AEB be described; and let the arc AEB be bisected at E. I say that E is a pole of the circle AB. For since the arcs AC, AD are equal, and likewise BC, BD, the whole arcs ACB, ADB will be equal. Therefore, since the great circle AEB bisects the circle AB, which is not a great circle, at A and B, ^c it will cut it through

the poles. So the point E, being equally distant from the circumference of the circle AB, is the pole of the circle AB. In the same way, if the remaining arc AFB is bisected at F, then F will be the other pole of the circle AB.

But now let the given circle AB be a great circle. Taking the points C, D again at random, ^d and bisecting the arcs CAD, CBD at A, B, we shall show, as before, that the whole arcs ACB, ADB are equal, and therefore that each is a semicircle of a great circle. So when one of the semicircles, namely ACB, is bisected at G, the straight line GA, subtending a quadrant of the circle, will be the side of the square inscribed in the great circle AB — as is clear from Proposition 6 of Book IV of Euclid. Accordingly, from the pole G, with radius GA, let a circle AEB be described, ^e which will be a great circle, since the straight line drawn from G, the pole, to its circumference — namely to the point A — is equal to the side of the square inscribed in the great circle AB. Finally let the arc AEB be bisected at E. I say that E is a pole of the circle AB. For since the great circle ACB passes through G, the pole of the great circle AEB, ^f conversely the great circle AEB will pass through the poles of the great circle ACB. Therefore the point E, equally removed from the circumference of the circle ACB, is a pole of the circle ACB. In the same way, when the arc AFB is bisected at F, F will be the other pole of the circle ACB. Therefore we have found the pole of any given circle in a sphere. Which was to be done.

SCHOLIVM.

[Margin: xxxiiij.]

In another version the following two theorems are demonstrated.

I.

If some point is taken on the surface of a sphere, and from that point more than two equal straight lines fall to the circumference of some circle given in the sphere, the point taken is the pole of that circle.

On the surface of the sphere ABC let a point A be taken, from which more than two equal straight lines AD, AE, AF fall to the circumference of the circle BC. I say that A is the pole of the circle BC. ^a For let a perpendicular AG be dropped from A to the plane of the circle BC, and let the straight lines DG, EG, FG be joined; then, by the third definition of Book XI of Euclid, all three angles at G are right angles. ^b Hence the square on AD equals the squares on AG, GD; likewise the square on AE equals the squares on AG, GE; and the square on AF equals the squares on AG, GF. Since, then, the squares of the equal straight lines AD, AE, AF are equal, the squares on AG, GD together will be equal to the squares on AG, GE together, and likewise to the squares on AG, GF together; and when the common square of the line AG is taken away, the remaining squares of the lines GD, GE, GF will be equal, and hence the straight lines GD, GE, GF themselves will be equal. ^c Therefore G will be the center of the circle BC; ^d and consequently the straight line GA, drawn from the center G perpendicular to the circle BC, will fall on the pole of the circle BC. So the point A is the pole of the circle BC. Which was the thing proposed.

[Margin: a — *Elements* XI.11 (11. undec.)] [Margin: b — *Elements* I.47 (47. pri.)]
[Margin: c — *Elements* III.9 (9. tertij)] [Margin: d — Scholium on Prop. 8 of this book (schol. 8. huius)]

- B (left): point on the circle
- C (right): point on the circle
- G (center, at the base): foot of the perpendicular, the center of circle BC
- D, E, F (along the base): points on the circumference of circle BC to which the equal lines are drawn

II.

[Margin: xxxiv.]

In a sphere, circles from whose poles the straight lines drawn to their circumferences are equal, are equal to one another. And of equal circles, the straight lines drawn from their poles to the circumferences are equal.

In the sphere ABCDEF, whose center is G, let there be two circles BF, CE, from whose poles A, D the straight lines AF, DE drawn to their circumferences are equal. I say that the circles BF, CE are equal. ^a From the poles A, D let perpendiculars AH, DI be drawn to the planes of the circles; ^b these will fall on their centers H, I, and, produced further, on the remaining poles, ^c and hence also on G, the center of the sphere. So when the radii of the sphere FG, EG are drawn, and the radii of the circles FH, EI, since the sides AG, GF are equal to the sides DG, GE, and the base AF to the base DE, ^d the angles AGF, DGE will be equal. Now the angles H, I are right angles, by the third definition of Book XI of Euclid. Therefore the triangles FGH, EGI have two angles equal to two angles; and they have also the side FG, opposite the right angle, equal to the side EG. ^e Therefore the radii FH, EI too will be equal, and hence the circles BF, CE are equal. Which was proposed in the first place.

Now let the circles BF, CE be equal. I say that the straight lines AF, DE drawn from their poles to the circumferences are also equal. For when the same construction is made, the radii FH, EI will be equal, ^f and the circles themselves will be equally distant from the center of the sphere. Therefore the perpendiculars GH, GI will be equal, and hence the remaining lines AH, DI will be equal too. Since, then, the sides AH, HF are equal to the sides DI, IE, and they contain the equal angles H, I — these being right angles, by the third definition of Book XI of Euclid — ^g the bases AF, DE will be equal. Which was proposed in the second place.

THEOR. 17. PROPOS. 22.

[Margin: o.[?]]

If in a sphere a straight line drawn through the center bisects some straight line not drawn through the center, it will cut it at right angles. And if it cuts it at right angles, it will also bisect it.

In the sphere whose center is A, let the straight line AB, drawn through the center, bisect at B the straight line CD, which is not drawn through the center. I say that CD is cut at right angles. For when a plane is passed through the straight lines AB, CD, ^a it makes the circle CD, ^b which will be a great circle, since it passes through the center of the sphere. Now in the circle CD, the straight line AB, passing through its center A, bisects at B the straight line CD, which is not drawn through the center; ^c therefore it cuts it at right angles. And if it cuts it at right angles, it will also bisect it. So if in a sphere a straight line, and so on. Which was to be demonstrated.

[Margin: a — Prop. 1 of this book (1. huius)] [Margin: b — Prop. 6 of this book (6. huius)] [Margin: c — *Elements* III.3 (3. tertij)]

- D (bottom right): endpoint of the chord

SCHOLIVM.

Here in the Greek exemplar another theorem is added, which is exactly the same as what was demonstrated in Proposition 7. Hence we have thought it superfluous to repeat it here.

FINIS LIBRI I. THEODOSII.

THEODOSIUS'S *SPHAERICA*, BOOK TWO

DEFINITION

In a sphere, circles are said to be tangent to one another when the common section of their planes touches each of the two circles.

For a straight line tangent to some circle in a sphere is tangent also to the surface of the sphere at the very point where it touches the circle. (Otherwise, if it did not touch the surface but cut it, it would necessarily cut the circle as well, since it lies in the circle's plane and would join two points on the sphere's surface — the two points at which it is said to cut it; and these two points would lie on the circumference of the circle too, since the plane of the circle is drawn through that straight line and is therefore cut by it at those two points.) It follows that the circumferences of two circles whose common section — the section produced by extending their planes — is tangent to both circles have in common only that single point at which the section touches the sphere. For at that point, and at no other, can that common section be tangent to both circles, since all its other points lie outside the surface of the sphere and hence outside each circle. Theodosius, then, was right to say that circles in a sphere are tangent to one another when the common section of their planes has touched each circle.

THEOR. 1. PROPOS. 1. [Margin series: j.]

In a sphere, parallel circles are around the same poles.

In the sphere ABCDEF, let BF and CE be parallel circles. I say that they are around the same poles. [Margin: a — 21. 1. huius (*Sphaerica* I.21)] Let A and D be the poles of circle BF, and let the straight line AD be joined; [Margin: b — 10. 1. huius (*Sphaerica* I.10)] this line will be perpendicular to circle BF and will pass through the center of the sphere. Since, then, the straight line AD is perpendicular to circle BF, [Margin: c — schol. 14. undec. (scholium on *Elements* XI.14)] it will also be perpendicular to the parallel circle CE. And since it passes through the center of the sphere, as has been shown, [Margin: d — 8. 1. huius (*Sphaerica* I.8)] it falls on the poles of circle CE. Therefore A and D are the poles of circle CE; but they are also the poles of circle BF. In the sphere, then, the parallel circles BF and CE are around the same poles A and D, and so on. Which was to be demonstrated.

Diagram. A sphere shown as a circle with a vertical axis. The two parallel circles are drawn as horizontal ellipses.

- A (top): pole; upper end of the axis

- D (bottom): pole; lower end of the axis, with a center dot marked on the axis AD
- B (left, mid-height): point on the upper parallel circle BF
- F (right, mid-height): point on the upper parallel circle BF
- C (lower left): point on the lower parallel circle CE
- E (lower right): point on the lower parallel circle CE

THEOR. 2. PROPOS. 2. [Margin series: ij.]

In a sphere, circles that are around the same poles are parallel.

In the same sphere ABCDEF, let BF and CE be circles around the same poles A and D. I say that they are parallel. When the straight line AD is joined, [Margin: a — 10. 1. huius (*Sphaerica* I.10)] it will be perpendicular to each of the two circles. [Margin: b — 24. undec. (*Elements* XI.24)] Therefore the planes of circles BF and CE are parallel. In the sphere, then, circles that are around the same poles are parallel. Which was to be shown.

SCHOLIUM

This theorem and the one that follows are demonstrated in another version as well.

In a sphere there are not more than two circles that are equal and parallel.

In any sphere, let there be, if possible, more than two circles that are equal and parallel — say three, AB, CD, EF — [Margin: c — 1. huius (*Sphaerica* II.1)] which will be around the same poles. Let their poles then be G and H, and let the straight line GH be joined; [Margin: d — 10. 1. huius (*Sphaerica* I.10)] it will pass through I, the center of the sphere, and through K, L, M, the centers of the circles, and it will be perpendicular to circles AB, CD, EF. Since, then, the circles AB, CD, EF are equal, [Margin: e — 6. 1. huius (definition 6 of *Sphaerica* Book I)] they will be equally distant from the center of the sphere I. By definition 6 of Book I of this work, therefore, the perpendiculars

Diagram. A sphere shown as a circle with a vertical axis GH; three parallel circles are drawn as horizontal ellipses, with their centers K, L, M marked on the axis.

- G (top): pole; upper end of axis GH
- H (bottom): pole; lower end of axis GH
- I (center): center of the sphere, on the axis

- A (upper left) / K (on axis) / B (upper right): the topmost parallel circle AB, with center K
- C (mid left) / L (on axis) / D (mid right): the middle parallel circle CD, with center L
- E (lower left) / M (on axis) / F (lower right): the lowest parallel circle EF, with center M

the perpendiculars IK, IL, IM will be equal — namely a part, IL, and the whole, IM. Which is absurd. In a sphere, therefore, there are not more than two circles that are equal and parallel. Which was to be demonstrated.

THEOR. 3. PROPOS. 3. [Margin series: iv.]

If in a sphere two circles cut, at one and the same point, the circumference of that great circle on which they have their poles, then those circles are tangent to one another.

In a sphere let two circles AB, AC cut, at the point A, the circumference of the great circle ABC that passes through their poles. I say that circles AB, AC are tangent to one another at A. Since the great circle ABC cuts circles AB, AC through their poles, [Margin: a — 15. 1. huius (*Sphaerica* I.15)] it will bisect them and cut them at right angles. Therefore the common sections of circle ABC with circles AB, AC — namely the straight lines AB, AC — are diameters of circles AB, AC. Let DE also be the common section of the planes in which circles AB, AC lie; it will pass through the point A, because the planes of the circles at A are supposed to cut circle ABC. And since the plane of circle ABC has been shown to be at right angles to the planes of circles AB, AC, conversely the planes of circles AB, AC will be at right angles to the plane of circle ABC; [Margin: b — 19. undeci. (*Elements* XI.19)] and hence DE, their common section, will also be perpendicular to that same plane of circle ABC. It will therefore also be perpendicular to the diameters AB, AC lying in the same plane, by definition 3 of Book XI of Euclid. [Margin: c — coroll. 16 tertij (corollary of *Elements* III.16)] Consequently DE is tangent to each of the circles AB, AC at A; and therefore, by the definition of this book, circles AB, AC are tangent to one another at the point A. If, then, in a sphere two circles cut, and so on. Which was to be shown.

Diagram. A great circle ABC drawn as a circle; two lens-shaped circles rise from the lower points to the shared apex, with several chords drawn to that apex.

- E, A (top, adjacent): E is one end of the common section DE; A is the shared point of contact / apex of the two circles

- D (center): point on the common section DE, on the axis running down from A/E
- B (lower left): point on circle AB
- C (lower right): point on circle AC [engraved as a slightly open loop; C by context]

THEOR. 4. PROPOS. 4. [Margin series: v.]

If in a sphere two circles are tangent to one another, the great circle described through their poles will pass through their point of contact.

In a sphere let circles AB, CB be tangent to one another at B; and through D, the pole of circle AB, and E, the pole of circle CB, [Margin: a — 20. 1. huius (*Sphaerica* I.20)] let the great circle DE be described. I say that circle DE passes through the point of contact B. For suppose, if possible, that it does not pass through the contact B but cuts the circumference — say of circle CB — at F. Then with pole D and radius DF let a circle FG be described; since it is described with a greater radius than circle AB, it will cut circle CB at F, seeing that circle AB is tangent to that same circle at the point B, beyond which circle GF, described from pole D, extends. But since in the sphere the two circles GF, CF cut, at one and the same point F, the great circle DFE described through their poles, [Margin: b — 3. huius (*Sphaerica* II.3)] the two circles GF, CF will be tangent to one another at F. Yet they also cut one another at F, as was said — which is absurd. Therefore the great circle DE does not cut the circles AB, CB anywhere but at B, their point of contact, and so it will pass through their contact. And so, if in a sphere two circles are tangent to one another, and so on. Which was to be shown.

Diagram. Two overlapping circles side by side; an arc (the great circle DFE) sweeps across from the left circle to the right.

- G (top left): point on the left circle (circle AB)
- A (upper middle-left): point inside/on the left circle
- D (left): point on the arc DFE
- B (center): point of contact / intersection of the two circles
- F (just above B): where the arc meets the circles
- C (top right): point on the right circle (circle CB)
- E (lower right): end of the arc DFE

THEOR. 5. PROPOS. 5. [Margin series: vj.]

If in a sphere two circles are tangent to one another, the great circle described through the poles of one and through the point of contact of both circles will pass through the poles of the other circle as well.

In a sphere let two circles AB, CB be tangent to one another at B, and let D, E be their poles. I say that the great circle described through D, the pole of circle AB, and through the contact B passes also through E, the pole of circle CB. For if it can be, suppose it does not pass through E but through some other point F — this being the great circle DBF. [Margin: a — 20. 1. huius (*Sphaerica* I.20)] Then through the poles D, E let the great circle DE be described, [Margin: b — 4. huius (*Sphaerica* II.4)] which will certainly pass through the contact B; and so the two great circles DBF, DBE will cut one another at D and B, [Margin: c — 11. 1. huius (*Sphaerica* I.11)] and hence bisect one another. Each arc DB, then, will be a semicircle. But since a great circle that passes through one of the poles of any circle in a sphere [Margin: d — coroll. 16, 1. huius (corollary of *Sphaerica* I.16) [?]] passes also through the other pole, and there is a semicircle of a great circle interposed between the two poles of that circle, it would follow that, D being one of the poles of circle AB, the point B would be the other pole. Which is absurd, for B lies on the circumference of the circle. Therefore the great circle DB passes through E. And so, if in a sphere two circles are tangent to one another, and so on. Which was to be shown.

Diagram. Two circles tangent at a central point B; several straight lines run from B to the outer labelled points.

- C (top left): point on the left circle (circle AB)
- A (top right): point on the right circle (circle CB)
- F (mid left): pole / point on the left circle
- B (center): point of contact of the two circles
- D (right): pole of one circle
- E (lower left): pole of the other circle

THEOR. 6. PROPOS. 6. [Margin series: vij.]

If in a sphere a great circle is tangent to any of the circles described on the spherical surface, it will also be tangent to another circle equal and parallel to it.

In a sphere let the great circle AB be tangent to circle AC at A. I say that circle AB is tangent also to another circle equal and parallel to AC. [Margin: a — 20. 1. huius

(*Sphaerica* I.20)] Let D be the pole of circle AC, and through D and A let the great circle DA be described; since it passes through D, the pole of circle AC, and through the contact A, [Margin: b — 5. huius (*Sphaerica* II.5)] it will pass also through the poles of circle AB. Now taking E, the other pole of circle AC, let the straight line DE be drawn; [Margin: c — 10. 1. huius (*Sphaerica* I.10)] it will pass through the center of the sphere and so will be a diameter of the sphere. From pole E, then, and with radius EB, let a circle BF be described. I say that the great circle AB is tangent also to circle BF at B, and that circle BF is equal and parallel to circle AC. For since the straight line DE, passing through the poles of circles AC, BF, [Margin: d — 10. 1. huius (*Sphaerica* I.10)] is perpendicular to those circles, [Margin: e — 24. undec. (*Elements* XI.24)] circles AC, BF will be parallel. [Margin: f — 11. 1. huius (*Sphaerica* I.11)] Again, since great circles in a sphere bisect one another, ACB will be a semicircle, and hence equal to the semicircle DCE. Therefore, when the common arc BD is removed, the arcs DA, EB remain equal; [Margin: g — 29. tert. (*Elements* III.29)] and hence the straight lines DA, EB, drawn from the poles D, E to the circumferences of circles AC, BF, are equal. [Margin: h — schol. 21. 1. huius (scholium on *Sphaerica* I.21)] Therefore circles AC, BF are equal. Finally, since the circles cut, at one and the same point B, the great circle AEB on which they have their poles, [Margin: i — 3. huius (*Sphaerica* II.3)] the circles AB, BF are tangent to one another at B. Therefore the great circle AB, being tangent in the sphere to circle AC, is tangent also to another circle BF, equal and parallel to AC. And so, if in a sphere a great circle is tangent to any of the circles, and so on. Which was to be demonstrated.

Diagram. A sphere shown as a circle with a vertical axis DE; two parallel circles (drawn as ellipses) and diagonal great-circle arcs crossing the interior.

- D (top): pole; upper end of axis DE
- A (upper left) / C (upper right): the upper parallel circle AC
- F (lower left) / B (lower right): the lower parallel circle BF
- E (bottom): pole; lower end of axis DE, with a center dot marked on the axis

COROLLARIUM

From this it is clear that the points of contact A, B are diametrically opposite. For it has been shown that ACB is a semicircle, and therefore that the straight line drawn from A to B is a diameter of the sphere, or of the great circle ACB, and so on.

THEOR. 7. PROPOS. 7. [Margin series: viij.]

If in a sphere there are two equal and parallel circles, a great circle that is tangent to one of them will be tangent to the other as well.

In the same figure let there be two equal and parallel circles AC, BF, and let the great circle AB be tangent to AC. I say that this same circle AB is tangent also to BF. For if AB were not tangent to BF, [Margin: a — 6. huius (*Sphaerica* II.6)] it would surely be tangent to another circle equal and parallel to AC. Then, since BF too is supposed equal and parallel to that same AC, there would be three circles in the sphere — namely AC, BF, and that other circle which AB touches — equal and parallel to one another. Which is absurd; [Margin: b — schol. 2. huius (scholium 2 of *Sphaerica* Book II)] for there are not more than two circles equal and parallel in a sphere. Therefore circle AB will be tangent to circle BF. And so, if in a sphere there are two equal and parallel circles, and so on. Which was to be shown.

SCHOLIUM

In another version the following theorem too is demonstrated. [Margin series: ix.]

Parallel circles in a sphere that some great circle is tangent to are equal to one another.

In this same figure let there be two parallel circles AC, BF, which the great circle AB touches at A, B. I say that circles AC, BF are equal to one another. Since the circles AC, BF are supposed parallel, [Margin: c — 1. huius (*Sphaerica* II.1)] they will be around the same poles, which let be D, E; [Margin: d — 20. 1. huius (*Sphaerica* I.20)] and through these and the poles of circle AB let the great circle AFB be described, [Margin: e — 4. huius (*Sphaerica* II.4)] which will pass through the contacts A, B. Now since great circles in a sphere cut one another in half, ADB will be a semicircle, and hence equal to the semicircle DBE. Therefore, when the common arc DB is removed, the arcs DA, EB remain equal; [Margin: f — 29. tert. (*Elements* III.29)] and hence also the straight lines DA, EB, drawn from the poles D, E to the circumferences of circles AC, BF, are equal. [Margin: g — schol. 21. 1. huius (scholium on *Sphaerica* I.21)] Therefore circles AC, BF will be equal. Which was the thing proposed.

THEOR. 8. PROPOS. 8. [Margin series: x.]

If in a sphere a great circle is oblique to some circle of the sphere, it will be tangent to two circles that are equal to one another and parallel to the aforesaid circle to which it is oblique.

In a sphere let the great circle AB be oblique to any circle CD. I say that circle AB is tangent to two circles that are equal to one another and parallel to CD itself. [Margin: a — 21. 1. huius (*Sphaerica* I.21)] Let E, F be the poles of circle CD, [Margin: b — 20. 1. huius (*Sphaerica* I.20)] and through these and the poles of circle AB let the great circle EAB be described, cutting AB at A and B. Then from pole E and with radius EA let a circle AG be described. And since circles AB, AG cut, at one and the same point A, the great circle EAB on which they have their poles, [Margin: c — 3. huius (*Sphaerica* II.3)] they are tangent to one another at A. Therefore the great circle AB, being tangent to circle AG, [Margin: d — 6. huius (*Sphaerica* II.6)] will be tangent to another circle equal and parallel to it, which let be BH. Now since the parallel circles AG, BH [Margin: e — 1. huius (*Sphaerica* II.1)] are around the same poles E, F — and E, F are also the poles of circle CD — the three circles AG, CD, BH will be around the same poles; [Margin: f — 2. huius (*Sphaerica* II.2)] and hence they will be parallel to one another. Therefore the great circle AB is tangent to two circles AG, BH, which are equal to one another and parallel to CD itself, to which it is oblique. And so, if in a sphere a great circle is oblique to some circle, and so on. Which was to be shown.

Diagram. A sphere shown as a circle with axis EF; a great circle AB drawn obliquely, the circle CD, and the two parallel circles AG and BH, with several arcs crossing the interior.

- E (top): pole; upper end of axis EF
- A (upper left): point where the oblique great circle meets circle AG
- G (upper right): point on circle AG
- C (left): point on circle CD
- D (right): point on circle CD
- H (lower left): point on circle BH
- B (lower right): point where the oblique great circle meets circle BH
- F (bottom): pole; lower end of axis EF

SCHOLIVM

Another theorem is added here in another recension, namely the following.

If in a sphere a great circle is tangent to some one of the circles on the spherical surface, it will be oblique to the other circles that it cuts, which are parallel to the one it touches.

In the same figure, let the great circle AB be tangent to circle AG, but cut circle CD, which is parallel to AG. I say that circle AB is oblique to circle CD. For the great

circle AB, being tangent to circle AG, does not pass through the poles of AG — since, if it were drawn through those poles, it would bisect AG [Margin: a — *Sphaerica* I.15] and not merely touch it. And so it does not pass through the poles of circle CD either, because the parallel circles AG and CD have the same poles [Margin: b — *Sphaerica* II.1]. Therefore the great circle AB will not cut circle CD at right angles — for otherwise it would pass through the poles of CD [Margin: c — *Sphaerica* I.13]. It is therefore oblique to circle CD, which is what was proposed.

Diagram. A sphere (large circle) carrying the tangent-and-parallel configuration of the tangency scholium: a great circle AB, a circle AG which it touches, and a parallel circle CD which it cuts.

- A (upper left, on the sphere): endpoint of the great circle AB / of circle AG
- E (top of the sphere): upper point
- G (upper right): second point of circle AG
- C (left, on the sphere): left endpoint of the cut circle CD
- D (right): right endpoint of circle CD
- H (lower left): point of the lower parallel circle
- B (lower right): the other endpoint of great circle AB
- F (bottom of the sphere): lowest point (pole)

THEOR. 9. PROPOS. 9.

[Margin: x ij]

If in a sphere two circles cut one another, a great circle drawn through their poles will bisect the segments of those circles.

In a sphere let two circles ABCD and EDFB cut one another at the points B and D, and through their poles let the great circle AFCE be described [Margin: a — *Sphaerica* I.20], cutting the said circles at the points A, C, E, F. I say that circle AFCE bisects the segments BAD, BCD, BED, BFD.

For since the great circle AFCE cuts the circles ABCD and EDFB in half and at right angles — because it is drawn through their poles [Margin: b — *Sphaerica* I.15] — the common sections AC and EF, which it makes with those circles, will be diameters of them, cutting one another at G. For the straight lines AC and EF will cut one another, since they lie in the same plane, that of circle AFCE; and the point F lies between the points A and C, and the point E lies between the same points. Let the straight lines BG and DG be joined. Then the three points B, G, D lie in the plane of each of the circles ABCD and EDFB, and therefore in their common

section; and their common section is a straight line [Margin: c — *Elements* XI.3]. Therefore BGD is a straight line.

And since circle AFCE has been shown to cut each of the circles ABCD and EDFB at right angles, each of them in turn is at right angles to circle AFCE; and so BD, their common section, will be perpendicular to that same circle [Margin: d — *Elements* XI.19 (printed "29")(?)]. The angles BGA, DGA, BGC, DGC will therefore be right angles, by the third definition of *Elements* XI. Since, then, the diameter AC passes through the centre of circle ABCD and cuts the straight line BD at right angles, it will bisect it [Margin: e — *Elements* III.3]. And so, since the sides AG, GB are equal to the sides AG, GD and contain equal angles, namely right angles [Margin: f — *Elements* I.4], the bases AB, AD, which subtend the arcs AB, AD, will be equal to one another [Margin: g — *Elements* III.28]; and the arcs AB, AD will accordingly be equal. In the same way we shall show that the arcs CB, CD are equal, and likewise the arcs EB, ED, and FB, FD. The circle AFCE therefore divides the segments BAD, BCD, BED, BFD in half. Hence, if in a sphere two circles cut one another, and so on. Which was to be demonstrated.

Diagram. A sphere in which two circles ABCD and EDFB intersect at B and D, with the great circle AFCE drawn through their poles; the diameters AC and EF meet at the interior point G.

- E (top): upper pole-point of the great circle AFCE
- C (upper right): intersection point
- D (upper left, interior): intersection of the two circles
- B (centre right): the other intersection of the two circles
- A (left): endpoint of the great circle
- G (centre, interior): where the diameters AC and EF cross
- F (bottom): lower point of the great circle AFCE

SCHOLIUM

Two other theorems are added here in another recension, namely these.

I.

[Margin: x iij]

If in a sphere circles cut one another, another circle that bisects their segments passes through their poles and is a great circle.

In the same figure let two circles ABCD and EDFB cut one another at the points B, D, and let some other circle AFCE bisect the segments BAD, BCD, BED, BFD. I say that circle AFCE passes through their poles and is a great circle. For since the arcs AD, AB are equal, and likewise CD, CB, the whole arcs ADC, ABC will be equal, and therefore semicircles; and in the same way EDF, EBF will be semicircles. The circle AFCE therefore bisects the circles ABCD and EDFB, and so its common sections with them, AC and EF, cutting one another at G, are the diameters of those circles. Now if the straight lines BG, DG are joined, then, since the three points B, G, D lie in the plane of each of the circles ABCD and EDFB, and hence in their common section — and their common section is a straight line [Margin: a — *Elements* XI.3] — the line BGD will be straight.

And since the subtending straight lines DA, DC are severally equal to the subtending straight lines BA, BC, on account of the equal arcs [Margin: b — *Elements* III.29], and they contain equal angles, namely right angles standing in semicircles [Margin: c — *Elements* III.31 (printed "21")(?)], the angles DAC, BAC will be equal [Margin: d — *Elements* I.4]. This may also be proved thus: since the sides DA, AC are equal to the sides BA, AC, and the base DC is equal to the base BC, the angles DAC, BAC will be equal [Margin: e — *Elements* I.8]. Again, since the sides AD, AG are equal to the sides AB, AG and contain equal angles, as has been shown, the angles AGD, AGB will be equal [Margin: f — *Elements* I.4], and therefore right angles. So BGD is perpendicular to the straight line AC. In the same way we shall show that this same line BGD is perpendicular to EF. Hence BGD will be perpendicular to the plane of circle AFCE, which is drawn through the straight lines AC and EF [Margin: g — *Elements* XI.4]; and consequently each of the planes of the circles ABCD and EDFB, drawn through the straight line BGD, will be at right angles to that same plane of circle AFCE [Margin: h — *Elements* XI.18]; and conversely circle AFCE will be at right angles to the circles ABCD and EDFB. And so circle AFCE cuts the circles ABCD and EDFB both in half and at right angles. It is therefore a great circle, and passes through their poles [Margin: i — Scholium to *Sphaerica* I.15]. Which is what was proposed.

II.

[Margin: xiv]

If in a sphere two circles cut one another, a great circle that bisects any two of their segments, yet has the arc lying between those segments unequal to a semicircle, passes through their poles and bisects the two remaining segments.

In a sphere let two circles ABCD and EBFD cut one another at the points B, D, and let the great circle AFCE bisect any two of their segments — namely BAD, BED — at the points A, E, while the arc AFCE, intercepted between the said segments, is not a semicircle. I say that circle AFCE passes through the poles of the circles ABCD and EBFD and bisects the remaining segments BCD, BFD. For if circle AFCE did not pass through their poles, let another great circle AGE be described, if possible, through their poles, which will bisect their segments [Margin: a — *Sphaerica* II.9] and so will pass through the points A, E. Then the great circles AFCE and AGE will bisect one another at A and E [Margin: b — *Sphaerica* I.11], and therefore AFCE will be a semicircle — which is contrary to the hypothesis. The circle AFCE therefore passes through the poles of the circles ABCD and EBFD, and so it will bisect all of their segments [Margin: c — *Sphaerica* II.9]. Which is what was proposed.

Diagram. Two overlapping circles ABCD (left) and EBFD (right), crossing at B (top) and D (bottom) in a lens-shaped region, with the horizontal great circle AFCE drawn through both.

- A (far left): endpoint of the great circle, on circle ABCD
- B (top, where the two circles cross): upper intersection
- F (left of centre, on the lens): point of the great circle
- C (right of centre, on the lens): point of the great circle
- E (far right): endpoint of the great circle, on circle EBFD
- G (centre of the lens): interior point
- D (bottom, where the two circles cross): lower intersection

THEOR. 10. PROPOS. 10.

[Margin: xv]

If there are parallel circles in a sphere, and through their poles great circles are described, then the arcs of the parallel circles intercepted between the great circles are similar, while the arcs of the great circles intercepted between the parallel circles are equal.

In a sphere let there be parallel circles ABCD and EFGH, whose pole is I — for parallel circles in a sphere are about the same poles [Margin: a — *Sphaerica* II.1]. Through I let great circles AEIGC and BFIHD be described in any manner. I say that the arcs of the parallels AB, EF are similar, and likewise BC, FG; also CD, GH; and DA, HE; and that the arcs of the great circles intercepted between the parallels, namely AE, BF, CG, DH, are equal.

For let the common sections of circle AIC with the parallels be the straight lines AC, EG, which will be parallel [Margin: b — *Elements* XI.16]; and let the common sections of circle BID with the same parallels be the straight lines BD, FH, which likewise will be parallel. And since the great circles AIC, BID, described through the poles of the parallels, cut the parallels in half [Margin: c — *Sphaerica* I.15], AC and BD will be diameters of circle ABCD, and the point L, where they intersect, its centre; likewise EG and FH will be diameters of circle EFGH, and the point K, where they intersect, its centre. Since, then, the straight lines EK, KF are parallel to the straight lines AL, LB and lie in different planes, the angles EKF, ALB, at the centres K, L, will be equal [Margin: d — *Elements* XI.10]. Hence the arcs AB, EF will be similar, by what we have shown in the scholium to *Elements* III.22. In the same way BC, FG and CD, GH, and also DA, HE, will be similar.

Again, since the straight lines dropped from the pole I to the points A, B, C, D are equal, by the definition of a pole, the arcs IA, IB, IC, ID will also be equal [Margin: e — *Elements* III.28]; and in the same way the arcs IE, IF, IG, IH will be equal. The remaining arcs AE, BF, CG, DH will therefore be equal to one another. Hence, if there are parallel circles in a sphere, and so on. Which was to be demonstrated.

Diagram. A sphere carrying two parallel circles ABCD and EFGH with common pole I, and two great circles AEIGC and BFIHD drawn through I; K and L are the centres of the two parallels.

- A (upper left): point of the outer parallel ABCD
- E (below A): point of the inner parallel EFGH
- H (upper right): point of the inner parallel
- D (right): point of the outer parallel ABCD
- I (upper centre): common pole of the parallels
- K (centre): centre of parallel EFGH
- L (just below K): centre of parallel ABCD
- F (lower left): point of parallel EFGH
- G (lower right): point of parallel EFGH
- B (bottom left): point of parallel ABCD
- C (bottom right): point of parallel ABCD

THEOR. 11. PROPOS. 11.

[Margin: xvj]

If upon the diameters of equal circles equal segments of circles stand at right angles, and from these there are taken equal arcs — each of them beginning at the extremity of its own segment, and being less than half the arc of the whole segment — and if from the points bounding the equal arcs equal straight lines are drawn to the arcs of the circles first set out, then the arcs of the circles first set out, intercepted between those straight lines and the extremities of the diameters, will be equal.

Upon the diameters AC, DF of the equal circles ABC, DEF let there stand, at right angles to those circles, the equal circular segments AGC, DHF; and let there be taken equal arcs AG, DH, so that the points G, H divide the segments AGC, DHF unequally. Finally, from G, H let there fall to the arcs of the circles ABC, DEF the equal straight lines GB, HE. I say that the arcs AB, DE are equal.

Let there be dropped from G, H the straight lines GI, Hk, perpendicular to the planes of the circles ABC, DEF [Margin: a — *Elements* XI.11], which will fall on the common sections AC, DF at the points I, k [Margin: b — *Elements* XI.38]. Taking also L, M as the centres of the circles ABC, DEF, let the straight lines LB, BI, AG and ME, Ek, DH be drawn; and first let the points I, k fall within the radii AL, DM. Since, then, the arcs AGC, DHF are equal, and likewise the arcs AG, DH, the arcs CG, FH will also be equal [Margin: c — *Elements* III.27]; and therefore the angles GAC, HDF, standing upon them, are equal.

Diagram. The first figure of Proposition 11: two equal circles set side by side. In the left circle ABC (diameter AC, centre L) the segment AGC stands on the diameter; in the right circle DEF (diameter DF, centre M) the segment DHF stands on the diameter. The feet I, k of the perpendiculars fall within the radii AL, DM.

- Left circle — A (left end of diameter AC), G (top of the segment), I (on AL, near L), L (centre), B (foot on the lower arc), C (right end of the diameter)
- Right circle — D (left end of diameter DF), H (top of the segment), K (on DM, near M), M (centre), E (foot on the lower arc), F (right end of the diameter)

And the angles AIG, DKH are also equal, since they are right angles by the third definition of *Elements* XI. And so the two triangles AIG, DKH have the two angles GAI, AIG equal to the two angles HDK, DKH. They have, moreover, the side AG equal to the side DH — on account of the equality of the arcs AG, DH [Margin: d — *Elements* III.29] — which subtends the equal angles I, K. Therefore the side AI will be equal to the side DK, and the side GI equal to the side HK [Margin: e — *Elements* I.26]. And since the angles GIB, HKE are right angles, by the third definition of *Elements* XI, the squares on GB, HE — which are equal to one

another, because the straight lines GB, HE are equal — will be equal to the squares on GI, IB and on HK, KE [Margin: f — *Elements* I.47]; and therefore, the equal squares on the equal straight lines GI, HK being taken away, the squares on the straight lines IB, KE will remain equal, and hence the straight lines IB, KE themselves are equal. And since AL, DM, the radii of the equal circles, are equal, while AI, DK have also been shown equal, the remainders IL, KM will be equal as well. Hence the sides IL, LB will be equal to the sides KM, ME; and the bases IB, KE have also been shown equal. Therefore the angles L, M at the centres will be equal [Margin: g — *Elements* I.8]; and consequently the arcs AB, DE will be equal [Margin: h — *Elements* III.26].

Next let the points I, K fall on the radii LA, MD produced to A and D — which indeed can happen when the segments AGC, DHF are greater than a semicircle — and let the same construction be made as before. We shall show, as before, that the angles GAC, HDF are equal [Margin: i — *Elements* III.27]; and therefore, since GAC together with GAI, and HDF together with HDK, are each equal to two right angles [Margin: k — *Elements* I.13], GAI and HDK will also be equal. Since, then, the angles I, K are also equal, namely right angles, and the sides GA, HD are equal, on account of the equal arcs AG, DH [Margin: l — *Elements* III.29], the perpendiculars GI, IA will be equal, as before, to the perpendiculars HK, KD [Margin: m — *Elements* I.26]; and therefore the whole lines IL, KM will be equal to one another. Then, as before, we shall show that the straight line IB is equal to the straight line KE [Margin: n — *Elements* I.47], and the angle L equal to the angle M [Margin: o — *Elements* I.8], and finally the arc AB equal to the arc DE [Margin: p — *Elements* III.26].

Diagram. The second figure of Proposition 11: two equal circles side by side, with the perpendicular feet I, k falling on the radii LA, MD produced beyond A and D. Left circle ABC (centre L, diameter AC, segment AGC on top); right circle DEF (centre M, diameter DF, segment DHF on top).

- Left circle — G (top of segment), I (on LA produced, near A), A (left end of diameter), L (centre), C (right end of diameter), B (foot on lower arc)
- Right circle — H (top of segment), K (on MD produced, near D), D (left end of diameter), M (centre), F (right end of diameter), E (foot on lower arc)

Thirdly, let the perpendiculars dropped from G, H fall, in the planes of the circles ABC, DEF, on the points A, D — which likewise can happen when the segments AGC, DHF are greater than a semicircle. Then, the straight lines AB, DE being drawn, the angles GAB, HDE will be right angles, by the third definition of *Elements* XI. Hence, as before, the squares on the straight lines GA, AB will be

equal to the squares on the straight lines HD, DE [Margin: q — *Elements* I.47]; but the squares on GA, HD are equal, because the straight lines GA, HD are equal, on account of the equal arcs AG, DH [Margin: r — *Elements* III.29]. Therefore the squares on AB, DE will also be equal, and consequently the straight lines AB, DE will be equal; and so the arcs AB, DE will be equal [Margin: s — *Elements* III.28]. Which is what was proposed. Hence, if upon the diameters of equal circles equal circular segments stand at right angles, and so on. Which was to be demonstrated.

Diagram. The third figure of Proposition 11: two equal circles side by side, with the perpendiculars from G, H falling exactly on the points A, D. Left circle ABC (centre L, diameter AC); right circle DEF (centre M, diameter DF).

- Left circle — G (top of segment), A (left end of diameter, foot of the perpendicular), L (centre), C (right end of diameter), B (foot on lower arc)
- Right circle — H (top of segment), D (left end of diameter, foot of the perpendicular), M (centre), F (right end of diameter), E (foot on lower arc)

THEOR. 12. PROPOS. 12.

[Margin: xvj[?] — expected xvij]

If upon the diameters of equal circles equal circular segments are set up, and from these segments equal arcs are cut off toward the extremities of the segments, less than half of those segments; and if from the circles themselves equal arcs are taken toward the same parts, namely toward the extremities of the diameters — then the straight lines drawn from the points on the arcs of the segments to the points on the arcs of the circles will be equal.

Let the figures of the preceding proposition be repeated, with the same constructions, and let the arcs AB, DE be set equal. I say that the straight lines GB, HE are also equal. For since, as was demonstrated in the preceding proposition, the straight lines AI, IG are equal to the straight lines DK, KH, the remainders IL, KM, taken from the radii AL, DM, will also be equal — as in the first figure, where the points I, k fall within the radii AL, DM — or else the whole lines IL, kM will be equal, as in the second figure, where the points I, k fall on the radii AL, DM produced to A and D. Since, then, IL, LB are equal to the straight lines kM, ME, and they contain equal angles at L, M, on account of the equality of the arcs AB, DE [Margin: a — *Elements* III.27], the bases IB, kE will also be equal [Margin: b — *Elements* I.4]. Therefore, since the sides GI, IB are equal to the sides Hk, kE and

contain equal angles GIB, HkE, namely right angles, by the third definition of *Elements* XI, the bases GB, HE will also be equal [Margin: c — *Elements* I.4]. Which is what was proposed.

The same is more easily concluded if the perpendiculars dropped from G, H into the planes of the circles ABC, DEF fall on the points A, D, as in the third figure. For since the straight lines GA, AB are equal to the straight lines HD, DE — on account of the equal arcs AG, DH and AB, DE [Margin: d — *Elements* III.29] — and they contain equal angles, namely right angles, by the third definition of *Elements* XI, the bases GB, HE will be equal [Margin: e — *Elements* I.4]. Therefore, if upon the diameters of equal circles equal segments, and so on. Which was to be shown.

Diagram. The figure of Proposition 12 (repeating the preceding proposition's first figure): two equal circles side by side. Left circle ABC (diameter AC, centre L, segment AGC, feet I within radius AL); right circle DEF (diameter DF, centre M, segment DHF, feet K within radius DM).

- Left circle — A (left end of diameter), G (top of segment), I (on radius AL, near L), L (centre), C (right end of diameter), B (foot on lower arc)
- Right circle — D (left end of diameter), H (top of segment), K (on radius DM, near M), M (centre), F (right end of diameter), E (foot on lower arc)

THEOR. 13. PROPOS. 13.

[Margin: xviiij.]

If in a sphere there are parallel circles, and great circles are drawn which touch one of the parallels but cut the rest, then the circumferences of the parallels intercepted between those semicircles of the great circles that do not meet will be similar; and the circumferences of the great circles intercepted between any two of the parallels whatever will be equal.

Let there be in the sphere parallel circles AB, CDE, FGH, which will have the same pole, namely I. [Margin: a — 1. huius (*Sphaerica* II.1)] Let the great circles AFK, BHK touch the parallel AB at the points A, B, and cut the rest at the points F, C, L, M and H, E, D, G; and let them cut each other at K, N, so that KMN, NFK, KGN, NHK are semicircles. For great circles bisect one another. [Margin: b — 11. 1. huius (*Sphaerica* I.11)] Let arc KO also be taken equal to arc NA, and arc KP equal to arc NB, so that AMO, OFA and BGP, PHB are likewise semicircles. Then the semicircles AMO, BHP will not meet, since they do not cut each other. (These semicircles are cut off by the circles AIRO, BITP, as appears in the second figure. In the first figure the circles AI, BI, produced through R and T, are to be

understood as passing through O, P, so as to cut off the same semicircles.) In the same way the semicircles BGP, AFO will not meet.

I say that the arcs of the parallels AB, LE, MH intercepted between the non-meeting semicircles AMO, BHP are similar; and likewise that the arcs AB, CD, FG intercepted between the non-concurrent semicircles BGP, AFO are similar; that the arcs of the great circles AC, AL, BD, BE are equal, and likewise the arcs CF, LM, DG, EH — of which the former lie between the parallels AB, CDE, the latter between the parallels CDE, FGH; and in the same way that the arcs AF, AM, BG, BH lying between the parallels AB, FGH are equal.

For through the pole I and the points of contact A, B let the great circles QAIR, SBIT be drawn, cutting the parallels at Q, S, V, X. [Margin: c — 20. 1. hui. (*Sphaerica* I.20)] These great circles will also pass through the poles of the circles AFK, BHK; [Margin: d — 5. huius (*Sphaerica* II.5)] and therefore they will bisect the segments CAL, DBE, CVL, DXE, as well as the segments FAM, GBH, FQM, GSH. [Margin: e — 9. huius (*Sphaerica* II.9)] Moreover the same circles will cut at right angles the parallels AB, CDE, FGH and the great circles AFK, BHK. [Margin: f — 15. 1. huius (*Sphaerica* I.15)]

Since, then, upon the diameters of the equal circles AFK, BHK there stand at right angles equal segments of circles — namely the semicircles beginning at the points A, B and passing through I until they again cut the circles AFK, BHK, namely at the points O, P, as appears in the second figure — the arcs AI, BI are equal, [Margin: g — 28. tert. (*Elements* III.28)] because by the definition of a pole the straight lines IA, IB are equal; and these arcs are indeed less than the half-parts of the semicircles. (For since [the arcs AI, BI] are halves of the arcs AIR, BIT — because, by the definition of a pole, the straight lines from I to the points A, B, R, T are equal, [Margin: h — 28. tert. (*Elements* III.28)] and so the arcs too are equal; but the arcs AIR, BIT are less than a semicircle, because the semicircles extend from A and B through I as far as the circles AFK, BHK, which in the second figure are ARO, BTP — the arcs AI, BI will be less than the half-parts of those semicircles.) The straight lines IC, IE are also equal, by the definition of a pole, [Margin: i — 11. huius (*Sphaerica* II.11)] so that the arcs AC, BE will be equal. But AC is equal to AL, and BE to BD, [Margin: k — 9. huius (*Sphaerica* II.9)] because the arcs CAL, DBE are bisected, as has been demonstrated. Therefore the four arcs AC, AL, BE, BD are equal. In the same way we shall show that the four arcs AF, AM, BH, BG and EH, DG are equal, each of which is intercepted between two parallels. This is what was proposed to be demonstrated in the second place.

And since the whole arcs CAL, DBE are equal, because their halves are equal, as has been demonstrated, the subtending chords CL, DE will also be equal, [Margin: l — 19. tertij (*Elements* III.19) — numeral uncertain; possibly III.29] which chords are likewise subtended by the arcs CVL, DXE; and therefore the arcs of the parallels CVL, DXE will also be equal. [Margin: m — 18. tert. (*Elements* III.18) — numeral uncertain; possibly III.28] Since, then, they are bisected at V, X, as has been said, their halves will be equal, namely the four arcs CV, VL, DX, XE. [Margin: n — 9. huius (*Sphaerica* II.9)] If therefore to the equal arcs CV, DX the common arc VD be added — or, in the second figure, taken away — the arcs CD, VX will be equal. But arc VX is similar to arc AB. [Margin: o — 10. huius (*Sphaerica* II.10)] Therefore CD too will be similar to the same AB. In just the same way we shall show that FG is similar to AB, and likewise that the arcs EL, HM are similar to the same arc AB. This is what was proposed to be demonstrated in the first place. If therefore in a sphere there are parallel circles, etc. Which was to be shown.

Diagram. The first figure ("prima figura") for Proposition 13: three large overlapping circles representing the parallels (AB, CDE, FGH) and the two great circles (AFK, BHK) with the auxiliary great circles through the pole. The labelled points read off the scan under magnification (upper region downward):

- T, R (upper centre): points where the auxiliary great circles cross near the top
- I (centre-top): common pole of the parallels
- F (far left), C, A, B, E, H (far right): the intersection points along the parallels
- V, X (below centre): points where the great circles through the pole cut the parallels
- D, L (centre, close together): further intersection points
- Q (left), G, M, S (right): lower intersection points
- P (lower left), O (lower right): the points where the produced circles pass
- K (bottom): the mutual intersection of the two great circles

Diagram. The second figure ("secunda figura") for Proposition 13, marked with the numeral 2 at its foot: a single sphere-outline crossed by the great circles and their semicircles, showing the same construction with the semicircles cut off by the circles AIRO, BITP. Labelled points read off the scan under magnification:

- K (top): mutual intersection of the great circles
- P (upper left), O (upper right)
- F (left), H (right)

- C, T, R (centre), E (right)
- I (centre): pole
- Q (left), A, B, M (right of centre)
- D, N (lower centre), Z [?], L (lower right)
- S (lower right); the figure-number 2 at lower left

SCHOLIVM.

The non-concurrent semicircles must begin at the points of contact A, B — such as AMO, BHP. Therefore, since any great circle has two semicircles between the points of contact of two opposite parallels, one must not take those semicircles of the two circles that cut each other between the points of contact of the two parallels; rather one must take the one verging toward that point of section and the other verging to the opposite side, so that the convex side of the one faces the concave side of the other, and con—

—versely, as appears in the aforesaid two semicircles. And so, if two semicircles AMO, DKY be taken (arc KY having been taken equal to DN itself), non-concurrent, as is evident, the arcs DL, GM will not be similar. Otherwise two great circles drawn through the pole I and the points D, I [?] would pass through the points G, M — since by [*Sphaerica* II.]¹⁰ they intercept similar arcs. But this cannot happen. For DG, LM would be semicircles, since by [*Sphaerica* I.]¹¹ great circles bisect one another.

PROBL. 1. PROPOS. 14.

[Margin: xvij.]

Given a circle in a sphere which is smaller than a great circle, and given some point on its circumference, to draw through that point a great circle that touches the given circle.

Let the given non-great circle in the sphere be AB, whose pole is C, and let it be required to draw through A — the given point on its circumference — a great circle that touches the circle AB. Through the pole C and the point A let the great circle CADEB be drawn, [Margin: a — 20. 1. hui. (*Sphaerica* I.20)] and in it let the quadrant AD be taken; and from the pole D, with radius DA, let the circle AE be drawn, [Margin: b — 17. 1. hu. (*Sphaerica* I.17)] which will be a great circle, because the chord DA subtending it is the side of the square inscribed in a great circle. I say that the great circle AE touches the circle AB at A. For since the two circles AB, AE cut the same circle CAD — which passes through their poles — at

the same point A, [Margin: c — 3. huius (*Sphaerica* II.3)] they touch one another at the point A. Therefore, given a circle in a sphere, etc. Which was to be done.

Diagram. The figure for Proposition 14: a single circle (the great circle CADEB) with two chords drawn inside it, illustrating the tangency of the great circle AE to the given circle AB. Labelled points:

- C (top): pole of the given circle AB
- A (upper left), B (upper right): endpoints of the given circle's diameter, A being the given point
- D (lower left), E (lower right): D the pole with radius DA, E on the great circle AE
- The chord A–E and the chord D–B are drawn across the figure; a small arc C sits at the top.

PROBL. 2. PROOS. 15.

[Margin: xix.]

Given a circle in a sphere which is smaller than a great circle, and given some point on the surface of the sphere lying between the given circle and another equal and parallel to it, to draw through that given point a great circle that touches the given circle, which is smaller than a great circle.

Let the given non-great circle in the sphere be AB, and let CD be equal and parallel to it, and let the given point be G, between the two circles AB, CD; and let it be required to draw through G a great circle that touches the circle AB. Let E, F be the poles of the parallels AB, CD [Margin: a — 1. huius (*Sphaerica* II.1)] (for parallels have the same poles), and through E, G let the great circle EAC be drawn, [Margin: b — 20. 1. hui. (*Sphaerica* I.20)] which will pass through the other pole F, by the corollary of the scholium of *Sphaerica* I.10. In it let the quadrant BH be taken; and the point H will fall either above D, or at D, or below D. Whichever of these happens, we shall carry out the matter thus.

From the pole E with radius EH, or from the pole F with radius FH, let the circle HI be drawn, [Margin: c — 2. huius (*Sphaerica* II.2)] which will be parallel to AB, CD, and will lie either above CD, or will be the same as CD, or will lie below CD, according as the point H was placed above D, at D, or below D. Again let the quadrant GK be taken, and the point K will be beyond H, since GH is less than a quadrant. Then from the pole G with radius GK let the circle KL be drawn, [Margin: d — 17. 1. hui. (*Sphaerica* I.17)] which will be a great circle, because the

chord subtending the quadrant GK is equal to the side of the square inscribed in a great circle. And let KL cut the circle HI at L [Margin: e — 20. 1. hui. (*Sphaerica* I.20)] (for it will necessarily cut it, since the point K is below H and does not reach I. For since the parallels AB, CD are equal, [Margin: f — Schol. 21. huius (Scholium to *Sphaerica* II.21) — numeral uncertain] the chords EA, FD will be equal, [Margin: g — 28. tertij (*Elements* III.28)] and therefore the arcs AE, DF will be equal. So, adding the common arc AF, the arcs EAF, AFD between the poles E, F will be equal; and AFD will also be a semicircle. But AI is a quadrant, [Margin: h — 10. huius (*Sphaerica* II.10)] since it is equal to the quadrant PH [?]. Therefore ID too will be a quadrant, and consequently IG greater than a quadrant. Hence, when the quadrant GK is taken, the point K will indeed fall below H, but will not reach I. From which it follows that the circle HI is cut by the circle KL.)

And through L, F let the great circle FL be drawn, which will pass through the other pole E, by the corollary of the scholium of *Sphaerica* I.10. And let this circle FLE cut the circle AB at M. [Margin: i — 10. huius (*Sphaerica* II.10)] Then the arcs ML, BH — of the great circles that pass through the poles E, F of the parallels, intercepted between the parallels AB, HI — will be equal; and by the construction LM will also be a quadrant. Then from the pole L with radius LM let the circle MN be drawn, [Margin: k — 17. 1. hui. (*Sphaerica* I.17)] which will be a great circle, because the chord subtending the quadrant LM is equal to the side of the square inscribed in a great circle. And since the great circle KL passes through L, the pole of the great circle NM, [Margin: l — Schol. 15. huius (Scholium to *Sphaerica* II.15)] conversely the great circle NM will pass through G, the pole of the circle KL; and thus the great circle NM passes through the given point G. I now say that the circles AB, GN cut the great circle EF — in which they have their poles — at the same point M; [Margin: m — 3. huius (*Sphaerica* II.3)] therefore they touch one another at M. So there has been drawn through G a great circle GN touching the circle AB at M. Therefore, given a circle in a sphere, etc. Which was to be done.

Diagram. For Proposition 15, a row of three sphere-outline figures illustrating the three cases (the point H falling above D, at D, or below D). Each sphere carries the same lettering; the labelled points read off the scan under magnification are:

- E (top): pole
- A (upper left), B (upper right)
- M (centre): intersection point
- G, N (upper region, near left)
- L (centre-low), H (right of L): the constructed points
- C (lower left), D (lower right)

- I (lower left, inside): quadrant point
- F (bottom), K (bottom right)

Diagram. The continuation of the Proposition 15 construction: again a row of three sphere-outline figures for the three cases, repeated at the head of the page for the scholium. Labelled points read off the scan under magnification:

- E (top): pole
- A (upper left), B (upper right)
- M (centre): intersection point
- G, N (near left of centre)
- L (centre-low), H (right of L)
- C (lower left), D (lower right)
- I (lower centre, inside)
- F (bottom), K (bottom right)

[Margin: q — 3. huius (*Sphaerica* II.3)]

(Continuing the scholium.) — [the circle drawn] will cut HI at [L?] a point, which again will be the pole of the tangent circle, as before. But if the given point G is the same as D, the pole of the tangent circle will be in the middle of the arc DCA, since this arc is a semicircle. And the circle drawn from that pole will touch AB at A, and CD at D, as is evident: because, namely, this great circle and the parallels AB, CD cut, at the points A, D, the circumference of the great circle ACDB, in which they have their poles.

And since, just as L has been shown to be the pole of the great circle GN that touches the circle AB, so too it can be shown that the other point — at which the great circle KL cuts the circle HI on the other side — is the pole of some other great circle which passes through G and touches the circle AB at another point: it is evident that through a point given in a sphere between two equal and parallel circles, two great circles can be drawn which touch the circle AB at two points.

THEOR. 14. PROPOS. 16.

[Margin: xx.]

Great circles which cut off similar circumferences of parallel circles in a sphere either pass through the poles of the parallels, or touch one and the same parallel.

In the sphere let the great circles ABC, DBE cut off from the parallels ADC, FG similar circumferences AD, FG. I say that the great circles ABC, DBE either pass through the poles of the parallels ADC, FG, or touch one and the same parallel. For either one of them, namely ABC, passes through the poles of the parallels — and then we shall show that the other passes through them too; or it does not pass through the poles of the parallels, but nevertheless touches one of them — and then we shall demonstrate that the other touches the same one; or, finally, it neither goes through the poles of the parallels nor touches one of them — and on this supposition we shall conclude that the given great circles touch some other parallel smaller than the given parallels.

First, then, let ABC pass through the poles of the parallels. I say that DBE too passes through them — that is, that the point B, at which the great circles ABC, DBE cut each other, is the pole of the parallels ADC, FG. For if B is not their pole, let H be their pole. And since the circle ABC is supposed to pass through their poles, H will be on the circumference of ABC. Through H, G let the great circle HG be drawn, cutting ADC at I. [Margin: a — 20. 1. hui. (*Sphaerica* I.20)] Then the arcs AI, FG will be similar, since they are intercepted between the great circles AH, HI drawn through the pole H. [Margin: b — 10. huius (*Sphaerica* II.10)] But the arc AD is also supposed similar to the arc FG. Therefore the arcs AI, AD are similar; and hence, since they are of the same circle, they will be equal to one another — the whole and the part. Which is absurd. Therefore no point other than B will be the pole of the parallels, if one of the circles ABC, DBE — namely ABC — is drawn through their poles. Therefore each great circle ABC, DBE passes through the pole B of the parallels, if one of them passes through it.

Diagram. The figure for the first case of Proposition 16: two concentric circles (the parallels ADC and FG) crossed by the two great circles ABC, DBE and the auxiliary great circle HG. Labelled points read off the scan under magnification:

- A (upper left), F (near A): on the outer parallel and the inner circle
- H, B (centre): B the intersection of the great circles, H the assumed pole
- G (below centre): on the inner parallel
- E (right): endpoint of a great circle
- D (lower left), I (below D): intersection points
- C (lower right): on the outer parallel

But now let two great circles ABC, DEF again cut off from the parallels ADC, BE similar circumferences AD, BE, and let neither of them pass through the poles of the parallels, but let one — namely ABC — touch one of them, say BE, at B. I say

that the circle DEF too touches the same BE at E. For if it does not touch it but cuts it, [Margin: c — 14. huius (*Sphaerica* II.14)] let a great circle GEH be drawn through E, the given point on the parallel BE, touching the parallel BE at E; and there will be semicircles, of which one is drawn from E through G, and the other passes from B through A, not meeting — as is established from the figure of *Sphaerica* II.13 and from what is demonstrated there. [Margin: d — 13. huius (*Sphaerica* II.13)] Therefore the arcs BE, AG will be similar; but BE, AD are also supposed similar. Therefore AG, AD are similar to one another; and hence, since they are of the same circle, they will be equal to one another — the whole and the part. Which is absurd. Therefore no other great circle drawn through E, besides DEF, touches the parallel BE at E, if ABC touches the same at B. Therefore, if ABC touches BE, DEF too will touch the same BE.

Diagram. The figure for the second case of Proposition 16: two concentric circles (the parallels ADC and BE) with the great circles ABC, DEF and the auxiliary great circle GEH tangent at E. Labelled points read off the scan under magnification:

- A (upper left): on the outer parallel
- D (left), G (below D): intersection points
- B (centre), E (right of B): B the point of tangency, E the point on the inner parallel
- F (lower right), H (right of F)
- C (bottom): on the outer parallel

Finally, let the great circles ABC, DEF cut off from the parallels ADC, GH [similar circumferences AD, GH]; and let neither of them be drawn through the poles of the parallels, nor touch one of them. I say that the great circles ABC, DEF touch some other parallel smaller than ADC, GH themselves. For since the great circle ABC neither passes through the poles of the parallels nor touches one of them, the great circle ABC will be oblique to each of the parallels ADC, GH. For if it were perpendicular, [Margin: e — 13. 1. hui. (*Sphaerica* I.13)] it would pass through their poles, which is not supposed. [Margin: f — 8. huius (*Sphaerica* II.8)] Therefore ABC will touch two circles equal to one another and parallel to both ADC, GH. Let it then touch the parallel BE, which will be smaller than each of ADC, GH (since ABC cuts them); and thus also the other, equal to it and parallel, will be smaller than each of ADC, GH; and consequently the parallels ADC, GH will lie between those two which the circle ABC touches. I say that DEF too touches the same BE. For if it does not touch it, [Margin: g — 15. huius (*Sphaerica* II.15)] let a great circle KH be drawn through the point H — which lies between the circle BE and the one equal and parallel to it, as we have shown — touching

BE at I; and there will be semicircles, of which one passes from I through H, the other from B through G, not meeting, as is established from the figure of *Sphaerica* II.13 and from what is demonstrated there. [Margin: h — 13. huius (*Sphaerica* II.13)] Therefore the arcs AK, GH will be similar; but AD, GH are also supposed similar. Therefore AK, AD are similar; and hence, since they are of the same circle, they will be equal to one another —

Diagram. The figure for the third case of Proposition 16: three concentric circles (the parallels ADC, BE, and GH) with the great circles ABC, DEF and the auxiliary great circle KH tangent at I. Labelled points read off the scan under magnification:

- A (upper left): on the outermost parallel
- G (below A): intersection point
- B, I, E (centre, left to right): B and I near the tangent point, E on the middle parallel
- D (lower left), H (below D), K (below D): intersection points
- F (right): endpoint of a great circle
- C (bottom): on the outermost parallel

they would be equal — the whole and the part — which is absurd. Therefore no other great circle drawn through H, apart from DEF, touches the parallel BE, provided ABC touches that same parallel at B. And so, if ABC touches circle BE, then DEF too will touch the same circle BE. Hence great circles that cut off similar arcs, and so on. Which was to be shown.

SCHOLIVM

It is moreover evident that the great circles ABC and DEF touch the same parallel BE in such a way that their semicircles, proceeding from the points of contact through similar arcs, do not meet. Otherwise the arcs cut off would not be similar, as is clear from Proposition 13 of this book.

THEOR. 15. PROPOS. 17.

[Margin: xxj.]

In a sphere, parallel circles between which and the greatest of the parallels equal arcs of great circles are intercepted are equal to one another; but those between which and the greatest of the parallels greater arcs of great circles are intercepted are smaller.

Let AB, CD, EF be parallel circles in a sphere, and let CD be the greatest of the parallels. Between the circle CD and each of the parallels AB and EF let there be intercepted equal arcs AC and CE of some great circle ACEFDB. I say that the parallels AB and EF are equal.

For let the common sections of the parallel planes and of the circle ACEFDB be the straight lines AB, CD, EF, [Margin: a — 16. undecimi (*Elements* XI.16)] which will be parallel to one another. First let the great circle ACE, FDB pass through the poles of the parallels. Once this is set up, the circle ACEFDB will cut the parallels AB, CD, EF in half and at right angles, [Margin: b — 15. primi huius (*Sphaerica* I.15)] and so AB, CD, EF will be diameters of the parallels. Now since the arcs AC and BD are equal, and likewise the arcs CE and DF, [Margin: c — 10. huius (*Sphaerica* II.10)] and since AC is assumed equal to CE, the arcs AC and BD together will be equal to CE and DF together. But the semicircles CABD and CEFD are equal, [Margin: d — 11. primi huius (*Sphaerica* I.11)] because the great circles CD and ACEFDB bisect each other. Therefore the remaining arcs AB and EF will be equal; [Margin: e — 29. tertij (*Elements* III.29)] and consequently the straight lines AB and EF — that is, the diameters of the circles AB and EF — are equal as well. Therefore the circles AB and EF are equal.

Diagram. A sphere shown in outline with three parallel chords drawn horizontally; each pair of endpoints is joined by lens-shaped (vesica) arcs representing the arcs of great circles between the parallels. This illustrates the first (through-the-poles) case of Proposition 17.

- A (upper left): endpoint of the upper parallel AB
- B (upper right): endpoint of the upper parallel AB
- C (middle left): endpoint of the greatest parallel CD
- D (middle right): endpoint of the greatest parallel CD
- E (lower left): endpoint of the lower parallel EF
- F (lower right): endpoint of the lower parallel EF

Now suppose the arc AC is taken greater than the arc CE. I say that the circle AB is smaller than the circle EF. For, with the same construction and demonstration, [Margin: f — 10. huius (*Sphaerica* II.10)] the arcs AC and BD will be equal as before, and likewise CE and DF. Since, then, AC is assumed greater than CE, the two arcs AC and BD together will be greater than the two arcs CE and DF together. Therefore the remainder AB, out of the semicircle CABD, will be smaller than the remainder EF, out of the semicircle CEFD; and consequently the straight line AB — that is, the diameter of circle AB — will be smaller than the straight line EF,

that is, than the diameter of circle EF, as we demonstrated in the scholium to Proposition 29 of Book 3 of Euclid, since the arcs AB and EF are less than a semicircle. Hence the circle AB will be smaller than the circle EF. Which was proposed.

But now let the great circle ACEFDB not pass through the poles of the parallels AB, CD, EF, and again let the arcs AC and CE be equal. I say that the circles AB and EF are still equal. For let G and H be the poles of the parallels AB, CD, EF, [Margin: g — 20. primi huius (*Sphaerica* I.20)] and through G, H and through the poles of the great circle ACEFDB let a great circle GIHK be described, [Margin: h — 15. primi huius (*Sphaerica* I.15)] which will cut the circle ACEFDB at two points, as at I and K, at right angles. Now since the great circle GIHK passes through the poles of the greatest circles ACEFDB and CD by construction, [Margin: i — Schol. 15. primi huius (scholium to *Sphaerica* I.15)] these circles will in turn pass through its poles. Therefore the points C and D, where these two circles intersect, will be the poles of the circle GIHK — otherwise neither of the circles ACEFD and CD would pass through the poles of the circle GIHK. Hence the drawn straight lines CI and CK will be equal, by the definition of pole, [Margin: k — 28. tertij (*Elements* III.28)] and consequently the arcs CI and CK will be equal to one another. But the arcs AC and CE are also equal, by hypothesis. Therefore the remaining arcs AI and EK will likewise be equal. Again, since the semicircle IGK is equal to the semicircle GKH [Margin: l — 11. primi huius (*Sphaerica* I.11)] — for the circles ACEFDB and GIHK bisect each other, and accordingly IGK is a semicircle, because G and H are the poles of the parallels — take away the common arc GK, and the remaining arcs GI and HK will be equal. Therefore, on the diameter of the circle ICKD, the equal segments of circles IGK and KHI, [Margin: m — 11. primi huius (*Sphaerica* I.11)] which are semicircles as we have shown, stand at right angles; and the arcs IG and KH are equal, and are not the halves of the segments, that is, quadrants, since G and H are not the poles of the circle ICKD. Likewise the arcs IA and KE are equal, as has been demonstrated; [Margin: n — 12. huius (*Sphaerica* II.12)] so the dropped straight lines GA and HE will be equal. [Margin: o — Schol. 26. primi huius (scholium to *Sphaerica* I.26)] Hence the circles AB and EF will be equal to one another.

Diagram. A sphere shown with an oblique great circle GIHK crossing a set of parallels, illustrating the second (oblique) case of Proposition 17.

- I (upper left): intersection of the oblique great circle with a parallel
- G (top): pole of the parallels
- B (upper center): point on the parallel near the top

- A (left of center): endpoint on the upper parallel
- L (center left): point on the oblique circle
- D (center): intersection point
- C (below D): intersection point / pole of GIHK
- F (right of center): endpoint on a parallel
- E (lower center): point on the middle parallel [?]
- H (bottom): pole of the parallels
- K (bottom right): intersection of the oblique great circle with a parallel

Now suppose the arc AC is taken greater than the arc CE. I say that the circle AB is smaller than the circle EF. For, taking an arc CL equal to the arc CE, it will follow — as was just demonstrated — that the parallel described through L is equal to the parallel EF; [Margin: p — 6. primi huius (*Sphaerica* I.6)] but the parallel AB is smaller than the parallel described through L, since AB lies farther from the greatest of the parallels, and so farther from the center of the sphere. Therefore the parallel AB is also smaller than EF. Which was proposed. So in a sphere, parallel circles between which and the greatest of the parallels, and so on. Which was to be demonstrated.

THEOR. 16. PROPOS. 18.

[Margin: xxij.]

In a sphere, the arcs of great circles intercepted between the greatest of the parallels and two other equal and parallel circles are equal; but those intercepted between the greater parallel and the greatest are smaller.

Diagram. A sphere in outline with three horizontal parallels — AB near the top, EF across the middle, CD near the bottom — illustrating Proposition 18.

- A (upper left): endpoint of the parallel AB
- B (upper right): endpoint of the parallel AB
- E (middle left): endpoint of the greatest parallel EF
- F (middle right): endpoint of the greatest parallel EF
- C (lower left): endpoint of the parallel CD
- D (lower right): endpoint of the parallel CD

In a sphere let there be two equal parallels AB and CD, and let EF be the greatest of the parallels; and let another great circle ACDB cut all these parallels. I say that the arcs AE, EC, and likewise BF, FD, are equal. For if they are not equal, let AE be the greater. [Margin: a — 17. huius (*Sphaerica* II.17)] Then the circle AB will be

smaller than the circle CD, which is contrary to the hypothesis. Therefore the arcs AE, EC, and likewise BF, FD, are equal.

But suppose the circle AB is taken greater than the circle CD. I say that the arc AE is smaller than the arc EC. For if it is not smaller, it will be either equal or greater. If equal, [Margin: b — 17. huius (*Sphaerica* II.17)] the circles AB and CD will be equal; if greater, [Margin: c — 17. huius (*Sphaerica* II.17)] the circle AB will be smaller than the circle CD — each of which is contrary to the hypothesis. Therefore the arc AE is smaller than EC. Accordingly, in a sphere the arcs of great circles intercepted, and so on. Which was to be shown.

THEOR. 17. PROPOS. 19.

[Margin: xxij.]

If in a sphere a great circle cuts several parallel circles drawn on the spherical surface — but not through the poles — it will cut them into unequal parts, except the greatest of the parallels. As for the segments of the parallels intercepted in one of the hemispheres: those lying between the greatest of the parallels and the visible pole are greater than a semicircle; the rest, lying between the greatest of the parallels and the hidden pole, are less than a semicircle. Finally, the alternate segments of equal and parallel circles are equal to one another.

In a sphere let the great circle ABCD cut the parallels EF, GH, IK in L, M; B, D; and O, P — not through the poles, which are Q and R; and let GH be the greatest of the parallels, Q the visible pole, and R the hidden pole, in the hemisphere that stands above the great circle ABCD and inclines toward F. I say that the circle ABCD does not cut the parallels in half, except the greatest, GH; [Margin: a — 11. primi huius (*Sphaerica* I.11)] for this one it does bisect. But the segment LFM, between the greatest parallel and the visible pole Q, is greater than a semicircle, and OKP is smaller. And finally, if the parallels EF and IK are equal, the alternate segments LFM and OIP are equal. [Margin: b — 20. primi huius (*Sphaerica* I.20)] For through the pole Q and the point B let the great circle QBRD be described; it will pass through the other pole R by the corollary to the scholium of Proposition 10 of Book 1 of this work, and also through the point D, [Margin: c — 11. primi huius (*Sphaerica* I.11)] since it bisects both the circle GBHD and the circle ABCD; and these circles are bisected in B and D. From this it follows that the circle QBRD cuts the parallel EF above the circle ABCD, but the parallel IK below it — as at the points S, T and V, X. [Margin: d — 15. primi huius (*Sphaerica* I.15)] Now since the circle QBRD bisects the parallels EF and IK, SFT and VKX will be semicircles; and

consequently the arc LFM will be greater than a semicircle, and OKP smaller than a semicircle. Which was proposed.

Diagram. A crowded sphere figure for Proposition 19: a great circle ABCD cutting several parallels obliquely, with the auxiliary great circles QBRD and AGCH and their intersection points marked throughout the interior.

- A (upper left): point on the great circle ABCD
- Q (top): visible pole of the parallels
- T (upper center): intersection on parallel EF [?]
- M (upper center-left): intersection of ABCD with parallel EF
- L (center left): intersection of ABCD with parallel EF
- S (center): intersection on parallel EF [?]
- D (center): intersection of the great circles
- G (far left): endpoint of the greatest parallel GH
- H (far right): endpoint of the greatest parallel GH
- B (center): intersection of the great circles
- V (lower center-left): intersection on parallel IK [?]
- P (lower center-right): intersection of ABCD with parallel IK
- I (lower left): endpoint of parallel IK
- X (bottom center-left): intersection on parallel IK [?]
- O (bottom center): intersection of ABCD with parallel IK
- C (bottom, right of O): point on the great circle ABCD
- K (lower right): endpoint of parallel IK
- R (bottom center): hidden pole of the parallels
- E (left): endpoint of parallel EF
- F (right): endpoint of parallel EF

Now let the parallels EF and IK be equal. I say that the alternate segments LFM and OIP are equal to one another, and likewise the alternate segments LEM and OKP. [Margin: e — 20. primi huius (*Sphaerica* I.20)] For through the poles of the parallels and the poles of the circle ABCD let the great circle AGCH be described, [Margin: f — 9. huius (*Sphaerica* II.9)] which will bisect the segments LAM and OCP. Therefore the arcs AL and AM are equal to one another, and CO and CP to one another. And since the great circle AGCH passes through the poles of the greatest circles GH and AC, [Margin: g — Schol. 15. primi huius (scholium to *Sphaerica* I.15)] these circles will in turn pass through its poles. Therefore the points B and D are the poles of the circle AGCH; and consequently the straight

lines BA and BC will be equal, by the definition of pole; [Margin: h — 28. tertij (*Elements* III.28)] and therefore the arcs BA and BC themselves will be equal. [Margin: i — 18. huius (*Sphaerica* II.18)] But the arcs BL and BO are also equal, because the parallels EF and IK are assumed equal. Therefore the remaining arcs AL and CO will be equal as well. But the arcs AL and CO are the halves of the arcs LAM and OCP, because AL was shown equal to AM, and CO to CP. Therefore the arcs LAM and OCP are also equal, [Margin: k — 29. tertij (*Elements* III.29)] and accordingly the subtending chords LM and OP will be equal. [Margin: l — 28. tertij (*Elements* III.28)] Hence from the equal circles EF and IK they will cut off equal arcs — the greater LFM equal to the greater OIP, and the smaller LEM equal to the smaller OKP (that is, alternate segment equal to alternate segment). Which was proposed. And so, if in a sphere a great circle cuts several parallel circles drawn on the spherical surface, and so on. Which was to be demonstrated.

THEOR. 18. PROPOS. 20.

[Margin: xxiv.]

If in a sphere a great circle cuts several parallel circles, but not through the poles: of the arcs taken from the parallels in one hemisphere, those that come nearer to the visible pole will be too great to be similar to those that lie farther from that same visible pole.

In a sphere let the great circle GHIKLMNO cut the parallels AB, CD, EF in H, O; I, N; K, M — not through the poles — and let the hemisphere GBL lie above it, with P the visible pole and Q the hidden pole. I say that the arc OBH is too great to be similar to the arc NDI, and that NDI is too great to be similar to the arc MFK. [Margin: a — 20. primi huius (*Sphaerica* I.20)] For through the pole of the parallels P and the points I, N let two great circles PI, PN be described, cutting the parallel AB above the circle GILN, in R and S: [Margin: b — 10. huius (*Sphaerica* II.10)] and the arc RBS will be similar to the arc IDN. Since, then, the arc OBH is greater than the arc RBS, it will also be too great to be similar to the arc NDI. In the same way we shall show that the arc NDI is too great to be similar to the arc MFK, provided that through the pole P and the points K, M two other great circles are described. Therefore, if in a sphere a great circle cuts several parallels, and so on. Which was to be demonstrated.

Diagram. A sphere for Proposition 20: a great circle GHIKLMNO cutting three parallels AB, CD, EF obliquely, with the auxiliary great circles through the pole P and the marked secant points.

- A (left): endpoint of the upper parallel AB
- G (top left): point on the great circle
- P (top): visible pole of the parallels
- B (top right): point on the upper parallel AB
- S (upper center): secant point on parallel AB
- H (center left): secant point on parallel AB
- N (center): secant point on parallel CD
- C (left): endpoint of the middle parallel CD
- D (right): endpoint of the middle parallel CD
- I (center left): secant point on parallel CD
- M (lower center): secant point on parallel EF
- E (lower left): endpoint of the lower parallel EF
- F (lower right): endpoint of the lower parallel EF
- K (bottom): secant point on parallel EF
- L (bottom): point on the great circle
- Q (bottom): hidden pole of the parallels
- O (secant point on parallel AB): [?]
- R (secant point on parallel AB): [?]

COROLLARIUM

From this it follows that the arc OBH is simply a greater part of its own parallel AB than the arc NDI is of its own parallel, and so on — inasmuch as the arc RBS is as great a part of its own parallel as the arc IDN is of its own parallel, since these arcs have been demonstrated to be similar, and so on.

THEOR. 19. PROPOS. 21.

[Margin: xxv.]

If in equal spheres great circles are inclined to great circles, the one whose pole stands higher above the underlying plane will be the more inclined; but those circles whose poles are equally distant from the underlying planes are equally inclined.

In equal spheres ABCD and EFGH, whose centers are I and K, let two great circles BND and FOH be inclined to the great circles ABCD and EFGH (whose poles are L and M), the poles of BND and FOH being P and Q; and first let the pole P stand higher above the plane of the circle ABCD than the pole Q stands above the plane

of the circle EFGH. I say that the circle BND is more inclined to the circle ABCD than FOH is to EFGH. [Margin: a — 20. primi huius (*Sphaerica* I.20)] For through the poles L, P and through the poles M, Q let the great circles ANC and EOG be described; and let the common section of the circles ABCD and BND be the straight line BD, the common section of the circles ABCD and ANC the straight line AC, and the common section of the circles BND and ANC the straight line NI — all which straight lines will pass through the center of the sphere I, [Margin: b — 6. primi huius (*Sphaerica* I.6)] since the great circles are drawn through the same center of the sphere. In the same order, in the other sphere let there be common sections of the circles: the straight line FH of the circles EFGH and FOH, the straight line EG of the circles EFGH and EOG, and the straight line OK of the circles FOH and EOG — all which straight lines will likewise pass through the center of the sphere K. And since the circle ANC, passing through the poles of the circles ABCD and BND, [Margin: c — 15. primi huius (*Sphaerica* I.15)] cuts them at right angles, in turn each of the circles ABCD and BND will be perpendicular to the circle ANC, [Margin: d — 19. undecimi (*Elements* XI.19)] and so the straight line BD, their common section, will be perpendicular to the same circle ANC. Hence the angles AID and NID will be right angles, by definition 3 of Book 11 of Euclid; and accordingly AIN will be the angle of inclination of the circle BND to the circle ABCD, by definition 6 of Book 11 of Euclid. In the same way, EKO will be the angle of inclination of the circle FOH to the circle EFGH. Now since the pole P of the circle BND is set higher above the circle ABCD than the pole Q of the circle FOH above the circle EFGH, the arc CP will be greater than the arc GQ. For these arcs, being perpendicular to the circles ABCD and EFGH, measure the heights of the poles P and Q above those circles. But the arcs PN and QO are equal, since they are quadrants. [Margin: e — Corol. 16. huius (corollary to *Sphaerica* II.16)] For the poles P and Q are a quadrant distant from the great circles BND and FOH. Therefore the arc CN will be greater than the arc GO, and consequently AN, the remainder of the semicircle ANC, will be smaller than EO, the remainder of the semicircle EOG. [Margin: f — Schol. 27. tertij (scholium to *Elements* III.27)] Hence the angle AIN will be smaller than the angle EKO, and accordingly the circle BND will be more inclined to the circle ABCD than the circle FOH is to the circle EFGH, as we wrote in the explanation of definition 7 of Book 11 of Euclid.

Diagram. The left of two sphere figures for Proposition 21: sphere ABCD with the great circles ANC and BND, their poles, and center I.

- A (top): endpoint of the great circle ABCD
- B (left): endpoint of the great circle ABCD
- C (bottom): endpoint of the great circle ABCD

- D (right): endpoint of the great circle ABCD
- N (upper left): point on the great circle ANC / on circle BND
- I (center): center of the sphere
- L (lower left): pole
- P (below L): pole of circle BND

Diagram. The right of two sphere figures for Proposition 21: sphere EFGH with the great circles EOG and FOH, their poles, and center K.

- E (top): endpoint of the great circle EFGH
- F (left): endpoint of the great circle EFGH
- G (bottom): endpoint of the great circle EFGH
- H (right): endpoint of the great circle EFGH
- O (upper left): point on the great circle EOG / on circle FOH
- K (center): center of the sphere
- M (lower left): pole
- Q (below M): pole of circle FOH

But now let the arcs CP and GQ be equal — that is, let the poles P and Q be equally distant from the planes of the circles ABCD and EFGH. I say that the circles BND and FOH are equally inclined to the circles ABCD and EFGH. For since the arcs CP and GQ are equal, if the quadrants PN and QO are added, the arcs CN and GO will also be equal; and consequently the remaining arcs AN and EO, taken from the semicircles, will be equal. [Margin: g — 27. tertij (*Elements* III.27)] Therefore the angles AIN and EKO will be equal, and consequently, by definition 7 of Book 11 of Euclid, the inclinations of the circles BND and FOH to the circles ABCD and EFGH will be similar, that is, equal. So if in equal spheres great circles are inclined to great circles, and so on. Which was to be shown.

SCHOLIVM

From this it follows that, of great circles inclined to others, if their poles are equally distant from the poles of the greatest circles to which they are inclined, the inclinations are equal; but the one whose pole is nearer to the pole of the circle to which it is inclined has the greater inclination. For if the arcs LP and MQ are equal, then CP and GQ will also be equal, [Margin: h — Corol. 16. primi huius (corollary to *Sphaerica* I.16)] since CL and GM are quadrants; and so the poles P and Q of the inclined circles will be equally distant from the underlying planes of the circles ABCD and EFGH. Hence, as was demonstrated in this proposition, the

inclinations of the circles BND and FOH to the circles ABCD and EFGH will be equal. But if the arc LP is smaller than the arc MQ, then the remaining arc CP, out of a quadrant, will be greater than the arc GQ, out of a quadrant. Therefore, as we showed in this proposition, the inclination of the circle BND to the circle ABCD will be greater than that of the circle FOH to the circle EFGH.

We shall also demonstrate the converse of this theorem and its scholium in the following manner.

If in equal spheres great circles are equally inclined to great circles, the distances of their poles from the underlying planes will be equal; but of the one that is more inclined, the pole will be higher. Likewise, the distances of the poles of those circles that are equally inclined, from the poles of the circles to which they are inclined, will be equal; but the distance of the pole of the circle that is more inclined, from the pole of the circle to which it is inclined, will be smaller.

For if the circles BND and FOH are equally inclined to the circles ABCD and EFGH, the angles AIN and EKO will be equal, by definition 7 of Book 11 of Euclid; [Margin: i — 26. tertij (*Elements* III.26)] and consequently the arcs AN and EO will be equal. Therefore, adding the quadrants NP and OQ, the arcs AP and EQ will be equal, and consequently the remaining arcs CP and GQ, taken from the semicircles, will be equal.

But if the circle BND is more inclined to the circle ABCD than the circle FOH is to the circle EFGH, the angle AIN will be smaller than the angle EKO, as we wrote on definition 7 of Book 11 of Euclid; [Margin: k — Schol. 26. tertij (scholium to *Elements* III.26)] and consequently the arc AH will be smaller than the arc FO. Therefore, adding the quadrants NP and OQ, the arc AP will be smaller than the arc EQ, and accordingly the remaining arc CP, out of the semicircle ANC, will be greater than the remaining arc GQ, out of the semicircle FOG.

Again, if the circles are equally inclined, the arcs CP and GQ will be equal, just as we showed above. [Margin: l — Corol. 16. 1.huius (Corollary to *Sphaerica* I.16)] Since, therefore, CL and GM are quadrants, the arcs LP and MQ will also be equal. Finally, if the circle BND is more inclined, then by what has just been demonstrated the arc PC will be greater than the arc GQ. The remainder LP, taken from the quadrant CL, will therefore be less than the remainder MQ, taken from the quadrant GM; and so on.

Two further theorems from another version have also been added here, namely the following.

I.

Great circles tangent to the same parallel are equally inclined to the greatest of the parallels; but one that is tangent to a larger parallel is more inclined to the greatest of the parallels. And great circles equally inclined to the greatest of the parallels are tangent to the same parallel; but one that is more inclined to the greatest of the parallels is tangent to a larger parallel.

Let the great circles AB and CB be tangent to the same parallel AC, and let DE be the greatest of the parallels. I say that the circles AB and CB are equally inclined to the circle DE. For let F be the pole of the parallels, [Margin: a — 20.1.hui. (Sphaerica I.20)] and through F and the points of contact A and C let the great circles FAD and FCE be described. [Margin: b — 5.huius (Sphaerica II.5)] These will pass through the poles of the circles AB and CB, [Margin: c — 15.1.hui. (Sphaerica I.15)] and hence will cut them at right angles. The arcs AF and CF will therefore measure the height of the pole F of the circle DE above the circles AB and CB. [Margin: d — 28.tertij (Elements III.28)] And since the arcs AF and CF are equal — because the straight chords FA and FC are equal, by the definition of a pole — the circle DE will be equally inclined [Margin: e — 21.huius (Sphaerica II.21)] to the circles AB and CB, and these in turn will be equally inclined to it.

Now let the great circle GH be tangent to a larger parallel GI. I say that the inclination of the circle GH to the greatest of the parallels, DE, is greater than that of the circle AB. For if a great circle FGE is described through F and the point of contact G, [Margin: f — 20.1.hui. (Sphaerica I.20)] it will, in the same way just demonstrated, measure by the arc FG the height of the pole F of the circle DE above the circle GH. But the arc FG is greater than the arc FA, because the circle GI is assumed larger than AC, and hence farther from the pole F. Therefore the circle DE will be more inclined to the circle GH than to the circle AB; [Margin: g — 11.1.hui.[?] (Sphaerica I.11?)] and conversely, GH will be more inclined to DE than AB is.

Again, let the great circles AB and CB be equally inclined to the circle DE, the greatest of the parallels. I say that they are tangent to the same parallel. For through F, the pole of the parallels, and through the poles of the circles AB and CB, let the great circles FAD and FCE be described, [Margin: h — 20.1.hui. (Sphaerica I.20)] cutting the circles AB and CB at A and C. And since [each] cuts

them at right angles, [Margin: i — 15.1.huius (Sphaerica I.15)] the arcs FA and FC will measure the height of the pole F of the circle DE above the circles AB and CB. But the arcs FA and FC are equal, [Margin: k — Schol.21.huius (Scholium to Sphaerica II.21)] because the circles AB and CB are assumed equally inclined to the circle DE, and hence it too to them. If, therefore, from the pole F, with radius FA or FC, a circle AC is described, [Margin: l — 3.huius (Sphaerica II.3)] it will be tangent to the circles AB and CB, because the circle AC and the circles AB and CB cut, at the same points A and C, the great circles FD and FE, which pass through their poles.

Now let the great circle GH be more inclined to the circle DE. I say that it is tangent to a larger parallel. For if a great circle FG is described through F, the pole of the parallels, and through the pole of the circle GH [Margin: m — 20.1.hu. (Sphaerica I.20)] — which will cut the circle GH at right angles, namely at the point G [Margin: n — 15.1.hui. (Sphaerica I.15)] — the arc FG will again measure the height of the pole F of the circle DE above the circle GH. [Margin: o — Scho.21.huius (Scholium to Sphaerica II.21)] But FG is greater than FA, because the circle GH is assumed more inclined than AB. Therefore the circle described from the pole F with radius FG will be larger than the circle described from the same pole F with radius FA. [Margin: p — 3.huius (Sphaerica II.3)] Since, then, AB and AC are mutually tangent at A, and GH and GI are likewise mutually tangent at G, the proposition is established.

Diagram. The figure for Theorem I: a cluster of great-circle arcs converging at the pole F above, with the tangent circles and their contacts shown below.

- F (apex, top): pole of the parallels
- A (upper left of center): contact of circle AB on the parallel AC
- C (upper right of center): contact of circle CB on the parallel AC
- G (right of center): contact of circle GH on the larger parallel GI
- I (left): point on the larger parallel
- B (center): crossing of the great circles
- H (lower center): point on the arc DE
- D (lower left): endpoint of great circle FAD
- E (lower right): endpoint of great circle FCE

II.

Great circles equally inclined to the greatest of the parallels have their poles on the circumference of the same parallel. And great circles that

have their poles on the circumference of the same parallel are equally inclined to the greatest of the parallels.

Let the great circles AB and CD, whose poles are E and F, be equally inclined to DB, the greatest of the parallels. I say that their poles E and F lie on the same parallel. For if, through G, the pole of the parallels, and through E and F, the poles of the circles AB and CD, the great circles GE and GF are described [Margin: a — 20.1.hui. (Sphaerica I.20)] — which will be at right angles to the circles AB and CD [Margin: b — 15.1.hui. (Sphaerica I.15)] — the arcs EG and FG, the distances of the poles E and F from the pole G, [Margin: c — Schol.21.huius (Scholium to Sphaerica II.21)] will be equal, because the circles AB and CD are assumed equally inclined to the circle DB. Therefore the circle EF, described from the pole G with radius GE or GF, is parallel to the circle DB; [Margin: d — 2.huius (Sphaerica II.2)] and on this parallel EF the circles AB and CD have their poles E and F. Which is what was proposed.

But now let the great circles AB and CD have their poles E and F on the parallel EF. I say that they are equally inclined to DB, the greatest of the parallels. For, by the definition of a pole, the straight lines GE and GF are equal, and on that account the arcs EG and FG [Margin: e — 28.tertij (Elements III.28)] will also be equal. Since, then, these same arcs are the distances of the poles E and F from G, the pole of the parallels, the circles AB and CD [Margin: f — Schol.21.huius (Scholium to Sphaerica II.21)] are equally inclined to DB, the greatest of the parallels.

Diagram. The first figure for Theorem II: a pointed (ogival) figure of two great-circle arcs meeting at the top, with the parallel crossing lower down.

- G (apex, marked with a small right-angle square): pole of the parallels
- A (apex, right of G): point on the meeting of the arcs
- E (middle left): pole of circle AB
- F (middle right): pole of circle CD
- D (lower left): endpoint on the parallel
- B (lower right): endpoint on the parallel

Diagram. The second figure for Theorem II (the converse case): a similar ogival figure, with the poles now marked on the parallel EF below.

- G (apex, marked with a small right-angle square): pole of the parallels
- A (upper left, below G): point on the great circle
- C (upper right, below G): point on the great circle

- D (middle left): point on the arc
- B (middle right): point on the arc
- E (lower left): pole on the parallel EF
- F (lower right): pole on the parallel EF

There now follows, in the Greek codex, the twenty-second proposition, whose demonstration is very long. Since in another version the same thing is proved much more briefly and more clearly, it has seemed good to insert here three other theorems from that other version, so that we may then more easily demonstrate the twenty-second proposition of this book. The first of these theorems is the second part of Proposition 1 of Book 3 of Theodosius, although stated more generally, as it is here proposed. The first theorem, then — which stands third in order in this scholium — is as follows.

III.

If a right segment of a circle be set up on the diameter of a circle, and the circumference of the standing segment be divided into two unequal parts, and from the point of division very many straight lines fall to the circumference of the first circle: the straight line subtending the smaller part of the standing segment will be the least of all, while the one subtending the greater part will be the greatest of all. Of the rest, the one nearer the greatest is always greater than the one more remote; but the one nearer the least is always less than the one more remote. And two equal straight lines fall from the same point onto the circumference of the circle, equally distant from the greatest.

On the diameter AD of the circle ABCDE let there be set up a right segment of a circle AFD, and let it be cut not into two equal parts at F, with AF the smaller part and DF the greater. Let there fall from F very many straight lines FA, FI, FH, FB, FC, FD, FE. I say that the least of all is FA and the greatest FD; that FC is greater than FB, and so on; that FI is less than FH, and so on; and finally that the two lines FE and FC are equal if they are equally distant from the greatest, FD — that is, if the arcs DE and DC are equal. [Margin: a — 21. vnd. (Elements XI.21)] For let a perpendicular FG be dropped from F onto the plane of the circle ABCDE; [Margin: b — 38. vnde. (Elements XI.38)] it will fall on AD, the common section, and the point G will lie either between the points A and D, as in the first figure (which always happens when the segment AFD is not greater than a semicircle, though the same can also happen in a greater segment); or at the same point as A; or outside the circle, on the diameter DA produced, as the two later figures indicate — which can happen only in a segment greater than a semicircle. In the first

figure G will not be the center of the circle ABCDF, because GF does not bisect the segment AFD; much less will G be the center of the circle ABCDE in the two later figures. Let the straight lines GI, GH, GB, GC, GE be joined; all the angles at G will be right, by definition 3 of Book 11 of Euclid.

Now of the straight lines falling from G onto the circle ABCDE, in the first figure and the third [Margin: c — 7. vel 8. tertij (Elements III.7 or 8)] the least is GA; in all the figures the greatest is GD; [Margin: d — 7. vel 15. vel 8. tertij (Elements III.7, 15, or 8)] GC is greater than GB; GI is less than GH; and finally GC and GE are equal. In the first and third figure, therefore, the two squares of the lines AG and GF are less than the two squares of the lines IG and GF; [Margin: e — 47.prim (Elements I.47)] and since these are equal to the squares of the lines FA and FI, the square of FA will also be less than the square of FI, and hence the line FA will be less than FI. In the same way we shall show that FA, in this same first and third figure, is less than FH, and so on. In the second figure, [Margin: f — 19.primi (Elements I.19)] FA is likewise less than FI or FH, and so on, because in the triangles AIF and AHF (in which the angle A is right, by definition 3 of Book 11 of Euclid, and hence the others acute) the line FA subtends an acute angle, I or H, while the line FI or FH subtends the right angle A. Therefore FA is the least of all.

Again, in all the figures the two squares of GD and GF are greater than the two squares of GC and GE; [Margin: g — 47.prim (Elements I.47)] and since these are equal to the squares of FD and FC, the square of FD will also be greater than the square of FC, and hence the line FD greater than the line FC. In no other way we show that FD is greater than FB, and so on. Therefore FD is the greatest of all. Moreover, in all the figures the two squares of GC and GF are greater than the two squares of GB and GF; [Margin: h — 47.prim (Elements I.47)] and since these are equal to the squares of FC and FB, the square of FC will also be greater than the square of FB, and hence the line FC greater than FB. In just the same way we show that FC, which is nearer the greatest, FD, is greater than any other more remote, and so on. Further, in all the figures the two squares of GI and GF are less than the two squares of GH and GF; [Margin: i — 47.prim (Elements I.47)] and since these are equal to the squares of FI and FH, the square of FI will be less than the square of FH, and hence the line FI less than FH. And in the same way we shall demonstrate that FI, which is nearer the least, FA, is less than any other more remote, and so on. Finally, the two squares of GC and GF are equal to the two squares of GE and GF; [Margin: k — 47.pri (Elements I.47)] and since these are equal to the squares of FC and FE, the lines FC and FE will be equal. What was proposed is therefore established. And, as is clear from the demonstration, we

call that line nearer the greatest, FD, which falls on a point closer to the point D; and that one nearer the least, FA, which falls on a point closer to the point A.

Diagram. Three companion circle-figures for Theorem III (the *first*, *second*, and *third* figures referred to in the proof), arranged in a row. In each, a circle ABCDE is drawn with the apex F above; the perpendicular foot G falls on the diameter AD (between A and D in the first figure, at A in the second, and outside the circle on DA produced in the third). From F the chords FA, FI, FH, FB, FC, FD, FE are drawn, and from G the joins GI, GH, GB, GC, GE.

- F (top, apex): point of the standing segment from which the lines fall
- G (interior, on the diameter AD): foot of the perpendicular from F
- A (left, on circle): endpoint of the diameter (smaller-part side)
- D (right, on circle): endpoint of the diameter (greater-part side)
- E (upper right, on circle): endpoint of chord FE
- C (lower, on circle): endpoint of chord FC
- B (lower left, on circle): endpoint of chord FB
- I (lower left, on circle): endpoint of chord FI
- H (lower, on circle): endpoint of chord FH

IV.

If, on the surface of a sphere, within the periphery of any circle a point be marked other than its pole, and from it very many arcs of great circles, less than a semicircle, be drawn to the circumference of the circle: the greatest is the one drawn through the pole of the circle, and the least is the one adjacent to it. Of the rest, the one nearer the greatest is always greater than the one more remote. And two arcs equally remote from the same greatest, or from the least, are equal to each other.

Let there be in a sphere a circle ABCDE, whose pole is F, and on the sphere's surface, within the periphery of the circle and other than the pole F, let any point G be marked, from which very many arcs of great circles are drawn to the circumference of the circle ABCDE. Of these, let GA, extended in both directions, pass through the pole F; let the arc GB be nearer to GA than GC is; and finally let the two arcs GB and GE be equally distant from the same GA, or from GD. Let all these arcs be less than a semicircle — which will be the case precisely when they do not intersect one another at any point other than G. [Margin: a — 11.1.hui.[?] (Sphaerica I.11?)] For since great circles bisect one another, the arcs GA and GE will be less than a semicircle so long as they do not yet intersect. And by the same reasoning the other arcs going out from G will be less than a semicircle, if they do

not intersect one another. But if one of them — say the arc GA — were a semicircle, all the others would pass through the point A and would themselves be semicircles as well; while if GA were greater than a semicircle, all the others would cut it before they reached the circum-

Diagram. The figure for Theorem IV: a single circle ABCDE with an interior point G, from which arcs radiate to the circumference; the arc GA passes through the interior pole F.

- E (upper left, on circle): endpoint of arc GE
- A (left, on circle): endpoint of arc GA (which passes through the pole F)
- F (interior, between A and G): pole of the circle ABCDE
- G (interior, center): the marked point from which the arcs are drawn
- D (right, on circle): endpoint diametrically opposite A along the arc through the pole
- B (lower left, on circle): endpoint of arc GB
- C (bottom, on circle): endpoint of arc GC

—ference, and would be greater than a semicircle, as is clear. Hence nothing could be inferred.

Diagram. The figure for Theorem IV, reprinted at the head of this page (a printer's convenience, since the demonstration spans the page break); it is identical to fig-p671-2. A circle ABCDE with the interior point G, arcs radiating to the circumference, and the arc GA passing through the interior pole F.

- E (upper left, on circle): endpoint of arc GE
- A (left, on circle): endpoint of arc GA (through the pole F)
- F (interior, between A and G): pole of the circle ABCDE
- G (interior, center): the marked point
- D (right, on circle): opposite endpoint along the arc through the pole
- B (lower left, on circle): endpoint of arc GB
- C (bottom, on circle): endpoint of arc GC

I say that the arc GA is the greatest of all, and GD the least; that GB is greater than the arc GC; and finally that the two arcs GB and GE are equal. [Margin: b — 15.1.hui. (Sphaerica I.15)] For since the arc AD cuts the circle ABC in two and at right angles, the straight chord AD will be the diameter of the circle ABC; and upon it stands the right segment of a circle AGD, which is cut unequally at G [Margin: c — 28.tertij (Elements III.28)] (for since, by the definition of a pole, the straight chords FA and FD are equal, the arcs FA and FD will also be equal, and

hence the arc AD will be bisected at F, and on that account not bisected at G), and the greater part is GA, the lesser GD. [Margin: d — Schol.21.huius (Scholium to Sphaerica II.21)] Therefore, of the straight lines drawn from G to the circumference of the circle ABC, the greatest is GA and the least GD; GB is greater than GC; and GB and GE are equal. And so, since the arcs they subtend are assumed less than a semicircle, [Margin: e — Schol. 28. tertij (Scholium to Elements III.28)] the arc GA will also be the greatest and GD the least; GB greater than GC; [Margin: f — 28. tertij (Elements III.28)] and finally the arcs GB and GE equal.

V.

If, on the surface of a sphere, outside the periphery of any circle a point be marked other than its pole, and from it very many arcs of great circles, less than a semicircle and cutting the circumference of the circle, be drawn to the circle's circumference: the greatest is the one drawn through the pole of the circle; and of the rest, the one nearer the greatest is always greater than the one more remote. The least is that [portion] of the greatest which is interposed between the point and the circle's circumference, outside the circle; and of the rest, the one nearer the least is always less than the one more remote. And two arcs equally remote from the same greatest, or from the least, are equal to each other.

Let there be in a sphere a circle ABCDE, whose pole is F, and on the sphere's surface, outside the periphery of the circle, let any point G be marked, other than the other pole of the circle ABCDE. From G let very many arcs of great circles be drawn to the circumference of the circle ABCDE, cutting it; of these let GDFA pass through the pole F; let the arc GHB be nearer to GDFA than GIC is; and finally let the two arcs GHB and GKE be equally distant from the same GDFA, or from GD. Let all these arcs be less than a semicircle — which will be the case precisely when they do not intersect one another at any point other than G, just as was shown in the preceding theorem. I say that the arc GA is the greatest of all, and GB greater than GC; that the least is GD, and GH less than GI; and finally that the two arcs GB and GE, as also GH and GK, are equal. [Margin: a — 15. 1. hui. (Sphaerica I.15)] For since the arc GA cuts the circle ABCDE in two and at right angles, the straight chord AD will be the diameter of the circle ABCDE, and upon it stands a right segment of a circle DG, which, beginning at D, is drawn through G until it cuts the circle ABCDE again at another point A. This segment is not bisected at G (because G is not the pole of the circle ABCDE, at which the said segment would be bisected, as was shown in the preceding theorem), and the greater part runs from the point G up to A, since the remaining pole lies within it

(otherwise the arc GDA would be drawn through both poles, and hence would be greater than a semicircle, since the arc between two poles is a semicircle); while DG is the lesser part. [Margin: b — Schol.21. huius (Scholium to Sphaerica II.21)] Therefore, of the straight lines drawn from G to the circumference of the circle ABCDE, the greatest is GA and the least GD; GB is greater than GC; and GB and GE are equal. Likewise GH is less than GI, and GH and GK are equal. Wherefore, since they are subtended by arcs less than a semicircle, by hypothesis, [Margin: c — Schol.28. tertij (Scholium to Elements III.28)] the arc GA will also be the greatest of all, and GD the least; while GB is greater than GC, and GH less than GI. [Margin: d — 28. tertij (Elements III.28)] Finally, GB and GE, as also GH and GK, are equal to each other. Which is what was proposed.

It is, moreover, evident that in the two preceding theorems the individual arcs drawn from G must not be greater than a semicircle; otherwise the greater lines would not cut off the greater arcs, and conversely, as is clear from the scholium to Proposition 28 of Book 3 of Euclid.

Diagram. The figure for Theorem V: a circle ABCDE with a point G outside it (to the right), from which arcs are drawn cutting the circle. The arc GDFA passes through the interior pole F; the other arcs cut the circumference at K, H, and I.

- E (upper left, on circle): endpoint of arc GKE
- F (interior): pole of the circle ABCDE, lying on the arc GDFA
- K (interior, upper right): point where arc GKE cuts the circle
- D (interior right, on the arc through the pole): point where GDFA meets the near circumference
- H (interior, lower): point where arc GHB cuts the circle
- I (interior, lower): point where arc GIC cuts the circle
- A (left, on circle): far endpoint of arc GDFA
- B (lower left, on circle): far endpoint of arc GHB
- C (bottom, on circle): far endpoint of arc GIC
- G (right, outside the circle): the external marked point

THEOR. 20. PROP. 22.

If in a sphere a greatest circle be tangent to one circle but cut another parallel to it — the latter placed between the sphere's center and the circle to which the greatest circle is tangent — and the pole of the greatest circle be between both parallels, and greatest circles be described tangent to the larger of the two parallels: all these will be inclined to the greatest circle. The most upright among them will be the

one whose point of contact is at the point where the greater segment of the larger parallel is bisected; the lowest and most inclined, the one whose point of contact is at the point where the lesser segment is bisected. Of the rest, those which are equally distant from either of the points at which the segments are bisected are similarly inclined; but the one whose point of contact is more remote from the point at which the greater segment is bisected is always more inclined than the one whose point of contact is nearer to that same point. Finally, the poles of the greatest circles will lie on one circle, which will be smaller than the circle to which the greatest circle was tangent at the start, and will be parallel to it.

In a sphere let there be a greatest circle ABCD, whose pole is E; let it be tangent to the circle AF, and let it cut another parallel to this, GHBD, placed between the sphere's center and the circle AF, in such a way that the circle GBHD is larger than AF; and let E, the pole of the greatest circle ABCD, be between both circles AF and GBHD. Now since the greatest circle ABCD cuts the circle GBHD not into two equal parts — because it does not pass through its poles, that is, through the poles of the parallels — [Margin: a — 19. huius (Sphaerica II.19)] the segment BHD, toward the visible pole (which let be I), will be greater than a semicircle, and BGD less. [Margin: b — 20. 1.hui. (Sphaerica I.20)] Let there be drawn through E the pole—

[The demonstration of **THEOR. 20. PROP. 22** continues from the preceding page.]

— through E, the pole of circle ABCD, and I, the pole of the parallels, let the great circle GAC be drawn, [Margin: (c) "9. huius" — Sphaerica II.9] which will bisect the segments BGD, BHD. Let the points M, N be equally distant from H, and let O be more distant from H than N is. [Margin: (d) "14. huius" — Sphaerica II.14] Now let the great circles GL, Hk, MP, Nk, OL touch the parallel GBHD at the points G, H, M, N, O. All of these will be inclined to the greatest circle ABCD, since they do not pass through E, its pole. For since E is placed as the pole between the parallels AF and GBHD, the circles tangent to the circle GBHD cannot pass through E — otherwise they would cut it, because the other pole, [Margin: (e) "Corol. 10. 1. huius" — Corollary to Sphaerica I.10] through which they must also necessarily pass, lies outside the said parallels, as is evident.

I say that the circle Hk is the most upright — that is, the least inclined — while GL is the lowest, that is, the most inclined; that MP and Nk are similarly inclined, and OL more so than Nk; and finally that the poles of these tangent circles [Margin: (f)

"Coroll. 16. 1. huius" — Corollary to Sphaerica I.16] lie in one and the same parallel, which is smaller than AF.

For since E is the pole of circle ABCD, EA will be a quadrant of the greatest circle. Let the arc HQ be taken equal to it. Then the point Q will lie between the points A and I, since the arc HA is greater than a quadrant (because EA has been shown to be a quadrant) and HI is less than a quadrant, [Margin: (g) "Coro. 16. 1. huius" — Corollary to Sphaerica I.16] because the arc extended from the pole I through H as far as the greatest of the parallels is a quadrant. If therefore from the pole I, at the distance IQ, a circle QTR is described, [Margin: (h) "2. huius" — Sphaerica II.2] it will be parallel to AF and smaller than it. In this parallel QTR, then, I say [Margin: (i) "20. 1. hui." — Sphaerica I.20] lie the poles of all the circles tangent to the parallel GBHD. [Margin: (k) "5. huius" — Sphaerica II.5] For through the pole I and the points of contact let the great circles MIS, NIT, OIV be described; [Margin: (l) "28. tertij" — Euclid III.28] these too will pass through the poles of the tangent circles. Now since the arcs HI, MI, NI, OI, GI are equal — because, by the definition of a pole, the straight lines subtending those arcs are equal — and by the same reasoning the arcs IQ, IS, IT, IV, IR are equal, the whole arcs HQ, MS, NT, OV, GR will be equal; and hence, since HQ is a quadrant, all those arcs will be quadrants. Therefore, since it has been demonstrated that these circles pass through the poles of the tangent circles, [Margin: (m) "Coro. 16. 1. huius" — Corollary to Sphaerica I.16] the points Q, S, T, V, R will be the poles of the tangent circles, all of which lie in the parallel QTR — which was the last thing proposed for demonstration.

Now, since the arcs of the great circles drawn from E, the pole of the greatest circle ABCD, to Q, S, T, V, R, the poles of the tangents, measure the distances of the pole E from the poles of the tangents — for these two are equally distant from the greatest one, EQ, on account of the arcs QS, QT, which are equal. [Margin: (n) "10. huius" — Sphaerica II.10] For the arc of the parallel VR, lying between the great circles HI, MI, NI, is similar to the arcs MH, NH; and so, since these latter are assumed equal, the former will also be equal — and since these are equal to the arcs QS, QT, each to each, [Margin: (o) "15. 1. hui." — Sphaerica I.15] because the common sections of the parallel VR and of the great circles HQ, MS, NT drawn through its poles are diameters of it. From this it follows, since the arcs between these diameters near R are equal to one another, [Margin: (p) "26. tertij" — Euclid III.26] that the arcs opposite to those, QS, QT, are also equal, on account of the angles at the center contained by the said diameters, [Margin: (q) "27. tertij" — Euclid III.27] which are equal, inasmuch as they stand on equal arcs near R. For from this it also follows that the vertical angles standing on the arcs QS, QT are

equal. And [Margin: (r) "Scho. 21. huius" — Scholium to Sphaerica II.21] EQ is the greatest of all, ER the least, while ES and ET are equal; and finally ET is greater than EV, because all these arcs are less than a semicircle — for EQ is less than the quadrant EA, and hence the rest will not cut it around the point Q, and so will be less than a semicircle. [Margin: (s) "Schol. 21. huius" — Scholium to Sphaerica II.21] Therefore the circle Hk will be the least inclined to the greatest circle ABCD, and GL the most; while MP and Nk are inclined equally, or similarly, and OL more than Nk — which was what was proposed for demonstration in the first place. And therefore, if in a sphere a greatest circle, etc. Which was to be demonstrated.

Diagram. A figure for THEOR. 20. PROP. 22. It shows the greatest circle **ABCD** (quartered by two diameters through its center) with several concentric parallels and a set of oblique tangent great circles, together with an inner parallel **QTR** carrying the poles of the tangent circles. Readable labels, by approximate position:

- G (top of the outer figure); L (top, just right of G)
- A (upper center, on the outer circle below G)
- O (upper right)
- B (left); D (right) — the horizontal extremities of circle ABCD
- F (inner, left of center)
- I (center of the figure — pole of the parallels)
- S (inner, upper); Q (inner, upper, near S); T (inner, left); V (inner, lower left); R (inner, lower center) — the inner ring of poles on the parallel QTR
- M (lower left); E (center, below I — pole of ABCD); N (lower right)
- P (lower left); H (bottom center); K (bottom, right of H)
- C (bottom of the outer figure)

THEOR. 21. PROP. 23. [Margin: xxxiv]

With the same things assumed, if the circumferences of the tangent circles from the points of contact to the nodes are equal, then the aforesaid great circles will be similarly inclined.

Once again, let **ABCD** be a greatest circle in the sphere, whose pole is E, touching the circle AF, and cutting another circle GBHD parallel to it — GBHD being placed between the center of the sphere and the circle AF, so that GBHD is greater than AF, and E, the pole of the greatest circle ABCD, lies between both circles AF and GBHD. Next let the great circles MO, NP touch GBHD at the points M, N, cutting ABCD at the nodes O, P; and let the arcs MO, NP be equal. I say that the circles

MO, NP are similarly inclined to the greatest circle ABCD. [Margin: (a) "20. 1. hui." — Sphaerica I.20] For let the great circle GAC be drawn through E, the pole of circle ABCD, and I, the pole of the parallels. Likewise through I, the pole of the parallels, and the points of contact, let the great circles IM, IN be drawn, [Margin: (b) "5. huius" — Sphaerica II.5] which will also pass through the poles of the tangent circles, [Margin: (c) "15. 1. hui." — Sphaerica I.15] and hence will cut them at right angles. Since, therefore, the equal segments of the circles — namely the semicir-

Diagram. A figure for THEOR. 21. PROP. 23; the same figure is reprinted at the top (described here once). It shows a greatest circle with an inscribed pattern of tangent great circles and their nodes. Readable labels, by approximate position:

- G (top); A (below G, on the circle)
- D (upper right); B (left)
- F (inner, left of center)
- I (center); E (center, below I)
- O (left, on the circle); P (right, on the circle)
- M (lower left of center); N (lower right of center)
- H (bottom center)
- T (lower right); S (lower left)
- Q (bottom left); K (bottom center); R (bottom, right of K)
- C (bottom of the figure)

—cles which extend from M and N through I until they again cut the tangent circles MO, NP — stand on the diameters of the circles MO, NP ([Margin: (d) "21[?]. 1. hui." — Sphaerica I.21] for the common section of the great circles IM, MO is a diameter of each, since they cut one another in half) at right angles, and are divided not into two equal parts at I, because I, the pole of the parallels, is not the pole of the tangents; and since the arcs MO, NP are assumed equal, [Margin: (e) "12. huius" — Sphaerica II.12] the drawn straight lines IO, IP will be equal. If therefore from I, the pole of the parallel, a parallel Ok is described at the distance IO, it will also pass through P. And since the greatest circle IM, passing through the poles of the circles MO, OQ which cut one another in O, Q, [Margin: (f) "9. huius" — Sphaerica II.9] bisects their segments, the arcs MO, MQ and SO, SQ will be equal. By the same argument the arcs NP, NR and TP, TR will be equal, as also kO, kP and CO, CP; [Margin: (g) "9. huius" — Sphaerica II.9] because the greatest circle IkC, passing through the poles of the circles OkP, OCP, bisects their segments at k and C. Since, therefore, the arcs MO, NP are assumed equal, the

wholes OMQ, PNR — of which these are the halves — will also be equal; [Margin: (h) "29. tertij" — Euclid III.29] and hence the subtending chords OQ, PR will be equal. [Margin: (i) "28. tertij" — Euclid III.28] Therefore the arcs OSQ, PTR will also be equal, and consequently their halves OS, PT will be equal. But the wholes kO, kP have been shown equal. Therefore the remainders kS, kT will be equal; and hence, since they belong to one and the same circle, they will be similar to one another. [Margin: (k) "10. huius" — Sphaerica II.10] And since the arcs HM, HN are similar to the arcs kS, kT, the arcs HM, HN will also be equal. [Margin: (l) "9. huius" — Sphaerica II.9] Therefore, since the segment BHD is bisected at H, and the arcs HM, HN are equal, [Margin: (m) "22. hui." — Sphaerica II.22] the circles MO, NP will be similarly inclined to the circle ABCD. Therefore, with the same things assumed, if the circumferences from the points of contact, etc. Which was to be demonstrated.

FINIS LIBRI II. THEODOSII.

THEODOSII SPHÆRICORVM LIBER TERTIVS.

[THEODOSIUS'S SPHERICS, BOOK THREE.]

THEOR. 1. PROP. 1.

If a straight line cuts a circle into unequal parts, and upon it there is set an erect circular segment that is not greater than a semicircle, and the circumference of the standing segment is divided into two unequal parts: then the straight line subtending the smaller of them is the least of the straight lines drawn from the same point to the greater part of the circumference of the first circle; and of the straight lines drawn from that same point to the circumference intercepted between that least line and the diameter — onto which the perpendicular drawn from that point falls — the one nearer the least is always less than the one farther off. But the greatest of all is the one drawn from that same point to the extremity of that same diameter. Likewise, the straight line subtending the greater circumference of the standing segment is the least of those that fall on the circumference intercepted between it and the diameter, and the one nearer to it is always less than the one farther off. If, however, the straight line cutting the subject circle is its diameter, and everything else is the same as above, then the straight line subtending the smaller part of the circumference of the standing segment is the least of the straight lines drawn from that same point to the circumference of

the first and of the subject circle; while the one that subtends the greater part of the circumference of the standing segment is the greatest.

Let the straight line AB cut the circle ACBD, whose center is E, into unequal parts, of which the greater is ACB. Upon AB let there stand an erect circular segment AFB, not greater than a semicircle, which is divided into unequal parts at F, and let the smaller part be BF. From F [Margin: (a) "11. vnde." — Euclid XI.11(?)] let a perpendicular FL be dropped onto the circle ACBD, [Margin: (b) "38. vnde." — Euclid XI.38(?)] which will fall on AB at the common section. Through E and L let the diameter CD be drawn; and from F let very many straight lines FB, FG, FH, FC, FA, FI, FK fall onto the circumference ACB of the greater segment of the circle ACBD. I say that FB is the least of all, and FG less than FH; but that FC is the greatest of all. Likewise FA is the least of those that fall from F onto the portion AC, and FI is less than FK. From L let the straight lines LG, LH, LI, LK be drawn; then, by definition 3 of Book XI of Euclid, all the angles at L which the line FL makes will be right. [Margin: (c) "7. tertij" — Euclid III.7] Since, therefore, the straight line LD is the least of all the straight lines falling from L, and LB is less than LG, LH, LC, LK, LI, LA, the squares on FL, LB will be less than the squares on FL, LG. [Margin: (d) "47. prim." — Euclid I.47] But the square on FB is equal to the squares on FL, LB, and the square on FG to the squares on FL, LG. Therefore the square on FB will also be less than the square on FG; and hence the line FB will be less than FG. In the same way we shall show that FB is less than FH, FC, FK, FI, FA. Therefore FB is the least of all.

Again, [Margin: (e) "7. tertij" — Euclid III.7] since LG is less than LH, the squares on FL, LG will be less than the squares on FL, LH. [Margin: (f) "47. prim." — Euclid I.47] But the square on FG is equal to the squares on FL, LG, and the square on FH to the squares on FL, LH. Therefore the square on FG will also be less than the square on FH; and hence the line FG will be less than the line FH.

Diagram. A figure for THEOR. 1. PROP. 1 of Book III. It shows the circle **ACBD** with center E, a horizontal secant/diameter, and a great many straight lines drawn from the apex point F down to points on the circumference, together with the auxiliary lines from L. Readable labels, by approximate position:

- F (top of the circle, apex of the pencil of lines)
- D (upper right)
- A (left, on the circle); B (right, on the circle)
- L (center, on line AB)
- E (center, below L — the center of the circle)

- I (lower left); K (lower left, below I)
- G (right, below B)
- H (lower right)
- C (bottom of the circle)

Lines drawn from F to B, G, H, C, A, I, K, and the auxiliary lines LG, LH, LI, LK are shown.

Moreover, [g: Elements III.7] since LC is the greatest of all the lines falling from L, the squares on FL and LC together will be greater than the squares on FL and LK together. [h: Elements I.47] But the square on FC equals the squares on FL and LC together, just as the square on FK equals the squares on FL and LK together. Therefore the square on FC will also be greater than the square on FK; and consequently the straight line FC will be greater than the straight line FK. In the same way we shall prove that the straight line FC is greater than FI and FA. Therefore FC is the greatest of all.

Likewise, [i: Elements III.7] since LA is less than LI, LK, and LC, the squares on FL and LA together will be less than the squares on FL and LI together. [k: Elements I.47] But the square on FA equals the squares on FL and LA together, just as the square on FI equals the squares on FL and LI together. Therefore the square on FA will be less than the square on FI; and for that reason the straight line FA too will be less than the straight line FI. In the same way we shall show that the straight line FA is less than FK and FC. Therefore FA is the least of all the straight lines falling from F onto the arc AC.

Finally, [l: Elements III.7] since LI is less than LK, the squares on FL and LI together will be less than the squares on FL and LK together; but the square on FI equals the squares on FL and LI together, just as the square on FK equals the squares on FL and LK together. Therefore the square on FI will be less than the square on FK, and hence the straight line FI is less than the straight line FK.

Now if the straight line AB cuts the circle ABCD into two equal parts, so as to be its diameter, we have already proved — in the third theorem of the scholium to proposition 21 of the preceding book — that the straight line FB is the least and FA the greatest. Hence there is no need to demonstrate the same thing in this place. Indeed, more was demonstrated there than is set forth here. Therefore, if a straight line cuts a circle into unequal parts, and so on. Which was to be shown.

THEOR. 2. PROP. 2.

If a straight line cutting a circle cuts off a segment that is not less than a semicircle, and upon that straight line another segment of a circle is set up which is not greater than a semicircle and is inclined to the other segment (which is not greater than a semicircle), and the circumference of the standing segment is divided into unequal parts: then the straight line subtending the smaller part of the circumference is the least of all the straight lines drawn from that point, from which it is drawn, to that circumference of the underlying circle which is not less than a semicircle; and all the rest that held in the preceding proposition follows here too.

Let the straight line AB cut off from the circle ABCD (whose center is E) a segment ACB that is not less than a semicircle — either equal to a semicircle, as in the first figure, or greater, as in the other figures; and upon the straight line AB let another segment of a circle, AFB, be set up that is not greater than a semicircle — either equal to a semicircle, as in the last of the three figures, or less, as in the first two figures — and inclined to the other segment ADB, which is not greater than a semicircle, since ACB is supposed either equal to or greater than a semicircle. Let the circumference AFB be divided at F into unequal parts, and let FB be the smaller. From F let a perpendicular FL be dropped onto the plane of the circle ACBD; it will fall toward the side of segment ADB, because the segment AFB is inclined toward segment ADB, so that the point L is either inside segment ADB, or outside, or else on the very circumference ADB. Through the center E and the point L let the diameter CD be drawn; and from F onto the circumference ACB let many straight lines fall — FB, FG, and the rest. I say that FB is the least of all; that FG is less than FH; that FC is the greatest of all; that FA is the least of all the lines that fall from F onto the circumference AC; and that FI is less than FK. Let the straight lines LB, LG, LH, LA, LI, LK be drawn from L, and all the angles at L that the perpendicular FL makes will be right angles, by definition 3 of book 11 of Euclid. [a: Elements III.7, or 8, or 15] Since therefore the straight line LD is the least of all (though this line amounts to nothing at all in that figure where the point L falls on D), and LB is less than LG, LH, LC, LK, LI, LA, while LC is the greatest of all, and so on, we shall demonstrate, as in the preceding proposition, that FB is the least of all the lines and FG less than FH; likewise that FC is the greatest of all, and FA the least of all those falling from F onto the circumference AC, and FI less than FK. Therefore, if a straight line cutting a circle, and so on. Which was to be shown.

Diagram. The set of three circle-figures illustrating Theorem 2 (the "first," "second," and "last of the three" figures referred to in the text). In each figure a chord AB is drawn roughly horizontally across the circle; the apex F stands at the top, the point C at the bottom, and D in the upper right. Many straight lines are drawn from F to the points on the circumference (FB, FG, FH, FA, FI, FK, FC), forming a fan of rays. The point L lies on the diameter CD (drawn through the center E); across the three figures L falls, respectively, inside, related to, and on the circumference of segment ADB.

- F (top, apex): vertex from which the rays are drawn
- A (left end of chord AB)
- B (right end of chord AB)
- C (bottom of circle): endpoint of diameter CD
- D (upper right): endpoint of diameter CD
- E (center of circle)
- L (on diameter CD): foot of the perpendicular from F
- G, H (on lower-right arc): ray endpoints
- I, K (on lower-left arc): ray endpoints

SCHOLIUM.

Let these two figures be added to the three of this second proposition, so that all the cases of the perpendicular line FL may be surveyed. For in the first of these figures the standing segment AFB is a semicircle, and the perpendicular FL falls inside segment ADB; but in the latter the same FL falls on the circumference ADB itself, the same standing segment AFB being a semicircle; just as also in the third figure of the said proposition the same standing segment AFB is a semicircle, and the perpendicular line FL falls outside segment ADB. This, kind reader, we did not wish to keep hidden from you.

Diagram. The two supplementary figures added by the scholium, each a circle with chord AB, apex F at the top, and a fan of straight lines drawn from F. In the first figure the perpendicular FL falls inside segment ADB; in the second, FL falls on the circumference ADB.

- F (top, apex)
- L (below F): foot of the perpendicular
- A (left end of chord AB)
- B (right end of chord AB)
- E (center)

- C (bottom)
- G, H (lower-right arc)
- I, K (lower-left arc)

THEOR. 3. PROPOS. 3.

If in a sphere two great circles cut one another, and from each of them equal arcs are taken on both sides from the point at which they intersect: then the straight lines that join the endpoints of the arcs on the same sides are equal to one another.

Let two great circles ABC, DBE in a sphere cut one another at B, and on each circle, on both sides of B, let two equal arcs BA, BC and BD, BE be taken, and let the straight lines AD, CE be joined. I say that the straight lines AD, CE are equal. For with B as pole and BA as radius let a circle be described; it will pass through C as well, on account of the equality of the arcs BA, BC. Now either this same circle passes through D also — and hence through E, on account of the equality of the arcs BD, BE — or it does not. Let it first pass through D and E, as in the first figure; and let the common sections of the great circles with the circle ADCE be the straight lines AC, DE. Since the great circles ABC, DBE, passing through B, the pole of the circle ADCE, [a: Sphaerica I.15] cut it into two equal parts, AC and DE will be diameters of the circle ADCE, and F its center; and consequently the straight lines FA, FD are equal to the straight lines FC, FE. [b: Elements I.15] Since therefore they also contain equal angles at the vertex F, [c: Elements I.4] the straight lines AD, CE will also be equal.

But now let the circle described from B as pole with radius BA not pass through D, but run out beyond point D and hence beyond point E. If the circle AGCH were to pass on the near side of point D — which would indeed happen if the arc BD were greater than the arc BA — a circle would have to be described from B with a radius equal to the greater arc BD, so that it runs out beyond point A. Let the arcs BD, BE be produced to G, H. [d: Elements III.28] Since then the arcs BG, BH are equal — because, by the definition of a pole, the subtending straight lines BG, BH are equal — and since BD, BE are also equal by hypothesis, the remaining arcs DG, EH will likewise be equal. And since the straight lines drawn AG, CH are equal, as was just demonstrated in the first part of this proposition, [e: Elements III.28] the arcs AG, CH will also be equal. Since therefore the great circle GBH, drawn through the pole B, [f: Sphaerica I.15] cuts the circle AG, CH into two equal parts and at right angles, the chord GH will stand perpendicular to the diameter of the circle AG, CH. Since then the arcs DG, EH are equal and less than half the arc GDH, and since the arcs GA, HC have also been shown equal, [g: Sphaerica

II.12] the straight lines DA, EC will be equal to one another. Therefore, if in a sphere two great circles cut one another, and so on. Which was to be demonstrated.

Diagram. The two figures for Theorem 3. In the first circle the chords AC and DE cross at the center F, together with the joining lines AD and CE. In the second circle the arcs BD, BE have been produced to G and H, so that the second (larger) circle AGCH is described.

First figure:

- A (top left)
- D (top right)
- B (center-left, at the mutual intersection)
- F (center): center of circle ADCE
- E (bottom left)
- C (bottom)

Second figure:

- A (top left)
- G (top right)
- D (right, below G)
- B (center, at the intersection)
- E (lower left)
- H (bottom left)
- C (bottom right)

THEOR. 4. PROPOS. 4.

If in a sphere two great circles cut one another, and from one of them equal arcs are taken on both sides from the point at which they intersect, and through the points bounding the equal arcs two parallel planes are drawn, one of which meets the common section of those circles outside the sphere on the side of the said point; and if one of those equal arcs is greater than either of the arcs intercepted on the other great circle between the said point and each of the parallel planes: then the arc that lies between that point and the plane which does not meet the common section of those circles is greater than the arc of the same circle that lies between the same point and the plane which does meet the common section of the circles.

Let two great circles ABC, DBE in a sphere cut one another at B, and in ABC let equal arcs BA, BC be taken, and through the points A, C let two parallel planes be drawn [a: Sphaerica I.1] producing on the surface of the sphere the circumferences of the circles AFG, CHI, which cut the circumference DBE at the points F, H; and let the arc BA, or BC, be greater than either of the arcs BF, BH intercepted between the point B and the parallel planes. Next, from the pole B with radius BA or BC let a circle ADCE be described; it will pass beyond the points F, H, because the arcs BF, BH are supposed less than the arcs BA, BC. Let the arcs BF, BH be produced as far as the circumference of the circle ADCE, to the points D, E; and let the common sections of the circle ADCE with the circles AFG, CHI be the straight lines AG, CI; and let the common sections of the great circles with the circle ADCE be the straight lines AC, DE, which will be its diameters, and K its center, [b: Sphaerica I.15] since the great circles cut it into two equal parts through the pole B. Let the straight line DE cut the straight lines AG, CI at M, N. Let the common section of the great circles, KB, likewise be a straight line, with which, produced toward B, the plane AFG (produced outside the sphere) meets at the point L. This being so, the other plane CHI will not meet the straight line KB on the side of B, lest it should meet the plane AFG parallel to it. I say that the arc BH is greater than the arc BF. For let the straight lines FM, HN be the common sections of the circle DBE with the circles AFG, CHI. And since the plane AFG, produced, meets [the straight line]

Diagram. A sphere-schematic for Theorem 4. The great circle ABC and the circle DBE cut at B; the circle ADCE is drawn through A, D, C, E with center K. The common section KB is produced to meet, outside the sphere, at the apex L above the sphere. The straight lines DE, AG, CI cross the interior; DE meets AG, CI at M, N; the common sections FM, HN are shown.

- L (top, outside the sphere): meeting point of the produced planes
- A (upper left)
- I (upper right)
- B (center, on the great-circle line)
- H (right of B)
- E (right edge)
- F (center-left)
- N (center-right)
- K (center): center of circle ADCE
- M (lower left)
- D (left edge)

- G (bottom left)
- C (bottom right)

[The demonstration of THEOR. 4 continues from the foot of the preceding page; the sphere-figure is reprinted at the top of this page — it is the same as fig-p677-2 above and is not re-described.]

the straight line KB, produced to L, the point L will be both in the plane DBE and in the plane AFG, and hence in their common section, namely in the straight line MF. Therefore MF, produced, will coincide with KB produced at L. Now since the plane DBE cuts the parallel planes AFG, CHI, [c: Elements XI.16] the sections made, ME and NH, will be parallel. Again, since the plane ADCE cuts the same parallel planes, [d: Elements XI.16] the sections made, AG and CI, will likewise be parallel. [e: Elements I.29] Therefore the alternate angles KAM, KCN are equal. [f: Elements I.15] But the angles AKM, CKN are also equal, being vertical, and the sides KA, KC are equal, since they are radii of the circle ADCE. [g: Elements I.26] Therefore the sides KM, KN will also be equal; and the radii KD, KE are equal as well. Hence the remaining straight lines DM, EN will be equal. Again, since the straight line BK, drawn from B, the pole of the circle ADCE, to its center K, [h: Scholium to Sphaerica I.8] is perpendicular to the plane of the circle, the angle MKL in the triangle KLM will be a right angle, by definition 3 of book 11 of Euclid. [i: Elements I.17] Therefore the angle KML will be acute. [k: Elements I.29] Since then the two angles FMN, HNM are equal to two right angles, the angle HNM will be obtuse. Wherefore, as we shall presently show by the following lemma, the arc EH will be less than the arc DF; and hence, [l: Elements III.28] since the arcs BD, BE are equal — because the subtending straight lines BD, BE are equal, by the definition of a pole — the arc BH will be greater than the arc BF. Therefore, if in a sphere two great circles cut one another, and so on. Which was to be demonstrated.

LEMMA.

That the arc EH is less than the arc DF we shall easily demonstrate, once the theorem here set down has first been proved.

If a straight line is subtended to an arc of a circle, and from the arc two perpendiculars are dropped to it cutting off, toward the ends of the arc, two equal arcs: these same perpendiculars will cut off two equal straight lines from the subtending line. And if two perpendiculars are drawn to the subtending line cutting off two equal straight lines: these same will cut off two equal arcs.

Let a straight line AD be subtended to the arc ABCD of a circle, and to it let two perpendiculars BE, CF be dropped from the arc, cutting off two equal arcs AB, DC. I say that they cut off equal straight lines AE, DF. For when the straight line BC is drawn, [m: Scholium to Elements III.27] AD and BC will be parallel, on account of the equality of the arcs AB, DC; [n: Elements I.28] and BE, CF are also parallel. Therefore BEFC is a parallelogram, [o: Elements I.34] and hence the straight lines BE, CF are equal. [p: Elements III.29] And since to the equal arcs AB, DC the subtending straight lines AB, DC are equal, the squares on AB, DC will be equal. [q: Elements I.47] Since therefore the one is equal to the squares on AE, BE together, and the other to the squares on DF, CF together, if the equal squares of the straight lines BE, CF are taken away, the squares of the straight lines AE, DF will be equal; and consequently the straight lines AE, DF will be equal. Which was proposed in the first place.

Diagram. The figure for the lemma. An arc ABCD stands over the straight base line AD. From the arc the perpendiculars BE and CF are dropped to AD (BE at E, CF at F), forming the parallelogram BEFC. For the second part, an equal arc AG is cut off and the perpendicular GH is dropped from G to AD.

- A (bottom left): end of the base line
- H (on AD, near A): foot of perpendicular GH
- E (on AD): foot of perpendicular BE
- F (on AD): foot of perpendicular CF
- D (bottom right): end of the base line
- G (top left, on the arc)
- B (top, above E, on the arc)
- C (top, above F, on the arc)

But now let the perpendiculars BE, CF cut off equal straight lines AE, DF. I say that they cut off equal arcs AB, DC. For if they are not equal, let the arc AB be the greater, if that be possible, and from it let an equal arc AG be cut off, and from G let a perpendicular GH be drawn to AD. Then, as was just demonstrated, the straight line AH will be equal to the straight line DF, and hence also to the straight line AE — a part equal to the whole: which is absurd. Therefore the arc AB is not greater than the arc DC; and by the same reasoning neither is it less. Therefore it is equal. Which was the thing proposed. From these things it is clear that the arc HE, in the figure of the proposition, is less than the arc DF. For since the angle FMK is acute and HMK obtuse, if perpendiculars were drawn from M, N to DE, they would fall on the arcs DF, BH and would cut off equal arcs, as we showed in the previous lemma. Wherefore the arc HE is less than the arc DF.

THEOR. 5. PROP. 5.

If on the circumference of a great circle there is a pole of the parallels, and this great circle is cut at right angles by two other great circles, of which one is one of the parallels and the other is oblique to the parallels; and if from this oblique circle equal arcs are taken in succession toward the same side of the greatest of the parallels, and through the points bounding these equal arcs parallel circles are described: then the arcs of that first-mentioned great circle intercepted between the parallels will be unequal, and always the one that is nearer to the greatest of the parallels will be greater than the one farther off.

On the circumference of the great circle ABCD let A be the pole of the parallels, and let two great circles BD, EC cut it at right angles, of which BD is the greatest of the parallels and EC is oblique to the parallels; and through F, G, H — the points which cut off equal arcs FG, GH from the oblique circle — let the parallel circles IK, LM, NO be described from the pole A. I say that the arc IL is greater than the arc LN. [a: Sphaerica I.20] For through the pole A and the point G let a great circle AP be described, cutting the parallels at P, Q. Since then a point G, distinct from the pole A, has been marked on the surface of the sphere within the periphery of the circle IK, and from G two arcs GP, GF of great circles fall onto the circumference of the circle

Diagram. A sphere-schematic for Theorem 5. The great circle ABCD is shown with the vertical diameter AC (A at the top, pole of the parallels; C at the bottom) and the horizontal diameter BD (B at the left, D at the right). The oblique great circle EC runs across, and the three parallel circles IK, LM, NO are drawn as arcs; the great circle AP through the pole A and the point G cuts the parallels at P, Q. The interior points F, G, H, P, Q cluster near the center.

- A (top): pole of the parallels
- C (bottom)
- B (left): endpoint of the horizontal diameter
- D (right): endpoint of the horizontal diameter
- E (upper left): on the oblique circle EC
- O (upper right): endpoint of parallel NO
- N (left, upper): endpoint of parallel NO
- L (left, middle): endpoint of parallel LM
- M (right, middle): endpoint of parallel LM
- I (left, lower) [?]: endpoint of parallel IK

- K (right, lower): endpoint of parallel IK
- H (upper center): point on the oblique circle
- Q (upper center, right of H): intersection of AP with a parallel
- G (center): point on the oblique circle
- P (center-lower) [?]: intersection of AP with a parallel
- F (center-lower): point on the oblique circle

(Continuation of THEOR. 5. PROP. 5 — the demonstration begun on the preceding page, broken off at the catchword "circuli.")

of the circle IK. [Margin: b — Sphaerica II.21, scholium] Then the arc GP will be the smallest of all, and therefore smaller than GF — because the arcs GP and GF are less than a semicircle, since they do not intersect one another before the parallel IK divides them. For since GP is part of the quadrant running from A through G as far as the greatest of the parallels BD, it will not be able to cut the arc GF except beyond the circle IK, otherwise GP would be either a semicircle or greater than a semicircle — namely if it were to cut GF either at F or short of F. Again, since the point G is marked on the surface of the sphere outside the circumference of the circle NO, apart from its pole, [Margin: c — Sphaerica II.21, scholium] the arc GQ will be the smallest of all those falling from G, that is, smaller than GH — because the arcs GQ and GH are less than a semicircle, since they do not meet one another before reaching the parallel NO (which will be demonstrated, just as was said a little earlier of the arcs GP and GF). Therefore each of the arcs FG and GH is greater than each of GP and GQ.

And the straight line drawn through G and the center of the sphere — that is, the common section of the greatest circles AP and EC — is cut by the parallel plane IK within the sphere (for that line will not reach the center of the sphere, that is, the center of the greatest circle BD, unless it first cuts the plane of the circle IK, since the parallel IK is placed between the greatest of the parallels and the point G). Consequently the same straight line will cut the plane of the parallel NO outside the sphere, if that line and the plane of the circle are produced toward the side of G — because the point G lies between the greatest of the parallels and the parallel NO. Therefore, since the two greatest circles AP and EC cut one another at the point G, and from the circle EC two equal arcs GF, GH have been taken on either side of the point G, and through F and H the parallel planes of the circles IK and NO have been drawn — of which NO meets the common section of the greatest circles AP and EC outside the sphere, as has been shown — and since each of the arcs GF and GH is greater than each of the arcs GP and GQ: [Margin: d — Sphaerica III.4] the arc GP will be greater than the arc GQ. [Margin: e —

Sphaerica II.10] But the arc GP is equal to the arc IL, and the arc GQ to the arc LN. Therefore the arc IL too will be greater than the arc LN. And so, if the pole of the parallels lies on the circumference of a greatest circle, and so on. Which was to be demonstrated.

THEOR. 6. PROP. 6.

[Margin: iv.]

If the pole of the parallels lies on the circumference of a greatest circle, and two other greatest circles cut this greatest circle at right angles — one of them being one of the parallels, the other oblique to the parallels — and if equal circumferences are taken in succession on the oblique circle toward the same side of that greatest parallel, and through the points bounding those equal circumferences, and through the pole, greatest circles are described: these will cut off unequal circumferences from the greatest of the parallels, of which the one nearer to the greatest circle first posited will always be greater than the more remote.

In the circumference of the greatest circle ABCD let A be the pole of the parallels, and let two greatest circles BD and EC cut it at right angles, of which BD is the greatest of the parallels, while EC is oblique to the parallels. On EC let equal arcs FG, GH be taken; and through the points F, G, H, [Margin: a — Sphaerica I.20] and through the pole A, let the greatest circles AI, AK, AL be described, cutting BD at I, K, L. I say that the arc KL is greater than the arc IK. For through the same points F, G, H let the parallels MN, OP, QR be described, cutting AK at V, G, X. [Margin: b — Sphaerica III.5] Then the arc MO will be greater than the arc OQ; and therefore, [Margin: c — Sphaerica II.10] since the arc VG is equal to the arc MO and the arc GX to the arc OQ, VG too will be greater than GX. Let the arc GY be taken equal to GX, and through Y let the parallel ST be described, cutting the circle AI at Z. Now since the arcs GY, GX are equal, as are GF, GH, [Margin: d — Sphaerica III.3] the drawn straight lines HX, YF will be equal. And since the greatest circle AI, passing through the pole A, [Margin: e — Sphaerica I.15] cuts the circle ST at right angles and bisects it, the common section — namely the straight line drawn from Z to the other section — will be a diameter of the circle ST, upon which stands a semicircle at right angles to the circle AI, namely the semicircle beginning at the point Z and proceeding through S as far as the other section (that is, a segment of the circle that is not greater than a semicircle). And that straight line cuts off from the circle AI a segment greater than a semicircle — namely the one drawn from the point Z through I as far as the other section with the circle ST; and YZ is an arc of the standing semicircle less than a quadrant

(because the arc IK, [Margin: f — Sphaerica II.10] which is similar to it, is also less than a quadrant, which can be shown as follows.

For since the greatest circles BD, EC are at right angles to the greatest circle ABCD, this in turn will be at right angles to them, and consequently will pass through their poles. [Margin: g — Sphaerica I.11] Hence it will bisect their segments, [Margin: h — Sphaerica II.9] which are semicircles — that is, into quadrants. Therefore the arc of the circle BD lying between B and the point where the circles BD, EC cut one another is a quadrant, and consequently IK is less than a quadrant. For the circle AK falls between the points B, I, since it cuts the circle ABCD at the other pole.) And therefore the remaining arc, intercepted by the standing semicircle between Y and the other section with the circle AI, is greater than a quadrant; [Margin: i — Sphaerica III.1] hence the straight line YZ will be the smallest of all the straight lines falling from Y onto the circumference ZI, and therefore smaller than YF — that is, than HX, which we showed to be equal to the straight line YF. And so, since the circle QR is smaller than the circle ST, the greater straight line HX will cut off from its own circle a greater arc than the smaller straight line YZ cuts off from its own, as we shall soon show. Therefore the arc HX is greater than can be similar to the arc YZ. [Margin: k — Sphaerica II.10] But to the arc HX the arc KL is similar, and to the arc YZ the arc IK. Therefore KL too is greater than can be similar to IK; and consequently, since they are in the same circle, the arc KL will be greater than IK. And so, if the pole of the parallels lies on the circumference of a greatest circle, and so on. Which was to be demonstrated.

Diagram. A sphere shown in perspective as a bounding circle, belonging to the demonstration of THEOR. 5 PROP. 5 (concluded at the top of this page). The pole **A** is at the top and **C** at the bottom; the bounding great circle carries **B** on the left rim and **D** on the right rim. Several parallel circles cross the sphere as near-horizontal arcs, cut by oblique great circles that intersect near the center.

- **A** (top): pole of the parallels
- **E** (upper left, below **A**): on an oblique great circle
- **B** (left rim): end of the greatest parallel
- **D** (right rim): opposite end of the greatest parallel
- **C** (bottom): pole opposite **A**
- **N** (left, upper): on a parallel circle
- **O** (right, upper): on a parallel circle
- **M** (right rim): on a parallel circle
- **K** (right, mid): intersection point

- L, I (left, mid): intersections on the left
- H (center-left): intersection of oblique great circles
- Q (center): intersection point near the axis
- G (center): common section point of the great circles AP, EC
- F (center, right of P): point on oblique circle
- P (center-left, below G): point on great circle

Diagram. The sphere for THEOR. 6 PROP. 6. The pole **A** is at the top, **C** at the bottom; a family of parallel circles runs across the globe, cut by two great circles at right angles (BD the greatest parallel, EC oblique) and by great circles drawn through the pole A to I, K, L on BD.

- A (top): pole of the parallels
- E (upper left, below A): on the oblique great circle EC
- Q, O, S, M, B (left rim, top to bottom): points on the left of the sphere
- R, P, T, N, D (right rim, top to bottom): points on the right of the sphere
- H, X (upper center): intersections on circle AK / parallels
- G (center): a division point of the equal arcs on EC
- Y (center, below G): point taken so that arc $GY = GX$
- V (center, lower): intersection of AK with a parallel
- F (center, lower): division point of the equal arcs
- L, K, I (lower center): feet on BD of the great circles from A
- C (bottom): pole opposite A

LEMMA.

That the straight line HX cuts off a greater arc from its own circle than the straight line YZ does from its own will become clear if the theorem that follows is first demonstrated.

Equal straight lines cut off unequal arcs from unequal circles, and the arc of the smaller circle is greater than can be similar to the arc of the greater circle.

Let there be unequal circles AB, CD about the same center E; and from E let two straight lines EA, EB be drawn in any manner, cutting the circle CD at the points C, D, and let the same angle E stand at the center. [Margin: a — Euclid VI, scholium 33] Then the arcs AB, CD will be similar, since the same angle E stands upon them at the center. And since the straight lines EA, EB are cut proportionally at the points C, D — because EA, EB are equal, as are EC, ED —

[Margin: b — Euclid VI.2] the drawn straight lines AB, CD will be parallel; [Margin: c — Euclid VI.4, corollary] and therefore the triangles EAB, ECD are similar, having the angles EAB, ECD equal to one another, and likewise the angles EBA, EDC, and the angle E common. [Margin: d — Euclid VI.4] Hence EA is to AB as EC is to CD. But EA is greater than EC. [Margin: e — Euclid V.14] Therefore AB too will be greater than CD. [Margin: f — Euclid IV.1] Let then a straight line BF equal to CD be fitted into the circle AB; [Margin: g — Euclid III, scholium 28] and the arc AB will be greater than FB. So, since the arc CD is similar to the arc AB, the arc CD will be greater than can be similar to FB. Therefore the equal straight lines FB, CD cut off unequal arcs from the unequal circles AB, CD, and the arc CD of the smaller circle is greater than can be similar to the arc FB of the greater circle. Which was what was proposed.

From this it is clear that a much greater line cuts off from the smaller circle a far greater arc than can be similar to the one which a smaller line cuts off from the greater circle. For since the straight line CD, equal to FB, cuts off the arc CD greater than can be similar to the arc FB, all the more will a line greater than CD cut off [Margin: h — Euclid III, scholium 28] a greater arc than can be similar to the arc FB — since that greater line cuts off a greater arc than CD does. And so in this sixth proposition too, the straight line HX, being greater than the straight line YZ, will cut off from the smaller circle QR the arc HX greater than can be similar to the arc YZ, which the straight line YZ cuts off from the greater circle ST.

But this demonstration is to be understood only of arcs less than a semicircle, such as BF, CD are, as is clear from the demonstration itself. For otherwise the angle at the common center E could not be constructed — which is nevertheless required for the demonstration. Yet it will still be true, if the smaller arc of the smaller circle is greater than can be similar to the smaller arc of the greater circle, that the greater arc of the smaller circle is much greater than can be similar to the smaller arc of the greater circle. And if it should ever happen that the straight line CD cuts off a semicircle from the smaller circle — that is, that it is its diameter — it is plainly evident that the semicircle of the smaller circle is greater than can be similar to the smaller arc of the greater circle: and then there will be no need of any other demonstration.

Now, with this lemma demonstrated, we shall also easily show that equal straight lines cut off from unequal circles arcs that are unequal without qualification — so that the arc of the smaller circle is absolutely greater than the arc of the greater circle, and not merely greater than can be similar to it. For let the straight lines CD, BF be equal, and let CD cut off the arc CED of the smaller circle, and FB the

arc FGB of the greater circle. I say without qualification that the arc CED is greater than the arc FGB. For when the straight line CD is made to coincide with the straight line FB, the arc CED will necessarily fall outside the arc FGB; and thus the arc CED will be greater than the arc FGB, since the latter contains the former wholly within itself, both arcs being concave toward the same side and having the same endpoints, as Archimedes requires in the postulates prefixed to Book 1 of *On the Sphere and Cylinder* [Archimedes, *De sphaera et cylindro* I, postulates]. Nor indeed will the arc CED coincide with the arc FGB or fall within it. For if it were said to coincide, then the whole circumference of the circle CED would also coincide with the whole circumference of the circle FGB, and thus the circles would be equal — which is absurd, since they are supposed unequal. But if the arc CED were said to fall within the arc FGB — such as the arc CAD is — then, since (as was shown a little earlier in this lemma) the arc CED, that is CAD, is greater than can be similar to the arc FGB, let an arc HFB be taken similar to the arc CAD, and therefore greater than the arc FGB. Then, taking a point A on the arc CAD, let straight lines AF, AB be drawn to both; and, the straight line FA being produced until it cuts the arc FGB at G, let the straight lines GH, GB be drawn. So then, since the arcs CAD, HFB are similar, the angles CAD, HGB standing in those [Margin: i — Euclid I.16] segments will be equal. But since the angle CAD is greater than the angle CGB — the external than the internal — and the angle CGB is also greater than the angle HGB — the whole than the part — the angle CAD will be much greater than the angle HGB. Which is absurd, for it was shown to be equal. Therefore the arc CED will not fall within the arc FGB; but neither does it coincide with it, as has been demonstrated. It falls, then, outside; and thus the arc CED will be greater than the arc FGB, as was said.

From this too it is plainly evident that a much greater line cuts off from the smaller circle an arc absolutely greater than the one which a smaller line cuts off from the greater circle.

Diagram. Two concentric circles about the common center **E**. The chord of the larger circle runs from **A** (left) to **B** (right); the chord of the smaller circle runs between **C** and **D**; **F** sits on the top of the larger circle. Radii EA, EB pass through C and D.

- F (top of the larger circle): endpoint of arc FB / vertex
- A (left, larger circle): endpoint of chord AB
- B (right, larger circle): endpoint of chord AB
- C (center-left, smaller circle): where EA meets the smaller circle
- D (center-right, smaller circle): where EB meets the smaller circle

- E (center): common center of both circles

Diagram. A wide arc standing on the base line **H–B**, with the arcs CED and FGB drawn near its top. The chords AF, AB and GH, GB of the construction are shown.

- H (left, base line): endpoint of the base
- B (right, base line): endpoint of the base / shared endpoint of the arcs
- C (upper left, on the arc): endpoint of arc CED / CAD
- E (top): summit of arc CED
- F (upper center): point on arc FGB / HFB
- A (center): point taken on the arc CAD
- G (upper center-right): where FA produced cuts arc FGB
- D (right, on the arc): shared endpoint of the arcs

Diagram. A smaller companion figure below the previous one: a single arc on the base line **C–D** with **E** at its summit.

- E (top): summit of the arc
- C (left): endpoint of the base
- D (right): endpoint of the base

THEOR. 7. PROP. 7.

[Margin: v.]

If in a sphere a greatest circle touches some circle of the sphere, and another greatest circle is oblique to the parallels and touches circles greater than those which the greatest circle first posited touches, and their points of contact are on the greatest circle first posited; and if from the oblique circle equal and successive circumferences are taken toward the same side of the greatest of the parallels, and through the points bounding the equal circumferences parallel circles are described: these will cut off unequal circumferences from the greatest circle first posited, of which the one that is nearer to the greatest of the parallels will be greater than the more remote.

In the sphere let the greatest circle ABCD touch the circle AE at the point A, [Margin: a — Sphaerica II.6] and therefore also another circle CF equal to it. Let another greatest circle GH, oblique to the parallels, touch two other circles greater than those which ABCD touches, and let the points of contact G, H be on the greatest circle ABCD; and let BD be the greatest of the parallels. Finally, on the oblique circle GH let equal arcs IK, KL be taken, and through the points I, K, L let

the parallels MN, OP, QR be described. I say that the arc MO is greater than the arc OQ. [Margin: b — Sphaerica I.20] For through K and S, the pole of the parallels, let the greatest circle SK be described, cutting the parallels at the points T, V. [Margin: c — Sphaerica II.15] Likewise through K let the greatest circle KE be described, touching the parallel AE at E, and cutting the other parallels at X, Y — yet in such a way that these points X, Y lie between the points L, T and V, I. This will come about as follows. [Margin: d — Sphaerica II.15, scholium] Since through K two circles can be described touching the circle AE, of which one falls between the arcs KG, KS, while the other falls outside them (for if both were to touch the circle AE on the same side, they would cut one another near the points of contact, in that one would meet the other — which is absurd, since they intersect at the point that is opposite to K, between the other pole and the greatest of the parallels): one of the two will touch the circle AE to the right of KS, which bisects the circle AE, and the other to the left, falling between KG and KS — such as KE is. For if it were to fall outside KG, it could not touch the parallel AE, because it does not meet KG before the point opposite to K, where they bisect one another.) If the former is taken, the points X, Y will fall between the points L, T and V, I, as is evident, since at K it cuts both KG, KS. Therefore, since on the surface of the sphere, within the periphery of the circle MN, the point K is marked, apart from the pole S, and from K three arcs fall onto its circumference, KV, KY, KI, [Margin: e — Sphaerica II.21, scholium] KV will be the smallest of all, and KY smaller than KI. Again, since on the surface of the sphere, outside the periphery of the circle QR, the point K is marked, apart from its pole, and from K three arcs KT, kX, KL fall onto its circumference, [Margin: f — Sphaerica II.21, scholium] KT will be the smallest of all, and KX smaller than KL. Therefore each of the arcs KI, KL is greater than each of KY, KX. And since the straight line drawn through K and the center of the sphere — that is, the common section of the greatest circles GH, EY — cuts the plane of the parallel QR outside the sphere, if that line and the plane of the circle QR are produced toward the side of K, as was stated in the demonstration of Proposition 5 of this book; [Margin: g — Sphaerica III.4] the arc kY will be greater than the arc kX. [Margin: h — Sphaerica II.13] But the arc MO is equal to the arc kY, and the arc OQ to the arc kX; for they are semicircles, of which one is drawn from A through B, the other from E through k, not coinciding, as is clear from what we said in the demonstration of Proposition 13 of the second book. Therefore the arc MO too will be greater than the arc OQ. If, then, in a sphere a greatest circle touches, and so on. Which was to be demonstrated.

Diagram. The sphere for THEOR. 7 PROP. 7, drawn as a large bounding circle with a small tangent circle below it. Near the top, a small circle around A carries S (the pole) and E, with G at the top left. A family of parallel circles crosses the

globe; **B/D** and the flanking letters mark the rims. The small circle at the bottom (touching the sphere at **H**) carries **C** and **F**.

- G (top left): point of contact on the oblique great circle
- A (top): point of contact of ABCD with circle AE
- E (near A, left): contact of circle KE with parallel AE
- S (below A, in the small upper circle): pole of the parallels
- Q, O, M, B (left rim, top to bottom): points on the left of the sphere
- R, P, N, D (right rim, top to bottom): points on the right of the sphere
- L, X, T, K, V, Y, I (central cluster, top to bottom): feet and intersections on the parallels
- H (on the small lower circle): point of contact
- C (center of the small lower circle): the tangent circle CF
- F (lower, on the small circle): endpoint of circle CF

THEOR. 8. PROPOS. 8.

[Margin: vi.]

If in a sphere a greatest circle touches some circle of the sphere, and some other greatest circle, oblique to the parallels, touches circles greater than those which the greatest circle first posited touched, and their points of contact are on the greatest circle first posited; and if from the oblique circle equal, successive circumferences are taken toward the same side of the greatest of the parallels, and through the points bounding these equal circumferences greatest circles are described which both touch the same circle that the greatest circle first posited touched, and intercept similar circumferences of the parallels, and have those semicircles which extend from the points of contact to the points bounding the equal circumferences of the oblique circle (through which they are described) of such a kind that they in no way coincide with that semicircle of the greatest circle first posited in which lies the contact of the oblique circle, between the apparent pole and the greatest of the parallels: then they will intercept unequal circumferences from the greatest of the parallels, of which the one nearer to the greatest circle first posited will always be greater than the more remote.

In the sphere let the greatest circle AB touch the circle AC at A, [Margin: a — Sphaerica II.6] and therefore another circle equal and parallel to it; and let another greatest circle DE, oblique to the parallels, touch other greater parallels,

and let the contacts be on the circle AB — such as the point D is; and let BE be the greatest of the parallels. Then, on the oblique circle DE let equal arcs FG, GH be taken; and through the points F, G, H let the greatest circles CI, kL, MN be described, touching the paralle-

(Continuation of THEOR. 8. PROPOS. 8, the demonstration of which began on the preceding page.)

the parallel AC in C, K, M, and cutting BE, the greatest of the parallels, in I, L, N, in such a way that they intercept similar arcs of the parallels, and their semicircles — beginning from the points C, K, M and passing through F, G, H — do not coincide with the semicircle of circle AB, which begins at A and passes through B. I say that arc IL is greater than arc LN.

For let there be described, through F, G, H, the parallels PF, QG, RH, cutting circle KL in O, S. [Margin: b — 7.huius (Sphaerica III.7)] Therefore arc PQ will be greater than arc QR; [Margin: c — 13.2.hui (Sphaerica II.13)] and since arcs GO, GS are equal to these, GO too will be greater than GS. Let GT be made equal to GS, and through T let the parallel VT be described, cutting circle MN in X. Now the common section of circles MN and VX — that is, the straight line drawn from section X to the other section — cuts off a segment which begins at X, passes through V, and reaches the other section, and this segment is less than a semicircle. [Margin: d — 19.2.hui (Sphaerica II.19)] (For circle MN, the greatest of the circles, cutting the parallel VX not through the poles, cuts off a segment greater than a semicircle — namely the one lying between the greatest of the parallels and the visible pole, such as the segment beginning at X, passing through α , and reaching the other section with circle MN.) It also cuts off from the greatest circle MN a segment greater than a semicircle — namely the one which, beginning at X and passing through N, reaches the other section; and segment XV is inclined, relative to segment XM, toward those parts. For if through N and Y, the pole of the parallels, a great circle YN be described, [Margin: e — 15.1 hui (Sphaerica I.15)] this will be perpendicular to BE. Therefore MN, which is set between these two circles,

[Margin: f — Scho.15.2. huius (Scholium to Sphaerica II.15)] (For since from point F two circles tangent to parallel AC can be drawn — one to the left of the great circle YN and the other to the right — we choose the former, so that it may be set between the great circles YN and BE.) is inclined toward the parts R relative to the same BE; and in turn BE, and hence also VX, which is parallel to it, will be inclined toward the same parts R relative to MN. Likewise the segment which begins at X, passes through V, and reaches the other section is cut unequally at T,

and TX is the lesser part, as we shall show shortly. [Margin: g — 2. huius (Sphaerica III.2)] Therefore the straight line TX is less than the straight line TF; [Margin: h — 3. huius (Sphaerica III.3)] but the straight line TF is equal to the straight line HS. Therefore the straight line TX will also be less than the straight line HS; and hence, as was demonstrated in the lemma to proposition 6 of this book, arc HS will be too great to be similar to arc TX. [Margin: i — 13.2. hui (Sphaerica II.13)] Since, then, arc IL is similar to arc HS, and arc LN to arc TX, arc IL too will be too great to be similar to arc LN; and hence, since they lie in the same circle, IL will be greater than LN. If, therefore, in a sphere a great circle touches some circle of the sphere, etc. Which was to be demonstrated.

Diagram. A large spherical figure for the demonstration of Theor. 8. The visible pole A is at the top, with the pole cluster crowded around it; a family of parallel circles runs across the sphere, cut obliquely by great circles. A separate small pair of concentric circles is drawn below the sphere (unlabeled). Because the woodcut is dense and the labels near the pole overlap, several small labels cannot be resolved individually; the figure

- A (top): visible pole of the parallels
- D, Y, Z (upper region, near the pole): points on the great circles near A [several adjacent tiny labels near the pole unresolved [?]]
- Q, P, V, B (left meridian, descending): points on the left-hand circles
- H, G, S (upper-middle): points where the oblique/parallel circles meet
- T, X, O, F (middle): X on circle MN; T, F on the parallels
- I, L, N, E (base): I, L, N on the greatest parallel; E on the oblique circle
- α (near X, lower-middle): the point through which the segment from X passes [Greek label, faint [?]]
- M, C (pole cluster): present but crowded [?]

LEMMA I.

That arc TX is less than half the segment which begins at X, passes through V, and extends to the other section, we shall demonstrate as follows. Through E let a great circle EZ be drawn, tangent to the parallel AC at the point Z, which is to be on the right-hand side of the great circle NY [Margin: k — Scho.15.2. huius (Scholium to Sphaerica II.15)] — since from E two circles tangent to AC can be described, one to the left of circle NY and the other to the right. And EZ will be a quadrant. For [Margin: l — 15.2. hui (Sphaerica II.15)] the great circle ZY passes through Y, the pole of circle AC, and through Z, [Margin: m — 9.2. hui (Sphaerica II.9)] the pole of the tangent circle EZ. Therefore this same circle YZ will bisect the

segments of the circles BE, EZ. [Margin: n — 11.1.hui (Sphaerica I.11)] Since, then, these great circles bisect one another, the segment from point E, through Z, as far as the other section, will be cut into two quadrants at point Z; and hence EZ will be a quadrant. In the same way ED will be a quadrant, if through the pole Y and the point of contact D a great circle YD be described. [Margin: o — Corol 16. 1.huius (Corollary to Sphaerica I.16)] Moreover, the arc of the great circle between E and Y, the pole, is a quadrant. Therefore the great circle described from E as pole, with radius EZ, will pass through the points Y and D. In no other way shall we show that NM is a quadrant, and hence that the great circle described from N as pole, with radius NM, passes through Y, the pole of the parallels — such as is the circle MY — and hence cuts arc BD beyond point D, and beyond the same arc DB: because the great circles ZYD and MY cut one another mutually at Y, the pole; and point M is beyond circle DYZ, as we shall show. And since the great circle MY, drawn through Y, [Margin: p — 5.2.hui (Sphaerica II.5)] the pole of parallel AC, and through the point of contact M, passes also through the pole of the tangent circle NM, it will pass [Margin: q — 9.2.hui (Sphaerica II.9)] through the poles of the circles XV and NM, which cut one another mutually at X. Therefore it will bisect their segments. Since, then, beyond point V it cuts the segment from X, through V, as far as another point where the circles XV, NM cut one another mutually — as has just been shown — arc XV will be less than half the segment from X, through V, to the other section; and hence TX will be much less than half that same segment. Which was the proposition. That the point of contact M lies beyond the great circle DYZ is demonstrated thus. Since the arc of the greatest of the parallels EB, between E and circle YD, [Margin: r — Coro. 16. 1.huius (Corollary to Sphaerica I.16)] is a quadrant, just as the arc of the same parallel between N and circle YM is a quadrant; and since point N is beyond E, toward B; circle YM too will be beyond YD; and hence M will lie beyond YD.

LEMMA II.

Given two unequal magnitudes, to find another, a mean, which is commensurable with any given magnitude whatsoever. [recte: PROPOSITIS; printed "PROROSITIS"]

Let there be set out two unequal magnitudes AB, AC, and some other given magnitude DG whatsoever; and let it be required to find another, a mean — that is, one which is greater than AC but less than AB, and commensurable with DG. Let DG first be less than BC, the excess between the magnitudes AB, AC; and let E be a multiple of DG that is the next multiple greater than AC. On this supposition, E will be less than AB. For if it were equal, then, if one magnitude equal to DG

(which is assumed to be less than BC) were subtracted from E, the remaining multiple of DG would still be greater than AC. Therefore E would not be the multiple of DG next greater than AC — which is absurd. Still less, then, will it be greater. Therefore it is less than AB; and hence, since it is also greater than AC, and commensurable with DG (being a multiple of it), the proposition is established.

But now let the given magnitude DG not be less than BC. Then let DG be bisected, and the half again bisected, and so on in succession, until there is left a part DF less than BC; let E be commensurable with DF, [Margin: a — 1. decim. (Elements X.1)] and hence also with DG, [Margin: b — 12. deci. (Elements X.12)] because both E and DG are commensurable with DF. Again, in the same way, as we demonstrated a little before, E will be less than AB. Since, then, it is also greater than AC, and commensurable with DG, the proposition is established.

Diagram. Three horizontal straight segments illustrating the commensurability lemma, each marked with subdivision ticks.

- Top segment: A — C — B (with tick marks between)
- Middle segment: D — G — E — (with equal tick marks, the multiple of DG)
- Bottom segment: D — I — G (with equal tick marks)

THEOR. 9. PROPOS. 9.

[Margin: viij.]

If the pole of the parallels lies on the circumference of a great circle which two other great circles cut at right angles — of which circles one is one of the parallels, while the other is oblique to the parallels — and if on this oblique circle equal arcs are taken which, though not continuous, nevertheless lie toward the same parts of that greatest parallel; and if through the pole and through each of the individual points bounding the equal arcs great circles are described: then these will intercept unequal arcs on the greatest parallel, of which the one nearer to the great circle first posited will always be greater than the more remote.

On the circumference of the great circle AB let A be the pole of the parallels, and let two great circles BC, DC cut it at right angles, of which BC is the greatest of the parallels and DC is oblique to the parallels; and on DC let there be taken equal, non-continuous arcs EF, GH. [Margin: a — 20.1.hui (Sphaerica I.20)] Through the points E, F, G, H and the pole A let the great circles AEI, AFK, AGL, AHM be described. I say that arc ML is greater than arc KI. For the intermediate arc FG is

either commensurable with both of the equal arcs EF, GH, or incommensurable. Let it first be commensurable. [Margin: b — 4.decim (Elements X.4)] Having found the greatest common measure X, let the three arcs EF, FG, GH be divided into parts equal to X, as appears in the first figure; [Margin: c — 20.1.hui (Sphaerica I.20)] and through the points of division and the pole A let great circles be drawn. Since, then, the arcs EQ, QF, FP, etc., are equal, [Margin: d — 6.huius (Sphaerica III.6)] arc MR will be greater than arc RL, and RL greater than LS, etc. Therefore, since MR is greater than KV and RL greater than VI, the whole ML will be greater than the whole KI. Which was the proposition.

But now let the intermediate arc FG be incommensurable with both of the equal arcs EF, GH. I say again that arc ML is greater than arc KI. For if it is not greater, it will be either less or equal. First, if it be possible, let ML be less than KI, as in the second figure; and from KI let KN be taken equal to ML, [Margin: e — 20.1.hui (Sphaerica I.20)] and through N and A let a great circle AON be described, cutting circle CD in O. Then by Lemma 2 of the preceding proposition let an arc FP be found, greater indeed than FO but less than FE, and commensurable with FG; [Margin: f — 20.1.hui (Sphaerica I.20)] let GQ be equal to FP (which is less than EF, and hence less even than GH...) equal; and through P, Q and A let the great circles APR, AQS be described. Since, then, the arcs PF, GQ are equal and non-continuous, and their intermediate arc FG is commensurable with them, arc SL will be greater than arc KR, as was demonstrated in the first figure. Therefore it will also be much greater than KN; and hence ML too will be much greater than KN. But KN was posited equal to ML. Which is absurd. Therefore ML is not less than KI.

Next, if it be possible, let arc ML be equal to arc KI, as in the third figure. The arcs EF, GH having been bisected at N, O, [Margin: g — 20.1.hui (Sphaerica I.20)] let the great circles ANP, AOQ be described through N, O and A. [Margin: h — 6.huius (Sphaerica III.6)] Then arc MQ will be greater than arc QL, and KP greater than PI. Therefore QL will be less than half of MLK, and KP greater than half of KI. Since, then, ML and KI are posited equal, QL will be less than KP — which is absurd. For since the arcs FN, GO, the halves of the equal arcs EF, GH, are equal and non-continuous, QL cannot be less than KP, as was just demonstrated in the second figure. Therefore arc ML is not equal to arc KI; but neither was it shown to be less. Therefore it is greater. If, then, the pole of the parallels lies on the circumference, etc. Which was to be demonstrated.

Diagram (first figure). A hemisphere for Theor. 9 : pole A at the top, D at the upper left, the oblique great circle DC running down to C at the lower right, the

greatest parallel BC along the base, and radiating great circles from A. The interior labels along the oblique circle are crowded and several cannot be resolved

- A (top): pole of the parallels

- Interior points: H, O, G, F, N

SCHOLIVM.

Just as Theodosius in this proposition 9 demonstrated concerning non-continuous arcs the same thing that he had taught concerning continuous arcs in proposition 6, so in another version the same things are demonstrated in three theorems concerning non-continuous arcs which Theodosius demonstrated concerning continuous arcs in propositions 5, 7, and 8. The first theorem is of this kind.

I.

[Margin: vij.]

If the pole of the parallels lies on the circumference of a great circle which two other great circles cut at right angles — of which circles one is one of the parallels, while the other is oblique to the parallels — and if on this oblique circle equal arcs are taken which, though not continuous, nevertheless lie toward the same parts of that greatest parallel; and if through the individual points bounding the equal arcs parallel circles are described: then the arcs of that great circle first posited, intercepted between the parallels, will be unequal, and the one nearer to the greatest of the parallels will always be greater than the more remote.

On the circumference of the great circle AB let there be the pole of the parallels, which two other great circles BC, AC cut at right angles, and let BC be the greatest of the parallels and AC oblique to the parallels. Let equal, non-continuous arcs DE, FG be taken; and through D, E, F, G let the parallels DH, EI, FK, GL be drawn. I say that arc HI is greater than arc KL. For the intermediate arc EF is either commensurable with both of the equal arcs DE, FG, or incommensurable. Let it first be commensurable. [Margin: a — 4.decim (Elements X.4)] Having found the greatest measure V, let the three arcs DE, EF, FG be cut into parts equal to V, and through the points of division let parallels be described, as appears in the first figure. Since, then, the continuous arcs DP, PE, EO, etc., are equal, [Margin: b — 3.huius (Sphaerica III.3)] arc HT will be greater than arc TI, and TI greater than IS, etc. Therefore, since HT is greater than KQ and TI greater than QL, the whole HI will be greater than the whole KL. Which was the proposition.

But now let EF be incommensurable with both DE, FG. I say that arc HI is still greater than arc KL. For if it is not greater, it will be either less or equal. First let it be less; and from KL (as in the second figure) let there be cut off KM equal to HI; and through M let the parallel MN be drawn. Then by Lemma 2 of proposition 8 of this book let an arc FO be found, greater indeed than FN but less than FG, and commensurable with the intermediate arc EF; and let EP be equal to FO (which is less than FG, and hence less even than DE, equal to FG...); and through O, P let the parallels OR, PQ be described. Since, then, the non-continuous arcs PE, FO are equal, and their intermediate arc EF is commensurable with both, arc QI will be greater than arc KR, as has already been demonstrated in the first figure. Therefore it will be much greater than KM; and hence arc HI too will be much greater than KM. But HI is posited equal to KM. Which is absurd. Therefore HI is not less than KL.

Next, if it be possible, let arc HI be equal to arc KL, as in the third figure. The arcs DE, FG having been bisected at M, N, [Margin: c — 5.huius (Sphaerica III.5)] let the

parallels MO, NP be drawn through M, N. Then arc HO will be greater than OI, and KP greater than half of KL. Therefore OI will be less than half of HI, and KP greater than half of KL. Since, then, HI and KL are posited equal, OI will be less than KP — which is absurd. For since the arcs EM, FN, the halves of the equal arcs DE, FG, are equal and non-continuous, OI cannot be less than KP, as was demonstrated in the second figure. Therefore arc HI is not equal to arc KL; but neither was it shown to be less. Therefore it is greater. Which was the proposition.

Diagram (first figure). A sphere for Scholium Theorem I : pole A at the top, the oblique great circle AC running down through the interior to C at the base, a family of parallel circles crossing it, and the common measure V marked at the center. Interior and rim labels are dense; several cannot be resolved

- A (top): pole of the parallels
- C (base): lower end of the oblique circle AC
- V (center): the common measure

II.

[Margin: ix.]

If in a sphere a great circle touches some circle of the sphere, and another great circle is oblique to the parallels and touches circles greater than those which the great circle first posited touches, and their points of contact are on the great circle first posited; and if on the oblique circle equal arcs are taken which, though not continuous, nevertheless lie toward the same parts of the greatest of the parallels; and if through the points bounding the equal arcs parallel circles are described: then these will intercept unequal arcs on the great circle first posited, of which the one nearer to the greatest of the parallels will be greater than the more remote.

This theorem will be demonstrated from proposition 7 of this book, just as the preceding theorem was demonstrated from proposition 5 — provided that the two great circles AB, AC of the preceding theorem touch two parallels, as was stated in proposition 7 of this book. The rest of the construction of the figure does not differ from the construction of the preceding theorem, etc.

III.

[Margin: x.]

If in a sphere a great circle touches some circle of the sphere, and some other great circle, oblique to the parallels, touches circles greater than those which the great circle first posited touched, and their points of contact are on the great circle first posited; and if on the oblique circle equal arcs are taken which, though not continuous, nevertheless lie toward the same parts of the greatest of the parallels; and if through the points bounding the equal arcs [parallel circles are described] ...

(Continuing the Scholium to Theorem III / Prop. 9, whose enunciation broke off at the catchword "ferentias" on the preceding page.)

let great circles be described which also touch the same circle that the great circle first posited was touching, and which intercept similar arcs of the parallels, and which have those semicircles — the ones extending from the points of contact to the points that bound equal arcs of the oblique circle through which they are drawn — so disposed that they in no way coincide with that semicircle of the great circle first posited on which lies the contact of the oblique circle between the apparent pole and the greatest of the parallels. Then these great circles will

intercept unequal arcs of the greatest of the parallels, of which the arc nearer to the great circle first posited will always be greater than the more remote one.

This theorem too will be demonstrated from proposition 8 of this book, just as proposition 9 was shown from proposition 6 — provided that the great circles of proposition 9, proceeding from A, touch the same circle, smaller than the one which DC must touch, etc.

THEOR. 10. PROPOS. 10.

[Margin: xj.]

If the pole of parallel circles lies on the circumference of a great circle which two other great circles cut at right angles — one of these being one of the parallels, the other oblique to the parallels — and if on this oblique circle two arbitrary points are taken on the same side of that greatest parallel, and through the pole of the parallels and through each of those points great circles are drawn: then, as the arc of the greatest parallel intercepted between the great circle first posited and the nearest great circle drawn through the pole and through one of the points is to the arc of the oblique circle intercepted between the same circles, so is the arc of the greatest parallel intercepted between the two great circles drawn through the pole and through each of the points to some arc which is less than the arc of the oblique circle intercepted between the two points.

Let A be the pole of the parallels, on the circumference of the great circle AB, which two other great circles BD, CD cut at right angles; let BD be the greatest of the parallels, and CD oblique to the parallels. On CD take two arbitrary points E, F; [Margin a: "30. 1. huius" = *Sphaerica* I.30 — the leading numeral is blurred and reads like 30, but by context (drawing a great circle through a given point and the pole) this is almost certainly I.20, as in notes c, l, m [?]] and through the pole A and through E, F draw the great circles AEG, AFH. I say that, as arc BH is to arc CF, so is arc HG to an arc less than arc FE.

For the arcs CF, FE are either commensurable or incommensurable. First let them be commensurable, as in the first figure; [Margin b: "3. decim." = Euclid, *Elements* X.3] and, having found their greatest common measure P, divide the arcs CF, FE into arcs equal to that greatest common measure, [Margin c: "20. 1. huius" = *Sphaerica* I.20] and through the points of division and the pole A draw the great circles IM, KN, LO. Since, then, the successive arcs CL, LK, KF, FI, IE are equal, [Margin d: "6. huius" = *Sphaerica* III.6] arc BO will be greater than ON, and ON greater than NH, and so on. [Margin e: "8. quinti" = *Elements* V.8] Therefore the

proportion of BO to CL will be greater than that of ON to LK; and the proportion of ON to LK greater than that of NH to KF, and so on. Since, then, there are any number of magnitudes BO, ON, NH and equally many CL, LK, KF, and the proportion of the first, BO, to the first, CL, is greater than that of the second, ON, to the second, LK, and the proportion of the second, ON, to the second, LK, greater than that of the third, NH, to the third, KF, [Margin f: "34. quint." = *Elements* V.34 (Clavius's numbering)] the proportion of BH to CF will be greater than that of NH to KF. [Margin g: "8. quinti" = *Elements* V.8] But the proportion of NH to KF is still greater than that of HM to FI, as has been shown. Therefore the proportion of BH to CF is much greater than that of HM to FI. [Margin h: "34. quin." = *Elements* V.34] But the proportion of HM to FI is still greater than that of HG to FE, because the arcs HM, MG are equal in number to the arcs FI, IE, [Margin i: "18. quinti" = *Elements* V.18] and the proportion of the first, HM, to the first, FI, is greater than that of the second, MG, to the second, IE, as has been said. Therefore the proportion of BH to CF is much greater than that of HG to FE. Let it be that, as BH is to CF, so HG is to P. Then the proportion of HG to P will also be greater than that of HG to FE; [Margin k: "10. quin." = *Elements* V.10] and consequently P will be an arc less than arc FE. Therefore, as arc BH is to arc CF, so is arc HG to arc P, which is less than FE. Which was proposed.

Diagram — first figure (the commensurable case). A sphere seen in projection; the bounding great circle is AB, with A at the top (the pole of the parallels) and B at the lower left. The greatest of the parallels, BD, runs along the base to D at the lower right; the oblique circle CD runs from C (upper left) down to D. Great circles drawn from the pole A through the division points meet the base parallel.

- A (top): apparent pole of the parallels
- C (upper left): endpoint of the oblique circle on circle AB
- D (lower right): common intersection of BD and CD
- B (lower left): endpoint of the base parallel
- E, F (interior, on the oblique CD): the two given points
- I, K, L (interior, on the oblique between C and F): points of division of the equal arcs
- G, H, M, N, O (along the base parallel BD, between B and D): feet of the great circles AEG, AFH, and of IM, KN, LO
- P (interior, marked with a short bracket): the greatest common measure arc

Diagram — second figure (the incommensurable case). Same construction; here a great circle KL is drawn through K and the pole A.

- A (top): pole
- C (upper left): endpoint of the oblique circle
- F, E, K, I (interior): the given point F, the point E, and the auxiliary points K, I
- B, H, G, L, D (along the base): B and D the endpoints, with H, G, L between

Diagram — third figure. Same construction, with arc FE bisected at I and a great circle IK drawn through I and the pole A.

- A (top): pole
- C (upper left): endpoint of the oblique circle
- F, I, E (interior): the given point F, the bisection point I, and the point E
- B, H, K, G, D (along the base): B and D the endpoints, with H, K, G between

But now let the arcs CF, FE be incommensurable, as in the second figure. I still say that, as arc BH is to arc CF, so is arc HG to an arc less than FE. For if this were not so, then, as BH is to CF, so HG would be either to an arc greater than FE or to FE itself. First, if possible, let it be that, as BH is to CF, so HG is to an arc FI greater than FE. By lemma 2 of proposition 8 of this book, let there be found an arc FK, greater indeed than FE but less than FI, and commensurable with CF; [Margin l: "20. 1. huius" = *Sphaerica* I.20] and through K and the pole A let the great circle KL be drawn. Since, then, the arcs CF, FK are commensurable, it will be (as has already been demonstrated in the first figure) that, as BH is to CF, so HL is to an arc less than FK. But, as BH is to CF, so HG was posited to FI. Therefore it will also be that, as HG is to FI, so HL is to an arc less than FK; and, alternately, as HG is to HL, so FI is to an arc less than FK. But arc HG is less than arc HL. Therefore arc FI too will be less than an arc that is itself less than FK — the whole less than the part. Which is absurd. Therefore it is not the case that, as BH is to CF, so HG is to an arc greater than FE.

Next, if possible, let it be that, as BH is to CF, so HG is to FE, as in the third figure. Bisecting arc FE at I, [Margin m: "20. 1. hu." = *Sphaerica* I.20] let the great circle IK be drawn through I and the pole A. Since, then, the successive arcs FI, IE are equal, [Margin n: "6. huius" = *Sphaerica* III.6] HK will be greater than KG; and hence HK will be greater than half of HG [printed "HC"; recte HG]. [Margin o: "8. quinti" = *Elements* V.8] Therefore the proportion of HK to FI will be greater than that of half of HG to FI. [Margin p: "15. quint." = *Elements* V.15] But as half of arc HG is to FI — that is, to half of arc FE — so is the whole arc HG to the whole arc FE. Therefore the proportion of HK to FI will be greater than that of HG to FE. But it is posited that, as HG is to FE, so BH is to CF. Therefore the proportion of HK to

FI will also be greater than that of BH to CF; [Margin q: "10. quint." = *Elements* V.10] and consequently, as BH is to CF, so HK will be to an arc greater than FI. Which is absurd. For it was just demonstrated in the second figure that it cannot be that, as arc BH is to CF, so is HK to an arc greater than FI. Therefore it is not the case that, as BH is to CF, so HG is to FE; nor yet, as BH is to CF, is HG to an arc greater than FE, as has been demonstrated. Therefore it will be that, as BH is to CF, so HG is to an arc less than FE. Therefore, if the pole of the parallels lies on the circumference [of a great circle], etc. Which was to be demonstrated.

COROLLARIUM.

Hence it follows that the proportion of arc BH to arc CF is greater than the proportion of arc HG to arc FE. [Margin r: "10. huius" = *Sphaerica* III.10] For since, as BH is to CF, so HG is to an arc less than FE, [Margin s: "8. quinti" = *Elements* V.8] and the proportion of arc HG to an arc less than FE is greater than its proportion to FE itself, the proportion of BH to CF will also be greater than that of HG to FE.

THEOR. 11. PROPOS. 11.

[Margin: xij.]

If the pole of parallel circles lies on the circumference of a great circle which two other great circles cut at right angles — one being one of the parallels, the other oblique to the parallels — and if another great circle, passing through the poles of the parallels, cuts the oblique circle between the greatest of the parallels and the circle which the oblique circle touches: then the diameter of the sphere has to the diameter of that circle which the oblique circle touches a greater ratio than the arc of the greatest parallel intercepted between the great circle first posited and the great circle passing through the poles of the parallels has to the arc of the oblique circle intercepted between the same circles.

On the circumference of the great circle AB let A be the pole of the parallels, and let two other great circles BC, DE cut it at right angles, of which BC is the greatest of the parallels and DE is oblique to the parallels, touching the parallel DF. Through the pole A let another great circle AE be drawn, cutting the oblique DE at the point E, which is set between the greatest parallel BC and the parallel DF that the oblique touches. I say that the diameter of the sphere has to the diameter of the parallel DF a greater ratio than the circumference BC has to the circumference DE.

Let AG be the common section of the circles AB, AE; and BG the common section of the circles AB, BC. Then AG, BG will be the semidiameters of those circles [Margin a: "11. 1. huius" = *Sphaerica* I.11] (since great circles bisect one another in a sphere), and hence also of the sphere, intersecting one another at G, the center of the sphere and of the great circles. Let DL also be the common section of the circles AB, DE, which too will be a diameter of the sphere passing through the center G. Again, let DM be the common section of the circles AB, DF; then DM will be the diameter of the circle DF, [Margin b: "15. 1. huius" = *Sphaerica* I.15] because the circle AB cuts the parallel DF in two through the poles. Likewise let FN, CG be the common sections of the circles DF, BC with the circle AE. From the pole A, with radius AE, let the parallel OE be described, and let OH, EH be its common sections with the circles AB, AE. Then FN, EH, CG will be the semidiameters of the circles DF, OE, BC, [Margin c: "15. 1. huius" = *Sphaerica* I.15] because the great circle AE bisects them through the poles; and hence the common sections, being diameters, will meet the diameters DM, OH, BG at the remaining points N, H, G. For OH too is a diameter of the circle OE, [Margin d: "15. 1. huius" = *Sphaerica* I.15] since the circle AB bisects it through the pole A. Again, let EG be the common section of the great circles AE, DE, which will also be a diameter passing through G, the center of the sphere. Finally, let EI be the common section of the circles DE, OE. [Margin e: "10. 1. huius" = *Sphaerica* I.10] And since the line AG, drawn through the poles of the parallel OE, is perpendicular to the plane of the parallel and falls on its center H, the angle GHI [printed "OHG"; recte the right angle at H in triangle GHI (?)] will be right, by Euclid, *Elements* XI, definition 3, in the triangle GHI; and hence the angle HGI is acute. [Margin f: "19. primi" = *Elements* I.19] Therefore the side GI will be greater than the side HI. Cut off the line IK equal to the line IH, and join the line EK. Again, since each of the circles DE, OE is perpendicular to the circle AB, [Margin g: "19. unde." = *Elements* XI.19] their common section EI too will be perpendicular to that same circle; and consequently, by *Elements* XI, definition 3, each of the angles EIH, EIK is right. Since, then, the two sides EI, IH of the triangle EIH are equal to the two sides EI, IK of the triangle EIK, and contain equal angles — namely right angles, as we have shown — [Margin h: "4. primi" = *Elements* I.4] the angles IHE, IKE will also be equal.

Now, since the proportion of the line GI to the line IK — that is, to the line IH equal to it — is greater than the proportion of the angle OHE (and of the angle equal to it) to the angle IGE, as we shall soon demonstrate; [Margin i: "10. undec." = *Elements* XI.10] and since the angle OHE is equal to the angle BGC [Margin k: "15. unde." = *Elements* XI.15] (for the lines OH, BG are the common sections of the parallel planes OE, BC made by the plane AB, and are therefore parallel; and

likewise the lines EH, CG are the common sections of the same planes made by the plane AE) — the proportion of the line GI to the line IK, that is, to the equal line IH, will also be greater than the proportion of the angle BGC to the angle DGE. [Margin l: "33. sexti" = *Elements* VI.33] But as the angle BGC is to the angle DGE, so is the arc BC to the arc DE. Therefore the proportion of GI to IH will also be greater than the proportion of arc BC to arc DE. [Margin m: "4. sexti" = *Elements* VI.4] But as GI is to IH, so is GD to DN, that is [Margin n: "15. quint." = *Elements* V.15], so is the whole diameter DL to the whole diameter DM [Margin o: "16. unde." = *Elements* XI.16] (for DN, OH are the common sections of the parallel planes DF, OE made by the plane AB, and are therefore parallel). Therefore the proportion of DL, the diameter of the sphere, to DM, the diameter of the parallel DF, will also be greater than the proportion of arc BC to arc DE. Therefore, if the pole of the parallels lies on the circumference of a great circle, etc. Which was to be demonstrated.

Diagram. A sphere in projection. The bounding great circle is AB (A at the top, B at the left). A dense network of chords and the diameters DL, DM, BG, OH, EG, EI is drawn; the oblique circle DE, the parallels BC and DF, and the described parallel OE all appear.

- A (top): pole of the parallels
- D (upper left): on the oblique circle
- M (upper right): endpoint of the diameter DM of the parallel DF
- N (below A, center): intersection point on the diameter DM
- O (left): endpoint on the described parallel OE
- I, F (interior, upper center): I on the common section EI; F on the parallel DF
- H (interior, center-right): center of the parallel OE
- E (interior, center-left): the cutting point of AE and DE
- K (interior, center): the point with $IK = IH$
- G (interior, center): center of the sphere
- B (left): endpoint of the greatest parallel BC
- C (lower center): on the greatest parallel BC
- L (lower right): endpoint of the diameter DL

LEMMA.

That the proportion of the line GI to the line IK is greater than the proportion of the angle IKE to the angle IGE, we shall demonstrate by the following theorem, here set out.

In every right triangle, if from one of the acute angles a straight line is drawn in any way whatever to the opposite side, the proportion of that side to the segment of it which lies next to the right angle is greater than the proportion of the acute angle which the drawn line makes with the said side to the remaining acute angle of the triangle.

Let EGI be a right triangle having the right angle I, and from the acute angle IGE let a straight line EK be drawn in any way to the opposite side GI. I say that the proportion of the line GI to IK is greater than the proportion of the acute angle IKE to the acute angle IGE. [Margin p: "31. primi" = *Elements* I.31] For through G draw the line GA parallel to EK, meeting the line IE (produced) at A. And since the angle I is right, the angle IEG will be acute, and therefore AEG obtuse. [Margin q: "19. prim" = *Elements* I.19] Therefore the side EG, in the triangle GEI, is greater than the side GI; but in the triangle AEG it is less than the side AG.

(Continuation of the Lemma demonstration.)

Therefore the arc of a circle described from the center G at the distance GE will cut the line GI, produced beyond I, namely at B, and the line GA, on the near side of A, namely at C. Since, then, the triangle GAE is greater than the sector GCE, [Margin r: "8. quinti" = *Elements* V.8] the proportion of the triangle GAE to the triangle GEI will be greater than that of the sector GCE to the triangle GEI. [Margin s: "8. quinti" = *Elements* V.8] But the proportion of the sector GCE to the triangle GEI is greater than its proportion to the sector GEB, because the triangle GEI is less than the sector GEB. Therefore the proportion of the triangle GAE to the triangle GEI is much greater than that of the sector GCE to the sector GEB. [Margin t: "28. quint." = *Elements* V.28 (Clavius's numbering)] And consequently, by composition, the proportion of the triangle GAI to the triangle GEI will be greater than that of the sector GCB to the sector GEB. [Margin u: "1. sexti" = *Elements* VI.1] But as the triangle GAI is to the triangle GEI, so is the line AI to the line IE; [Margin x: "Cor. 1. 33. sexti" = Corollary 1 to *Elements* VI.33] and as the sector GCB is to the sector GEB, so is the angle BGC to the angle BGE. Therefore the proportion of AI to IE will also be greater than that of the angle BGA — that is [Margin y: "29. prim." = *Elements* I.29], than that of the angle IKE equal to it — to the angle IGE. [Margin z: "2. vel 4. sexti" = *Elements* VI.2 or VI.4] But as AI is to IE, so is GI to IK. Therefore the proportion of the line GI to the line IK will also be greater than that of the angle IKE to the angle IGE. Which was proposed.

Diagram — figure for the Lemma. A right triangle with the right angle at I. From the acute angle at G a line EK is drawn to the opposite side; GA is drawn

parallel to EK, and a circular arc from center G at radius GE cuts GI (produced) at B and GA at C.

- A (upper left): where GA meets IE produced
- E (top center): the acute-angle vertex from which EK is drawn
- B (top right): where the arc cuts the line GI produced
- C (left, below A): where the arc cuts GA
- I (right, below B): the right-angle vertex
- K (center-right): the foot of EK on GI
- G (bottom): the acute-angle vertex from which GA is drawn

SCHOLIVM.

In another version, the following theorem is added at this place.

With the same things posited, the diameter of the sphere has to the diameter of the parallel described through that point of the oblique circle at which the great circle passes from the pole a smaller ratio than the arc of the greatest of the parallels intercepted between the great circle first posited and the great circle passing through the poles of the parallels has to the arc of the oblique circle intercepted between the same circles.

Let the circles be described as in the preceding proposition. I say that the proportion of the diameter of the sphere to the diameter of the parallel GE is smaller than that of the circumference BC to the circumference DE. Let GH, BI be the common sections of the circles GE, BC with the circle AB, which will be their diameters, [Margin a: "15. 1. hui." = *Sphaerica* I.15] since AB, drawn through their poles, cuts them in two and at right angles. Therefore BI will also be a diameter of the sphere. And since the circle DE is posited perpendicular to AB, [Margin b: "13. 1. hui." = *Sphaerica* I.13] DE will pass through the poles of AB itself. In the same way BC will pass through the poles of the same AB, since it is posited perpendicular to it. Therefore M, the point where they mutually intersect, will be the pole of the circle AB; and consequently the segment DEL, which is perpendicular to the circle AB, will be divided unequally at the point E, where the circles DE, GE intersect one another, and ED will be the smaller part, [Margin c: "28. tertij" = *Elements* III.28] seeing that the arcs MD, ML are equal, because the lines subtending them are, by the definition of a pole, equal. [Margin d: "Sch. 21. 2. huius" = the Scholium to *Sphaerica* II.21] Therefore the line ED, when drawn, will be smaller than the line EG; and hence, since the circle GE is smaller than the circle DE, the circumference EG will be greater than the circumference DE. [Margin e: "lemma 6. huius" = Lemma 6 of this book] For if a line equal to the line

ED cuts off from the circle GE a greater arc than the line DE cuts off from the circle DE, much more will the line EG, which is greater than the line ED (as we have shown), cut off a greater arc, and so on. [Margin f: "8. quinti" = *Elements* V.8] Therefore the proportion of arc BC to arc GE will be smaller than its proportion to arc DE.

Now, since, as arc BC is to the whole circumference of the circle BC, so is arc GE to the whole circumference of the circle GE — on account of the similarity of the arcs BC, GE (for the similarity of arcs consists in just this: that they have the same proportion to the whole circumferences of their circles, as we have set out in the scholium to proposition 33 of *Elements* Book VI) — and hence, alternately, as arc BC is to arc GE, so is the whole circumference of the circle BC to the whole circumference of the circle GE: the proportion of the circumference of the circle BC to arc DE will also be smaller. And as the circumference of the circle BC is to the circumference of the circle GE, so is the diameter BI (which is also a diameter of the sphere) to the diameter GH, as Pappus demonstrated and as we too have shown in our little book on Archimedes' *Measurement of the Circle*. Therefore the proportion of BI, the diameter of the sphere, to GH, the diameter of the parallel GE, will also be smaller than the proportion of arc BC to the circumference DE. Which was proposed.

Diagram. A sphere in projection with bounding great circle. A network of parallels and the diameters GH, BI, DEL is drawn; the oblique circle DE and the parallels GE, DF appear, with M the common pole and E, K, N interior intersection points.

- A (top): pole of the parallels
- D (upper left): on the oblique circle
- O (upper center, below A): interior intersection point
- F (upper right): on the parallel DF
- G (left): endpoint of the diameter GH
- H (right): endpoint of the diameter GH
- N (center): interior intersection point
- E (center-left): where the circles DE, GE intersect
- K (center): interior point
- B (left): endpoint of the diameter BI
- I (right): endpoint of the diameter BI
- C (lower center-left): on the greatest parallel
- M (lower center): the common pole of the circle AB

- L (bottom): endpoint of the segment DEL

COROLLARIVM.

Hence it follows, the same things being posited, that the ratio of the circumference BC of the greatest of the parallels — intercepted between the great circle AB first posited and the great circle AC passing through the poles of the parallels — to the circumference DE of the oblique circle intercepted between the same circles, is greater than the ratio of the circumference AE of the great circle passing through the poles of the parallels; but smaller than the ratio of the circumference AD of the great circle first posited, intercepted between the poles of the parallels and the oblique circle. For since it has been shown by this theorem that the ratio of the [diameter of the] sphere to the diameter of the parallel GE is greater [than that of arc BC to arc DE], [Margin g: "15. quint." = *Elements* V.15] and since, as the diameter BI of the sphere is to GH, the diameter of the circle GE, so is BK, the semidiameter — that is, the whole sine [sinus totus] — to GN, the semidiameter — that is, to the sine of the arc AE [Margin h: "10. 2. hui." = *Sphaerica* II.10] (for since the arcs AG, AE are equal, and GN is the sine of the arc AG, GN will also be the sine of the arc AE): therefore the ratio of arc BC to arc DE will also be greater than the ratio of the whole sine BK to GN, the sine of the arc AE.

[Margin i: "11. huius" = *Sphaerica* III.11] Again, since it has been shown that the ratio of arc BC to arc GE is smaller than the ratio [of the diameter of the sphere to the diameter] of the parallel DF; [Margin k: "15. quin." = *Elements* V.15] and since, as the diameter of the sphere BI is to DF, the diameter of the parallel DF, so is BK, the whole sine, to DO, the sine of the arc AD: therefore the proportion of arc BC to arc DE is also smaller than the proportion of the whole sine to the sine of the arc AD. Which was proposed. Moreover, what a sine is will be understood from the following treatise.

THEOR. 12. PROPOS. 12.

[Margin: xiv.]

If in a sphere great circles touch one and the same of the parallels, and intercept similar arcs of the parallels lying between each pair of the great circles; and if another great circle, oblique to the parallels, touches circles greater than those which the great circles first posited touch, and this same oblique circle cuts those same great circles first posited at points lying between the greatest of the parallels and the circle which the great circles first posited touch: then the diameter of the sphere has to

the diameter of the circle which the oblique circle touches a greater ratio than the arc of the greatest parallel intercepted between the circles first posited (which touch the same circle) has to the arc of the oblique circle intercepted between the same circles.

In a sphere let two great circles AB, CD touch the same parallel AC, and intercept similar arcs of the parallels lying between them; and let another great circle EF touch the parallel EG, greater...

(The demonstration of Prop. 12 breaks off here and continues on the following page.)

•

Diagram. A sphere shown in oblique projection, with the pole at the top and a system of parallel circles crossed by oblique great circles. The demonstration of THEOR. 12 refers to it. Labels read off the figure:

- L (top): pole of the parallels
- E, A, C (upper region, left to right): points on the upper parallels / great circles
- G (upper right): endpoint of the diameter EG
- H (left margin of sphere): point on the greatest parallel
- I (small point, near center): intersection point
- O, P (middle): O on parallel KO, P where KO cuts circle AB
- K (middle right): point on the oblique circle
- M, B, N, D, F (bottom row, left to right): points on the lower parallels and circles

it [the oblique circle] meets the parallel AC at E, and let it be oblique to the parallels, and let it cut the two former circles AB and CD — between HF, the greatest of the parallels, and the parallel AC — at the points I and K. I say that the ratio of the diameter of the sphere to the diameter of the parallel EG is greater than that of the circumference BD to the circumference IK. [Margin a: Sphaerica I.20] For through L, the pole of the parallels, and through the points E, I, K, let the great circles LH, LM, LN be described; and through K let the parallel KO be drawn, cutting circle AB at P. [Margin b: Sphaerica III.11] Now since the ratio of the diameter of the sphere to the diameter of circle EG is greater than that of arc HM to arc EI, and the ratio of arc HM to arc EI [Margin c: Corollary to III.10] is greater than that of arc MN to arc IK, the ratio of the diameter of the sphere to the diameter of circle EG will also be greater than that of arc MN to arc IK. And since

arc PK is similar to arc BD by hypothesis, [Margin d: Sphaerica II.10] and arc OK is similar to arc MN, and arc PK is smaller than arc OK, arc BD will also be smaller than arc MN; [Margin e: Elements V.8] and therefore the ratio of arc BD to arc IK will be smaller than that of arc MN to the same arc IK. Since, then, it has been shown that the ratio of the diameter of the sphere to the diameter of circle EG is greater than that of arc MN to arc IK, the ratio of the diameter of the sphere to the diameter of circle EG will be much greater than that of arc BD to arc IK. If, therefore, in a sphere great circles touch one [and the same of the parallels], etc. Which was to be demonstrated.

SCHOLIVM

In the Greek exemplar it is stated that the ratio of twice the diameter of the sphere to the diameter of circle EG is greater than that of arc BD to arc IK. This is indeed clearly established from our demonstration. For since the diameter of the sphere has a greater ratio to the diameter of circle EG than arc BD has to arc IK, twice the diameter of the sphere will have a much greater ratio to the diameter of circle EG than arc BD to arc IK; [Margin f: Elements V.8] because twice the diameter of the sphere has a greater ratio to the diameter of circle EG than the diameter of the sphere has to the same diameter of circle EG.

THEOR. 13. PROPOS. 13.

[Margin: proposition xv]

If in a sphere parallel circles intercept equal circumferences of some great circle on both sides from that point at which the great circle itself cuts the greatest of the parallels; and if through the points that bound the equal circumferences, and through the poles of the parallels, great circles are described — or if great circles are described which touch one and the same of the parallels — they will intercept equal circumferences on the greatest of the parallels.

Diagram, first figure. A sphere with parallel circles and great circles drawn through the poles of the parallels. Labels read off the figure:

- A (top): pole
- C, K, D (upper region, left to right): points on the upper parallel and great circles
- B (left margin): endpoint on the greatest parallel
- H, G, I (middle row, left to right): G the point where circle AF cuts the greatest parallel; H, I the cutting points on the greatest parallel

- E, L, F (bottom row, left to right): points on the lower parallel and great circles

Diagram, second figure. A companion sphere, for the alternative case in which the great circles touch one and the same parallel (shown as a small circle near the top). Labels read off the figure:

- A (top): pole, with the small touched parallel just below it
- C, K, D (upper region, left to right)
- B (left margin), H, G, I (middle row, left to right)
- E, L, F (bottom row, left to right)

In sphere AB let the parallel circles CD, EF cut off from the great circle AF two equal circumferences GC, GF, on both sides from the point G at which circle AF cuts BG, the greatest of the parallels; and through the points C, G, F let great circles be drawn — either through the poles of the parallels, as in the first figure, or touching one and the same parallel, as in the second figure — cutting the greatest of the parallels at H and I. I say that arcs GH, GI are equal. For since arcs GC, GF are supposed equal, [Margin a: Sphaerica II.17] the parallels CD, EF will be equal. [Margin b: Sphaerica II.18] Therefore arcs GK, GL will also be equal. [Margin c: Sphaerica III.3] Hence the straight lines drawn CK, FL will be equal; [Margin d: Elements III.28] and consequently, in the equal circles CD, EF, [the equal straight lines] will cut off equal arcs CK, FL; and for that reason arcs CK, FL will be similar to each other. [Margin e: Sphaerica II.10 or II.13] But arc GH is similar to arc CK, and arc GI to arc FL. Therefore arcs GH, GI will be similar to each other, and consequently — since they belong to the same circle — equal to each other. If, therefore, in a sphere a great circle, etc. Which was to be demonstrated.

SCHOLIVM

From this it is also clear that, with the same things assumed, all the arcs of the great circles intercepted between the parallels are equal to each other — namely CH, HE, KG, GL, DI, IF. For since arcs GC, GH are equal to arcs GF, GI, [Margin f: Sphaerica III.3] the straight lines CH, FI will also be equal; [Margin g: Elements III.28] and therefore arcs CH, FI will also be equal. [Margin h: Sphaerica II.10 or II.13] But to arc CH the arcs KG, DI are equal, and to arc FI the arcs LG, EH are equal. Therefore all those six arcs will be equal.

THEOR. 14. PROPOS. 14.

[Margin: proposition xvj]

If in a sphere a great circle touches some circle, and another great circle, oblique to the parallels, touches circles greater than those which the first-placed great circle touched: they will intercept unequal circumferences of the parallel circles, of which those nearer to either of the poles will be too great to be similar to the more remote ones.

Diagram. A sphere with an oblique great circle, showing a small parallel circle touched near the top and two larger parallels cut by the oblique circle. Labels read off the figure:

- D, A (top): D on the oblique circle, A at the apex; the small touched circle sits just below A
- Inside the small upper circle: C[?], L, F (leftmost letter ambiguous between C and G)
- G (left), H (right): points on the greatest parallel
- B (lower left), I (lower right): endpoints of the parallel BI
- K, M (center): cutting points on the parallels
- N, E (bottom): points on the oblique circle and lower parallel

In a sphere let the great circle AB touch circle AC; and let another great circle DE touch another, greater circle DF, and let it cut any two parallels GH, BI at K and E. I say that arcs KH, EI are unequal, and that KH — nearer the visible pole — is too great to be similar to arc EI, the more remote one; or, alternatively, that EB itself, nearer the hidden pole, is too great to be similar to arc KG, the more remote one.

[Margin a: Sphaerica II.15] For through the points E, K let the great circles LE, CN be described, touching circle AC, in such a way that the semicircles proceeding from C through N and from A through B do not meet; likewise the semicircles from L through E and from A through I, tending toward each other, do not meet.

[Margin b: Sphaerica II.13] Therefore arcs MH, EI will be similar. Hence KH is too great to be similar to arc EI. In the same way, since arcs BN, GK are similar, BE — nearer the other pole — will be too great to be similar to arc GK, which is more remote from the same pole. And so, if in a sphere a great circle touches some circle, etc. Which was to be demonstrated.

FINIS LIBRI III. THEODOSII. — *End of the Third Book of Theodosius.*

CHRISTOPHER CLAVIUS of Bamberg, of the Society of Jesus

Sines, or the Halves of the Straight Lines Subtended in a Circle: the Lines Tangent and Secant

[*Verbatim title as printed: CHRISTOPHORI CLAVII BAMBERGENSIS E SOCIETATE
IESV — SINVS VEL SEMISSES RECTARVM IN CIRCULO SVBTENSARVM: LINEÆ
TANGENTES ATQVE SECANTES.*]

PRÆFATIO — Preface

[Margin: *The usefulness of sines* (Sinuum vtilitas)]

It can scarcely be said how great a usefulness the knowledge of sines has in matters both astronomical and geometrical — since almost innumerable astronomical and geometrical problems are brought back, for practical use, to the calculation and reckoning of sines, as is clear both from our treatment of rectilinear and spherical triangles, and from Ptolemy's *Almagest*, from our *Gnomonica*, and from the various books of many astronomers. Therefore, since the demonstrations of sines have been set out by only very few, I judge it will be worth my while if, with all the brevity and clarity I can, I gather from various authors — especially from Ptolemy [Ptolemæus], Peurbach [Purbachio, Georg Peurbach], and Johannes Regiomontanus [Regiomontanus] — the demonstrations by which we may have the sines and chords of all arcs known; so that we may both examine the tables of sines and of chords already computed by many writers (for an error is easily committed in the printing of numbers), and, when circumstances require, construct new ones of our own (once the whole sine, or the diameter, has been posited as consisting of any number of parts you please).

But since more recent writers have, with the greatest success, collected from the sines still other lines — namely tangents and secants — so as to demonstrate certain things more easily and briefly, we shall treat of these lines too. For these lines have an outstanding use in astronomical and geometrical matters, as will become clear from our treatment of plane and spherical triangles. We shall, however, begin from the definitions.

SINES

DEFINITIONES [Definitions]

I.

The **complement** of any arc is the excess by which the quadrant exceeds it, if the arc is smaller than a quadrant; or by which it is exceeded by the arc, if the arc is larger than a quadrant.

[Margin: What the complement of an arc is.]

II.

The **chord** (which some call the *subtense*, others the *inscribed line*) is a straight line subtending any arc whatever in a circle.

[Margin: What a chord is.]

III.

The **right sine** (which by some is called the *first right sine*) is half of the chord that subtends double the arc of which it is called the right sine.

[Margin: What the right sine is.]

Or otherwise.

The right sine is a perpendicular line falling from one end of the arc — of which it is called the right sine — onto the diameter of the circle drawn from the other end of the same arc.

IV.

The **versed sine** (which some call the *arrow* [*sagitta*]) is the part of the circle's diameter intercepted between the end of the given arc — of which it is called the versed sine — and the right sine of the same arc.

[Margin: What the versed sine is.]

V.

The **sine of the complement** of any arc (which by some is called the *second right sine*) is the right sine of the other arc, which is the complement of that arc of which it is called the sine of the complement.

[Margin: What the sine of the complement is.]

VI.

The **whole sine** [*sinus totus*] is the radius, or semidiameter of the circle; that is, the right sine (or the versed sine) of the quadrant of the circle.

[Margin: What the whole sine is.]

VII.

The **sine** — whether right, versed, or of the complement — of any rectilinear angle is the sine of that arc which, in a circle described from the angle, is intercepted between the two straight lines that constitute the angle.

[Margin: What the sine of a rectilinear angle is.]

Let a circle ABCD be set out, whose centre is E, through which let two diameters AC, BD be drawn, cutting one another at right angles [Margin: a — Elements III.26] and dividing the whole circle into four equal quadrants — inasmuch as they are subtended by equal right angles at the centre. Let equal arcs AF, AG be taken, and likewise BF, BI; and let the straight lines FG, FI be drawn, cutting the diameters at H and K. The arc FB, then, is called the complement of arc FA, because the quadrant AB exceeds arc FA by the arc FB. By the same reasoning, arc FA is named the complement of arc FB. Likewise arc BI is called the complement of arc AI, because the quadrant AB is exceeded by the arc AI by the amount of the arc BI.

[Margin: Examples of the definitions.]

The straight line FG, next, is called the chord of arc FAG, and the straight line FI the chord of arc FBI. And since the diameter AC, cutting the arc FAG in half, also cuts the straight line FG in half — as is established from corollary 1 of proposition 10 of Euclid, Book 13 (which, however, we shall show more briefly in the following lemma) — the straight line FH will be the right sine of arc FA, according to the former definition of the right sine: for it is half of the chord FG, which subtends the arc FAG, double the arc FA, of which FH is called the sine. And so, if we bisect any arc and its chord, half the chord will be called the right sine of the halved arc. Hence it has come about that most people call the right sines the *halves* [*semisses*] of the straight lines subtended in the circle. [Margin: Why the right sines are called the halves of the straight lines subtended in the circle.] The same straight line FH will also be the right sine of the same arc FA according to the latter definition of the right sine: since it is a perpendicular drawn from F, the end of the said arc, to the diameter AC drawn from the other end A of the same

arc; because the straight line EA, cutting the straight line FG in half, cuts it at right angles. [Margin: b — Elements III.3.]

The straight line AH, however, is the versed sine of the same arc FA, since it is the part of the diameter AC intercepted between A, the end of the said arc, and its right sine FH. This sine is called "versed" because it is placed in a reversed manner when compared with the right sine. [Margin: Why the versed sine is called the arrow.] Some call it the *arrow* [*sagitta*], because it is like an arrow shot from the chord FG in the arc FAG.

Furthermore, the straight line FK is the sine of the complement of arc FA, because it is the right sine of arc FB, which is the complement of arc FA.

And the straight line KB is the versed sine of the complement of arc FA — that is, the versed sine of arc FB, which is the complement of arc FA. [Margin: What the versed sine of the complement of an arc is.]

Diagram. A circle with two perpendicular diameters. The horizontal diameter runs B (left) — E (centre) — D (right); the vertical diameter runs A (top) — E (centre) — C (bottom). Two symmetric points F and G sit on the upper arc, on either side of A, with the chord FG drawn across (crossing the vertical diameter at H, just below A). Further out on the upper arc lie Q (upper left, beyond F) and M (upper right, beyond G). The point I lies on the lower-left arc. Radii/straight lines run from the centre E out to F, G, Q, M, and I. Perpendiculars are dropped from the upper points to the horizontal diameter, meeting it at the labelled feet; from the left group the feet R and K lie between B and E, and from the right group the feet L and O lie between E and D. Interior points P (near F) and N (near G) mark auxiliary constructions used later in the demonstrations. This same figure is reprinted at the head of the two following pages for continued reference.

- A (top of vertical diameter): endpoint of arcs AF, AG
- B (left end of horizontal diameter): endpoint of arcs BF, BI
- C (bottom of vertical diameter): opposite A
- D (right end of horizontal diameter): opposite B
- E (centre): centre of the circle
- F (upper arc, left of A): common endpoint of arcs FA, FB, FC
- G (upper arc, right of A): endpoint of arc AG (= AF)
- Q (upper-left arc, beyond F): auxiliary point for the greater/smaller-arc proof
- M (upper-right arc, beyond G): endpoint of the smaller arc DM in the later demonstration

- I (lower-left arc): endpoint of arc BI
- H (on vertical diameter AC, below A): foot of the right sine FH; intersection of chord FG with AC
- K (on horizontal diameter, between B and E): foot of the right sine FK
- R (on horizontal diameter, left of K): foot of perpendicular QR
- L (on horizontal diameter, between E and D): foot of the right sine GL
- O (on horizontal diameter, right of L): foot of perpendicular MO
- P (interior, near F): auxiliary point (KP cut off equal to MO)
- N (interior, near G): foot of perpendicular MN dropped to GL

(The construction figure printed at the head of this page is identical to the one above.)

Some astronomers, moreover, call the sine which we have called the *right* sine the "first right sine," and the sine which we have called the *sine of the complement* they call the "second right sine." Thus they call the straight line FH the first right sine of arc FA, and the straight line FK the second right sine of the same arc.

[Margin: The first and second right sine; likewise what the "first sine" and "second sine" are, according to some.] There are also others who call the right sine simply the "first sine," and the versed sine the "second sine." I mention this so that you may understand the authors who have spoken variously about sines. We ourselves have kept the common way of speaking. But whenever writers speak of some sine, they always mean the right sine — unless they call it the sine of the complement, or the versed sine. [Margin: When some sine is mentioned without qualification, the right sine is understood.]

The semidiameter AE, next, is both the right sine and the versed sine of the quadrant AB; it is called the *whole* (or *maximum*) sine, because it is the greatest of all sines, both right sines and sines of complements — indeed, even greater than all the versed sines of those arcs that are smaller than a quadrant. It is smaller only than the versed sines of those arcs that are greater than a quadrant (as we shall say below), which in fact come into use more rarely than the others.

[Margin: Why the whole or maximum sine is so called.] Or it is certainly called the whole (or maximum) sine because, in the table of sines — in which only the right sines are set down — the greatest of all the sines is the one that corresponds to the quadrant, or to 90 degrees, as will be plain from the table of sines which we shall set down below.

Finally, when the straight line EF has been drawn, the straight line FH will be the right sine of angle FEH; the straight line FK, the sine of the complement of the

same angle; and the straight line AH, the versed sine of the same angle. For the straight line FH is the right sine of arc FA, which — in the circle described from the angle FEH — is intercepted between the straight lines EF, EA that constitute the said angle; the straight line FK is the sine of the complement of the same arc; and the straight line AH is its versed sine.

For the rest, two arcs constituting a semicircle have exactly the same sine, both right and of the complement — just as two arcs making up a whole circle have one and the same chord. Their versed sines, however, differ, and together make up the whole diameter of the circle. [Margin: Two arcs making up a semicircle have the same sine, just as two arcs making up a circle have the same chord; yet their versed sines differ, and together make up the whole diameter.] Thus the two arcs FA, FC, which make up the semicircle ABC, have the same right sine FH — just as the two arcs FAG, FCG, their doubles, which make up the circle, have the same chord FG, of which the half is the right sine FH, as the former definition of the right sine requires. And this right sine FH is a perpendicular line drawn from the common end F of both arcs FA, FC to the diameter AC drawn from the remaining ends A, C of the same arcs, as the latter definition of the right sine requires. The same two arcs FA, FC have the same sine of the complement, FK, because the arc FB, whose right sine is FK, is the complement of each of them. Their versed sines, however, are not the same: rather, AH is the versed sine of arc FA, and CH is the versed sine of arc FC — and these two versed sines make up the diameter AC. Here you see that the versed sine CH of arc FC, which exceeds a quadrant, is greater than the semidiameter, or whole sine, CE. [Margin: The versed sine of an arc greater than a quadrant is greater than the whole sine.]

In the same way, too, two angles equal to two right angles have the same sine, both right and of the complement. [Margin: Two angles equal to two right angles have the same sine, but different versed sines, which make up the whole diameter.] This is clear in the angles AEF, FEC, of each of which the right sine is FH and the sine of the complement FK; because they stand upon the arcs AF, FC, of each of which the right sine is FH and the sine of the complement FK, as has been said. Yet the versed sines of these same angles are not the same: rather, AH is the versed sine of angle AEF, namely of arc AF; and HC is the versed sine of angle FEC, that is, of arc FC. And both versed sines together make up the whole diameter AC.

Again, the right sine of any arc is equal to the segment of the diameter lying between the centre and the right sine of the complement of the same arc; while the sine of the complement of any arc is equal to the segment of the diameter

placed between the centre and the right sine of the same arc. [Margin: To what segment of the diameter the sine — both right and of the complement — is equal.] Thus FH, the right sine of arc FA, is equal to the segment of the diameter EK [Margin: c — Elements I.34]; and FK, the sine of the complement of the same arc FA, is equal to the segment of the diameter EH — because of the parallelogram HK, for both the straight lines HF, EK and the straight lines KF, EH are parallel, on account of the right angles at H, E, K, F. [Margin: d — Elements I.28.] Hence it comes about that, if there are two arcs of which one is the complement of the other, the right sine of either is equal to the *complement of the versed sine* of the other arc. Now by "complement of the versed sine" we mean the segment of the diameter by which the versed sine itself is exceeded by the semidiameter, if its arc is smaller than a quadrant; or by which it exceeds the semidiameter, if its arc is greater than a quadrant. [Margin: What the complement of the versed sine is.] Thus we call HE the complement both of the versed sine AH, which corresponds to arc FA, and of the versed sine CH, which corresponds to arc FC. You see, therefore, that of the two arcs FA, FB, of which one is the complement of the other, the right sine FK of arc FB is equal to HE, the complement of the versed sine AH of the other arc FA [Margin: e — Elements I.34]; and the right sine FH of arc FA is equal to EK, the complement of the versed sine BK of the other arc FB. By the same reasoning, since arc FB is the complement of arc FC, you see that the right sine FH of arc FC is equal to EK, the complement of the versed sine BK of the other arc FB; and the right sine FK of arc FB is equal to EH, the complement of the versed sine CH of the other arc FC. So too the sine of the complement of any arc is equal to the complement of the versed sine of the same arc. Thus FK, the sine of the complement of arc AF (or FC), is equal to HE, the complement of the versed sine AH (or CH) of arc AF (or FC).

By like reasoning, in the same circle — or in equal circles — the sines, both right and versed, of equal arcs, and the sines of the complements of equal arcs smaller than a quadrant, are equal; and conversely, of equal sines (both right and versed, or of the complements) the arcs smaller than a quadrant are equal. [Margin: In the same circle, or in equal circles, the sines of equal arcs are equal, and conversely; but the sines of unequal arcs are unequal, and conversely.] But of unequal arcs smaller than a quadrant, the sines are unequal: the sine, both right and versed, of the greater arc is greater and of the smaller arc smaller, while the sine of the complement of the greater is smaller and of the smaller greater. And conversely, of unequal sines (both right and versed, or of the complements) the arcs are unequal: for the greater right or versed sine belongs the greater arc, and for the smaller the smaller; but for the greater sine of the complement belongs the smaller arc, and for the smaller the greater. [Margin: Of two arcs, of which

one is the complement of the other, the right sine of either is equal to the complement of the versed sine of the other arc.] For let the arcs BF, DG be equal. I say that their right sines FK, GL are equal; likewise the versed sines KB, LD, and also the sines of the complements EK, EL. For since the arcs BF, DG are equal, the angles BEF, DEG will also be equal [Margin: f — Elements III.27]; and the right angles K, L are also equal, and the sides EF, EG are equal, being semidiameters. Therefore both the sides FK, GL and the sides EK, EL will be equal to one another — namely the right sines to one another, and [the sines] of the complements [Margin: g — Elements I.26]...

(The construction figure printed at the head of this page is identical to the one above.)

and their complements to one another. And when the equal EK, EL are subtracted from the semidiameters EB, ED, the remaining versed sines KB, LD will be equal. Which is what was proposed.

Now let the sines be equal — whether the right sines FK, GL, or the versed sines KB, LD, or the sines of the complements EK, EL. I say that the arcs BF, DG are equal. For if FK, GL are equal, their squares will be equal. Since, then, the squares of the straight lines EF, EG are also equal [Margin: h — Elements I.47] — and the former equals the squares on FK, KE, the latter the squares on GL, LE — the two squares on the straight lines FK, KE are consequently equal to the two squares on GL, LE. If the two equal squares of the straight lines FK, GL are subtracted, the squares on EK, EL will remain equal; and consequently the straight lines EK, EL will also be equal. Wherefore, since the sides EF, EK are equal to the sides EG, EL and the base FK is equal to the base GL, the angles FEB, GED will be equal [Margin: i — Elements I.8]; and consequently the arcs BF, DG will also be equal [Margin: k — Elements III.26]. Which is what was to be shown.

But if the sines of the complements EK, EL are equal, we shall show in the same way that the straight lines FK, GL are equal; and so, as before, the arcs BF, DG will be equal. If, finally, the versed sines KB, LD are supposed equal, then when these are taken from the semidiameters EB, ED, the sines of the complements EK, EL will be left equal; wherefore again we shall show, as before, that the arcs BF, DG are equal. Which was to be shown.

Now let the arc BF be greater than arc DM, and let the sine MO be drawn. I say that the right sine FK is greater than the right sine MO; likewise, that the versed sine KB is greater than the versed sine OD; but that the sine of the complement EK is smaller than the sine of the complement EO. For, an arc DG being set equal

to arc BF, then (as we have demonstrated) both the right sines FK, GL, and the versed sines KB, LD, and the sines of the complements EK, EL will be equal. Since, then, LD is greater than OD, the versed sine KB will also be greater than the versed sine OD; likewise, since EL is smaller than EO, the sine of the complement EK will also be smaller than the sine of the complement EO. Let MN be drawn perpendicular to GL [Margin: l — Elements I.34], and NL will be equal to MO. Since, then, GL is greater than NL — that is, than MO — the right sine FK will also be greater than the right sine MO. Which was to be demonstrated.

Finally, let the right sine FK be greater than the right sine MO, the versed sine KB greater than the versed sine OD, and the sine of the complement EO greater than the sine of the complement EK. I say that the arc BF, which corresponds to the greater right and versed sine, is greater than the arc DM, which corresponds to the smaller right and versed sine; but that the arc DM, which corresponds to the greater sine of the complement, is smaller than the arc BF, which corresponds to the smaller sine of the complement.

For if FK is greater than MO, let KP be cut off equal to MO, and let PQ be drawn perpendicular to FK, and QR perpendicular to BE, which will be equal to PK — that is, to MO [Margin: m — Elements I.34]. Consequently, as was shown a little before, the arcs BQ, DM will be equal, on account of the equality of the right sines QR, MO. Since, then, the arc BF is greater than arc BQ, the same arc BF will be greater than arc DM. But if KB is greater than OD, let BR be cut off equal to DO, and let RQ be drawn perpendicular to BE; and the arcs BQ, DM will be equal, as we showed a little before, on account of the equality of the versed sines RB, OD. Wherefore, since the arc BF is greater than arc BQ, the same arc BF will be greater than arc DM. If, finally, EO is greater than EK, let EL be cut off equal to EK, and let LG be drawn perpendicular to ED; and the arcs BF, DG will be equal, on account of the equality of the sines of the complements EK, EL, as was shown a little before. For this reason, since the arc DM is smaller than arc DG, the same arc DM will be smaller than arc BF. Which is what was proposed.

Exactly the same must be said of the sines of angles. For equal angles too have equal sines — both right, and of the complements, and versed, and so on — because equal angles stand at the centre upon equal arcs, and so on. [Margin: Equal angles have equal sines, etc.]

Finally, in every right triangle, if the side opposite the right angle is set as the whole sine, the remaining two sides are the right sines of the remaining acute angles to which they are opposite. [Margin: If in a right triangle the side opposite the right angle is the whole sine, either of the remaining sides will be the right

sine of the acute angle opposite it.] Thus in the right triangle EKF, in which EF is the whole sine — being the semidiameter of the circle described from E — the side FK is the right sine of angle FEK, by definition 7. So too, if the same circle were described from F, the side EK would be the right sine of angle EFK, by the same definition 7. This is also clear from the following: that angle EFK is equal to the alternate angle AEF [Margin: n — Elements I.29], whose right sine, by definition 7, is the straight line FH [Margin: o — Elements I.34] — which is indeed equal to the side EK.

In the same way, either of the remaining sides in a right triangle is the sine of the complement of the acute angle adjacent to it — namely, the sine of the complement of that arc of which the other side is the right sine. [Margin: If in a right triangle the side opposite the right angle is the whole sine, either of the remaining sides will be the sine of the complement of the angle adjacent to it, of which of course the other side is the right sine.] Thus in the same right triangle EKF, the side FK is the sine of the complement of angle EFK, or of arc FA, to whose right sine FH the other side EK is equal. Likewise the side EK is equal to FH, the sine of the complement of angle FEK, or of arc FB, of which the other side FK is the right sine. But now let us demonstrate the lemma of which we made mention above.

LEMMA.

If in a circle a straight line drawn from the centre bisects another straight line not drawn through the centre, the same line will also bisect the arc which that straight line subtends; and if it bisects the arc, it will also bisect the straight line subtended by it.

[Margin: A straight line drawn from the centre, cutting another straight line in half, also cuts in half the arc which that line subtends; and conversely.]

Let the straight line EA, in the same figure, bisect the straight line FG at H. I say that it also bisects the arc FG at A, and conversely. For, when the straight line EG has been drawn: since the two sides EF, EH of triangle EFH are equal to the two sides EG, EH of triangle EGH, each to each, and the base HF is by hypothesis equal to the base HG, the angle FEH will be equal to the angle GEH [Margin: p — Elements I.8]. Therefore the arc AF will be equal to the arc AG [Margin: q — Elements III.26]. Which is what was proposed.

But now let the straight line EA bisect the arc FG at A. I say that it also bisects the straight line FG at H. For since the arcs AF, AG are equal, the angles FEH, GEH will also be equal [Margin: r — Elements III.27]. Therefore, since the two sides EF, EH

of triangle EFH are equal to the two sides EG, EH of triangle EGH, the bases HF, HG will also be equal [Margin: s — Elements I.4]. Which is what was proposed.

From this it follows that the straight line EA, which bisects the arc FG in half at A, also bisects the straight line FG in half at H, as we posited above.

[Margin: All sines are expressed in the parts into which the whole sine is conceived as divided. — Into how many parts the semidiameter of the circle is divided by Ptolemy and al-Zarqālī [Arzahel].]

Now the whole sine [*sinus totus*]*—*that is, the semidiameter of any circle*—*is understood by astronomers to be divided into some number of equal parts, so that all other sines may be measured by the ratio of these parts, and so that the proportions of all the sines to the whole sine, or to the semidiameter, may be expressed in numbers. I must therefore explain briefly into how many parts they have divided the semidiameter, for they have not all divided it in the same way. Ptolemy cuts the semidiameter into 60 equal parts, and the whole diameter into 120; each part he then conceives as divided into 60 minutes, and each minute into 60 seconds. Nearly all the ancients, and some of the moderns*—*among them Oronce Finé [Orontius]*—*followed this division. In Book I of the *Almagest*, Ptolemy computed a table of all chords, corresponding to arcs that increase in order by half a degree over a semicircle, beginning from an arc of 30 minutes, in parts of which the whole diameter contains 120. Oronce Finé, by contrast, drew up a table of all sines, corresponding to arcs of the quadrant that increase in order by one minute, beginning from an arc of 1 minute, in parts of which the semidiameter*—*the whole sine*—*contains 60. The Arab al-Zarqālī [Arzahel] set the semidiameter at 150 parts, and accordingly the whole diameter at 300, which parts he again divided into minutes and seconds, as Ptolemy did. But in whichever way the semidiameter or the diameter is divided, it is extremely troublesome to work out all the other sines or chords in such parts, since multiplication, division, and the extraction of roots must always be carried out through astronomical fractions; or else the parts must be converted into minutes and seconds, and conversely the minutes and seconds into parts*—*a task that is very laborious not only for those little practiced in arithmetic, but even for the most expert.

[Margin: The division of the semidiameter, or whole sine, into 10000000 or 100000 particles is more convenient than into 60.]

For this reason other astronomers*—*among them Georg Peurbach [Georgius Purbachius], Regiomontanus [Ioannes Regiomontanus], and Peter Apian [Petrus

Appianus]—divided the semidiameter, that is, the whole sine, into far more equal parts, namely into 10000000 or 100000 parts. In this way there is no need to divide these parts further into minutes and seconds, since one of these parts is either much smaller than a single second of the semidiameter divided into 60 parts in Ptolemy's manner, or at any rate not much larger. For one second is $1/216000$ of the whole semidiameter divided into 60 parts, since the 60 parts contain 216000 seconds; whereas one particle of the semidiameter divided into 10000000 or 100000 parts is $1/10000000$ or $1/100000$ of the whole semidiameter. Now it is clear that this small quantity, $2/10000000$ [numerator uncertain — the sense expects $1/10000000$] [?], is much smaller than that $1/216000$, while $1/100000$ is not much larger than that same $1/216000$. And so, even if in some sine roughly one particle out of the 10000000 particles of the whole sine is at times neglected, a much smaller error is committed than if one whole second out of the 216000 seconds into which the whole sine is understood to be divided were neglected; and if roughly one particle out of the 100000 particles of the whole sine is neglected, no much greater error is committed than if one whole second out of the 216000 seconds into which the whole sine is divided were neglected.

[Margin: How large the whole sine is according to common usage, and how large the author fixes it. — Also, that the calculation is made more accurate the larger the whole sine is.]

There are also those who divide the whole sine into 6000000 or 60000 parts; and there exist tables of sines composed by Regiomontanus in which the whole sine is set to contain that many particles. But more usual among astronomers is the division of the whole sine into 10000000 or 100000 particles. Indeed the common practice of nearly everyone has prevailed, that in computations drawn from the sines the whole sine be set at 100000 particles—as I too have adopted, both in the [treatise on the] sphere and in gnomonics and other works—although the larger the whole sine, the more accurate the computation and reckoning turn out to be. Regiomontanus further constructed a table of all the sines corresponding to the arcs of the quadrant that increase in order by one minute, in the parts of the whole sine divided into 10000000 parts, beginning from an arc of 1 minute. I have examined this table with the greatest care and diligence, and corrected it in certain places, since through the carelessness of the printers it was by no means free of errors. I shall append this corrected table below, once I have first set out the demonstrations—drawn chiefly from Regiomontanus—by which the sines of all arcs can be expressed in numbers, in the parts of the whole sine however it is divided. After the use of the table, I shall also add the demonstrations of Ptolemy

and others, by which the chords of all arcs may be expressed in numbers, from which in turn a table of sines can readily be constructed.

Diagram. A quadrant ABC drawn inside a square frame. The right angle is at A (bottom-right corner): the vertical semidiameter AB runs up the right side to B (top-right), and the horizontal semidiameter AC runs along the bottom to C (bottom-left). The quarter-circle arc runs from B down to C, bulging toward the (unlabeled) top-left corner. The arc is marked off in nine equal steps of ten degrees, labelled along it from B toward C: **10, 20, 30, 40, 50, 60, 70, 80, 90** (90 at C). An interior grid of horizontal and vertical lines (the sine lattice) connects these divisions to the two semidiameters. Along the bottom edge (semidiameter AC) is written **10000000**, and up the right edge (semidiameter AB) is written **10000000** (vertically), indicating each semidiameter divided into ten million particles.

- B (top-right): endpoint of the arc / top of semidiameter AB
- A (bottom-right): center of the quadrant (right angle)
- C (bottom-left): endpoint of semidiameter AC, marked 90
- 10–90: ten-degree divisions of the arc BC
- 10000000: number of particles into which each semidiameter is divided

And first of all, if on some plane a quadrant were constructed large enough that its arc could conveniently be divided into 90 degrees, and each degree into 60 minutes, and likewise each of its two semidiameters—that is, the whole sine—into 10000000 equal parts (or even into more or fewer), then the magnitudes of all the sines could be found easily, without any trouble or labor of computation, if from each minute of the arc straight perpendiculars were drawn to each of the two semidiameters. As in this quadrant ABC: if the arc BC is divided into degrees and minutes—for want of space I have divided it into nine parts, so that each takes in ten degrees—and likewise each semidiameter is divided into 10000000 particles, or into more or fewer, and perpendiculars are drawn to each semidiameter, then the perpendiculars drawn to the semidiameter AB will be the right sines [*sinus recti*] of the arcs of the quadrant beginning from the point B, and equal to them are the portions of the semidiameter AC lying between the point A and the perpendiculars drawn to the semidiameter AC. Therefore, however many particles, out of those 10000000, these portions contain, of just so many particles will the right sines of the arcs of the quadrant be. In the same way both the sines of the complements of those arcs and the versed sines are found. For the perpendiculars dropped to the semidiameter AC are the sines of the complements, and equal to them are the portions of the semidiameter AB lying between the point B and the said perpendiculars drawn to the semidiameter AB;

while the portions of that same semidiameter AB [between B and those perpendiculars] are the versed sines [*sinus versi*] of those same arcs beginning from the point B. But since it is impossible to find a quadrant large enough to admit so many divisions conveniently, we shall investigate the magnitudes of the sines by geometrical demonstrations, the whole sine being set at any number of particles, in the following propositions. And it will be enough for us to seek out the right sines of all arcs; for once these are known, both the sines of the complements and the versed sines of those same arcs will be made clear, as we shall set out in the use of the table of sines.

THEOR. 1. PROPOS. 1.

[Margin: Perpendiculars drawn from equal arcs of a quadrant to either of the semidiameters, or to a straight line parallel to a semidiameter, cut off unequal segments; and the greater is the one nearer to the other semidiameter.]

If, in a quadrant of a circle, equal arcs are taken, and from their endpoints perpendiculars are drawn to either of the semidiameters or to a straight line parallel to a semidiameter, then the segments of the semidiameter—or of that parallel—intercepted between those perpendiculars will be unequal; and the greater will be the one that is nearer to the other semidiameter.

Let ABC be a quadrant in which the arcs DE and EF are equal. From their endpoints let the perpendiculars DKG, ELH, FMI be drawn to the semidiameter AC, or to the straight line RS parallel to AC. I say that the segments GH and HI—or KL and LM—are unequal, and that GH is greater than HI, and KL greater than LM. For, completing the semicircle BCN, let the straight lines DG, EH, FI be produced as far as O, P, Q. Drawing also the straight lines ET and FV perpendicular to DO and EP, let the straight lines EO and FP [printed: EP; recte FP] be joined. Since the arcs DE and EF are equal, the angles DOE and EPF standing upon them will also be equal [Elements III.27]; and the right angles at T and V are equal as well. Therefore, since the three angles of triangle EOT are equal to the three angles of triangle FPV—both sets being equal to two right angles [Elements I.32]—the remaining angle TEO will be equal to the remaining angle VFP; and so triangles EOT and FPV will be equiangular. Hence OE is to ET as PF is to FV [Elements VI.4]. But the straight line OE is greater than the straight line PF, because OE is nearer the center than PF [Elements III.15]; therefore the straight line ET is also greater than the straight line FV [Elements V.14]. Now since ET is equal to the segments GH and KL (because TH and TL are parallelograms), and FV is equal to the segments HI and LM (because VI and VM

are parallelograms) [Elements I.34], the segment GH will also be greater than the segment HI, and the segment KL greater than the segment LM. Therefore, if in a quadrant of a circle equal arcs are taken, and so on. Which was to be demonstrated.

A shorter proof. Let the straight line DF be drawn, cutting the drawn semidiameter AE at Z and the straight line EH at a, and let the straight line FV be produced as far as b. Since, then, the arc DF is bisected at E, the straight line DF will also be bisected at Z, by the lemma laid down among the definitions; and accordingly Da will be greater than aF. Since therefore Da is to aF as bV is to VF [Elements VI.2], bV will also be greater than VF—that is, GH greater than HI, and KL greater than LM.

Diagram. The quadrant of Proposition 1, with the semicircle completed. The right angle is at A (right side): semidiameter AB rises on the right to B (top-right), and semidiameter AC runs left to C. The quarter arc carries the equally spaced points D, E, F (near the top, with equal arcs DE and EF); X lies farther along toward C. From D, E, F perpendiculars DKG, ELH, FMI fall to the base AC, meeting the parallel straight line RS (the horizontal row through S...R) at K, L, M and the base at G, H, I (row C, Y, I, H, G, A). The chords/lines DG, EH, FI are produced downward across the completed semicircle to O, P, Q, N (bottom row). T and V are the feet of the auxiliary perpendiculars ET and FV.

- B (top-right): top of semidiameter AB
- A (right): center of the quadrant (right angle)
- C (bottom-left): end of semidiameter AC
- D, E, F: points on the arc marking equal arcs DE, EF
- X: a further point on the arc
- G, H, I: feet of the perpendiculars on AC
- K, L, M: intersections of the perpendiculars with the parallel RS
- S, R: endpoints of the parallel straight line RS
- Y: point on AC below X
- T, V: feet of the perpendiculars ET, FV
- O, P, Q, N: points on the completed lower semicircle
- [Additional small labels near E and V — the auxiliary points Z, a, b of the shorter proof — are not clearly resolvable on the tile.] [?]

COROLLARIUM.

[Margin: The differences of the right sines gradually decrease from the beginning of the quadrant to its end, so that the sines of smaller arcs have greater differences than the sines of larger arcs, provided the arcs have equal differences.]

From this proposition it is clear that, if any number of arcs of the quadrant, all beginning from the same semidiameter, have equal differences or increments, then the right sines of the smaller arcs have greater differences than the sines of the larger arcs—so that the differences of the sines continually decrease from the beginning of the quadrant to its end. For if, in the same figure of this proposition, the arc FX is taken equal to the arcs DE and EF, and the straight line XY is drawn perpendicular to the semidiameter AC, the four arcs BX, BF, BE, BD will have equal increments, since BX exceeds BF by the arc FX; BF exceeds BE by the arc EF, which is set equal to the arc FX; and the arc BE exceeds the arc BD by the arc DE, which is equal to the arc EF. Now the right sines of those arcs are AY, AI, AH, AG, as I taught above in the exposition of the definitions, since they are the portions of the semidiameter AC lying between the center A and the sines of the complements, as is evident. And since in this proposition I have demonstrated that GH is greater than HI, and HI greater than IY, it is clear that the excess GH, between the sines of the smaller arcs BE and BD, is greater than the excess HI, between the sines of the larger arcs BF and BE; and likewise that the excess HI, between the sines of the smaller arcs BF and BE, is greater than the excess IY, between the sines of the larger arcs BX and BF. The same reasoning holds for the rest. It is therefore established that the differences of the right sines gradually decrease from the beginning of the quadrant to its end—which is plainly evident from the table of sines. That sometimes several neighboring sines, especially at the beginning of the quadrant, have the same difference, or even (though rarely) that two later ones have a greater difference than two earlier ones, arises from the fact that the sines of the [ensuing] table are not entirely accurate, as is clear from the way they were found. If the whole sine were set greater than 10000000, the differences of the sines would appear more clearly.

PROBL. 1. PROPOS. 2.

[Margin: How the sides of the decagon and pentagon in one and the same circle are found.]

To find the sides of an equilateral decagon and pentagon in one and the same circle.

Although these sides can be found by what Euclid demonstrated in Book 4, they are nonetheless investigated by Ptolemy, in Book I, chapter 9 of the *Almagest*, by another method, which contributes much to the finding of very many sines. The method is this. Let there be a circle, or (what suffices) a semicircle ABC; and from its center D let the perpendicular DB be erected to its diameter AC. Bisecting the semidiameter CD at E, draw the straight line EB, and cut off EF equal to it, and join the straight line FB. I say that the straight line BF is the side of the pentagon, and DF the side of the decagon, in the circle ABC. For since the straight line CD is bisected at E, and DF is added to it, the rectangle contained by CF and DF, together with the square of the straight line DE, will be equal to the square of the straight line EF [Elements II.6], and therefore to the square of the straight line EB, which is equal to EF. But the square of the straight line EB is equal to the squares of the straight lines BD and DE [Elements I.47]. Therefore the rectangle contained by CF and DF, together with the square of the straight line DE, is equal to the squares of the straight lines BD and DE. And accordingly, taking away the common square of the straight line DE, there will remain the rectangle contained by CF and DF equal to the square of the straight line BD—that is, to the square of the straight line CD;

Diagram. A semicircle on the diameter AC (A at the left end, C at the right end), with center D. The perpendicular radius DB rises from the center to B at the top. On the diameter, E is the midpoint of DC, and F lies between A and D, so that the base reads, from left to right, A, F, D, E, C. The chords EB, FB (and BD, the radius) are drawn; BF is the side of the pentagon and DF the side of the decagon.

- B (top): endpoint of the perpendicular radius DB
- A (left), C (right): endpoints of the diameter
- D: center of the semicircle
- E: midpoint of CD
- F: point on the diameter with $EF = EB$; DF is the decagon side, BF the pentagon side

[The pentagon/decagon semicircle is reprinted at the head of this page because the demonstration of PROPOS. 2 carries over the page break; it is the same figure as fig-p695-2 above and is not re-described here.]

it will follow that CF is to CD as CD is to DF [Elements VI.17]; and therefore the straight line CF will be divided at D in extreme and mean ratio. Since, then, the greater segment CD is the side of the hexagon in the circle ABC (by the corollary to Proposition 15 of Book 4 of Euclid), the lesser segment DF will be the side of the

decagon in the same circle, as we demonstrated on Proposition 9 of Book 13 of Euclid. Again, since the square of the side of the hexagon BD, together with the square of the side of the decagon DF, is equal to the square of the side of the pentagon in the same circle [Elements XIII.10]—and the square of the straight line BF is equal to those same squares of BD and DF [Elements I.47]—the square of the side of the pentagon will be equal to the square of the straight line BF; and therefore the straight line BF is equal to the side of the pentagon. We have therefore found the sides of the equilateral decagon and pentagon in one and the same circle. Which was to be done.

PROBL. 2. PROPOS. 3.

[Margin: Given the right sine of any arc, how the sine of the complement of that same arc is found; and given the chord of any arc, by what method the chord of the remaining arc of the semicircle is found.]

Given the right sine of any arc less than a quadrant, to find the sine of the complement of that same arc; and likewise, given the chord of any arc less than a semicircle, to find the chord of the remaining arc of the semicircle.

First, let the right sine DE of the arc BD be known, and let the sine of the complement of that arc be DF, which we must find. When the straight line DA has been drawn, the square of the straight line DA will be equal to the squares of the straight lines DE and EA [Elements I.47]. If, then, from the square of the whole sine DA (which is known, for the whole sine is set at a fixed number of particles) the square of the right sine DE—known in the parts of the whole sine DA—is subtracted, there will remain the square of the straight line EA, known; and accordingly, by its square root, EA will be known in those same parts. Since, then, the straight line EA is equal to the sine of the complement of the arc BD—that is, to the straight line DF [Elements I.34]—DF, the sine of the complement of the arc BD, will be known, whose right sine DE was set as known.

Next, let the chord AB of the arc AB be known, and let BC be the chord subtending the remaining arc BC of the semicircle, which we are directed to find. Since the angle B is a right angle in a semicircle [Elements III.31], the square of the diameter AC will be equal to the squares of the chords AB and BC [Elements I.47]. If, then, from the square of the diameter AC (which is known, for the diameter is set as divided into a fixed number of particles) the square of the chord AB—known in the parts of the diameter AC—is taken away, the square of the chord BC will remain known; and accordingly, by its square root, the chord BC will become

known in those same parts. Thus from the right sine of any arc, and so on, we have found what was sought. Which was to be done.

Diagram. The left of the two constructions for this problem: a quarter-circle with the right-sine construction. The base runs C, F, A (left to right); B is at the top and D on the arc at the upper left, with E just below B. The right sine DE and the complement sine ($DF = EA$) are shown; a right triangle is formed at E.

- B (top): endpoint of the arc
- D: point on the arc (endpoint of the arc BD)
- E: foot of the right sine DE
- C, F, A: points on the base semidiameter (A the center)

Diagram. The right of the two constructions: a semicircle on the diameter AC (A at left, C at right, center dot marked), with B on the circle toward the upper right. The chords AB and BC are drawn, meeting at the right angle at B (right angle in a semicircle).

- A (left), C (right): endpoints of the diameter
- B (upper right): point on the semicircle; angle ABC is a right angle
- chords AB and BC subtend the arc AB and the remaining arc BC

COROLLARIVM.

[Margin: The versed sine of any arc is found from its right sine, once that is known.]

From this it follows that the versed sine of any arc can also be found once its right sine is known. For since the sine of the complement DF —that is, AE —is found from the right sine DE , then, if the sine of the complement of the given arc BD is subtracted from the whole sine AB , the versed sine EB of the given arc BD will remain known. By the same reasoning, if the right sine DE —that is, AF —of the given arc BD is subtracted from the whole sine AC , the versed sine CF of the complement of the given arc BD will remain known.

THEOR. 2. PROPOS. 4.

[Margin: The right sine of any arc less than a quadrant is a mean proportional between half the whole sine and the versed sine of another arc, which is double the first and also less than a quadrant.]

The right sine of any arc less than a quadrant is a mean proportional between half the semidiameter (that is, of the whole sine) and the versed

sine of another arc, which is double the first arc and likewise less than a quadrant. Likewise, the whole sine has the same ratio to twice the given sine as the given sine has to the versed sine of the double arc.

Let CE be any arc less than a quadrant, whose half is CD. Bisecting the semidiameter AC at G, from E draw EF perpendicular to AC, and join the straight line AD, which will cut the drawn chord CE at H, bisecting it—by the lemma demonstrated by us above at the definitions—and indeed at right angles [Elements III.3]. Then CH will be the right sine of the arc CD, and CF the versed sine of the arc CE, which is double the arc CD, since EF is the right sine of that same arc CE, as is clear from the definitions. I say that CH, the right sine of the arc CD, is a mean proportional between CG, half the whole sine, and CF, the versed sine of the arc CE, which is double the arc CD. Likewise, that AC, the whole sine, is to CE, twice the sine CH, as the given sine CH is to CF, the versed sine of the double arc CE. For since the two angles ACH and AHC of triangle ACH are equal to the two angles ECF and EFC of triangle ECF—because the angle C is common to both triangles, and the angles at H and F are right angles [Elements I.32]—the triangles ACH and ECF will be equiangular. Therefore AC is to CH as EC is to CF [Elements VI.4]; and, alternately, AC is to CE as CH is to CF. But as AC is to CE, so is CG, half of AC, to CH, half [of...] [Elements V.15]

the half of CE. Therefore it will also hold that, as CG is to CH, so CH is to CF; and consequently CH, the right sine of arc CD, is the mean proportional between CG, the half of the whole sine, and CF, the versed sine of arc CE (of which arc CD is the double). Therefore the right sine of any arc less than a quadrant [and so forth]. Which was to be demonstrated. The other part is established, since it has been shown that, as AC, the whole sine, is to CE (the double of the sine CH), so CH, the given sine, is to CF, the versed sine of arc CE, of which arc CD is the double.

[Margin: From the known right sine of any arc, the right sine of another arc which is its half becomes known.]

COROLLARIUM.

It is gathered from this that, if the right sine of some arc is known, the right sine of another arc which is its half also becomes known: so that, from EF, the known right sine of arc CE, there is also found CH, the right sine of arc CD, which is the half of arc CE. For from the known right sine EF the sine EI of the complement becomes known; and when this is subtracted from the whole sine AC ([Margin: e] since the sine EI is equal to the line AF), the versed sine CF of arc CE is left known, as was stated in the corollary to the preceding proposition. [Margin: c — Elements

I.34] Since, then, CH ([Margin: f — Proposition 4 of this treatise]) is the mean proportional between the half of the whole sine and the versed sine CF, as we have shown, [Margin: g — Elements VI.17] the rectangle contained by the half of the whole sine and the versed sine CF will be equal to the square of the sine CH. Therefore, if the half of the whole sine is multiplied into the versed sine CF, there will be produced the square number of the sine CH, whose square root will give the right sine CH known. And the reasoning is the same for the rest.

The same thing can also be shown by this method. Since EF, the right sine of arc CE, is set down as known, [Margin: h — Proposition 3 of this treatise] EI too, the sine of the complement of the same arc — that is, the line AF, [Margin: i — Elements I.34] which is equal to it — will become known. Therefore, when the line AF (that is, the sine of the complement of arc CE) is subtracted from the whole sine AC, the versed sine FC of that same arc CE will be known, as we also showed in the corollary to Proposition 3. And since the square of the line CE is equal to the squares of the lines EF and FC, it comes about that the squares of the known lines EF and FC, collected into one sum, make up the square of the line CE; whose square root will render the line CE itself known; and hence the half of this root will give CH, the right sine of arc CD (which is the half of the given arc CE), known.

[Margin: From the known right sine of any arc, the right sine of another arc which is its double becomes known, provided it be less than a quadrant.]

By converse reasoning, from this same Proposition 4 it is gathered that, if the right sine of some arc is known, the right sine of another arc which is its double also becomes known, provided the double be less than a quadrant: so that from CH, the known right sine of arc CD, there is also found EF, the right sine of arc CE, of which arc CD is the double. For since CH is the mean proportional between the half of the whole sine and the versed sine FC, as we have shown, the rectangle contained by the half of the whole sine and the versed sine FC will be equal to the square of the right sine CH. Therefore the square of the known sine CH will be that rectangle; and when it is divided by the half of the whole sine, the versed sine FC comes out known. And since the line CE, being the double of the known sine CH, is itself known, its square too will be known; and if the square of the known versed sine FC is subtracted from it, the square of the line EF is also left known (since the square of the line CE is equal to the squares of the lines CF and FE). And hence the square root of that quantity will give the right sine EF known.

SCHOLIUM.

But if it should happen that the perpendicular EF bisects the semidiameter AC, as it does in this figure, then CH, the sine of arc CD, will still be the mean proportional between CF, the half of the whole sine, and CF, the versed sine of arc CE (of which arc CD is the double). For the triangles ACH and ECF will again be equiangular; [Margin: k — Elements VI.4] and consequently, as AC is to CH, so is EC to CF; and, by alternation, as AC is to CE, so is CH to CF. [Margin: l — Elements V.15] Since, then, it holds that as AC is to CE, so is CF (the half of AC) to CH (the half of CE), it will also hold that as CF is to CH, so is CH to CF; and on that account CH, the right sine of arc CD, is the mean proportional between CF, the half of the whole sine, and CF, the versed sine of arc CG [recte: CE], which is the double of arc CD.

From this it follows that, if the perpendicular EF bisects the semidiameter AC, the line CH is equal to the line CF. For if it were greater or less, it could not hold that as CF is to CH, so is CH to CF, since the one ratio would be one of greater inequality and the other one of lesser inequality.

Diagram. The scholium figure: a quadrant with its right angle at A (bottom-right), the arc running from B (top) down to C (bottom-left).

- B (top): upper end of the arc.
- E (upper-left, on the arc): endpoint of arc CE.
- D (left, on the arc, below E): endpoint of arc CD (the midpoint arc of CE).
- H (interior): foot/intersection point; CH is the right sine of arc CD.
- C (bottom-left): center-side vertex, origin of the arcs.
- F (bottom, between C and A): foot of the perpendicular EF on CA; F is the midpoint of CA in this special case.
- A (bottom-right): center of the quadrant (right angle).

The lines AE, AD (radii/chords), the perpendicular EF, and the segment CH are drawn.

THEOR. 3. PROPOS. 5.

The right sine of an arc of 54 degrees is composed of the half of the whole sine and the right sine of an arc of 18 degrees. The versed sine of an arc of 72 degrees is composed of the half of the whole sine and the versed sine of an arc of 36 degrees.

[Margin: The right sine of 54 degrees equals the half of the whole sine together with the sine of 18 degrees; the versed sine of 72 degrees equals the half of the whole sine together with the versed sine of 36 degrees.]

In the quadrant ABC let BD be an arc of 54 degrees; its complement CD is therefore 36 degrees. Bisect CD at H, so that each of the arcs CH and HD is 18 degrees. Draw DM perpendicular to AB, as the sine of the 54-degree arc, and DE perpendicular to AC, as the sine of the 36-degree arc. Also join the line AH, which — by the lemma demonstrated among the definitions — will bisect the line CD at I, [Margin: a — Elements III.3] and consequently at right angles as well; and therefore CI will be the right sine of the arc CH, 18 degrees. Finally, taking a line EF equal to EC, let AC and AF be bisected at G and K, and from K draw KL perpendicular to AG. I say that the right sine DM of the 54-degree arc — that is, the line AE, [Margin: b — Elements I.34] which is equal to it — is composed of AG (the half of the whole sine) and CI...

Diagram. The figure for Proposition 5: a quadrant ABC (right angle at A, bottom-right) with the arc from B (top) to C (bottom-left), carrying the construction points of the demonstration. This same figure is reprinted at the top of p. 698 to accompany the continuation of the demonstration.

- L (top, on the arc): endpoint of arc BL.
- B (top-right corner): upper end of the quadrant.
- N (just below B): foot of the perpendicular LN on AB.
- D (left, on the arc): endpoint of arc BD / CD.
- M (interior, right): foot of the perpendicular DM on AB.
- H (left): midpoint of arc CD region; CH.
- I (interior, below D): midpoint of chord CD; CI, the right sine of 18 degrees.
- C (bottom-left): center-side vertex.
- E, F, G, K (along the base, left to right): points of the base construction (E foot of DE; F, G, K the bisection points).
- A (bottom-right): center of the quadrant.

and CI, the right sine of the 18-degree arc — that is, that the line GE (which together with AG makes up the whole line AE) is equal to the right sine CI. Likewise, that the versed sine of the 72-degree arc is composed of the half of the whole sine and CE, the versed sine of arc CD (36 degrees); that is, that the line EK (which, together with the versed sine CE, makes up the line CK) is equal to the half of the whole sine, while CK itself is the versed sine of the 72-degree arc; that is, that the arc CL, whose versed sine is CK, is 72 degrees.

For, drawing the line LN perpendicular to AB, as the sine of arc BL, let the lines AD and DF be joined. Now since the arc CH of 18 degrees contains one-fifth of the quadrant BC (because five times 18 makes 90), the arc CD will contain two-fifths of the same quadrant; and therefore the ratio of arc CD to arc BC will be as 2 to 5. [Margin: c — Elements VI.33] But as arc CD is to arc BC, so is the angle CAD to the right angle BAC. Therefore the ratio of the angle CAD to the right angle BAC will likewise be as 2 to 5; and so the angle CAD will contain $\frac{2}{5}$ of one right angle. Since, then, the three angles of triangle CAD contain $\frac{10}{5}$ of a right angle — that is, [Margin: d — Elements I.32] are equal to two right angles — and [Margin: e — Elements I.5] the two angles ACD and ADC are equal to each other, each of them will contain $\frac{4}{5}$ of one right angle. [Margin: f — Elements I.5] And since the angle DFC is equal to the angle DCF — because the lines DF and DC are equal (for since DE and EF, the sides of triangle DEF, are equal to DE and EC, the sides of triangle DEC, and the angles at E which they contain are equal, being right angles, [Margin: g — Elements I.4] the bases DF and DC will be equal) — the angle DFC too will contain $\frac{4}{5}$ of one right angle. And consequently the remaining angle DFA, out of two right angles — that is, out of $\frac{10}{5}$ of a right angle — will contain $\frac{6}{5}$ of one right angle. Now the angle DAF [contains $\frac{2}{5}$ of a right angle], and [Margin: h — Elements I.31 (recte I.32?)] since all three angles in triangle AFD contain $\frac{10}{5}$ of one right angle, while the angle DFA has been shown to contain $\frac{6}{5}$, the angle ADF will contain $\frac{2}{5}$ of one right angle, and will therefore be equal to the angle DAF. [Margin: i — Elements I.6] Hence the sides DF and AF will be equal. And since the line DF has been shown equal to the line DC, the line AF will also be equal to DC; and therefore KF, the half of AF, will be equal to CI, the half of DC.

Again, since AK and KF are equal, then, adding the equal segments EC and FE, the line composed of AK and EC will be equal to the line KE; and consequently KE will be the half of the semidiameter AC, since AC is divided into two equal parts, of which one is KE and the other the line composed of AK and EC. Therefore KE is equal to CG. So, when the common line GE is taken away, the remainders GK and EC will be equal. But EC was taken equal to EF; therefore GK too will be equal to EF; and, adding the common line FG, EG will be equal to FK — that is, to CI, to which we showed above that the line KF is equal. Therefore AE (which is equal to the sine DM of the 54-degree arc) is composed of AG, the half of the whole sine, and GE, which has been shown equal to the sine CI of the 18-degree arc. This is the first point.

Now, since KF has been shown equal to EG, and EG to CI, KF will be equal to the right sine CI. But KF is equal to AK; therefore AK too will be equal to CI. [Margin:

k — Elements I.34] Since, then, AK is equal to the sine LN, the sine LN will also be equal to the sine CI. But CI is the sine of an 18-degree arc; therefore LN too will be the sine of an 18-degree arc, and so the arc BL, whose sine is LN, will contain 18 degrees; hence its complement CL will contain 72 degrees. And the versed sine of CL, namely KC, is composed of CG (the half of the whole sine) and GK, which has been shown equal to the versed sine EC of arc CD (36 degrees). This is the second point. And so the right sine of the 54-degree arc is composed [as stated], and so on. Which was to be demonstrated.

[The figure for this proposition (see fig-p697-2 above) is reprinted at the top of this page, beside the margin key "c — Elements VI.33"; it is described once at its first appearance on p. 697 and not re-rendered here.]

COROLLARIVM.

It is established from this that the triangle ACD — whose base CD subtends 36 degrees and whose apex lies at the center — is isosceles, and that each of its two equal angles C and D is double the remaining angle at the center. For the angle CAD was shown to contain $\frac{2}{5}$ of a right angle, whereas each of C and D contains $\frac{4}{5}$.

THEOR. 4. PROPOS. 6.

[Margin: The difference between the chords of two arcs, of which one is as much less than an arc of 120 degrees as the other is greater, equals the chord of the arc by which either of the said arcs differs from the 120-degree arc.]

The difference between the chords of two arcs of a semicircle — of which one is as much less than an arc of 120 degrees as the other is greater — is equal to the chord of the arc by which either of the said arcs differs from the 120-degree arc.

In the semicircle ABC let the arc BA be 120 degrees, and let arc BD be as much less [than the 120-degree arc] as arc BE is greater; their chords are BD and BE. Cut off BF equal to BD, and join the lines AD, AE, AF. I say that EF, the difference of the two chords BD and BE, is equal to the chord AE, or AD. For, when the circle is completed and an equilateral triangle ABG is inscribed in it — one side of which is AB, the chord of the 120-degree arc, since it subtends a third part of the circumference — [Margin: a — Elements I.32] the angle AGB will be a third part of two right angles. [Margin: b — Elements III.21] Since, then, the angle AEB, lying in the same segment AGB as that angle, is equal to it, AEB too will be a third part of two right angles. Next, since the sides DB and BA of triangle DBA are equal to

the sides FB and BA of triangle FBA, [Margin: c — Elements III.27] and contain equal angles, the bases AD and AF will be equal to each other. [Margin: d — Elements III.29] Since, then, AD is equal to AE — because the arcs AD and AE are equal — AF too will be equal to that same AE; [Margin: e — Elements I.5] and therefore the angles AEF and AFE will be equal to each other. But AEF, as we showed, is a third part of two right angles; therefore AFE too will be a third part of two right angles; [Margin: f — Elements I.32] and hence the remaining angle EAF will also be a third part of two right angles.

Diagram. Two companion circle-figures for Proposition 6, drawn side by side, each with horizontal diameter BC.

Left figure:

- D (top-left, on the circumference): endpoint of arc BD.
- A (top): apex of the inscribed equilateral triangle ABG.
- E (right, on the circumference near C): endpoint of arc BE.
- F (interior, on the diameter BC): point with $BF = BD$.
- B (left): left end of the diameter.
- C (right): right end of the diameter.
- G (bottom): third vertex of the inscribed equilateral triangle ABG.
- The chords BA, BD, AD, AE, AF and the dotted lines toward G are drawn.

Right figure (mirror configuration):

- D (top-left, on the circumference).
- A (top).
- F (interior, on the diameter).
- E (right, on the circumference).
- B (left end of the diameter); C (right end).
- G (bottom).
- The corresponding chords and dotted segments are drawn.

Therefore triangle AEF will be equilateral, by the corollary to Proposition 6 of Book 1 of Euclid; and so the line EF, the difference of the chords BD and BE, will be equal to the chord AE, or AD. The difference, then, of the chords of two arcs of a semicircle [is as stated], and so on. Which was to be demonstrated.

COROLLARIUM.

It follows from this that, if the chords of two arcs which together make up 120 degrees are joined together, there results the chord of the arc composed of the 120-degree arc and the smaller of those two arcs — provided they are unequal. For in this way you see that the chords BD and DA — of the arcs BD and DA, which together make 120 degrees — taken together are equal to the chord BE of the arc BAE, which is composed of the arc BA (120 degrees) and the arc AE (equal to the smaller arc AD); because, as was demonstrated, the difference EF between the chords BD and BE is equal to the chord AD.

[Margin: The two chords of two arcs making up 120 degrees together equal the chord of the arc composed of the 120-degree arc and the smaller of those two arcs.]

THEOR. 5. PROPOS. 7.

[Margin: If one quantity exceeds another, the half of the one will exceed the half of the other by half the excess.]

If one quantity exceeds another, the half of the former exceeds the half of the latter by the half of the excess.

Let the quantity AB exceed the quantity C by the excess DB; let DB be bisected at E, and let AF be set equal to EB. Since, then, AF and EB together are equal to the whole excess DB, the remainder FE will be equal to C. Bisect FE at G. Since GE and GF are equal, then, adding the equal segments EB and FA, GB and GA will also be equal; and consequently AB too will be bisected at G. Therefore BG, the half of AB, exceeds GE — the half of FE, that is, of C — by the excess EB, which is the half of the excess DB. So, if one quantity exceeds another, and so on. Which was to be demonstrated.

We shall demonstrate the same thing differently, having first laid down this theorem:

If one quantity exceeds another, the excess of equimultiples of them will be the same multiple of the original excess.

Let the quantity AB exceed the quantity CD by the excess EB; and let AG and CI be equimultiples of AB and CD. I say that AG exceeds CI by an excess which is the same multiple of the excess EB as AG is of AB, or CI of CD. For if BG and DI are divided into the magnitudes BF, FG and DH, HI, equal respectively to AB and CD, then BF and FG will exceed DH and HI by the excesses KF and LG, which are

equal to the excess EB; and AE, BK, FL will together be equal to the whole CI. Therefore AG will exceed CI by as many excesses equal to EB as AG is a multiple of AB (or CI of CD). Which was to be demonstrated.

From this the truth of this Proposition 7 is manifest. For by whatever excess the half of AB exceeds the half of CD, the whole AB will exceed the whole CD by double that excess, as we have just shown. Therefore the excess EB, by which AB exceeds CD, is double the excess by which the half of AB exceeds the half of CD; and consequently the half exceeds the half by the half of the excess. Which is what was proposed.

Diagram. Three line-schematics for Proposition 7, each showing an upper segment from A to B and a lower segment beginning at C, with the intermediate division points F, G, D, E marked. The three rows show the points in different arrangements (the several cases of the construction).

- Row 1: A — F — G — D — E — B (upper); C — (lower, shorter).
- Row 2: A — D — F G — E — B (upper); C — (lower).
- Row 3: A — F — D — E — B, with G marked just below D (upper); C — (lower).

THEOR. 6. PROPOS. 8.

[Margin: The difference between the sines of two arcs of a quadrant, of which one is as much less than an arc of 60 degrees as the other is greater, equals the sine of the arc by which either of the said arcs differs from the 60-degree arc.]

The difference between the sines of two arcs of a quadrant — of which one is as much less than an arc of 60 degrees as the other is greater — is equal to the sine of the arc by which either of the said arcs differs from the 60-degree arc.

In the quadrant ABC let arc CD be 60 degrees, and let arc CE be as much less [than 60] as arc CE [recte: CF] is greater; their right sines are EG and FH. I say that the difference of these sines is equal to the sine of the arc DE, or DF. For, when the quadrant is produced, together with the sines EG and FH, to I and K, take an arc

CL equal to arc CD, so that the whole arc DCL contains 120 degrees. And since the arcs CI and CK are equal to the arcs CE and CF — because, by the lemma laid down among the definitions, [Margin: a — Elements III.3] the line BC bisects the arcs ECI and FCK, and bisects the lines EI and FK as well — the remaining arcs LI and LK will likewise be equal to the remaining arcs DE and DF. Taking also arcs EM and FN equal to the arcs DE and DF, draw the chords LM and LN. And since arc FN is equal to arc LK, and arc EM to arc LI, then, adding the common arcs FL and MI, arc NL will be equal to arc FK, and arc ML to arc EI; [Margin: b — Elements III.29] and consequently the chord NL is equal to the chord FK, and the chord ML to the chord EI. Since, then, arc LM is as much less than arc LD (120 degrees) as arc LN is greater than it, the difference of the chords LN and LM will, by Proposition 6, be equal to the chord DN, or DM; that is, the line KF will exceed the line IE by the chord DN, or DM. Therefore, by the preceding proposition, the half HF — that is, the sine of arc CF — will exceed the half GE — that is, the sine of arc CE — by the half of the chord DN, or DM; that is, by the sine of arc DF, or DE. Which was to be demonstrated.

Alternatively: In the quadrant ABD let the arc BE be 60 degrees, and let the arcs EF and EG be equal; and so arc BF is as much less than arc BE as arc BG is greater than that same arc BE. Draw FH and GI perpendicular to BD; these will be the sines of the arcs BF and BG. Now, when the chord FG is drawn, let the semidiameter DE, when drawn, cut it at L. And since the arc FG is bisected at E, the line FG too will be bisected...

Diagram. Two companion quadrant/semicircle figures for the demonstration of Proposition 8, drawn side by side (mirror configurations), carrying the construction of the sines EG, FH, the produced sines to I, K, and the arcs CL, DCL, with chords LM, LN. Many interior points overlap in the engraving and their exact placement is hard to resolve at this resolution; the readable labels are listed.

Left figure (opening to the right):

- A (top-left corner); N, F, D (on the arc near the top).
- E (interior, upper); M (interior, lower).
- B (left end of the horizontal); H (just below B).
- G (on the horizontal, center); C (right end of the horizontal).
- K, L, I (at the bottom).

Right figure (semicircle, mirror of the left):

- A (top); F, D (on the arc); N (interior, upper).
- E (right, on the arc).
- B (left end of the diameter); H (interior); G (center-right); M (near the right end); C (right end).
- I (lower right); L (bottom center); K (bottom left).

Radii, sine-perpendiculars, and the chords of the construction are drawn throughout both figures.

(Continuing the Aliter — the alternative demonstration — of THEOR. 6 / PROPOS. 8 begun on the previous page.)

cut at L, as shown by the lemma demonstrated among the definitions; and therefore also at right angles (Elements III.3). FL is thus the sine of the arc EF, and GL the sine of the arc EG. Now draw the straight line FK perpendicular to GI; then IK will be equal to the straight line FH (Elements I.34), because FI is a parallelogram. Therefore GK will be the difference of the sines FH and GI.

I claim that this difference GK is equal to the sine FL, or GL. For draw the straight line BE, which is the side of a hexagon and therefore equal to the semidiameter DE (by the corollary to *Elements* IV.15); bisect BD at M, and join the straight line EM. Since, then, the sides DM, ME are equal to the sides BM, ME, and the base DE is equal to the base BE, the angles at M will be equal (Elements I.8), and hence right angles. When the semicircle ABC has been completed, and the straight lines GI and EM produced to N and O, the arc NO will be equal to the arc GE — that is, to the arc EF (by the scholium to *Elements* III.27) — because the straight lines GN and EO are parallel, on account of the right angles at I and M (Elements I.28). Adding the common arc FO, the arc FN will be equal to the arc EO. But the arc EO is double the arc BE. (For the straight line DB, cutting the straight line EO at right angles, bisects it (Elements III.3), and hence also bisects the arc EO, by the scholium set among the definitions.) Therefore the arc FN too will be double the same arc BE. So, drawing the straight lines DF and DN, the angle FDN will likewise be double the angle EDB (Elements VI.33). But this same angle FDN, standing at the center, is double the angle FGN standing at the circumference (Elements III.20). Therefore the angles EDM and FGK are equal; and the right angles M and K are also equal. The triangles EDM and FGK are therefore equiangular, and hence ED is to DM as FG is to GK (Elements VI.4). Since, then, ED is double DM — for DB, which was bisected at M, is equal to DE — FG too will be double GK. But FG is also double FL, or GL. Therefore the straight line GK, the difference of the sines FH and GI, is equal to the straight line FL, the sine of the

arc EF, or to the straight line GL, the sine of the arc EG. So the difference of the sines of two arcs of the quadrant, and so on. Which was to be demonstrated.

Diagram. A semicircle standing on the horizontal diameter DB, with the circle completed below. Read on the leaf, the labelled points are:

- A: upper left, on the arc
- G: top of the arc, right of A
- E: top of the arc, right of G
- F: upper right, on the arc
- K: interior, upper left
- L: interior, upper middle (right of K)
- D: left end of the horizontal diameter
- I: on the diameter, left of center
- M: center of the diameter
- H: on the diameter, right of center
- B: right end of the diameter
- C: lower left, on the completed circle
- N: bottom, left of center
- O: bottom, right of N

Chords DF, DN, GI (produced to N), EM (produced to O), GN, EO, BE, and FK are drawn among these points.

SCHOLIVM

Otherwise: let the sine GI cut the semidiameter DE at P, and join the straight line FP (Elements I.4); this will be equal to GP, because the triangles GLP and FLP have the sides GL, LP equal to the sides FL, LP, and the angles at L equal. Therefore the angles G and F will be equal in the isosceles triangle FGP (Elements I.5), and so too the two angles at P (Elements I.4). Since, then, the angle EPG is equal to the interior angle EDA, which is 30 degrees, the whole angle FPG will be 60 degrees (Elements I.29). Therefore each of G and F will also contain 60 degrees, so that all three together contain 180 degrees. The triangle FGP is therefore equilateral; and consequently GL and GK, the halves of the equal sides GF and GP, will be equal.

That GK is the half of the straight line GP is clear from the fact that FK, being perpendicular to the side GP, bisects it, by the scholium to *Elements* I.26.

Diagram. The same semicircle on diameter DB as in the previous figure, but here with the additional interior point P (used in this alternative proof). Read on the leaf, the labelled points are:

- A: upper left, on the arc
- G: top of the arc
- E: top of the arc, right of G
- F: upper right, on the arc
- K: interior, upper left
- L: interior (right of K)
- P: interior, below L
- D: left end of the diameter
- I: on the diameter, left of center
- M: center of the diameter
- H: on the diameter, right of center
- B: right end of the diameter
- C: lower left, on the completed circle
- N: bottom, left of center
- O: bottom, right of N

The straight line FP is drawn, together with the triangle FGP.

COROLLARIVM

From this it follows that if the sines of two arcs which together make up 60 degrees are added together, the result is the sine of the arc composed of an arc of 60 degrees and the smaller of those two arcs, when they are unequal. For this is what you see in the figure of the later demonstration of this proposition: the right sines FH and FL, of the arcs BF and FE — which together make up 60 degrees — taken together are equal to the right sine GI of the arc BEG, an arc composed of the arc BE of 60 degrees and the arc EG, which is equal to the smaller arc EF; because, as was demonstrated, the difference GK, between the sines FH and GI, is equal to the sine FL.

[Margin: *Two sines of two arcs together making up 60 degrees are equal to the sine of the arc composed of an arc of 60 degrees and the smaller of those two arcs. By this method the right sines of all arcs may be computed.*]

PROBL. 3. PROPOS. 9.

To compute the right sines of all the arcs of the quadrant, which exceed one another in order by one minute, expressed in parts of the whole sine when it is divided into any number of parts whatever.

First of all we shall compute the right sines in terms of a whole sine of 100000 parts — the number commonly adopted by everyone, and set by us as well, as we said above. But to make the computation more accurate, in these computations we shall set the whole sine at 10000000 parts. For in this way, once the first two figures on the right are dropped from each of the sines found (adding a unit, however, if the two figures dropped exceed the number 50), the sines that remain are more precise with respect to a whole sine of 100000 parts.

But if anyone should want sines of more parts — setting the whole sine, of course, at 10000000 parts, the number Johannes Regiomontanus [Regiomontanus] adopted, and the one we shall lay down in the following table — then the whole sine must be set at 1000000000 parts. For in this way, when the first two figures on the right are dropped from each of the sines found, as was said, there will remain sines that are more precise with respect to a whole sine of 10000000 parts. The reason for this is that in the investigation of a sine an error can occur only in one or the other figure on the right; so that when the two figures on the right are dropped, the sines left are the most precise with respect to the smaller whole sine. Anyone will easily verify this in the computation of the sines, and we ourselves shall demonstrate it below. By the same reasoning, if sines are to be investigated with respect to some other whole sine containing more or fewer parts than 100000 or 10000000, the whole sine to be set for the computation must be one that exceeds the given one by these two figures, 00, on the right — so that it is a hundredfold of it, just as here 10000000, which we assume in the calculation, is a hundredfold of the 100000 that we, with the other astronomers, adopt in practice.

[Margin: *How many parts the whole sine — in terms of whose parts the other sines are reckoned — should be set at, so that the other sines may be found more precise with respect to a whole sine of 100000 parts, or of fewer or of more.*]

Diagram. A quadrant (quarter-circle) figure, used for PROPOS. 9 and reprinted at the top of the following page. Read on the leaf, the labelled points are:

- B: top right corner (apex of the quadrant)
- F: interior, upper left
- E: left side, below F

- L: center
- D: left side, below E
- H: right side
- I: right side, below H
- K: interior, lower left
- C: bottom left corner
- G: bottom, right of C
- A: bottom right corner (the right angle of the quadrant)

Numerous chords are drawn among these points (AE, EB, AD, AF, CE, BC, EH, DI, EG, and others).

(The quadrant figure ABC of PROPOS. 9 is reprinted at the top of this page; it is described above at fig-p700-3.)

[Margin: *Computation of the sines of arcs exceeding one another by 15 degrees — namely the arcs of 15, 30, 45, 60, 75, and 90 degrees.*]

So let there be, in the quadrant ABC, the arc CD of 15 degrees, CE of 30, CF of 45, and hence EB of 60 and DB of 75 — since these are the complements of the arcs of 30 and 15 degrees. We shall compute the right sines of these arcs as follows. Draw EH and DI perpendicular to AB; these will be the right sines of the arcs of 60 and 75 degrees. Let the chord BC be bisected at L by the straight line AF, by the lemma demonstrated among the definitions (Elements III.3), and therefore cut at right angles; then BL will be the right sine of 45 degrees, that is, of the arc BF. Again draw EG perpendicular to AC as the sine of 30 degrees. Likewise let the chord CE be bisected at K by the straight line AD, by the said lemma, and therefore at right angles; then CK will be the right sine of 15 degrees. Finally join the straight lines AE and EB.

Now since the arc BE of 60 degrees is a sixth part of the whole circumference of the circle — for six times 60 make 360 degrees — the straight line BE will be the side of a hexagon, and hence equal to the semidiameter AE (by the corollary to *Elements* IV.15). Therefore the angles EAB and EBA will be equal (*Elements* I.5); and the angles at H are also equal, being right angles. Since, then, the two angles EAH and EHA are equal to the two angles EBH and EHB of the triangle BEH, and the side AE is equal to the side BE, the side AH will be equal to the side BH (*Elements* I.26); and hence AH is the half of the semidiameter AB. Therefore, since EG, the right sine of 30 degrees, is equal to this AH (*Elements* I.34), the right sine of 30 degrees will be equal to half the semidiameter, that is, of the whole sine. So,

when the whole sine is set at 10000000, EG, the sine of 30 degrees, will be 5000000 of those same parts — namely, the half of the whole sine.

[Margin: *The right sine of 30 degrees is equal to half the whole sine.*]

That half the whole sine is the sine of the arc of 30 degrees we shall show most easily as follows. Since the whole sine is equal to the chord of the arc of 60 degrees — namely, to the side of a hexagon (by the corollary to *Elements* IV.15) — it follows, from the definition of the right sine, that half the whole sine, or of the chord of the arc of 60 degrees, is the sine of the arc of 30 degrees, which is the half of the arc of 60 degrees.

From this sine, by PROPOS. 3, the sine of the complementary arc will be known — namely the sine EH of 60 degrees — provided that the square of the sine, 5000000, is subtracted from the square of the whole sine, 10000000, and the square root of the remaining number is taken, which is about 8660254.

Next, since the straight line AF, bisecting the arc BC, likewise bisects the straight line BC by the lemma of the definitions, and therefore also at right angles (*Elements* III.3), CL will be the sine of the arc CF of 45 degrees, which we shall find thus. Since in the triangle CAL the angle L is a right angle, and the angle CAL is half a right angle, the angle ACL will also be half a right angle (*Elements* I.32), and hence equal to the angle CAL. Therefore the straight lines AL and CL will be equal (*Elements* I.6). Since, then, the square of the straight line AC is equal to the squares of the straight lines AL and CL together (*Elements* I.47), the square of the whole sine AC will be double the square of the sine CL of 45 degrees. Half the square of the whole sine will therefore be the square of the straight line CL, whose square root will give the sine CL, about 7071068, for the arc of 45 degrees. This will also be found in the following way. Since the square of the straight line BC is equal to the squares of the straight lines AB and AC (*Elements* I.47), and hence to double the square of the whole sine AC, then if the square of the whole sine is doubled, we obtain the square of the straight line BC, whose square root will give the straight line BC, of 14142136 parts, about; and its half, 7071068, will give the sine CL of 45 degrees.

Again, since the straight line AD, bisecting the arc CE, likewise bisects the straight line CE at K by the lemma of the definitions, and therefore at right angles (*Elements* III.3), CK will be the sine of the arc CD of 15 degrees, which we shall find as follows. Since, by PROPOS. 4, the sine CK is the mean proportional between half the whole sine and the versed sine CG (which is indeed obtained if EH, the sine of 60 degrees, is subtracted from the whole sine AC, as we said in the

corollary to PROPOS. 3), CG being the half of the arc CE — for if half the whole sine is multiplied into the known versed sine CG, the square of the straight line CK is produced, since the rectangle contained by half the whole sine and the versed sine CG is equal to the square of the mean proportional CK (Elements VI.17). If, then, the root of the square of the straight line CK is extracted, the sine CK will be obtained, of 2588190 parts, as we taught in the said corollary to PROPOS. 4. This sine we shall also investigate in this other way. Since the square of the straight line EC is equal to the squares of the known straight lines EG and GC (Elements I.47), the square of the straight line EC will become known; and the square root of its square will give the straight line EC as known, whose half will be the known sine CK.

From the sine of 15 degrees, once known, there will also be known, by PROPOS. 3, the sine DI of the complement of the arc CD — that is, the sine of the arc BD of 75 degrees — which will be found to be 9659258 parts. And so the right sines of the arcs containing 15, 30, 45, 60, 75, and 90 degrees have now been found, as appears in this table.

Arcus (G.)	Sinus
15	2588190
30	5000000
45	7071068
60	8660254
75	9659258
90	10000000

Now with the help of these sines we shall proceed to the investigation of others as follows. Since, by the corollary to PROPOS. 4, from the known right sine of any arc the right sine of half that arc is also known, from the sine of the arc of 15 degrees we shall know the sine of the arc of 7 degrees 30 minutes; and from this, the sine of the arc of 3 degrees 45 minutes — an arc which cannot be further bisected without seconds (for its half contains 1 degree 52 minutes 30 seconds), which are neglected in the treatment of sines. Then, since by PROPOS. 3 from the known right sine of any arc the sine of that arc's complement is also made known, from the sine of the arc of 7 degrees 30 minutes we shall know the sine of the arc of 82 degrees 30 minutes; and from this, by the corollary to PROPOS. 4, the sine of the arc of 41 degrees 15 minutes; and from this, the sine of the arc of 48 degrees 45 minutes. Likewise, from the sine of the arc of 3 degrees 45 minutes we shall know, by PROPOS. 3, the sine of the arc of 86 degrees 15 minutes. And if the

other arcs whose sines have been found are likewise bisected, and their halves again bisected, and so on in succession, until arcs are reached whose minutes are odd in number and so cannot be further divided in two without seconds; and if the complements of these halves are taken, which again are to be continually bisected in the same way until arcs of odd minutes are reached; and the complements of the halves are taken, and so on — then, by the corollary to PROPOS. 4 and by PROPOS. 3, we shall know the sines of all these halves and complements. These sines, together with the six first found, will constitute the sines of 24 arcs exceeding one another in order by 3 degrees 45 minutes, as you see in this table.

[Margin: *Computation of the sines of arcs exceeding one another by 3 degrees 45 minutes.*]

Arcus (G M)	Sinus	Arcus (G M)	Sinus	Arcus (G M)	Sinus	Arcus (G M)	Sinus
3 45	65403 1	26 15	44228 87	48 45	75183 98	71 15	946930 1
7 30	13052 62	30 0	50000 00	52 30	79335 33	75 0	965925 8
11 15	19509 03	33 45	55557 02	56 15	83146 96	78 45	980785 3
15 0	25881 90	37 30	60876 14	60 0	86602 54	82 30	991444 9

22 30	38268 34	45 0	70710 68	67 30	92387 95	90 0	100000 00

[Margin: *Computation of the sine of the arc of 36 degrees.*]

After this, by means of what we demonstrated in PROPOS. 2 concerning the finding of the side of a decagon and of an equilateral pentagon in the same circle, we shall seek the sine of the arc of 36 degrees in this way. Let the figure of Proposition 2 be repeated, where it was demonstrated that DF is the side of a decagon and BF the side of an equilateral pentagon. And since the squares of the known straight lines BD and DE (for BD is the whole sine and DE its half) are equal to the square of the straight line EB (Elements I.47), the square of the straight line EB will be known, and therefore the straight line EB itself — that is,

the straight line EF, which is equal to it — will be known, namely about 11180339 parts. If from this the straight line ED, half the whole sine of 5000000 parts, is subtracted, the straight line DF will become known, of 6180339 parts; and if the square of DF is added to the square of the whole sine BD, the sum of the squares described on the straight lines DF and BD will become known — and hence also the square of the straight line BF, which is equal to those two (Elements I.47), will be known; whose square root will give the straight line BF as known. And since BF subtends 72 degrees in the circle ABC, being a fifth part of the circumference — because it is the side of a pentagon — it will be the known chord of the arc of 72 degrees; and its half, of 5877852 parts, will give the right sine of the arc of 36 degrees, which is half of it.

Diagram. A semicircle standing on the horizontal diameter AC, the figure repeated from PROPOS. 2. Read on the leaf, the labelled points are:

- B: apex, at the top of the arc
- A: left end of the diameter
- F: on the diameter, right of A
- D: on the diameter, near the center
- E: on the diameter, right of D
- C: right end of the diameter

Straight lines are drawn from B down to A, F, D, E, and C.

[Margin: *Computation of the sines of arcs exceeding one another by 2 degrees 15 minutes, and of certain others.*]

Furthermore, from this sine of the arc of 36 degrees we shall find, by PROPOS. 3, the sine of its complement — that is, the sine of the arc of 54 degrees. And if we bisect these two arcs, and again bisect their halves, and so on in succession, until we come to arcs whose minutes are odd in number and can no longer be divided, we shall likewise find, by the corollary to PROPOS. 4, the sines of these halves, and also, by PROPOS. 3, the sines of their complements. And if we again bisect these complements as far as we can, and take the complements of these halves, which again we bisect, and so on, we shall find in the same way the sines of all the arcs contained in this table.

Arcus (G M)	Sinus	Arcus (G M)	Sinus	Arcus (G M)	Sinus	Arcus (G M)	Sinus
36 0	58778 52	2 15	39259 8	40 30	64944 80	15 45	27144 05

Arcus (G M)	Sinus	Arcus (G M)	Sinus	Arcus (G M)	Sinus	Arcus (G M)	Sinus
54 0	80901 70	87 45	99922 90	49 30	76040 60	74 15	96245 52
18 0	30901 70	27 0	45399 05	20 15	34611 71	38 15	61909 40
72 0	95105 65	63 0	89100 65	69 45	93819 13	51 45	78531 69
9 0	15643 45	13 30	23344 54	42 45	67880 07	24 45	41865 97
81 0	98768 83	76 30	97236 99	47 15	73432 25	65 15	90814 32
4 30	78459 1	6 45	11753 74	31 30	52249 86	29 15	48862 12
85 30	99691 73	83 15	99306 85	58 30	85264 02	60 45	87249 60

And if we now arrange in order these sines together with those found up to this point, we shall have the right sines of all the arcs exceeding one another in order by 2 degrees 15 minutes, beginning from the arc of 2 degrees 15 minutes up to the arc of 87 degrees 45 minutes inclusive; and in addition the sines of 17 other arcs which do not keep to this increment. As appears in this table.

31 30	52249 86	63 0	89100 65	15 0	25881 90	90 0	100000 00

From this it is manifest that the sine of 54 degrees — that is, 8090170 — is composed exactly of the sines of 18 and 30 degrees — that is, of 3090170 and 5000000. And since the sine of 30 degrees is equal to half the whole sine, as was shown above, it is clear that the sine of 54 degrees is composed precisely of half the whole sine and the right sine of 18 degrees. This is what we demonstrated in PROPOS. 6.

Now we shall investigate the sine of the arc of 12°, using the sines of 30° and 54°, which have by now been determined. [Margin: Computation of the sine of the arc of 12°.] In the quadrant ABC let the arc BD be 30° and BE 54°, so that the arc DE, their difference, is 24°. Draw DF and EG perpendicular to AB; these will be the right sines of the arcs BD and BE. Likewise draw the lines DH and EI perpendicular to AC; these will be the right sines of the arcs CD and CE — that is, 60° and 36° — which are the complements of the arcs BD and BE. Let the line DH cut the line EG at K. Now since the sine DF (that is, KG, which equals it) and EG are known, their difference EK is also known. [Margin: Elements I.34] Similarly, since the sine EI (that is, KH, which equals it) and DH are known — by Prop. 3, being the sines of the complements of the arcs BE and BD — [Margin: Elements I.34] their difference DK is likewise known. Hence the two squares of the known

lines EK and DK are known; [Margin: Elements I.47] and since together they equal the square of the line DE, the square of DE is known too, and therefore the line DE itself is known — namely the chord of the arc of 24° . From this its half is known as well, that is, the right sine of the arc of 12° , which contains 2079117 particles.

Diagram. A quadrant ABC with center A at the lower right, the vertical radius AB rising on the right, and the arc BC sweeping from B at the top to C at the lower left. Two radii to points on the arc, DF and EG, are dropped perpendicular to AB, and DH, EI perpendicular to the horizontal radius AC (the bottom edge, C–I–H–A). The perpendiculars DH and EG cross at K.

- B (top right): endpoint of the vertical radius, top of the arc
- A (bottom right): center of the quadrant
- C (bottom left): endpoint of the horizontal radius / arc
- D (on the arc, upper middle): endpoint of arc BD (30°)
- E (on the arc, left of D): endpoint of arc BE (54°)
- F (on radius AB, below B): foot of perpendicular from D
- G (on radius AB, below F): foot of perpendicular from E
- H (on bottom radius): foot of perpendicular from D
- I (on bottom radius): foot of perpendicular from E
- K (interior): intersection of DH and EG

By this same method, if the sines of any two arcs whatsoever are known, the sine of half their difference will also be found. For example, if the sines of the arcs BD and BE — whatever they may be, even if they do not amount to 30° and 54° — are known, then the sines of their complements CD and CE are also known by Prop. 3; and so, as we have just shown, the chord DE will become known, and consequently its half as well, namely the sine of half the arc DE. [Margin: From the known sines of two arcs, the sine of half their difference likewise becomes known.]

Moreover, starting from the sine of the arc of 12° — if we bisect this arc repeatedly, as far as we can, and take the complements of the halves, together with the sine of the complement of the arc of 12° (which we again bisect repeatedly, and so on) — we shall find, by the corollary of Prop. 4 and by Prop. 3, the sines of all these arcs, which are contained in the following table. If we arrange these sines together with the sines of the immediately preceding table in order, we shall have the sines of 120 arcs. [Margin: Computation of the sines of arcs increasing successively by 45 minutes.]

Arc (G°M')	Sine	Arc (G°M')	Sine	Arc (G°M')	Sine	Arc (G°M')	Sine

which follow one another in continuous order by 45 minutes, the first being the arc of 0°45' and the last the whole quadrant of 90°, such as are the arcs of the

following table. For you will find that the sines of all these arcs have been obtained in the two immediately preceding tables, although they are not arranged there in this order.

Arc (G M)	Arc (G M)	Arc (G M)	Arc (G M)	Arc (G M)	Arc (G M)	Arc (G M)	Arc (G M)	Arc (G M)	Arc (M G)

Finally, we shall find the sines of the other arcs as follows. In the quadrant ABC let the arc BD be 1° , the arc BE $1^\circ 30'$, and the arc BH $0^\circ 45'$. Draw the line EK perpendicular to AB; divide the arc BH into three equal parts BF, FG, GH, and the arc DE into two parts DI, IE, so that each small arc contains $15'$. From F, G, H, D, I drop the perpendiculars FL, GM, HN, DO, IP to EK. Then EK will be the right sine of the arc BE, and OK the right sine of

the arc BD, since OK equals the line drawn perpendicular from D to AB, which is indeed the sine of the arc BD. [Margin: Elements I.34] And by the same reasoning NK will be the right sine of the arc BH. Let it then be proposed to find the sine OK of the arc BD, 1° . Since NK, the sine of $0^\circ 45'$, has been found to be 130896, its third part — namely 43632 — will be greater than MN; for by Prop. 1, KL is greater than LM, and LM greater than MN, so that MN is less than a third part of NK, that is, less than 43632. Therefore the same third part of the line NK, namely 43632, will be much greater than NO, since by the same Prop. 1, MN is also greater than NO. Hence, if we add 43632 to 130896 — that is, to NK, the sine of $45'$ — we shall produce the number 174528, which will be greater than OK, the right sine of 1° ,

since to NK we are adding more than the line NO, as has been said. [Margin: Computation of the sine of 1° .]

Diagram. A quadrant ABC with center A at the lower right and vertical radius AB on the right. From B down the arc are marked, in succession, the small division-points F, G, H (dividing arc BH into three equal parts), then D and I (dividing arc DE), down to E. The horizontal line EK runs from E to K near A, and onto it the perpendiculars from the arc-points fall at L, M, N, O, P.

- B (top right): top of the arc
- A (bottom right): center of the quadrant
- C (bottom left): far end of the arc
- F, G, H (on the arc, descending from B): the points trisecting arc BH
- D (on the arc, below H): endpoint of arc BD
- I (on the arc, below D): midpoint of arc DE
- E (on the arc, lowest of the labelled points): endpoint of arc BE
- L, M, N, O, P (on line EK, from K toward E): feet of the perpendiculars from F, G, H, D, I respectively
- K (right end of line EK, near A): foot of the perpendicular from B

Again, since EK, the sine of $1^\circ 30'$, has been found to be 261769, if we subtract from it the sine NK of $45'$, namely 130896, there remains the line EN of 130873 particles, whose third part — namely 43624 approximately — will be less than NO; for by Prop. 1, NO is greater than OP, and OP greater than PE, so that NO is greater than a third part of EN, that is, greater than 43624. Hence, if we add 43624 to 130896 — that is, to NK, the sine of $45'$ — we shall produce the number 174520, which will be less than OK, the right sine of 1° , since to NK we are adding less than the line NO. It is therefore established that the right sine of 1° lies between these two numbers, 174528 and 174520, the former being greater and the latter less. Let us accordingly set it as 174524, exactly midway between those numbers; for this number will not differ appreciably from the true sine of 1° .

From this sine of 1° we shall find, by Prop. 3, the sine of its complement — that is, the sine of the arc of 89° — to be 9998477. We may find it in this way as well. Since the number 174528 is greater than the sine of 1° , as we said, the complement's sine derived from it, by the doctrine of Prop. 3 — the sine of 89° — comes out as 9998476 and a little more, which will necessarily be less than the true sine of the arc of 89° , since for the sine of 1° we took a number greater than the true sine. Again, since the number 174520 is less than the sine of 1° , as we said, the complement's sine derived from it, by the doctrine of Prop. 3 — the sine

of 89° — comes out as 9998477 and a little more, which will necessarily be greater than the true sine of 89° , since for the sine of 1° we took a number less than the true sine. The sine of 89° is therefore established between these two numbers — 9998476 and a little more, and 9998477 and a little more — and so, without appreciable error, we shall set it as 9998477, which is precisely what we found for it from the sine of 1° . From this it is clear that the sine of 1° has been correctly established as 174524 particles, since from it, by Prop. 3, the sine of its complement has been found to contain exactly as many particles as it truly and really ought to contain. [Margin: Computation of the sine of 89° .]

Furthermore, from the sine of the arc of 1° we shall find, by the corollary of Prop. 4, the right sine of the arc of $30'$; and from this, by Prop. 3, the sine of its complement, namely the sine of $89^\circ 30'$. Likewise, from the sine of the arc of $30'$ we shall find, by the corollary of Prop. 4, the sine of the arc of $15'$; and from this the sine of its complement, that is, the sine of $89^\circ 45'$. [Margin: Computation of the sine of $30'$ and the sine of $89^\circ 30'$; likewise the sine of $15'$ and the sine of $89^\circ 45'$.]

Now, just as above we found from the right sines of 30° and 54° the right sine of 12° — which is half the chord of the arc of 24° , by which the said arcs of 30° and 54° differ from each other — so too from the right sines of the arc of $30'$ and the arc of $52^\circ 30'$, once known, we shall find the right sine of 26° , which is half the chord of the arc of 52° by which the said arcs of $30'$ and $52^\circ 30'$ differ from each other, as we showed above. And from the sine of 26° there will also be made known, by Prop. 3, the sine of its complement, namely the sine of 64° . [Margin: Computation of the sine of 26° and of 64° .]

If, then, we bisect repeatedly, as far as we can, the arcs of 26° , 64° , and $89^\circ 30'$, whose sines have been found, and take the complements of the halves — which in turn we divide repeatedly in two, and so on — applying that doctrine by which from the known sines of two arcs the sine of half their difference is found, we shall obtain the sines of 240 arcs. When these are set in order together with the sines of the 120 arcs previously found, they will make up the sines of 360 arcs, following one another in order by 15 minutes. [Margin: Computation of the sines of arcs increasing successively by 15 minutes.]

But since it is laborious and tedious to hunt out so many sines in this way, it will be enough to have found, with such difficulty, those sines of the 120 higher arcs that follow one another in order by 45 minutes. For from these we shall easily find, by the rule of proportions, the sines of the arcs that follow one another in order by 15 minutes; then from these the sines of the arcs that follow one another by 5 minutes; and finally, from these, the sines of the arcs extended through

single minutes — and never in this computation will an appreciable error arise. For when we have set the whole sine a hundred times greater than 100000, it follows that, when the first two figures on the right are discarded (as was said above), sines of the greatest exactness are left with respect to the whole sine of 100000, since the whole error that can occur in this computation lies in the first figure on the right, or at most in the first two. Therefore, when the two first figures are discarded, there will remain the very same sines that would have been found by that earlier geometrical method, with respect to the same whole sine of 100000, if in the computation the whole sine were set a hundred times greater still — namely of 10000000 particles — and two figures were rejected from the sines so found. Experience will teach this. We shall carry out the matter as follows: let those arcs be set in order together with their sines, and to the right of each sine let there be written the difference by which it differs from the preceding sine, as you see done here in five arcs. [Margin: Another computation of the sines of arcs increasing successively by 45 [?] minutes.]

Arc (G°M')	Sine	Difference
0°0'	000000	—
0°45'	130896	130896
1°30'	261769	130873
2°15'	392598	130829
3°0'	523360	130762
3°45'	654031	130671

Then say: if 45 minutes require the difference 130896, to be added to the sine of 0 minutes so as to make the sine of 45 minutes, what difference do 15 minutes demand, to be added to the same sine of 0 minutes so as to make the sine of 15 minutes? You will find that the difference required is 43632, which added to the sine of 0 minutes will constitute the sine of 15 minutes, of 43632 particles. Again say: with the same things posited, what difference do 30 minutes require, to be added to the same sine of 0 minutes so as to make the sine of 30 minutes? You will find the difference 87264, which added to the sine of 0 minutes will make 87264, the sine of 30 minutes.

Likewise say: if 45 minutes — by which the arc of 45 minutes differs from the following arc of 1°30' — require the difference 130873, to be added to the sine of 45 minutes so as to make the sine of 1°30', what difference do 15 minutes demand, to be added to the same sine of 45 minutes so as to make the sine of 60 minutes, that is, the sine of 1°? You will find the difference 43624, which added to

130896, the sine of 45 minutes, makes 174520, the sine of 1° . This, although somewhat less than the one we found by the other method, yet, when the two first figures are discarded — 20 — leaves the sine 1745, exceedingly exact with respect to the whole sine of 100000.

Say further: with the same posited, what difference do 30 minutes demand, to be added to the same sine of 45 minutes so as to make the sine of 75 minutes, that is, the sine of $1^\circ 15'$? You will find the difference 87249, which added to 130896, the sine of 45 minutes, will make 218145, the sine of $1^\circ 15'$. This, although somewhat less than the one the earlier method yields, yet, when the two first figures are discarded — 45 — will leave the sine 2181, exceedingly exact with respect to the whole sine of 100000.

Likewise say: if 45 minutes — by which the arc of $1^\circ 30'$ differs from the following arc of 2°

15 minutes — require the difference 130829, to be added to the sine of $1^\circ 30'$ so as to make the sine of $2^\circ 15'$, what difference do 15 minutes demand, to be added to the same sine of $1^\circ 30'$ so as to make the sine of $1^\circ 45'$? And further, what difference do 30 minutes require, to be added to the same sine of $1^\circ 30'$ so as to make the sine of 2° ? You will find the former difference to be 43610, which added to 261769, the sine of $1^\circ 30'$, will yield 305379, the sine of $1^\circ 45'$. The latter difference you will find to be 87219, which added to 261769, the same sine of $1^\circ 30'$, will compose 348988, the sine of 2° . These two sines, although less than those the earlier method yields, yet, when the two first figures are rejected from each, leave the sines 3053 and 3489, exceedingly exact with respect to the whole sine of 100000.

By this same method one must proceed in the rest, until the sines of all the arcs extended by 15 minutes, up to the arc of 45° , have been found. Beyond this it is not expedient to proceed by this route, since the sines of the complements of those arcs can be investigated more exactly, by Prop. 3, with respect to the whole sine of 10000000, than by the rule of proportions. The reason is that, as we showed above in the corollary of Prop. 1, the differences of the sines toward the end of the quadrant are smaller than near its beginning; and so the differences of the sines change more often near the end of the quadrant than near the beginning. From this it comes about that sines are more correctly found by the rule of proportions near the beginning of the quadrant than near the end, since there one and the same difference serves several sines, whereas here it serves fewer, as has been said. Experience too demonstrates this most plainly. [Margin:

Why sines are found more exactly by the rule of proportions near the beginning of the quadrant than near the end.]

If, then, all the sines of the arcs proceeding by 15 minutes, beginning from the arc of 0 minutes, are set in order together with their differences, we shall find by the same device the sines of all the arcs extended by 5 minutes; and from these, in turn, by the same method, we shall explore the sines of all the arcs proceeding by single minutes. And so we shall complete the table of sines up to the arc of 45° . From the sines of these arcs we shall then elicit, by Prop. 3, the sines of the complements of the same arcs. Thus the whole table of sines will be complete; and accordingly we shall have computed the right sines of all the arcs of the quadrant, following one another in order by one minute, in the particles of the whole sine divided into however many parts. Which was to be done. [Margin: Computation of the sines of arcs by 5 minutes and by single minutes.]

SCHOLIUM

Moreover, that you may see the rationale of the computation of sines by the rule of proportions: in the quadrant ABC let the sines DF, EG of the arcs BD, BE be known, from which it is proposed to elicit the sine HI of the arc BH, which lies between those two arcs. [Margin: Demonstration of the computation of sines by the rule of proportions.] Draw the line DK perpendicular to EG; then the lines LI, KG will be equal to the sine DF, and so HL, EK will be the differences between the sines HI, EG and the sine DF. Now since the arc DE — such as we posit it, namely of 45, or 15, or 5 minutes (for it is only from these intermediate arcs that we seek the sines) — does not differ from a straight line as far as sense can tell, and much less does the arc DH, the triangles DEK, DHL will be in a manner rectilinear and equiangular to each other. [Margin: Elements VI.4] Therefore it will hold that: as DE, the difference between the arc BD and the arc BE, is to EK, the difference between the sine DF and the sine EG, so is DH, the difference between the arc BD and the arc BH, to HL, the difference between the sine DF and the sine HI. Since, then, the first three magnitudes are known — namely the arc DE, by which the arc BE exceeds the arc BD; the line EK, by which the sine EG exceeds the sine DF; and also the arc DH, by which the arc BH, whose sine is sought, exceeds the arc BD — the fourth magnitude will also be known, that is, the line HL, which must be added to the sine DF to make the sine HI. It is therefore established that the sines found by the rule of proportions do not differ appreciably from the true sines, especially when the arc DE, by which the arcs of the known sines differ from one another, is very small, so that it scarcely differs from a straight line.

Diagram. A quadrant ABC with center A at the bottom and vertical radius AB on the right. On the arc, from the top B downward, are D, H, E; from these the sines DF, EG, HI fall on the vertical radius at F, G, I. The line DK is drawn perpendicular to EG (with a small right-angle mark near L), producing the two small nearly-rectilinear triangles used in the proof.

- B (top right): top of the arc
- A (bottom): center of the quadrant
- D (on the arc, upper): endpoint of arc BD
- H (on the arc, below D): endpoint of arc BH (its sine HI is sought)
- E (on the arc, below H): endpoint of arc BE
- F (on radius AB): foot of the sine DF
- I (on radius AB, below F): foot of the sine HI
- G (on radius AB, below I): foot of the sine EG
- K (on line EG): foot of the perpendicular DK
- L (near H, at the right-angle mark): intersection on HI with the perpendicular from D

A great abridgement in this task will also be afforded us by Prop. 8. For from it we shall obtain very many sines from others already found, by mere addition or subtraction. [Margin: A wonderful shortcut for finding very many sines.] For if we add the sine of any arc that is not greater than 30° to the sine of the arc that falls short of 60° by that same arc taken, we shall compose the sine of the arc that exceeds 60° by that same arc taken; because the difference between the sines of these two greater arcs is equal to the sine of that taken arc, which is supposed not greater than 30° , as we demonstrated there. For example, if we add 3461171, the sine of the arc of $20^\circ 15'$, to 6394390, the sine of the arc of $39^\circ 45'$ — which falls short of the arc of 60° by the said arc of $20^\circ 15'$ — we shall produce 9855561, the sine of the arc of $80^\circ 15'$, which exceeds the arc of 60° by the same arc of $20^\circ 15'$. Likewise, if we add 5000000, the sine of the arc of 30° , to the sine 5000000 of the arc of 30° by which the arc of 60° exceeds the said arc of 30° , we shall compose 10000000, the sine of the arc of 90° , which exceeds the arc of 60° by the same arc of 30° taken.

Likewise, if we subtract the sine of any arc that is not greater than 30° from the sine of the arc that exceeds 60° by that same arc taken, there will be left the sine of the arc that falls short of 60° by that same arc taken. For example, if we subtract 3502075, the sine of the arc of $20^\circ 30'$, from 9862856, the sine of the arc of $80^\circ 30'$ — which exceeds the arc of 60° by the said arc of $20^\circ 30'$ — the remainder

will be 6360781, the sine of the arc of $39^{\circ}30'$, which the arc of 60° exceeds by the same arc of $20^{\circ}30'$.

Again, if from the sine of any arc greater than 60° we subtract the sine of the arc that is as much less than 60° as the former is greater, there will be left the sine of the arc by which each of them differs from the arc of 60° . For example, if from 9781476, the sine of the arc of 78° , we take away 6691306, the sine of the arc of 42° , the remainder will be 3090170, the sine of the arc of 18° , by which each of them differs from the arc of 60° . All of which are gathered from the aforesaid Prop. 8.

And so it is enough to find, by the rule of proportions, the sines of all the arcs from the beginning of the quadrant up to the arc of 30° . For if from these the sines of the complements are elicited, and from these found sines the former sines are subtracted, there will remain the sines of all the arcs between the arc of 30° and the arc of 60° . Likewise, if the sines of all the arcs from the arc of 30° up to the end of the quadrant were known, and the sines of all the arcs smaller than the arc of 60° were subtracted from the sines of all the arcs greater than 60° , there would remain the sines of all the arcs from the beginning of the quadrant up to the arc of 30° . Finally, if the sines of all the arcs from the beginning of the quadrant up to the arc of 60° were found, and the sines of all the arcs smaller than 30° were added to the sines of all the arcs greater than 30° , the sines of all the arcs greater than 60° would be composed.

But let us now append the table of sines of all the arcs of the quadrant, extended through single minutes, computed by Johannes Regiomontanus — a table which, however, we have purged in very many places of the errors that had crept in through the carelessness of the printers. [Margin: What is to be done so that the following table of sines...] In this table the whole sine contains 10000000 particles, on which basis all the other sines have been found. If from each the first two figures on the right are rejected (adding, however, a unit if the two figures discarded make up a number greater than 50), there will be left the sine with respect to the whole sine of 100000. If, however, anyone should wish to construct the same table by his own effort, following the precepts already handed down, then, with the whole sine set at 10000000000 [?] particles, he must set the whole sine in the computation at 10000000000 [?] particles. For if from each of the sines found

with the two first figures on the right dropped, as we said, the remaining ones will be sines with respect to the whole sine 10000000 — the very same ones that are set out in the table of Johann Regiomontanus [Regiomontanus]. I say this so that you will not be surprised that not all the sines found by the rule of proportions from the sines of arcs increasing successively by 45 minutes — the whole sine being put at 10000000 — answer exactly, to the last digit, to the sines of this table. For in order that a sine be found exactly with respect to some whole sine, the whole sine must be made a hundred times greater in the calculation, as was said above.

[Margin: Why, when the two first figures are dropped from any sine taken with respect to the whole sine 10000000, the same sine remains with respect to the whole sine 100000 — even though the former was not found exactly.]

It is evident, moreover, that when the two first figures on the right are dropped from each individual sine, exact sines remain with respect to the whole sine 100000, even though those earlier ones were not found exactly. For since the whole sine bears some determinate ratio to any given right sine, it follows that all the parts of that whole sine — however many they be — bear the same ratio to the parts found for this [smaller sine] with respect to those parts of the whole sine, as all the parts of the same whole sine (fewer than the former) bear to the parts of the same whole sine taken in fewer parts. Otherwise the whole sine would not always bear the same ratio to the same sine, but would sometimes be of greater magnitude with respect to it and sometimes of less — which is absurd. Therefore, if the sine of any arc — for example, of the one containing 28 degrees — has been found with respect to the whole sine divided into any number of particles whatever, we shall easily find, by the rule of proportions, the same sine with respect to the same whole sine divided into fewer parts. Let us put it this way. If the whole sine of 10000000 parts gives the sine of the arc of 28 degrees as 4694716 parts, how many parts will the same whole sine of 100000 parts give for the sine of the same arc of 28 degrees? We shall in fact find the sine to be 46947 parts, and a further $\frac{1600000}{10000000}$. But if this fraction is omitted (since it is less than unity), the same sine will contain just 46947 parts — exactly as it is set down in the tables of sines, in which the whole sine contains 100000 parts. Here you see that this is the sine that is left when the two first figures on the right are dropped from it.

[Margin: If two figures are added on the right to any sine taken with respect to the whole sine 100000, one obtains the same sine with respect to the whole sine 10000000.]

The reason for this dropping is as follows. Since that sine of 28 degrees, multiplied by the whole sine 100000 — which multiplication is done by appending five ciphers, thus: 469471600000, as we taught in chapter 4 of our *Arithmetic* — is then divided by the whole sine 10000000 (as the rule of proportions prescribes; it is enough, if from the product-number 469471600000 there be removed as many figures as there are ciphers in the divisor 10000000, that is, seven figures, namely, the first figure, 4694716; and moreover $\frac{1600000}{10000000}$, as is plain from what has been said), from which precisely there is obtained that sine 4694700, such as we found it. But the prior sine [4694716], from which the two figures are dropped, is not omitted altogether with respect to the whole sine 100000; it only [becomes] this 4694700. And it ought indeed to be 46947, and over and above that $\frac{1600000}{10000000}$. Yet although these 16 units are neglected, and there be taken instead a sine of these units with respect to the whole sine $\frac{16}{10000000}$, which with respect to the whole sine 60 may deservedly be neglected — for this small quantity, although it be somewhat greater than $\frac{22}{500}$ [?], is nonetheless much less than $\frac{1}{3850}$ [?], that is, than one Minute with respect to the whole sine 60. (What we said of the whole sines of 10000000 and 100000 parts is to be understood likewise of all others.)

[Margin: In what way larger sines are made smaller, and conversely, whatever number of particles the whole sine be set at.]

For always, from sines taken with respect to a larger whole sine, in order to obtain the sines with respect to a smaller whole sine, as many figures are to be dropped as the number of ciphers by which the larger whole sine exceeds the smaller. And it is demonstrated in the same way: if, when the three first figures on the right are dropped from each sine, the remaining ones will be sines with respect to the whole sine 10000000 — that is, when sines are reckoned with respect to the whole sine 10000000, and to the [sines] found with respect to 10000. three ciphers are added — they become sines with respect to the whole sine 100000000, and so of the rest.

From these things the reason of that operation is plain, which I have often used, both in my *Gnomonics* and in other places: namely, when, of two straight lines, one is known with respect to some measure as though it were the whole sine, and then one of them is again known with respect to another straight line, to find in what way the other is known with respect to this other measure. This is a thing very familiar to astronomers.

[Margin: Given two straight lines with respect to some measure, and then one of them known with respect to another measure, in what way the other may be

known with respect to this other measure — which is most familiar to astronomers.]

Diagram. Near the foot of the page stand six horizontal straight line-segments of differing lengths, each drawn with terminal ticks and labelled at its left end. From top to bottom they are lettered A through F; A is the longest, the others shorter in varying degree, illustrating the proportion of measured lines discussed in the text.

- A: longest segment (given below as of 91354 parts, and again of 80901 parts)
- B: a shorter segment (40673 parts, and again 36019 parts)
- C: a long segment (serving as one "whole sine" measure of 100000 parts)
- D: a long segment (serving as another "whole sine" measure of 100000 parts)
- E: a short segment (equal to one palm)
- F: a segment of several palms (namely five)

For example: two straight lines A and B being known with respect to the straight line C — as though C were the whole sine, containing 100000 particles — line A being of 91354 parts and line B of 40673 parts; then A being found again, with respect to another, larger line D (as though D were the whole sine, likewise embracing 100000 particles), to be of 80901 parts, or of 4 palms with respect to the measure E, which is equal to one palm, or with respect to that said measure E, or F, which contains several palms, namely five — I ask, how many parts, or palms, will the same line B give? For line B will be found to be of 36019 parts, and a little more, or of $1\frac{3566}{4567}$ palms [?]. The reason of this operation does not differ from that above, since the straight line A bears always one and the same, determinate ratio to the straight line B.

67

SEQVITVR — There follows:

TABLE OF RIGHT SINES, EXTENDED THROUGH THE INDIVIDUAL MINUTES OF THE QUADRANT, and once computed by Johann Regiomontanus [Regiomontanus], but now examined by me, and in very many places amended and corrected.

[Latin display title, verbatim: *TABVLA SINNVVM RECTORVM PER SINGVLA QVADRANTIS MINVTA EXTENSA, ET à Ioan. Regiomontano quondam supputata, nunc autem per me examinata, & plerisque in locis castigata, atque correcta.*]

(The remainder of the page is blank.)

68

TABLE. Degrees of the Quadrant for the right sines of the arcs of the same Quadrant. [Verbatim banner (top): *T A B V L A. Gradus Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis.*]

Two-way sine table. Read top-down with the left-hand minute column (0 → 60) under the degree-headings **0, 1, 2, 3, 4**: this gives the right sine of the arc (whole sine = 10000000, here truncated to the six/seven leading figures — degree 0 shows only the significant leading figures). Read bottom-up with the right-hand minute column (0 → 60, i.e. the labels 60 → 0 as printed top-to-bottom) under the foot-banner degrees **89, 88, 87, 86, 85**: this gives the right sines of the complements. [Left vertical label: *Minuta Graduum Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis.* — Right vertical label: *Minuta Graduum Quadrantis pro sinibus rectis complementorum arcuum eiusdem Quadrantis.*]

Foot-banner (bottom): *Gradus Quadrantis pro sinibus rectis complementorum arcuum eiusdem Quadrantis.* — complementary degree-labels beneath the columns, left→right: **89** | **88** | **87** | **86** | **85**.

Canon of Sines — Degrees 5°–19° (right sines of arcs of the quadrant)

Three full-page numeric tables from the *Canon sinuum* [Canon of sines]. Each page carries five degree columns. The **top** banner gives the degree (*Gradus*) whose right sine [sinus rectus] is tabulated, read with the left-hand minute column running 0'→60' downward. The **bottom** banner gives the complement degree [complementum], read with the right-hand minute column running 60'→0' downward (heading: *pro sinibus rectis complementorum arcuum eiusdem Quadrantis* — "for the right sines of the complements of the arcs of the same quadrant"). Sine values are given to a radius of 10,000,000 (leading zero of the fraction omitted in print, as is usual). The narrow *Differentia* value printed beside each column is the difference per second [per secundum] of arc; it is listed after each table with the minute at which it changes.

Left margin (vertical), all pages: *Minuta Graduum Quadrantis pro sinibus rectis [arcuum eiusdem Quadrantis]* — "Minutes of the degrees of the quadrant, for the right sines." Right margin (vertical), all pages: *...bus rectis complementorum*

arcuum eiusdem Quadrantis — "...right [sines] of the complements of the arcs of the same quadrant."

Differentiae (per second), as printed beside each column, top→bottom:

- 5°: 48.3 → 48.2 (near foot, printed at 60')
- 6°: 48.2 → 48.1 (printed at 60')
- 7°: 48.1 → 48.0 (printed at 60')
- 8°: 48.0 → 47.9 (printed at 60')

- 9°: 47.9 → 47.8 (mid-column, ≈13') → 47.7 (printed at 60')

Differentiae (per second), as printed beside each column, top→bottom:

- 15°: 46.8 → 46.7 ($\approx 20'$) → 46.6 ($\approx 45'$)
- 16°: 46.6 → 46.5 ($\approx 12'$) → 46.4 ($\approx 37'$)
- 17°: 46.4 → 46.3 ($\approx 2'$) → 46.2 ($\approx 25'$) → 46.1 ($\approx 49'$)
- 18°: 46.1 → 46.0 ($\approx 11'$) → 45.9 ($\approx 35'$) → 45.8 ($\approx 56'$)
- 19°: 45.8 → 45.7 ($\approx 17'$) → 45.6 ($\approx 40'$)

Canon of Sines (Tabula Sinuum) — degrees 20°–34°

Christoph Clavius [Christophorus Clavius], Opera Mathematica, Tomus I (Mainz, 1611). Full-page numeric sine tables. Radius (sinus totus) = 10,000,000; entries are seven-figure right sines. Each degree-column runs from 0' (top) to 60' (bottom); the left minute index counts 0→60 (direct sines, *sinus recti*), the right minute index counts 60→0 (complements, *sinus recti complementorum*). The 60' value of each column equals the 0' value of the next column (verified — see QA).

Running head across the opening: **TABVLA SINVVM** ("Table of Sines"). Verso pages carry TABVLA, the recto carries SINVVM. Left-margin label (verso, direct): *Minuta Graduum Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis*. Right-margin label (complements): *Minuta Graduum Quadrantis pro sinibus rectis complementorum arcuum eiusdem Quadrantis*.

degrees 20–24

Top banner (verbatim): 20 | 21 | 22 | 23 | 24 Bottom banner (verbatim): 69 | 68 | 67 | 66 | 65 Sub-head: *T A B V L A / Gradus Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis.*

Differentiae (per-second differences, printed at block boundaries, in column order 20→24): 20°: 45.5 / 45.4 / 45.3 / 45.3 · 21°: 45.3 / 45.2 / 45.1 / 45.0 · 22°: 44.9 / 44.8 / 44.7 / 44.6 · 23°: 44.6 / 44.5 / 44.4 / 44.3 · 24°: 44.3 / 44.2 / 44.0 / 43.9.

degrees 25–29 (printed top banner 29–25)

Top banner (verbatim, as printed): 29 | 28 | 27 | 26 | 25 Bottom banner (verbatim): 64 | 63 | 62 | 61 | 60 Sub-head: *S I N V V M. / Gradus Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis.*

Note on this page's header: the printed top-banner degree labels run **29, 28, 27, 26, 25** left-to-right, but the columns' actual right-sine content is **sin 25°, 26°, 27°, 28°, 29°** left-to-right (0' heads 4226183 = sin 25° ... 4848096 = sin 29°; 60' of the last column = 5000000 = sin 30°). The bottom banner (64, 63, 62, 61, 60 = 89 – true degree) is internally consistent with the true degrees. The top-banner inversion is a feature/anomaly of the print — see QA. Column headers below are given as printed-banner (= true degree).

Differentiae (per-second, in column order 30→34): 30°: 42.0 / 41.9 / 41.8 / 41.7 / 41.6
 · 31°: 41.5 / 41.4 / 41.3 / 41.2 / 41.1 · 32°: 41.1 / 41.0 / 40.9 / 40.8 / 40.7 · 33°: 40.6 /
 40.5 / 40.4 / 40.3 / 40.2 · 34°: 40.2 / 40.1 / 40.0 / 39.9 / 39.8 / 39.7.

Printed page number 74. Column-34 60' entry 5735764 = sin 35° (0' head of the next column, continued in the following opening).

Canon of Sines (*Sinus recti*) — degrees 35°–49°

Opera Mathematica, Tomus I (Clavius, Mainz 1611), trigonometric tables. Global (printed folios 75–77).

Structure of each page (a standard Clavius/Rheticus double-entry sine canon): a top degree banner names five whole degrees (ascending left→right); the leftmost column gives the minute argument 0'→60' (top→bottom) for the **direct sine** reading; the rightmost column gives the minute argument 60'→0' for reading the same columns as **complement sines** against the bottom banner. Each seven-digit entry is the *sinus rectus* to radius 10,000,000. To the right of each *Sinus* column stands its **Differentia** column — the proportional part per second of arc (i.e. the per-minute first difference ÷ 60), printed sparsely and decreasing toward 90°. The degree banner is printed ascending and matches the true column identity (no mirrored/stale banner on these three pages).

Continuity: the batch continues the canon from the prior opening, whose final value was $\sin 35^\circ 0' = 5735764$ — reproduced here as the first cell (35°, 0'). All internal and cross-page column seams were checked (each column's 60' value = the next column's 0' value).

Folio 75 — degrees 35°–39°

Gradus Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis. (*The degrees of the quadrant, for the right sines of the arcs of the same quadrant.*)

[bottom banner] 44 | 43 | 42 | 41 | 40 Gradus Quadrantis pro sinibus rectis complementorum arcuum eiusdē Quadrantis.

Differentiae (proportional parts, per second; top→bottom, positions approximate):

- 45°: 34.3 (0'), 34.2 (≈3'), 34.1 (≈13'), 34.0 (≈23'), 33.9 (≈33'), 33.8 (≈43'), 33.7 (≈52')
- 46°: 33.7 (0'), 33.6 (≈3'), 33.5 (≈13'), 33.4 (≈22'), 33.3 (≈33'), 33.2 (≈42'), 33.1 (≈52')
- 47°: 33.1 (0'), 33.0 (≈3'), 32.9 (≈10'), 32.8 (≈20'), 32.7 (≈30'), 32.6 (≈40'), 32.5 (≈50')
- 48°: 32.4 (0'), 32.3 (≈9'), 32.2 (≈18'), 32.1 (≈28'), 32.0 (≈37'), 31.9 (≈47'), 31.8 (≈57')
- 49°: 31.8 (0'), 31.7 (≈5'), 31.6 (≈15'), 31.5 (≈25'), 31.4 (≈36'), 31.3 (≈46'), 31.2 (≈57'), 31.1 (60')

The canon continues from $\sin 49^\circ 60' = \sin 50^\circ = 7660445$ into the following opening.

Canon of Sines (Sinus rectus), degrees 50°–64°

Running header p. 78: TABVLA — p. 79: SINVVM — p. 80: TABVLA

Top banner (all three pages, verbatim): **Gradus Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis.** ("Degrees of the quadrant, for the right sines of the arcs of the same quadrant.")

Bottom banner (all three pages, verbatim): **Gradus Quadrantis pro sinibus rectis complementorum arcuum eiusdem Quadrantis.** ("Degrees of the quadrant, for the right sines of the complements of the arcs of the same quadrant.")

Each page prints five degree-blocks. The leftmost column is the minute (*Minuta / Scrupula*, 0'→60' read top-down); each degree-block gives the *Sinus rectus* value and, to its right, a *Differentia* (the per-second difference, printed as a block label — see the *Differentiae* note under each table). The right-hand minute column (60'→0') and the bottom degree-banner serve the complement (cosine) reading. Continuity confirmed: $\sin 50^\circ 0' = 7660445$ (= $\sin 50^\circ$ carried over from the preceding folio).

degrees 50°–54°

Differentiae (per-second, top→bottom as printed):

- 60°: 24.2, 24.1, 24.0, 23.9, 23.8, 23.7, 23.6, 23.5
- 61°: 23.5, 23.4, 23.3, 23.2, 23.1, 23.0, 22.9, 22.8
- 62°: 22.7, 22.6, 22.5, 22.4, 22.3, 22.2, 22.1, 22.0
- 63°: 22.0, 21.9, 21.8, 21.7, 21.6, 21.5, 21.4, 21.3
- 64°: 21.2, 21.1, 21.0, 20.9, 20.8, 20.7, 20.6, 20.5

*Bottom complementary degree-banner (verbatim, left→right): 29 | 28 | 27 | 26 | 25.
Right minute column runs 60→0.*

Canon of Sines (*Tabula sinuum*) — degrees 65°–79°

Christoph Clavius [Clavius], *Opera Mathematica*, Tomus I. Continuation of the canon of right sines (*sinus recti*) for whole degrees, radius = 10,000,000. Three full table-openings covering 65°–79°, each degree column running from 0' to 60'.

Layout of every column block (as printed): a left **Minuta** column (0'→60', reading the tabulated degree at the top banner), then for each degree a **Sinus** column paired with a **Differentia** column (the per-second first difference, printed once per row-group, e.g. 20. 5 = 20.5"), and a right **Minuta** column (60'→0') that reads the same values as sines of the **complement** (bottom banner). Top banner = tabulated degree; bottom banner = its complement (89 – top).

Header glosses (Latin retained in the tables): *Sinus* = Sine; *Minuta* = minutes; *Differentia(e)* = first difference(s); *complementorum* = of the complements. Running display-caps across the opening spell **SINVVM... TABVLA... SINVVM**.

degrees 65°, 66°, 67°, 68°, 69°

Printed table title (top): *Gradus Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis*. ("Degrees of the quadrant, for the right sines of the arcs of the same quadrant.") Printed table title (bottom, for the right-hand minute column): *Gradus Quadrantis pro sinibus rectis complementorum arcuum eiusdem Quadrantis*.

Seam checks: 65°60' = 66°0' = 9135455 ✓; 66°60' = 67°0' = 9205049 ✓; 68°60' = 69°0' = 9335804 ✓. **67°60' = 9271839 vs 68°0' = 9271836 — 3-unit mismatch (flagged).**

Bottom complement banner (per degree): 75°→**14**, 76°→**13**, 77°→**12**, 78°→**11**, 79°→**10**.

Canon of Right Sines — conclusion (80°–90°), and the Explanation and Use of the Table

[The table of right sines (canon sinuum) concludes on this opening: the direct-sine columns run 80°–89° across the two table pages, and the last cell — degree 89, minute 60' — gives the whole sine, $\sin 90^\circ = 10000000$. A page of prose (the Explicatio atque usus tabulae*) then follows, explaining how to use the table.]*

[Table page — printed p. 84] Right Sines, arcs 80°–84°

Table banner (top): *Gradus Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis*. — "Degrees of the quadrant, for the right sines of the arcs of the same quadrant." Left margin (vertical): *Minuta Graduum Quadrantis pro sinibus rectis arcuum eiusdem Quadrantis*. Right margin (vertical): *Minuta Graduum Quadrantis pro sinibus rectis complementorum arcuum eiusdem Quadrantis*.

Read the direct sine of an arc with the **left** minute column (0'→60', top→bottom) under the head-degree; read the complement sine with the **right** minute column (60'→0'). Whole sine = 10000000.

[Prose page — printed p. 86] EXPLANATION AND USE OF THE PRECEDING TABLE OF RIGHT SINES

Explicatio, atque usus tabulae praecedentis Sinuum rectorum.

[Margin: The layout of the parts of the table of sines.] [Margin: How the complement of any arc may be drawn from this table.] At the head of the preceding table the 90 degrees of the quadrant are set out in order, and down the left side the 60 minutes, descending. Then, along the bottom side, the same 90 degrees of the quadrant are placed again, but in reverse order, and up the right side the 60 minutes, ascending. We did this so that the complement of any arc might be recognized at once. For any degree placed at the head of the table, taken together with any minute set on the left, has for its complement the degree on the bottom side that corresponds to the degree taken at the head, together with the minute on the right that corresponds to the minute set on the left. Thus, since to the degree 46 at the head, with minute 0 set on the left, there corresponds on the bottom side degree 43 with minute 60 set on the right, the arc will be 43° 60' — that is, 44° 0' — the complement of the arc 46° 0'. In the same way the arc 43° 13' will have as its complement the arc 46° 47'. By the same reasoning, any degree placed on the bottom side, taken with any minute set on the right, has for its complement the degree at the head that corresponds to the degree taken on the bottom side, together with the minute on the left that corresponds to the minute taken on the right. Finally, beneath the degrees set out at the head of the table are placed the right sines of all the arcs advancing through each single minute of the quadrant, on the basis that the whole sine is 10000000. And if from each sine the two leading figures on the right are cast away — adding a unit, however, if the two figures cast away exceed the number 50 — the remainder will be the sines of the same arcs on the basis that the whole sine is 100000, as we said above. Hence

whatever we prescribe in the use of this table about sines relative to a whole sine of 10000000 must be understood also of the sines relative to a whole sine of 100000, by casting away the two leading figures on the right, as we have said.

[Margin: The use of the table of sines is twofold.] The use of this table is twofold. For by it either the sine of any given arc is sought, or the arc belonging to any known sine is investigated. [Margin: How the right sine of any arc smaller than a quadrant is found in the table.] When, then, you seek the right sine of a given arc smaller than a quadrant, take its degrees at the head of the table and its minutes on the left. At the common cell — proceeding, that is, from the minutes toward the right until you reach the place beneath the degrees taken — you will find the right sine at once. Thus you will find the right sine of the arc of 25° , beneath the head 25, in the row of minute 0 set on the left, to be 4226183. The right sine of the arc of $25^\circ 19'$ you will find to be 4276209. And the right sine of the arc of $25^\circ 50'$ you will come upon as 4357549.

[Margin: By what method the right sine of any arc greater than a quadrant is found.] But if you want the right sine of an arc greater than a quadrant yet smaller than a semicircle, subtract the given arc from the semicircle and take the right sine of the remaining arc, as before. For this sine will at the same time be the right sine of the arc greater than a quadrant, because two arcs that together make up a semicircle have the same right sine, as we said in the exposition of the definitions. Thus, if the given arc is $138^\circ 47'$, subtract it from the semicircle, that is, from 180° ; for the right sine 6589082 of the remaining arc of $41^\circ 13'$ is also the right sine of the arc of $138^\circ 47'$, since that arc, together with the arc of $41^\circ 13'$, makes up a semicircle.

[Margin: How the right sine of any arc that has seconds besides minutes is drawn out by the proportional part.] But if the given arc, besides degrees and minutes, has also seconds, the proportional part must be sought, in this way. Take the difference between the right sine of the next smaller arc and the right sine of the next larger arc, and reason: If 60 seconds (by which successive arcs in this table differ from one another) require that whole difference to be added to the sine of the next smaller arc in order to compose the sine of the next larger arc, how great a difference do the given seconds require to be added to that same sine of the next smaller arc, to make the sine of the proposed arc? For the difference found will be the proportional part which, added to the sine of the next smaller arc, produces the right sine of the proposed arc. For example, let the proposed arc be $20^\circ 43' 20''$. Take the difference 2721 between the sine 3537469 of the arc $20^\circ 43'$ (the next smaller) and the sine 3540190 of the arc $20^\circ 44'$ (the next larger), and

reason: If 60 seconds require the difference 2721 to be added to the sine 3537469 of the arc $20^{\circ} 43'$, so that the sine of the arc $20^{\circ} 44'$ is produced, how great a difference do the proposed 20 seconds require to be added to that same sine 3537469 of the arc $20^{\circ} 43' 20''$? You will find the difference, or proportional part, to be 907, which, added to the sine 3537469, will yield 3538376, the sine of the arc $20^{\circ} 43' 20''$.

[Margin: Seconds are commonly neglected by astronomers in the handling of sines.] Commonly, however, astronomers neglect the seconds in this business, if they are fewer than 30; but if more, they add for them one minute to the [given] minutes. For no error of any moment arises from this. And so for the given arc $20^{\circ} 43' 20''$ they take the sine of the arc $20^{\circ} 43'$, disregarding those 20 seconds; but for the arc $20^{\circ} 43' 48''$ they take the sine of the arc $20^{\circ} 44'$, reckoning those 48 seconds as one minute.

[Margin: For a semicircle, and for an arc greater than a semicircle, no right sine is to be sought; indeed, none of them has a right sine.] As for a semicircle, and an arc greater than a semicircle, there is no reason to investigate its right sine, since the sines of such arcs are never used in astronomical computations — as is plain to those who are practiced in rectilinear and spherical triangles, in which the whole science of sines is engaged. Indeed, a semicircle has no sine at all, as is clear from each of the two definitions of the right sine. The same may be said of a greater arc — unless someone, in the first figure of the definitions, wishes to call the line FK the right sine of the arc DBF, according to the later definition of the right sine, and the line FH the right sine of the arc ACF; which does not seem to be properly said, since the earlier definition of the right sine can in no way agree with lines of this kind, as is plain from the same figure.

[Margin: How the sine of the complement of an arc smaller than a quadrant is found in the table.] But when you seek the sine of the complement of a given arc smaller than a quadrant, take its degrees in the lower part of the table and its minutes on the right. At the common cell you will find the sine of the complement — that is, the right sine of that arc which is the complement of the given arc. For that right sine belongs to the arc whose degrees are placed at the head of the table and whose minutes are placed on the left side, and which is the complement of the given arc, as we said above. Thus you will find the sine of the complement of the arc of 30° , in the row of minute 0 (on the bottom side of the table) set on the right, to be 8660254 — which indeed is the right sine of the arc of $59^{\circ} 60'$, that is, of the arc of 60° , which is the complement of the arc of 30° . Likewise you will find

the sine of the complement of the arc of $30^{\circ} 49'$ to be 8588110, which is the right sine of the arc of $59^{\circ} 11'$, the complement of the arc of $30^{\circ} 49'$.

But if an arc is offered that is greater than a quadrant yet smaller than a semicircle, you will find the sine of its complement thus. Subtract a quadrant from it, and take the right sine of the remaining arc. For since this remaining arc is the complement of the given arc, its right sine will be the sine of the complement of the given arc. [Margin: By what art the sine of the complement of any arc greater than a quadrant is detected.] Thus, if the arc offered is $127^{\circ} 30'$, subtract a quadrant from it, that is, 90° ; for the right sine 6087614 of the remaining arc of $37^{\circ} 30'$ is the sine of the complement of the given arc $127^{\circ} 30'$, since that arc is the complement of this one.

* But if the given arc, besides degrees and minutes, has also seconds: if indeed it is smaller than a quadrant, you will investigate the sine of its complement by the rule of proportions, just as we said above about the right sine — except that here the difference found, or proportional part, must be *subtracted* from the sine of the next smaller arc. But if the given arc is greater than a quadrant yet smaller than a semicircle, then, a quadrant having been subtracted, you will seek the right sine of the remaining arc by the same rule of proportions, in the way we set out above concerning the right sine — although the seconds may be neglected, as we taught above, in this business of sines. An example. Let the given arc be

* [Footnote, foot of page:] *How the sine of the complement of any arc having seconds besides minutes is drawn out by the proportional part.*

arc of $69^{\circ} 16' 40''$. Take the difference 2721, which lies between the sine 3540190 (of the arc $69^{\circ} 16'$, the next smaller, entered in the lower part of the table) and the sine 3537469 (of the arc $69^{\circ} 17'$, the next larger, placed in that same lower part of the table); and reason thus. If 60 seconds require the difference 2721, to be subtracted from the sine 3540190 (of the arc $69^{\circ} 16'$, set in the lower part of the table) so that there remains the sine 3537469 (of the arc $69^{\circ} 17'$, described in that same lower part of the table), how great a difference do 40 seconds demand — to be subtracted from that same sine 3540190 (of the arc $69^{\circ} 16'$, placed in the lower part of the table) so that there remains the sine of the arc $69^{\circ} 16' 40''$ contained in that same lower part of the table? You will find the difference, that is, the proportional part [pars proportionalis], to be 1814; and this, subtracted from the sine 3540190, leaves the sine 3538376, set in the lower part of the table. This is indeed the right sine [sinus rectus] of the arc $20^{\circ} 40' 20''$ — that is, of the complement of the given arc $69^{\circ} 16' 40''$.

Let there again be given an arc of $110^{\circ} 43' 20''$. Take away a quadrant, that is, 90° , and for the residual arc of $20^{\circ} 43' 20''$ seek the right sine, as we taught above. By the proportional part you will find the sine 3538376, which is the sine of the complement of the proposed arc.

[Margin: Another method of finding the sine of the complement of an arc less than a quadrant.]

You may also find the sine of the complement of a proposed arc less than a quadrant in this way. Subtract the proposed arc from a quadrant, so as to obtain its complement. The right sine of that complement, found as we described for the right sine, is exactly what is sought. Thus, if the sine of the complement of the arc $69^{\circ} 16' 40''$ is wanted, subtract this arc from 90° ; then for the residual arc of $20^{\circ} 43' 20''$ (which is the complement of the given arc $69^{\circ} 16' 40''$) seek the right sine, which you will find to be 3538376. And this is the sine of the complement of the given arc $69^{\circ} 16' 40''$.

[Margin: The sine of the complement of a semicircle, or of an arc greater than a semicircle, need not be sought.]

Here too, the sine of the complement of a semicircle, and of an arc greater than a semicircle, need not be sought, for the reason stated above.

[Margin: How the versed sine of any arc, whether less or greater than a quadrant, is obtained.]

Finally, when you want the versed sine [sinus versus] of a proposed arc: if it is less than a quadrant, subtract its sine of the complement from the whole sine [sinus totus]; but if it is greater than a quadrant yet less than a semicircle, add its sine of the complement to the whole sine. The remaining number, or the sum, will be the versed sine of the given arc. This is because the sine of the complement of any arc equals the complement of the versed sine of the same arc, as we showed above in the definitions. Hence the sine of the complement of any arc, when taken from the whole sine or added to it, leaves or makes up the versed sine of the same arc — which is plain from the first figure that we set out in the exposition of the definitions.

Example. Let the versed sine of the arc $20^{\circ} 57'$ be sought. Its sine of the complement is 9338928, which subtracted from the whole sine 10000000 leaves the versed sine 661072 of the given arc $20^{\circ} 57'$. Again, let the versed sine of the arc $138^{\circ} 31'$ be investigated. Its sine of the complement is 7491484, which added to the whole sine 10000000 yields the versed sine 17491484 of the proposed arc 138°

31'. Lastly, let the versed sine of the arc $69^{\circ} 16' 40''$ be found. The sine of its complement is 3538376, found by the proportional part; this, subtracted from the whole sine 10000000, leaves the versed sine 6461624 of the given arc $69^{\circ} 16' 40''$. In the same way the versed sine of the arc $159^{\circ} 16' 40''$ will be found to be 19353068 by the proportional part.

[Margin: Both the right and the versed sine of a quadrant equal the whole sine, while its sine of the complement is nothing.]

Moreover, for a quadrant both the right sine and the versed sine equal the whole sine, whereas its sine of the complement is nothing — as is evident from the first figure set out in the definitions.

[Margin: How an arc less than a quadrant is derived from a known right sine.]

Now, from a known right sine you will find the arc as follows. Look for the proposed right sine among the sines of the table; or, if you do not find it, take the next larger or next smaller — that is, the one that differs from the proposed sine by the fewest units. For at the top of the table you will find the degrees, and at the left, opposite the sine taken, the minutes of the arc that corresponds to the proposed sine. Thus, suppose the known sine is 7510767. I find the sine 7510722, the next smaller, which differs from the known sine by fewer units than does the next larger sine, 7512642. To this next-smaller sine there correspond, at the top of the table, 48° , and at the left, 41'. I therefore say that the arc $48^{\circ} 41'$ belongs to the proposed sine; for the units by which the proposed sine differs from the sine of that arc do not introduce a notable error.

[Margin: How a more precise arc, less than a quadrant, is derived from a given sine by the proportional part.]

If, however, you want a more precise arc, the proportional part must be investigated by this method. Take the difference between the next-smaller and the next-larger sine; likewise the difference between the proposed sine and the one found in the table from which it differs least; and reason thus. If the difference between the two sines found in the table gives 60 seconds — to be added to the arc of the next-smaller sine, or subtracted from the arc of the next-larger sine (according as the difference was taken between the proposed sine and the next-smaller or the next-larger sine), so as to obtain the arc of the next-larger or next-smaller sine — how many seconds does the difference between the proposed sine and the next-smaller or next-larger sine demand, to be added to the arc of the next-smaller sine or subtracted from the arc of the next-larger sine, so as to obtain the arc of the proposed sine? For this second [second-term], added

to the arc of the next-smaller sine or subtracted from the arc of the next-larger sine, will give the arc of the proposed sine.

Thus in the given example, say: the difference 1920 between the sine 7510722 [the next-smaller occurrence is printed 7510772; recte 7510722, consistent with the difference 1920], the next smaller, and the sine 7512642, the next larger, gives 60 seconds to be added to the arc $48^{\circ} 41'$ (which corresponds to the next-smaller sine, since the proposed sine differs less from the next-smaller than from the next-larger sine), so as to obtain the arc $48^{\circ} 41' 60''$, that is $48^{\circ} 42'$, corresponding to the next-larger sine. How many seconds, then, does the difference 45 between the proposed sine and the next-smaller sine demand, to be added to that same arc of the next-smaller sine, so as to make the arc of the given sine? You will find 1 second and a little more must be added, giving the arc $48^{\circ} 41' 1''$ and a little more — so that to the proposed sine 7510767 there corresponds the arc $48^{\circ} 41' 1''$ and a little more.

Again, let the sine 455630 be given, which I do not find as an entry in the table. I therefore take the next larger, 456536 (for the proposed sine differs less from this than from the next smaller, 453630), to which there corresponds the arc $2^{\circ} 37'$. But if I want a more precise arc, I inquire the proportional part in this way. The difference 2906 between the sine 456536, the next larger, and the sine 453630, the next smaller, gives 60 seconds, to be subtracted from the arc $2^{\circ} 37'$ (which corresponds to the next-larger sine) so that the remaining arc is $2^{\circ} 36'$, corresponding to the next-smaller sine. How many seconds, then, does the difference 906 between the proposed sine and the next-larger sine demand, to be subtracted from that same arc of the next-larger sine so as to make the arc of the given sine? I find nearly 19 seconds, which taken from the arc $2^{\circ} 37'$ leave the arc $2^{\circ} 36' 41''$, belonging to the given sine 455630.

But since the same right sine corresponds to two arcs that together make up a semicircle, as we said above, if the arc found from the right sine by the stated method is subtracted from a semicircle — that is, from 180° — the remainder will be the other arc, greater than a quadrant, which also belongs to the said sine. Thus, if the arc $48^{\circ} 41' 1''$ found above is taken from 180° , there remains the arc $131^{\circ} 18' 59''$, belonging to the same right sine 7510767. The operation in triangles — both rectilinear and spherical — will neatly show whether the arc corresponding to the proposed sine should be taken greater than a quadrant or smaller, as will appear in its proper places.

[Margin: How an arc less than a quadrant is derived from the sine of the complement.]

But if the known sine is the sine of the complement of the sought arc, the degrees must be taken in the lower part of the table, and the minutes at the right. In this way the sought arc is obtained. Or else the arc corresponding to the given sine, treated as a right sine, must be found, and this subtracted from a quadrant so that the sought arc remains. Thus, if 7510767 is the known sine of the complement of some arc, I find the sine 7510722, the next smaller, since here it differs from the known sine by fewer units than does the sine 7512642, the next [larger]...

larger in the table of sines. To this next-smaller sine there correspond, at the very foot of the table, 41° , and at the right, 19'. The arc $41^\circ 19'$ is therefore the one sought; for its complement is the arc $48^\circ 41'$, to which the given sine belongs. The same arc $41^\circ 19'$ will also be obtained if the arc $48^\circ 41'$ — corresponding to the given sine at the top of the table and at the left — is subtracted from a quadrant.

[Margin: How a more precise arc, less than a quadrant, is found from the sine of the complement.]

But if you subtract the proportional part found above, namely 1", from the arc $41^\circ 19'$ so found (because we assigned to the given sine 7510767 an arc larger than is proper), you obtain the more precise arc $41^\circ 18' 59''$. This will also be found if you subtract from a quadrant the arc $48^\circ 41' 1''$ — the proportional part being included — that was found above.

Again, let 455630 be given as the sine of the complement of some arc, which I do not find as an entry in the table. I therefore take the next larger, 456536 (since it differs less from this than from the next smaller, 453630), to which in the lower part of the table there corresponds the sought arc $87^\circ 23'$; for its complement is the arc $2^\circ 37'$, belonging to the given sine treated as a right sine. But if you add the proportional part found above, namely 19", to the arc $87^\circ 23'$ so found (because we assigned to the given sine 455630 an arc smaller than is proper), you obtain the more precise arc $87^\circ 23' 19''$. You will also find it if you subtract from a quadrant the arc $2^\circ 36' 41''$ — belonging to the same sine treated as a right sine, and found by the proportional part.

[Margin: How an arc greater than a quadrant is investigated from the sine of the complement.]

Now if the proposed sine is the sine of the complement of an arc greater than a quadrant (when this occurs the operation in triangles, whether rectilinear or spherical, will neatly show), the arc corresponding to it at the top of the table, as though to a right sine, must be taken and added to a quadrant, so that the sought

arc is made up. Thus, if 7510767 is known to be the sine of the complement of some arc greater than a quadrant, the arc corresponding to it at the top of the table, together with the proportional part — namely $48^{\circ} 41' 1''$ — must be taken and added to a quadrant. There will then be composed the arc $138^{\circ} 41' 1''$, which is sought, and to whose complement the given sine belongs.

[Margin: How an arc is derived from the versed sine.]

Finally, from a known versed sine you will inquire the arc thus. If the given versed sine is less than the whole sine, subtract it from the whole sine; the remainder will be the sine of the complement of the sought arc, from which, as we just taught, you will find the sought arc. But if the given versed sine exceeds the whole sine, subtract the whole sine from it; there will remain the right sine of an arc which, added to a quadrant, makes up the sought arc.

Example. Let the versed sine 9544370 be given. I subtract this from the whole sine 10000000, and there remains 455630, the sine of the complement of the sought arc, from which the arc $87^{\circ} 23'$ is found — or, more precisely by the proportional part, $87^{\circ} 23' 19''$. Likewise, let the versed sine 10455630 be given. From this I subtract the whole sine 10000000, and there remains 455630, a right sine, whose arc is $2^{\circ} 37'$ — or, more precisely by the proportional part, $2^{\circ} 36' 41''$ — which added to a quadrant yields the sought arc $92^{\circ} 37'$, or more precisely $92^{\circ} 36' 41''$.

The reasoning of this operation is evident from the first figure set out in the exposition of the definitions. For in it the versed sine AH, taken from the whole sine AE, [leaves] the sine of the complement of the arc AF, which belongs to the said versed sine AH. Likewise, from the versed sine HC the whole sine EC is subtracted, and this leaves EH, or KF, the right sine of the arc FB, which added to the quadrant BC composes the arc FC corresponding to the said versed sine HC.

[Margin: By what method the chord of any arc, and conversely the arc of any chord, is obtained from the table of sines.]

From the same table of right sines we shall also track down the chord of any arc, and conversely we shall find the arc of any given chord. For if we take the right sine of half the proposed arc and double it, we shall form the chord of the said arc. Likewise, if we take half the given chord as a right sine and derive its arc, this doubled arc will give the arc corresponding to the given chord. This is clear from the same first figure that we drew in the explanation of the definitions. For in it FH, the right sine of the arc AF or FC, is half the chord FG of the arc FAG or FCG, and so on.

But since to derive the proportional part in the way we have described is exceedingly tedious, we wished to relieve students of this labor. We have therefore ourselves computed the proportional parts that answer to the individual seconds, and have arranged them in the columns of this table; and we shall briefly explain their use.

On Finding the Proportional Part of Sines and Arcs by an Easier Method

[De parte proportionali sinuum, et arcuum faciliore modo inquirenda.]

[Margin: An explanation of the numbers for deriving the proportional part of the sines.]

Before we teach by what method the proportional part is more easily derived from the preceding table of sines, we must first explain what the two numbers interposed among the columns of sines signify, and by what device they were produced. The former contains the parts of the difference between the two sines between which it is written, answering to one second of the arc that the degrees at the top of the table and the minutes at the side of the same table express; the latter number embraces the tenth-parts of one part of the aforesaid difference. Thus, since between the two sines of $16^{\circ} 12'$ and $16^{\circ} 13'$ these two numbers, 46 and 5, are placed, we shall gather that to one second, between $12'$ and $13'$ of the 16th degree, there answer $46 \frac{5}{10}$ parts — from the difference 2793 between the two sines 2789911 and 2792704 of the aforesaid arcs $16^{\circ} 12'$ and $16^{\circ} 13'$, which whole difference belongs to 60 seconds, that is, to one minute. The same is to be understood of the sines of the following arcs, as far as the arcs $16^{\circ} 37'$ and $16^{\circ} 38'$, between whose sines these other numbers, 46 and 4, are placed, so that now to one second there answer $46 \frac{4}{10}$ parts from the difference of the two nearest sines. And so of the rest.

[Margin: The production of the numbers for deriving the proportional part of the sines.]

These numbers placed among the sines were produced in the following way. Having found the differences of all the sines, we divided each by 60 seconds, in order to produce the parts belonging to one second; the remaining fraction we reduced to tenths, multiplying it by 10, as we taught in problem 14 of chapter 16 of our *Arithmetic* [Clavius, *Epitome Arithmeticae Practicae*]. For in this way the proportional part is derived with less labor, as will soon be plain. For example: the aforesaid difference 2793, if divided by 60, gives a quotient of 46, and there

remain $33/60$, which make 5 tenths and a half. Setting aside the half — for when the fraction of one tenth exceeds $1/2$ we added one tenth in the table, but when it does not exceed $1/2$, but is either equal or smaller, we neglected it — we wrote in the table 46 and 5, standing for $46 \frac{5}{10}$ whole parts of the difference, which make 465 tenths of one part. These are also produced if the whole difference 2793 is multiplied by 10 and the product 27930 is divided by 60. And because in the following differences, right up to the difference of the sines of $16^\circ 37'$ and $16^\circ 38'$ exclusive, this same number 465 is found by this reasoning — that is, the part 46 and 5 tenths — this proportional part will serve us up to $16^\circ 37'$ and $16^\circ 38'$ exclusive, where now a smaller number is found, namely 46 and 4 tenths. Thus, since the difference between the sines 2837364 and 2840153 (of $16^\circ 29'$ and $16^\circ 30'$ [?]) is 2789, if this is multiplied by 10 and the product 27890 is divided by 60, the quotient will be 464, and there will remain $50/60$, which exceed $1/2$. We shall therefore again have the parts 46 and 5 tenths. And so of the rest.

By the benefit of these numbers the proportional part will be found very quickly, namely by a single multiplication or division. For if the right sine of some arc is to be sought, which besides the minutes comprises also seconds, one must take from the table the sine answering to the degrees and minutes of the proposed arc set at the top of the table, and add to it the number produced by multiplying the interposed number immediately preceding into the number of seconds. Thus, if the right sine of $19^\circ 36' 40''$ is sought: since this arc is immediately preceded in the table by the numbers 45 and 7 — that is, 457 tenths — which multiplied into 40 seconds produce 18280 tenths, that is, 1828 whole parts, we shall add 1828 to 3354516, the sine of $19^\circ 36'$, so as to make up 3356344, the sine of the proposed arc $19^\circ 36' 40''$.

[Margin: Finding the right sine together with the proportional part.]

Conversely, if the arc is to be inquired from the right sine, one must take the arc answering to the next-smaller sine, and append to it as many seconds as there are units contained in the quotient, when the difference between the proposed sine and the next-smaller sine (a zero [ziphra] having first been appended, so that it may be reduced to tenth-parts) is divided by the number of tenths found in the table. Thus, if the sine 3356344 is given, we shall take the arc $19^\circ 36'$ corresponding to the next-smaller sine 3354516, and shall adjoin to it 40 seconds; this number is generated by dividing 1828, the difference between the proposed sine and the next-smaller sine — a zero having first been appended, so that we divide 18280 by 457, the tenths found in the table. For thus the sought arc will be $19^\circ 36' 40''$. A zero is appended to the difference found, 1828, because, since it

must be divided by $45 \frac{6}{10}$, it must be multiplied by 10 and the product divided by 457, as is clearly established from our *Arithmetic*.

[Margin: Finding the arc together with the proportional part from a given right sine.]

But if the sine of the complement of some arc less than a quadrant is to be investigated, which besides minutes also has seconds, one must take from the table the sine answering to the degrees and minutes of the proposed arc set in the lower part of the table, and subtract from it the number produced by multiplying the upper interposed number into the number of seconds. Thus, if the sine of the complement of $70^\circ 23' 20''$ is sought: since these interposed numbers 45 and 7 — that is, 457 tenths — serve this arc, we shall multiply 457 into 20 seconds, and the resulting number, which is 9140 tenths, that is, 914 whole parts, we shall subtract from 3357256, the sine of the complement of the arc $70^\circ 23'$, so that there remains the sine 3356342 of the complement of the arc $70^\circ 23' 20''$.

[Margin: Finding the sine of the complement together with the proportional part.]

Otherwise, and perhaps more conveniently, so that the rules are not multiplied: take the complement of the given arc, and investigate its right sine, as we have already taught. Thus in the same example, the complement of the arc $70^\circ 23' 20''$ is the arc $19^\circ 36' 40''$, whose right sine will be found to be 3356344 — greater by two units than the one found by the other method just above. This happens because the proposed arc lies but little short of the following, smaller interposed number.

[Margin: A more convenient way of finding the sine of the complement of an arc less than a quadrant, together with the proportional part.]

When the arc whose complement's sine is sought is greater than a quadrant but less than a semicircle, we shall subtract a quadrant from the given arc and inquire the right sine of the remaining arc. Thus, if the sine of the complement of the arc $109^\circ 36' 40''$ is sought, then, a quadrant being taken away, there remains the arc $19^\circ 36' 40''$, to which the sine 3356344 belongs.

[Margin: Finding the sine of the complement of an arc greater than a quadrant, together with the proportional part.]

Conversely, if the arc is to be elicited from the sine of the complement, one must take the arc, together with the proportional part, answering to the given sine as though to a right sine; and this must be subtracted from a quadrant, if the given sine is the sine of the complement of an arc less than a quadrant, or added to a

quadrant when the given sine answers to the complement of an arc greater than a quadrant. But the operation itself, in triangles whether spherical or rectilinear, will neatly show whether the proposed sine agrees with the complement of an arc less than a quadrant or greater. Thus, if the proposed sine is 3356342, of the complement of an arc less than a quadrant, it will be found — the arc $19^{\circ} 39' 40''$ [?; recte $19^{\circ} 36' 40''$] being taken — which subtracted from a quadrant leaves the sought arc $70^{\circ} 32' 20''$ [?; recte $70^{\circ} 23' 20''$]. But if the same sine belongs to the complement of an arc greater than a quadrant, we shall add the arc found for it to a quadrant, and make up the arc $109^{\circ} 36' 40''$. For to its complement, namely the arc $19^{\circ} 36' 40''$, the sine 3356342 corresponds.

[Margin: Finding the arc, together with the proportional part, from a given sine of the complement.]

Finally, the versed sine of an arc which, besides degrees and minutes, has seconds annexed as well, will be found if the sine of its complement — found together with the proportional part — is either taken from the whole sine or added to the whole sine, according as the arc is less or greater than a quadrant. Thus, if the versed sine of the arc $70^{\circ} 23' 20''$ is sought, we shall find the sine of its complement, namely of $19^{\circ} 36' 40''$, to be 3356342, which subtracted from the whole sine 10000000 makes the remainder — the sought versed sine — 6643658. But if the versed sine of the arc $109^{\circ} 36' 40''$ is desired, we shall find the sine of its complement, namely of $19^{\circ} 36' 40''$, to be 3356342, which added to the whole sine 10000000 makes up the sought versed sine 13356342.

[Margin: Finding the versed sine together with the proportional part.]

By the same reasoning, if the arc is to be found from the versed sine, we shall subtract it from the whole sine, or the whole sine from it — the smaller, that is, from the larger. For thus the remainder becomes the sine of the complement of the sought arc, from which the sought arc will be elicited. Thus, if the given versed sine is 6643658, we shall subtract it from the whole sine 10000000, and with the remainder 3356342, as though with a right sine, we shall fish out the arc $19^{\circ} 36' 40''$, which taken from a quadrant leaves the sought arc $70^{\circ} 23' 20''$. But if the given versed sine is 13356342, we shall subtract the whole sine from it, and with the remainder 3356342 we shall track down the arc $19^{\circ} 36' 40''$, which added to a quadrant makes up the sought arc $109^{\circ} 36' 40''$.

[Margin: Finding the arc, together with the proportional part, from a given versed sine.]

But since we do not always have the table of sines at hand, I judged it would not be unwelcome to students if I briefly taught here, before proceeding to other matters, by what method we may use sines geometrically — without the aid of numbers — in setting out the theorems and problems of astronomers and geometers: so that by the help of the compass alone we may attain all those things that are usually inquired by long multiplications and divisions of the numbers contained in the table of sines. For by this means those especially will be well served who either feel great trouble in the reckoning of numbers, or have not much practiced themselves in it. To carry this out the more conveniently, we shall set out the whole matter with one or two examples.

[Margin: In what way sines are to be used geometrically, without the table of sines.]

Let it be proposed, then, for example's sake, to investigate the declination of any point of the ecliptic, say the 20th degree of Taurus. Let there be described a circle ABCD, together with two diameters AC and BD cutting one another at right angles at the center E. And since, as we showed in the corollary to proposition 1 of book 1 of our *Gnomonics* [Clavius, *Gnomonice* I, coroll. prop. 1], the ratio of the whole sine to the sine of the greatest declination is as the sine of that arc by which the given point is distant from the nearer equinoctial point to the sine of the declination of that same point — let the arc of the greatest declination DF be taken (which indeed will easily be done if there is at hand a bronze or wooden quadrant accurately divided into 90 degrees, of which we wrote at the beginning of our *Gnomonics*; for without such a quadrant it would not be worth the trouble to wish to use sines without numbers), and the arc DG of 50° , by which the given 20th degree of Taurus is distant from the beginning of Aries. And from F and G let the perpendiculars FI, GH be dropped to DE — which will easily be done if on the arcs DF, DG there are taken...

Diagram. A composite geometric construction printed at the foot of the page, illustrating the compass-only method for finding the declination of a point of the ecliptic. At the left is a circle lettered ABCD with two perpendicular diameters AC (vertical, A at top, C at bottom) and BD (horizontal, B at left) crossing at the center E; the interior is filled with a construction of chords and dropped perpendiculars (small right-angle marks are visible). To the right of the circle is an unfolded arrangement of straight-line (rectilinear) triangles carrying further letters — the portion of the construction whose explanatory text (the perpendiculars FI and GH to DE, and what follows) runs on beyond this page. This figure: many small

peripheral labels could not be assigned roles with confidence, and the construction is completed in the following pages.

Labels read on the leaf (roles per this page's text where stated; positions approximate):

- A (top of circle): endpoint of the vertical diameter AC.
- C (bottom of circle): opposite endpoint of the vertical diameter AC.
- B (left of circle): endpoint of the horizontal diameter BD.
- D: endpoint of the horizontal diameter BD (right side / carried into the right-hand figure).
- E (center): intersection of diameters AC and BD.
- F, G: points on the arc from D (the text takes arc DF = greatest declination, arc DG = 50°).
- H, I: feet of the perpendiculars GH and FI dropped to DE.
- K, L (right-hand figure): points of the auxiliary rectilinear triangles [role given on the following pages].
- Q, R, S (upper part of circle) [?]: interior/perimeter construction points, roles not stated on this page.
- P, N (left of circle) [?]: interior/perimeter construction points.
- M (interior, right of E) [?]: construction point.
- X, O (lower-left interior) [?]: construction points (near a small square).
- T (lower-left of circle) [?], V (lower-left of circle) [?]: perimeter points.

the arcs DK and DL are equal. For the straight lines that join the points G, L and F, K will be perpendicular to DE — since, by the scholium set down among the definitions, they are bisected at H and I,^a [Margin (a): *Elements* III.3] and therefore meet it at right angles. And FI, GH will be the right sines of the arcs DF, DG. Therefore, if from three given straight lines — ED (the whole sine), FI (the sine of the greatest declination), and GH (the sine of the arc by which the given point is distant from the equinox) — a fourth proportional is found,^b [Margin (b): *Elements* VI.12] the fourth proportional found will be the right sine of the declination sought.

We shall find this fourth proportional without much labour by Euclid's method. Draw two straight lines AB, AC making any angle at A. On one of them take AD equal to the first line, that is, to the whole sine ED; and DB equal to the second line, namely to FI, the sine of the greatest declination. On the other take AE equal to the third line, namely to GH. Then, having drawn the straight line DE, draw BC parallel to it through B. EC will be the fourth proportional — that is, the right sine

of the declination of the 20th degree of Taurus. We shall then find its arc as follows.

Having found the straight line EC, cut off from the semidiameter EA a part EM equal to it, and through M draw MN parallel to EB. The arc BN will be the arc of the declination sought, since it corresponds to the right sine EM (that is, EC): for, when the right sine NO has been drawn, the arc NB and the straight lines EM, ON are equal to one another because of the parallelogram MO. We shall obtain the same arc in yet another way. Having found the straight line EC, cut off CF equal to it, so that EF is double EC — that is, the chord of the arc that is double the arc whose right sine is EC.^c [Margin (c): *Elements* I.34] For if we fit into the circle a chord PQ equal to the straight line EF, and bisect its arc PQ at R, then QR (or PR) will likewise be the arc of the declination sought, corresponding to the sine EC — that is, to the half of the chord PQ — as is clear from the definition of the right sine. Moreover, the quadrant divided into 90 degrees will show (if one also wishes to know this) how many degrees and minutes are contained in BN, or in PR, the arc of declination — though the minutes must be taken by estimation, because the degrees of the quadrant, unless it were very large, cannot be divided into minutes.

Again, let the right ascension of the 20th degree of Taurus be sought. Now, as we demonstrated in the scholium to Proposition 9 of Book 2 of the *Gnomonice*, the sine of the complement of the declination of the proposed point is to the sine of the complement of the arc by which the given point is distant from the nearer equinoctial point, as the whole sine is to the sine of the complement of the right ascension. So, in the same figure, take the arc BN of the declination of the 20th degree of Taurus, which in the table of declination amounts to 17 degrees 47 minutes, and draw NM perpendicular to EA — this will be the sine of the complement of the said declination. Take also the arc DG of 50 degrees, by which the given point is distant from the vernal equinox, and to EA draw the perpendicular GS, namely the sine of the complement of the said arc DG. After this, from three straight lines — NM (the sine of the complement of the declination of the given point), GS (the sine of the complement of the arc DG, by which the given point is distant from the equinoctial point), and ED (the whole sine) — let a fourth proportional LI be found, as was done in the lines GH, GI cutting one another at G: for there GK was taken equal to NM, and KH equal to GS, and GI equal to the whole sine ED, and so on.^d [Margin (d): *Elements* I.34] For LI, once found, will be the sine of the complement of the right ascension of the given 20th degree of Taurus. Therefore, if from the semidiameter EC a straight line ET equal to LI is cut off, and TV is drawn parallel to EB, and VX parallel to EC,

the straight lines ET, VX will be equal. Since, then, the arc BV corresponds to the sine VX, its complement VC will be the right ascension of the 20th degree of Taurus. And the quadrant divided into 90 degrees will indicate how many degrees the arc VC comprises.

In the same way we shall carry out geometrically, by means of sines, all the other problems — even if it is sometimes necessary to use versed sines, which are found from given arcs with the same ease, and from which we recover the arcs whose right sines and sines of the complements we already have. For if the given arc is less than a quadrant, as AG, then, when GS is drawn perpendicular to AE, AS will be the versed sine of the arc AG. But if the given arc is greater than a quadrant, as AV, then, when VT is drawn perpendicular to EC, AT will be the versed sine of the arc AV, as is evident from the definition.

But let us now proceed to the geometric investigation of chords, from which we shall in turn compose the table of sines with little trouble.

Diagram. The declination construction begun in the preceding pages (circle *ABCD* with centre *E*, the greatest-declination arcs *DF*, *DG* and their right sines *FI*, *GH*), here reprinted in its fuller form with the whole apparatus of sines, versed sines and the auxiliary fourth-proportional triangle. The description continues that of the prior construction; see it there. This is a densely lettered figure and several peripheral labels are hard to resolve even at high magnification.

- Circle centred at *E*, with the vertical diameter through *A* (top) and *C* (bottom).
- *A* (top of circle): endpoint of the diameter / vertex of the external triangle.
- *E* (centre): centre of the circle.
- *D* (right, on circle): endpoint from which the declination arcs are measured.
- *F*, *G* (near right of centre): endpoints of the declination arcs *DF*, *DG*.
- *H*, *I* (right of centre): feet of the perpendiculars / sine points (*FI*, *GH*).
- *M* (centre-right, interior): *EM* cut equal to *EC*.
- *N*, *O* (left interior): *MN* parallel to *EB*; *NO* the right sine.
- *S* (upper interior): perpendicular foot (*GS* / *NM* complement-sine construction).
- *B*, *O* (left on circle): *B* the arc endpoint.
- *P*, *R* (upper left, on circle): chord *PQ* bisected at *R*.
- *V*, *T*, *L*, *K* (lower and right interior): points of the right-ascension construction (*ET*, *TV*, *VX*).

- X (left interior): [?]
- To the right, external to the circle: the fourth-proportional triangle with vertex at A, sides AB and AC, on which AD (= whole sine ED), DB (= FI, sine of greatest declination), AE (= GH) are laid off, and BC drawn parallel to DE so that EC is the fourth proportional; the labelled points read D, B (top), G, E, C, F, K, H, L, I descending along the two rays.

THEOR. 7. PROPOS. 10.

If two unequal arcs are taken in a circle, the chord of the greater being greater than the chord of the lesser, then the ratio of the greater arc to the lesser is greater than the ratio of the chord of the greater arc to the chord of the lesser arc.

[Margin: *The ratio of the greater arc in a circle to the lesser arc is greater than the ratio of the chord of the greater arc to the chord of the lesser.*]

In the circle ABCD let there be unequal arcs AB, BC — the former greater, the latter lesser. I say that the ratio of the arc AB to the arc AC is greater than the ratio of the chord AB to the chord BC. For let the chords AB, BC contain the angle ABC, so that the arcs are continuous and together less than the whole circumference. For if they were equal to the whole circumference, the chord of each arc would be the same; and if they exceeded the whole circumference, the chord of the lesser arc would be greater than that of the greater, as is clear in the second figure, if the lesser arc were BAI. Now let the angle ABC be bisected by the straight line BD, and let the straight lines AC, AD, CD be joined, of which AC cuts the straight line BD at E.^a [Margin (a): *Elements* I.9] The straight lines AD, CD will be equal,^b [Margin (b): *Elements* III.29] because the arcs AD, CD, which are subtended under the angles ABD, CBD — equal by construction — are equal to one another.^c [Margin (c): *Elements* III.26] And since in the triangle ABC the straight line BE bisects the angle ABC, it will follow that as AB is to BC, so is AE to EC.^d [Margin (d): *Elements* VI.3] But the straight line AB is greater than the straight line BC by hypothesis. Therefore AE too will be greater than EC. Hence, when AC is bisected at F, the point F will lie in the greater segment AE. And when the straight line DF has been drawn: since the sides AF, FD of the triangle AFD are [equal to] the sides CF, FD of the triangle CFD, and the base AD has been shown equal to the base CD, [the angle AFD is equal to the angle CFD...]

Diagram. Two circles for Theorem 7 (the second figure recurs at the top of the following page and is described here only). *First figure:* circle with A (left), B (upper right), C (right), D (bottom); the chords AB, BC are drawn, with the bisector

BD, and AC meeting BD at E; further lines AD, CD, DF, with interior points H, E, F, G (F the centre). *Second figure*: a circle with I (left), A, B (upper right), C (right), D (bottom) and interior points H, E, F, G — illustrating the case in which the lesser arc is BAI (arcs together exceeding the circumference).

- A: left vertex / arc endpoint.
- B: upper arc endpoint (greater-arc side).
- C: right arc endpoint.
- D: foot of the bisector on the circle.
- E: intersection of AC with BD.
- F: centre / midpoint of AC.
- G, H: auxiliary points of the sector/triangle comparison.
- I (second figure): endpoint of the arc BAI.

SINVS

equal. The angle AFD will be equal to the angle CFD;^e [Margin (e): *Elements* I.8] and since they are equal, each of them will therefore be a right angle.^f [Margin (f): *Elements* I.17] Since, then, in the triangle DEF the two angles E, F are less than two right angles, the angle E will be acute, and consequently the remaining angle CED obtuse.^g [Margin (g): *Elements* I.16] Hence in the triangle CDE the two angles C, E are less than two right angles, so the angle C is acute. Therefore in the triangle DEF the side DE is greater than the side DF, and in the triangle CDE it is less than the side CD. Consequently, an arc of a circle described from D as centre through E will cut the straight line DF, produced, at H, and the straight line CD, below the point C, at G. Now the sector DHE has a greater ratio to the triangle DEC than the triangle DFE has to the same triangle DEC;^h [Margin (h): *Elements* V.8] likewise the same sector DHE has a greater ratio to the sector DEG than it has to the triangle DEC;ⁱ [Margin (i): *Elements* VI.33, corollary 1] and so the sector DHE will have a much greater ratio to the sector DEG than the triangle DFE has to the triangle DEC. But as the sector DHE is to the sector DEH, so is the angle GDE to the angle EDG. Therefore the ratio of the angle HDE to the angle EDG will also be greater than that of the triangle DFE to the triangle DEC.^k [Margin (k): *Elements* VI.1] But as the triangle DFE is to the triangle DEC, so is the straight line FE to the straight line EC. Therefore the ratio of the angle HDE to the angle EDG is also greater than that of the straight line FE to the straight line EC.

And by composition the ratio of the angle HDG to the angle EDG will also be greater than that of the straight line FC to the straight line EC.^l [Margin (l): *Elements* V.28] Now since it holds that as the angle ADC is to the angle HDG, so is

the straight line AC to the straight line FC (for in both the ratio is double), while the angle HDG has to the angle EDG a greater ratio than the straight line FC to the straight line EC, as we have shown,^m [Margin (m): *Elements* V.31] it follows *ex aequo* that the ratio of the angle ADC to the angle EDG will also be greater than that of the straight line AC to the straight line EC, as appears in this scheme.ⁿ [Margin (n): *Elements* V.29] Therefore *by division* the ratio of the angle ADE to the angle EDG will also be greater than that of the straight line AE to the straight line EC.^o [Margin (o): *Elements* VI.33] But as the angle ADE is to the angle EDG, so is the arc AB to the arc BC;^p [Margin (p): *Elements* VI.3] and as the straight line AE is to the straight line EC, so is the chord AB to the chord BC. Therefore the ratio of the arc AB to the arc BC will also be greater than that of the chord AB to the chord BC. Therefore, if two unequal arcs are taken in a circle, and so on. Which was to be demonstrated.

Anguli [Angles]	Rectæ [Straight lines]
ADC.	AC.
HDG.	FC.
EDG.	EC.

SCHOLIVM

Although this theorem is proposed only for those unequal arcs of which the greater subtends the greater chord, it nonetheless holds also in those unequal arcs of which the chord of the greater is smaller than the chord of the lesser. For since in that case the greater arc has to the lesser a ratio of greater inequality, while the chord of the greater arc has to the chord of the lesser arc a ratio of lesser inequality, the ratio of the greater arc to the lesser will be greater than that of the chord of the greater arc to the chord of the lesser arc.

COROLLARIVM

It follows from this proposition that the ratio of the lesser arc to the greater is smaller than that of the chord of the lesser arc to the chord of the greater. For since the greater arc has to the lesser a greater ratio than the chord of the greater arc to the chord of the lesser, as has been demonstrated,^q [Margin (q): *Elements* V.26] then, *by conversion*, the lesser arc will have to the greater a smaller ratio than the chord of the lesser arc to the chord of the greater.

THEOR. 8. PROPOS. 11.

If a quadrilateral together with its diagonals is described in a circle, then the rectangle contained by the diagonals is equal to the two rectangles together that are contained by the opposite sides.

[Margin: *The rectangle contained by the diagonals of a quadrilateral described in a circle is equal to the two rectangles contained by the opposite sides.*]

In the circle ABCD let ABCD be a quadrilateral whose diagonals are AC, BD. I say that the rectangle contained by AC, BD is equal to the two rectangles together contained by AD, BC and by AB, DC. Make the angle BAE equal to the angle DAC; and the straight line AE will fall either upon the straight line AC itself, or between the straight line AC and the point B, or, finally, between the straight line AC and the point D. In the first case the angle BAC will be [equal to] the angle DAE; in the second case the whole angle BAC will equal the whole angle DAE, because the common angle EAC is added; and in the third case the remaining angle BAC will equal the remaining angle DAE, because the common angle EAC is subtracted.^a [Margin (a): *Elements* III.21] And since the angle ACB is also equal to the angle ADB,^b [Margin (b): *Elements* I.32] the remaining angle ABC in the triangle ABC will likewise be equal to the remaining angle AED in the triangle AED. Therefore it will follow that as AC is to CB, so is AD to DE.^c [Margin (c): *Elements* VI.4] Hence the rectangle under AC, DE is equal to the rectangle under CB, AD.^d [Margin (d): *Elements* VI.16] Again, since the angle BAE is equal to the angle DAC by construction, and the angle ABD to the angle ACD,^e [Margin (e): *Elements* III.21] the remaining angle AEB in the triangle AEB will be equal to the remaining angle ADC in the triangle ADC. Therefore it will follow that as AC is to CD, so is AB to BE.^f [Margin (f): *Elements* VI.4] Hence the rectangle under AC, BE is equal to the rectangle under CD, AB.^g [Margin (g): *Elements* VI.16] Now since the rectangle under AC, DE has been shown equal to the rectangle under CB, AD, and the rectangle under AC, BE to the rectangle under CD, AB, and since the rectangles under AC, DE and under AC, BE are together equal to the rectangle under AC, BD,^h [Margin (h): *Elements* II.1] the rectangle under AC, BD will be equal to the rectangles contained under BC, AD and under CD, AB. Therefore, if a quadrilateral is described in a circle, and so on. Which was to be demonstrated.

Diagram. Three circles for Theorem 8, one for each position of the auxiliary line AE. Each shows an inscribed quadrilateral ABCD with the diagonals AC, BD drawn, and the point E where the line making the angle BAE equal to DAC meets AC (or falls within the quadrilateral).

- A, B, C, D: the four vertices of the inscribed quadrilateral (A upper left, B lower left, C lower right, D upper right).
- E (interior): the intersection point produced by making angle BAE = angle DAC — falling on AC in the first figure, between AC and B in the second, and between AC and D in the third.

SINVS

SCHOLIVM

When the figure described in the circle is a square, as in the first figure, the theorem will be demonstrated more easily, in this way. Since the rectangle under AC, BD — that is, the square on AC (for the diagonals in a square are equal)ⁱ [Margin (i): scholium on *Elements* I.34] — is equal to the squares on AD, DC,^k [Margin (k): *Elements* I.47] that is, to the rectangles contained under AD, BC and under AB, DC (because of the equality of the straight lines AD, BC and AB, DC), what is proposed is clearly established.

PROBL. 4. PROP. 12.

From a given circle-diameter of any number of parts, to find, in the same parts, the sides of the equilateral triangle, the square, the hexagon, the pentagon, and the decagon described in the same circle.

[Margin: *In what way, from a given circle-diameter, the sides of the equilateral triangle, square, hexagon, pentagon, and decagon of the same circle are found.*]

Let the diameter be posited as 20000000 parts. Since, then, the side of the hexagon is equal to the semidiameter of the circle,^a [Margin (a): *Elements* IV.15, corollary] it will become known as 10000000 parts.

Again, since the square described on the diameter of any square is double that same square,^b [Margin (b): scholium on *Elements* I.47] and since the diameter of a square inscribed in a circle is the same as the diameter of the circle: if the square on the diameter of the circle is taken, namely 400000000000000, its half, namely 200000000000000, will be the square of the side of the square, whose square root, 14142136, will give the side of the square. This is also found in the following way. Since the square inscribed in a circle is double the square described on the semidiameter, as is clear in the right triangle ADE of the first figure of the preceding proposition,^c [Margin (c): *Elements* I.47] and as has been demonstrated by us in the lemma to Proposition 16 of Book 1 of Theodosius: if the square of the semidiameter, 100000000000000, is doubled, the square inscribed in the circle

will become 20000000000000 parts, whose square root, 14142136, will again give the side of the square.

Furthermore, since the side of the equilateral triangle inscribed in a circle is in square triple the semidiameter of the same circle,^d [Margin (d): *Elements* XIII.12] it comes about that the tripled square of the semidiameter gives the square of the side of the triangle, 30000000000000, whose square root will exhibit that same side as 17320508 parts.

Let there be, in addition, AB, the semidiameter of any circle,^e [Margin (e): *Elements* VI.30] which, divided in extreme and mean ratio at C so that the greater segment is BC, and with AB produced and BD cut off equal to the greater segment BC,^f [Margin (f): *Elements* XIII.5] then AD too will be divided at B in extreme and mean ratio, and the greater segment will be AB;^g [Margin (g): *Elements* IV.15, corollary] which, since it is the side of the hexagon in the circle whose semidiameter is AB, means that BD will be the side of the decagon in the same circle.^h [Margin (h): scholium on *Elements* XIII.9] This is made known in the following way. When AB is bisected at E,ⁱ [Margin (i): *Elements* XIII.3] the square of the straight line DE — composed of the lesser segment DB and half of BE, the greater segment BA — will be five times the square of the straight line BE, which is known, since it is half the semidiameter AB and therefore 5000000 parts. Hence, if the square of the straight line BE is quintupled, the square of the straight line DE becomes 125000000000000, whose square root will give the straight line DE as 11180340 parts. If from this the straight line BE, 5000000 parts, is subtracted, the remainder will be BD, the side of the decagon, 6180340 parts.

Finally, since the side of the pentagon is in square equal to the side of the hexagon and the side of the decagon together,^k [Margin (k): *Elements* XIII.10] if the square of the side of the hexagon, 100000000000000, and the square of the side of the decagon, 38196602515600, are put together, the square of the side of the pentagon becomes 138196602515600, whose square root will give the side of the pentagon as 11755705 parts. And thus the sides of the equilateral triangle, the square, the pentagon, the hexagon, and the decagon have been made known in parts of the circle's diameter, in which they are described. Therefore, from a given circle-diameter of any number of parts we have found the sides of the equilateral triangle, the square, and so on. Which was to be done.

Diagram. A single straight line (the extreme-and-mean-ratio / decagon construction), with the points marked, from left to right, A, C, E, B, D.

- A: left endpoint (one end of the semidiameter AB).

- C: the point of division of AB in extreme and mean ratio.
- E: the midpoint (bisection) of AB.
- B: right end of the semidiameter AB / division point of the whole AD.
- D: right endpoint, with BD cut off equal to the greater segment.

PROBL. 5. PROPOS. 13.

From the given chords of two unequal arcs, to find the chord of the arc by which the greater arc exceeds the lesser.

[Margin: *By what method, from two known chords, the chord of the difference by which the arcs of the given chords differ from one another is found.*]

In the semicircle ABCD let the chords AB, AC, and BC be given, BC being the chord of the arc by which the greater arc AC exceeds the lesser AB; and let it be required to find the chord BC. When the straight lines BD, CD have been drawn: since the chords AB, AC are posited, the chords BD, CD will also be known.^a

[Margin (a): Proposition 3 of this treatise] Therefore the rectangle contained under the given straight lines AB, CD will be known; likewise the rectangle under the given straight lines AC, BD. But the rectangle under the straight lines AC, BD is equal to the two rectangles under AB, CD and under BC, AD.^b [Margin (b): Proposition 11 of this treatise] Therefore, when the known rectangle under AC, CD [i.e. AB, CD] is subtracted, the remaining rectangle under BC, AD becomes known. And this, divided by the known diameter AD, will make the chord BC known. Therefore, from the given chords of two unequal arcs we have found the chord of the arc by which the greater arc exceeds the lesser. Which was to be done.

Diagram. The semicircle for Problem 5: diameter AD (A at lower left, D at lower right) with B and C on the arc; the chords AB, AC, BC and BD, CD are drawn.

- A: left endpoint of the diameter.
- B: point on the arc (endpoint of the lesser arc AB).
- C: point on the arc (endpoint of the greater arc AC), between B and D.
- D: right endpoint of the diameter.

COROLLARIVM

[Margin: *Praxis.*] And so, given the chords of two unequal arcs, if the chord of the greater is multiplied by the chord of the arc which together with the greater arc makes up the semicircle — which is given by Proposition 3 — and if from the product there is subtracted the number produced from the chord of the lesser arc

multiplied by the chord of the arc which together with the greater arc completes the semicircle — which is given by the same Proposition 3 — and if the remaining number is then divided by the diameter, there will be returned, as known, the chord of the arc by which the greater arc exceeds the lesser: as is clear from the figure and the demonstration of this proposition.

PROBL. 6. PROPOS. 14.

Given the chords of two arcs, to find the chord of the arc that is composed of those two arcs.

[Margin: By what art, from two given chords, the chord of the arc composed of the two arcs of the two given chords may be found.]

In the circle $ABCDE$, whose center is F , let two chords AB and BC be given, and let it be required to find the chord AC of the arc ABC , which is composed of the two arcs AB and BC . Draw the two diameters AD and BE , together with the straight lines BD , CE , and CD . Since the chord AB is given, the chord BD — that of the arc BCD , the remaining arc in the semicircle ABD — will also be given [Margin: a — Prop. 3 of this treatise]. By the same reasoning, since the chord BC is given, the chord CE — that of the arc CDE , the remaining arc in the semicircle BCE — will likewise be given. And since the angles AEB and DFE are equal [Margin: b — Elements I.15], and the sides FA , FB are equal to the sides FD , FE , the bases AB and DE will also be equal [Margin: c — Elements I.4]; and therefore, since AB is given, DE too will be given. Now, since the rectangle contained by the given lines BD , CE is equal to the rectangles contained by the lines BC , DE together with that contained by the diameter BE and the line CD [Margin: d — Prop. 11 of this treatise]: if the rectangle under BC , DE — which is given — be subtracted from the given rectangle under BD , CE , the remaining rectangle under BE , CD is left known; and when this is divided by the known diameter BE , the chord CD becomes known. Consequently the chord AC also, of the remaining arc ABC in the semicircle ACD , will be known [Margin: e — Prop. 3 of this treatise].

Diagram. A circle with center F and five points on its circumference, joined by chords and two diameters (the figure for Proposition 14).

- A (circumference, left): endpoint of diameter AD ; vertex of the composite arc ABC .
- B (circumference, upper left): junction of the two given chords AB , BC ; endpoint of diameter BE .
- C (circumference, top): junction of the two given chords AB , BC .

- D (circumference, right): endpoint of diameter AD; opposite B.
- E (circumference, bottom): endpoint of diameter BE.
- F (center): center of the circle.

Alternatively. Since the chord AB is given, BD too will be given [Margin: f — Prop. 3 of this treatise] — the chord of the remaining arc BCD in the semicircle ABD. But BC is given as well. Therefore, since the chords BD and BC are given, the chord CD of the arc CD — by which the greater arc BD exceeds the smaller arc BC — will also be given [Margin: g — Prop. 13 of this treatise]; and hence again the chord AC of the remaining arc ABC in the semicircle ACD will be given [Margin: h — Prop. 3 of this treatise]. Therefore, given the chords of two arcs, we have found the chord of the arc composed of those two arcs. Which was to be done.

COROLLARIVM.

Therefore, given the chords of two arcs: if the chords of the arcs that, together with those arcs, complete their semicircles (which are found by Prop. 3) are multiplied together, and from the product the number produced by multiplying the two given chords by one another is subtracted, and the remaining number is divided by the diameter, there is left a chord from which, if it be investigated by Prop. 3, a chord results; and this chord will be the one subtending the arc composed of the two arcs of the two given chords. This operation is clear from the figure and from the earlier demonstration of this proposition.

The same operation can also be gathered from the later demonstration, as is evident.

PROBL. 7. PROP. 15.

Given the chord of any arc, to find the chord of half that arc.

[Margin: How, from a given chord, the chord of half the arc of the given chord may be found.]

In the circle ABC, whose center is E, let the chord BC and its arc BDC be given, of which let the half be the arc BD, and let its chord BD be the thing to be found. Draw the diameter DG; it will cut BC into two equal parts (by the lemma set down in the definitions) [Margin: a — Elements III.3], and hence at right angles. Now, joining the straight lines BA and BG, the two triangles ABC and EFC will be equiangular, since the angle EFC has been shown to be right [Margin: b — Elements III.31], the angle ABC is likewise right, being in a semicircle, and the angle C is common. Therefore CF is to FE as CB is to BA [Margin: c — Elements

VI.4]; and, alternately, as CF is to CB, so is FE to BA. Since, then, CF is half of CB, as we showed, EF too will be half of AB; and therefore, since AB is given from the given chord BC [Margin: d — Prop. 3 of this treatise], EF will also be given, and when it is subtracted from the semidiameter ED, the remainder FD is known. Now, in the triangle GBD, the angle B is right [Margin: e — Elements III.31], and from it the perpendicular DB is let fall to the base GD [Margin: f — Corollary of Elements VI.8]; the line DB will therefore be the mean proportional between GD and FD, and so the rectangle under GD, FD (both known) is equal to the square on the line DB [Margin: g — Elements VI.17]. The square on DB is therefore known, and consequently its square root will exhibit the line DB as known. We shall also come to know it in this way: since FD has been made known, the squares on the lines FD and FB will be known; and since these are equal to the square on the line BD [Margin: h — Elements I.47], this square too will be known, and its square root will again make the line BD known. Which is what was proposed.

Diagram. A circle with center E, carrying the diameter DG and the chord BC bisected at F, with the auxiliary lines BA, BG drawn (the figure for the first demonstration of Proposition 15).

- A (circumference, left): vertex of triangle ABC.
- B (circumference, upper left): endpoint of the given chord BC and of the half-arc chord BD.
- C (circumference, right): endpoint of the given chord BC.
- D (circumference, top): endpoint of the diameter DG; end of the sought chord BD.
- E (center): center of the circle.
- F (on chord BC, near center): foot where the diameter DG cuts BC at right angles.
- G (circumference, bottom): the other endpoint of the diameter DG, opposite D.

Alternatively. Let there again be, in the semicircle ABC, the given chord BC with its arc BDC, of which let the half be the arc DC, and let its chord DC be the thing to be given. Draw the chord AB, cut off AE equal to it, and join the straight lines BD, DE. Bisect EC also at F, and let fall the perpendicular DF. Since, then, the two sides BA, AD are equal to the two sides EA, AD [Margin: i — Elements III.27], and they contain equal angles (because the arcs BD, DC are equal), the bases BD and DE will be equal [Margin: k — Elements I.24]. But BD is a straight line equal to the straight line DC [Margin: l — Elements III.29]; therefore the line DE too will be equal to DC. Hence, since the two sides EF, FD are equal to the two sides CF, FD,

and the base DE is equal to the base DC, the angles at F will be equal, and therefore right [Margin: m — Elements I.8]. Now, since the chord AB is known from the given chord BC [Margin: n — Prop. 3 of this treatise], AE — equal to AB — will be known; and when this is subtracted from the diameter AC, the remainder EC is known, and hence also its half FC. Now, since CD is the mean proportional between AC and FC [Margin: o — Corollary of Elements VI.8], the rectangle under AC, FC will be equal to the square on the line DC [Margin: p — Elements VI.17]. Since, then, that rectangle is known, because AC and FC are known, the square on DC too will be known; and consequently its square root will make the line DC known. Therefore, given the chord of any arc, we find the chord of half that arc. Which was to be done.

Diagram. A semicircle on the diameter AC, with the points B and D on the arc, and E, F marked on the diameter, carrying the chords AB, BD, DE, DC and the perpendicular DF (the figure for the alternative demonstration of Proposition 15).

- A (left end of diameter): endpoint of the diameter AC.
- B (arc, upper left): endpoint of the given chord BC.
- C (right end of diameter): endpoint of the diameter AC and of the given chord BC.
- D (arc, top): endpoint of the sought chord DC; foot of the perpendicular DF above F.
- E (on diameter): point where AE, cut off equal to AB, ends.
- F (on diameter, between E and C): midpoint of EC, foot of the perpendicular DF.

COROLLARIVM.

Therefore, if by Prop. 3 the chord is found of the arc that, together with the arc of the given chord, will complete the semicircle: then, if half of this chord thus found be subtracted from the semidiameter, and the remaining number be multiplied by the diameter, the square root of this product will give the chord of half the arc whose chord is given. Or, if the square of that remaining number be joined to the square of half the given chord, a number is formed whose square root will exhibit the sought chord as known. This operation is easily gathered from the figure and from the earlier demonstration of this proposition.

[Margin: Practice.]

Likewise, if by Prop. 3 the chord is found of the arc that, together with the arc of the given chord, completes the semicircle, and this chord thus found be subtracted from the diameter, and half of the remaining number be multiplied by the diameter: the square root of this product will give the chord of half that arc, whose chord is given. As is clear from the figure and from the later demonstration of this proposition.

PROBL. 8. PROPOS. 16.

To compute the chords of all the arcs of a semicircle, which successively exceed one another by one minute, in terms of the parts of the diameter, the diameter being distributed into any number of parts whatever.

[Margin: By what method the chords of all arcs may be computed.]

Let us lay it down that the chords of all the arcs are to be computed with respect to a diameter divided into 200000 parts. But to do this more accurately, the diameter must, in the computations, be set at 20000000 parts. For thus it will come about that, by rejecting the first two figures on the right from each of the chords found, there are left chords more exactly refined with respect to a diameter of 200000 parts — just as we taught at the beginning of Prop. 9 on Sines, where we also added how many parts the whole sine ought to be taken to have in the computation, if the whole sine is wanted in a table of more parts. And this must be understood here of the whole diameter as well, by always setting the diameter, in the computation, at twice as many parts as we there assigned to the whole sine.

First, then, there were found in Prop. 12 the chords of the arcs of 36° , 60° , 72° , 90° , and 120° — namely the sides of the decagon, hexagon, pentagon, square, and equilateral triangle — of 6180340, 10000000, 11755705, 14142136, and 17320508 parts, of which the whole diameter is set at 20000000. And from the chords 6180340 and 11755705 of the arcs of 36° and 72° , there will be found the chords of the remaining arcs in the semicircle, such as those of 144° and 108° , of 19021130 and 16180340 parts, as we showed in Prop. 3.

Next, by Prop. 13 and its corollary, there will be found the chords of all the arcs that are the differences of any two arcs whose chords are known. Thus from the chord of the arc of 120° and the chord of the arc of 36° we shall find the chord of the arc of 84° , which is their difference. Likewise from the chord of the arc of 90° and the chord of the arc of 60° we shall come to know the chord of the arc of 30° , by which those two differ from each other. And in the same way we shall investigate the chords of very many arcs.

Again, by what we demonstrated in Prop. 14 and its corollary, we shall find the chord of any arc composed of two arcs whose chords are known. Thus from the chord of the arc of 60° and the chord of the arc of 90° , the chord of the arc of 150° , composed of those two, will be made known. So too, from the chord of the arc of 90° and the chord of the arc of 36° , the chord of the arc of 126° will be recognized. And so on.

Moreover, by the doctrine of Prop. 15 and its corollary, once the chord of any arc is known, we shall also know the chord of the halved arc. Thus from the chord of the arc of 60° we shall produce the chord of the arc of 30° ; from this, the chord of the arc of 15° ; from this, the chord of the arc of $7^\circ 30'$; and from this, the chord of the arc of $3^\circ 45'$. Likewise from the chord of the arc of 72° we shall explore the chord of the arc of 36° ; from this, that of 18° ; from this, that of 9° ; from this, that of $4^\circ 30'$; and from this, that of $2^\circ 15'$. So too, since by Prop. 13 and its corollary the chord of the arc of 12° — by which the two arcs of 36° and 48° differ from each other — is known from their chords, we shall learn from the chord of the arc of 12° the chord of the arc of 6° ; from this, the chord of the arc of 3° ; from this, the chord of the arc of $1^\circ 30'$; and from this, the chord of the arc of $0^\circ 45'$. Then, if by what has been demonstrated we carefully seek out the chords of the remaining arcs from those already found, we shall find the chords of all the arcs that successively exceed one another by $45'$, in such a way that the first arc contains $0^\circ 45'$, the second $1^\circ 30'$, the third $2^\circ 15'$, and the last of all is the whole semicircle of 180° . Indeed, if, as we have just taught, the chord of the arc of $0^\circ 45'$ has been found, we shall find from it, by the doctrine of Prop. 14 and its corollary, the chords of all the arcs successively exceeding one another by $45'$ — provided we first investigate the chord of the arc of $1^\circ 30'$, composed of two arcs of $45'$ and $45'$; then the chord of the arc of $2^\circ 15'$, which is composed of the two arcs of $1^\circ 30'$ and $45'$; and afterward the chord of the arc of 3° , which is composed of the arc of $2^\circ 15'$ and the arc of $45'$; and so on, always adding an arc of $45'$ to the preceding arc.

[Margin: The computation of the chords of the arcs successively exceeding one another by 45 minutes.]

[Margin: The computation of the chord of the arc of 1° .]

Lastly, we shall investigate the chords of the other arcs by this device. Let there be, in the semicircle ABCDE, the chord AB of the arc of $45'$, and AD the chord of the arc of $1^\circ 30'$, while AC is the chord of the arc of 1° , which is proposed to be found. Since, then, the ratio of arc AC to arc AB is greater than that of chord AC to chord AB [Margin: a — Prop. 10 of this treatise] — and arc AC has to arc AB the sesquitertian ratio (4:3) — chord AC will have to chord AB a ratio less than

sesquitertian. Since, then, the chord AB of the arc of $45'$ has been found from the foregoing to be about 130899 parts, the chord AC of the arc of 1° (which, of course, has to chord AB, that is, to 130899, a ratio less than sesquitertian) will be less than 174532 [Margin: b — Elements V.10], since this number has to that one the sesquitertian ratio. Again, since the ratio of arc AD to arc AC is greater than that of chord AD to chord AC [Margin: c — Prop. 10 of this treatise] — and arc AD has to arc AC the sesquialteran ratio (3:2) — chord AD will have to chord AC a ratio less than sesquialteran. Since, then, the chord AD of the arc of $1^\circ 30'$ has been found from the foregoing to be about 261792 parts, the chord AC of the arc of 1° (to which, of course, chord AD, that is, the number 261792, has a ratio less than sesquialteran) will be greater than 174528 [Margin: d — Elements V.10], since the number 261792 has to this number the sesquialteran ratio. It is settled, therefore, that the chord of the arc of 1° lies between these two numbers, 174532 and 174528, since the former is greater and the latter less.

Diagram. A semicircle on the diameter AE, with the points B, C, D marked on the arc toward the left, and the chords AB, AC, AD drawn from A (the figure for the interpolation of the chord of 1°).

- A (left end of diameter): common origin of the chords AB, AC, AD.
- B (arc, lower left): endpoint of chord AB (arc of $45'$).
- C (arc, upper left): endpoint of chord AC (arc of 1° , the chord sought).
- D (arc, top): endpoint of chord AD (arc of $1^\circ 30'$).
- E (right end of diameter): the far endpoint of the diameter AE.

We shall accordingly set it

at 174530, exactly midway between those numbers. For thus it will not perceptibly differ from the true chord of the arc of 1° .

But you must not think that by this same device the chord of any arc of several degrees can be investigated from the two known chords of the two arcs surrounding it. For since in larger arcs the difference between the arcs and the chords is great, it will be hard to judge what number, from among the intermediates between the two found, ought to be established as the chord of the proposed arc. We shall make this clear by the following example. Let the chords of the arcs of $59^\circ 46'$ and $60^\circ 30'$ be known, of 9964712 and 10075480 parts. If, then, someone wished to extract from these the chord of the arc of 60° , he would have to proceed thus. Since the ratio of the arc of $59^\circ 46'$ to the arc of 60° is less than that of chord to chord [Margin: e — Corollary of Prop. 10 of this treatise]: now 9964712, the chord of the arc of $59^\circ 46'$, has to 10003614 1608/1793 [?: small

fraction digits uncertain] the same ratio which the arc of $59^{\circ}46'$ has to the arc of 60° ; the chord of the arc of 60° will therefore be less than 10003614 1608/1793 [?] [Margin: f — Elements V.10], inasmuch as the chord 9964712 has to it a greater ratio than it has to 10003614 1608/1793 [?]. Likewise, since the ratio of the arc of $60^{\circ}30'$ to the arc of 60° is greater than that of chord to chord [Margin: g — Prop. 10 of this treatise]: now 10075480, the chord of the arc of $60^{\circ}30'$, has to 9992211 60/121 [?] the same ratio which the arc of $60^{\circ}30'$ has to the arc of 60° ; the chord of the arc of 60° will therefore be greater than 9992211 60/121 [?] [Margin: h — Elements V.10], inasmuch as the chord 10075480 has to it a ratio less than it has to 9992211 60/121 [?]. The chord of the arc of 60° would therefore have to be established between these two numbers, 10003614 1608/1793 [?] and 9992211 60/121 [?]; and since these differ greatly from each other (for their difference is about 11403), it will be doubtful how great a value should be assumed. This ambiguity has no place in the thorough investigation of the chord of the arc of 1° , since in such small arcs the chords differ little from the arcs.

Now that the chord of the arc of 1° has been found, we shall also find, by Prop. 15 and its corollary, the chord of the arc of $30'$, and from this the chord of the arc of $15'$. But this last we shall also find by Prop. 13 and its corollary, since the arc of $15'$ is the difference between the arc of 1° and the arc of $45'$, whose chords are now known. By the chord of the arc of $15'$, moreover, we shall come to know, by Prop. 14 and its corollary, the chord of the arc of $30'$, which is composed of the arc of $15'$ and the arc of $15'$. Likewise the chord of the arc of $45'$, composed of the arcs of $30'$ and $15'$. Likewise the chord of the arc of 1° , from the arcs of $45'$ and $15'$. And the chord of the arc of $1^{\circ}30'$ — although all these chords have already been made known by another method. Finally, by this route we shall find the chords of all the arcs successively exceeding one another by $15'$, although we could investigate many of them by other methods, as is clear from Props. 13, 14, 15, and their corollaries.

[Margin: e — Corollary of Prop. 10 of this treatise; f — Elements V.10; g — Prop. 10 of this treatise; h — Elements V.10.]

[Margin: The computation of the chords of the arcs extended by 15 minutes.]

Now, if all the arcs successively exceeding one another by $15'$ are set out in order, together with their chords, and to the right of each chord is written the difference by which it differs from the preceding chord, we shall find, by the rule of proportions, the chords of the other intermediate arcs extended by every five minutes; and from these, the chords of all arcs progressing by single minutes — just as we said above concerning the finding of the sines. That this may be

understood more easily, we shall set out this one example. Let the chord of the arc of 20' be sought. Since, then, the difference between 43632, the chord of the arc of 15', and 87264, the chord of the arc of 30', is 43632, say: if the 15' by which the arc of 15' differs from the arc of 30' require the difference 43632 to be added to the chord of the arc of 15' in order that the chord of the arc of 30' may result, how great a difference do the 5' by which the arc of 15' differs from the arc of 20' demand to be added to the same chord of the arc of 15', in order that the chord of the arc of 20' may be composed? For you will find that a difference of 14544 is required, which, added to 43632, the chord of the arc of 15', will constitute 58176, the chord of the arc of 20'. And the same reasoning holds for the rest.

[Margin: The computation of the chords of the arcs extended by single minutes.]

SCHOLIVM.

But Proposition Six will bring us a great shortcut in this matter. For from it we shall produce very many chords out of others already found, by mere addition or subtraction. For if we take the chord of any arc by which the arc of 120° exceeds a smaller arc, once that arc is assumed, we shall compose the chord of the arc that exceeds the arc of 120° by that same assumed arc — because the difference between the chords of these two greater arcs is equal to the chord of that assumed arc, which is posited no greater than 60°, as we there showed. Thus if we add 3472964, the chord of the arc of 20°, to 15320890, the chord of the arc of 100° — which the arc of 120° exceeds by the said arc of 20° — we shall compose 18793854, the chord of the arc of 140°, which exceeds the arc of 120° by that same arc of 20°. So too, if we add 10000000, the chord of the arc of 60°, to the chord 10000000 of the arc of 60° — which the arc of 120° exceeds by that said arc of 60° — we shall produce 20000000, the chord of the arc of 180°, which exceeds the arc of 120° by that same arc of 60°.

[Margin: A wonderful shortcut for finding very many chords.]

Likewise, if we subtract the chord of any arc not greater than 60° from the chord of the arc that exceeds the arc of 120° by that assumed arc, there will be left the chord of the arc that the arc of 120° exceeds by that same assumed arc. Thus if we subtract 3472964, the chord of the arc of 20°, from 18793854, the chord of the arc of 140° — which exceeds the arc of 120° by that assumed arc of 20° — there will remain 15320890, the chord of the arc of 100°, which is exceeded by the arc of 120° by that same arc of 20°.

Again, if from the chord of any arc greater than 120° there be subtracted the chord of the arc that is as much less than 120° as the former is greater, there will

remain the chord of the arc by which either of them differs from the arc of 120° . Thus if from 18793854, the chord of the arc of 140° , we take away 15320890, the chord of the arc of 100° , there will be left 3472964, the chord of the arc of 20° , by which each of them differs from the arc of 120° . All of which is gathered from the said Prop. 6.

It is enough, therefore, to investigate by the rule of proportions the chords of all the arcs from the beginning of the semicircle up to the arc of 60° . For if from these we find the chords of the arcs that, together with them, complete the semicircle, and from these last the former ones already found are subtracted, there will remain the chords of all the arcs between the arc of 60° and the arc of 120° . Likewise, if the chords of all the arcs from the arc of 60° up to the end of the semicircle were known, and the chords of all the arcs less than the arc of 120° were subtracted from the chords of all the arcs greater than 120° , the remainders would be the chords of all the arcs from the beginning of the semicircle up to the arc of 120° , thus found. Finally, if the chords of all the arcs from the beginning of the semicircle up to the arc of 120° were found, and the chords of all the arcs less than 60° were added to the chords of all the arcs greater than 60° , there would be composed the chords of all the arcs greater than 120° .

[Margin: By what method the sines of all arcs may be found from the chords.]

Furthermore, if the chords of all the arcs of the semicircle are reduced into a table, and the chords of all the arcs which successively

if they exceed 2 minutes, let them be bisected; the sines of all the arcs advancing by single minutes will then be found, as is clear from definition 3.

From this it is evident that the moderns did more correctly in reducing the sines to a table than those who [tabulated] the chords. For sines it is enough to extend the quadrant of the circle through the individual minutes; but for chords one must necessarily extend the whole semicircle through the individual minutes, so that a table of chords comes out twice as large as a table of sines. I say nothing of the fact that the use of sines in astronomical and geometrical matters is far more expeditious, briefer, and easier than that of chords — as is plain to those who have at some time trained themselves in this kind of use.

[Margin: Those who construct a table of sines do more correctly than those [who construct one] of chords.]

Now, just as the differences of the sines gradually decrease from the beginning of the quadrant all the way to its end — so that, when several arcs are set down

exceeding one another equally, the sines of the smaller ones have greater differences than the sines of the larger, as we showed in the corollary to Proposition 1 — so too the differences of the chords gradually decrease from the beginning of the semicircle to its end. For when several arcs are set down whose differences are equal, the chords of the smaller ones have greater differences than the chords of the larger. This we shall now demonstrate.

[Margin: The differences of the chords gradually decrease from the beginning of the semicircle to its end, so that the chords of smaller arcs have greater differences than the chord of larger arcs, provided the arcs have equal differences.]

Let there be, in the semicircle ABCDE, the arcs AB, AC, AD, whose differences BC and CD are equal, and let the chords of these same arcs be AB, AC, AD. Let the straight line AF be cut off equal to the chord AB, and the straight line AG equal to the chord AC. I say that FC, the difference between the chords AB and AC, is greater than GD, the difference between the chords AC and AD. For once the straight line AF (equal to the chord AB) has been cut off, and the straight lines BC, CD, CG, CH have been joined: since the sides HA, AC are equal and the angles they contain at A are equal (on account of the equal arcs BC, CD) [b: I.4], the bases BC, CH will be equal. But the straight line BC is equal to the straight line CD, because of the equal arcs BC, CD. Therefore the straight line CH will also be equal to the straight line CD [c: III.29]. Hence the angles CHD, CDH will also be equal; and since they are less than two right angles, each of them will be acute. In the same way each of the angles ACG, AGC will be acute [d: I.5], because the straight lines AC and AG are equal to each other [f: I.5]. Since, then, in the triangle CGH the angles at G and H are acute, the perpendicular CI dropped to DH will fall within the triangle, onto the straight line GH — as we demonstrated in the scholium to Proposition 13 of Book 2 of Euclid. Therefore, since the two angles CHI, CIH of the triangle CHI are opposite equal right angles — or at any rate the side CI is common — the two sides CH, CD will [have their opposite parts] equal [e: I.27]. Since, then, ID is greater than GD, HI too, and a fortiori HG, will be greater than GD [g: I.26]. But HG is equal to FC, because the straight lines AC, AG are equal to one another, and likewise the straight lines AF, AH are equal to one another. Therefore FC too, the difference of the chords AB, AC, will be greater than GD, the difference of the chords AC, AD. Which was the thing proposed.

[Margin references keyed to the demonstration: a) III.27 — Margin: a 27.tertij; b) I.4; c) III.29; d) I.5; e) I.27; f) I.5; g) I.26.]

Diagram. A semicircle standing on the diameter AE. On the arc, three points B, C, D are marked (left to right), with the chords AB, AC, AD drawn from A; the chords BC and CD subtend the equal successive arcs. Interior straight lines CG, CH are joined and the perpendicular CI is dropped.

- A (lower-left, left end of the diameter): vertex from which the chords are drawn
- E (lower-right, right end of the diameter): other end of the diameter
- B (on the arc, upper-left): first arc point
- C (on the arc, top): second arc point
- D (on the arc, upper-right): third arc point
- F (interior, near the top): point cut off so that AF = chord AB
- G (interior): point cut off so that AG = chord AC
- H (interior, left of I/G): endpoint used in the equal-triangle argument
- I (interior, between H and G): foot of the perpendicular CI

Now it must not be passed over that, if a diameter of 120 parts is assumed and we inquire into the chords of the arcs in parts, minutes, and seconds — as Ptolemy [Ptolemy] did — the chords of arcs smaller than 60° have more parts, minutes, and seconds than the arcs of which they are the chords; whereas the chords of arcs larger than 60° have fewer parts, minutes, and seconds than the arcs corresponding to them. This is manifest in the table set out here, which I have taken over and transcribed from Ptolemy's table. In it you see that the chords of arcs smaller than 60° are greater — as to their number of parts, minutes, and seconds — than the arcs corresponding to them (as to degrees and minutes); while the chords of arcs larger than 60° are smaller than the arcs corresponding to them, as to the same numbers. Of this the demonstration is as follows.

Arcus		Chordæ		
G	M	Par.	M.	Sec.
0	30	0	31	25
10	0	10	27	32
20	0	20	50	16
45	0	45	55	19
50	0	50	42	51
60	0	60	0	0
66	30	65	47	43

Arcus	Chordæ			
80	30	77	32	6
90	0	84	51	10
120	0	103	55	23
170	0	119	32	37

In the semicircle ABCDE let the arc AC be 60° and AB smaller, namely 45° ; and let AD be larger, say $80^\circ 30'$. Let the chords AB, AC, AD be drawn. I say that the chord AB is greater than 45 parts, and the chord AD smaller than 80 parts 30 minutes [h: Prop. 10 of this treatise]. For since the proportion of the arc AC to the arc AB is greater than the proportion of the chord AC to the chord AB — while the proportion of the arc AC to the arc AB is the same as 60 to 45 — the proportion of the chord AC to the chord AB will be less than 60 to 45. Therefore, since the chord AC is of 60 parts (being equal to the radius, by the corollary to Proposition 15 of Book 4 of Euclid), the chord AB will be greater than 45 parts [i: V.8], because 60, to a number which is greater than 45, has a smaller proportion than it has to 45. And thus in the table above you see the chord of the arc of 45° to be 45 parts 55 minutes [and] seconds [19].

Diagram. A semicircle on the diameter AE. Near the left of the arc three points B, C, D are marked close together, with the chords AB, AC, AD drawn from A.

- A (lower-left, left end of the diameter): vertex from which the chords are drawn
- E (lower-right, right end of the diameter): other end of the diameter
- B (arc, upper-left): arc point for the 45° arc
- C (arc, above B): arc point for the 60° arc
- D (arc, upper): arc point for the $80^\circ 30'$ arc

[Margin: 18.quinti — i.e. V.18]

Again, since the proportion of the arc AD to the arc AC is greater than the proportion of the chord AD to the chord AC [k: Prop. 16 of this treatise] — and the proportion of the arc AD to the arc AC is the same as $80^\circ 30'$ to 60° — the proportion of the chord AD to the chord AC will be less than 80 parts 30 minutes to 60. And since the chord AC is of 60 parts, the chord AD will be smaller than 80 parts 30 minutes [l: V.8], because a number which is smaller than 80 parts 30 minutes has a smaller proportion to the same number 60 [than 80 parts 30 minutes has]. And so you see in the table above that the chord of the arc of $80^\circ 30'$ contains only 77 parts 32 minutes 6 seconds. And the same reasoning holds for

the other chords, both smaller and larger than AC — that is, than the chord of the arc of 60° .

[Margin references keyed to the demonstration: h) Prop. 10 of this treatise; i) V.8; k) Prop. 16 of this treatise; l) V.8.]

LINEÆ TANGENTES, ATQVE SECANTES.

[TANGENT LINES, AND SECANTS.]

Although astronomers could explain all their problems and theorems by means of sines alone — as is commonly done by everyone — nevertheless, because many things are dispatched more easily and more briefly if, together with the sines, the tangent and secant lines are also employed (as will be plain from the doctrine of triangles), and because the moderns devised these lines with truly useful judgment and reduced them to tables, it has seemed good to set out these lines too in a few words, so that our doctrine of triangles may come out more complete. For the whole doctrine of triangles seems to consist chiefly in these three kinds of lines — namely, in sines, in tangent lines, and in secants. First, then, one must explain what the tangent line and what the secant of any given arc are.

[Margin: In what the doctrine of triangles consists.]

When, therefore, from one end of any arc smaller than a quadrant a radius has been drawn, at whose extremity a straight line touches the circle, and through the other end of the same arc another straight line is extended from the center up to the tangent line: the portion of the tangent line lying between the two straight lines going out from the center is called the **tangent line** (by others it is called the *Prosinus*, or the "inscribed line") of that arc which those same two straight lines drawn out from the center enclose. And the other straight line, opposite the point of contact, [lying] between the center and the tangent line, is called the **secant line** (which others call the *hypotenuse*, or the *transsinuosa*) of the same arc. Thus, if in the circle AB, whose center is C, an arc AB smaller than a quadrant is taken, and at the extremity A of the radius AC, the straight line AD drawn from the endpoint A touches the circle, while the straight line CD cuts the circle, meeting AD at D (for it will necessarily meet it, because the two angles CAD, DCA are less than two right angles — since the former is a right angle and the latter is less than a right angle, on account of the arc AB being smaller than a quadrant): then AD will be called the **tangent** of the arc AB, and CD the **secant** of the same arc. Some

call the tangent the "inscribed line" (*adscripta*), because it is in a certain way inscribed to the circle; the secant they call the *hypotenuse*, because in the right triangle ACD (for the angle A at the point of contact is a right angle) [a: III.18] it subtends the right angle. And the radius AC — or the whole sine — they call the base of the same triangle.

[Margin: What a tangent line and a secant are.]

[Margin: What the "inscribed line" and the "hypotenuse" are. — a) III.18]

Now, just as in every right triangle, if the side opposite the right angle is set as the whole sine, the remaining two sides are the right sines of the remaining acute angles to which they are opposite; likewise each of the two remaining sides is the sine of the complement of the angle adjacent to it, as was set down in the definitions of sines — so also, if one or the other of the sides about the right angle is established as the whole sine, then the other side about the right angle will be the tangent of the acute angle opposite it, while the side opposite the right angle will be the secant of the same angle. Thus in the right triangle ACD the side CA is the whole sine, namely the radius of the circle AB; and AD is the tangent of the angle C, or of the arc AB, and CD is the secant of the same. In the same way, if DA is established as the whole sine, then AC will be the tangent of the angle D, and DC the secant of the same.

[Margin: If in a right triangle one or the other of the sides about the right angle is set as the whole sine, the other side about the right angle will be the tangent of the acute angle opposite it, and the side opposite the right angle the secant of the same.]

Diagram. A circle with center C. From C, the radius reaches A on the circle (upper left). The straight line AD, tangent at A, runs to the point D outside the circle (upper right). The line CD from the center passes through the point B on the circle to D, so that CD is the secant.

- A (on the circle, upper left): point of contact of the tangent AD
- B (on the circle, right): point where the secant CD crosses the circle
- C (center of the circle): center
- D (outside the circle, upper right): meeting point of the tangent AD and the secant CD

And although we have said that the tangent and secant are taken with respect to an arc smaller than a quadrant, nevertheless the same tangent and secant are customarily referred also to the arc which completes a semicircle with it — so

that two arcs making up a semicircle, or two angles equal to two right angles, have one and the same tangent and secant, just as they have the same right sine, as we set forth in the treatment of sines. Accordingly, if the tangent and secant of some arc larger than a quadrant are sought, one must take the tangent and secant of the arc smaller than a quadrant which completes a semicircle with it.

[Margin: Two arcs making up a semicircle, or two angles equal to two right angles, have the same tangent and secant. How the tangents stand when compared with the whole sine.]

Furthermore, by what method the tangents and secants of all the arcs of a quadrant are rendered known in the parts of the whole sine — and therefore by what route a table of tangents, and likewise a table of secants, is to be constructed — will be made plain in the following propositions, which concern the tangent and secant lines.

THEOR. 9. PROPOS. 17.

The tangent of half a quadrant is equal to the whole sine; the tangent of an arc larger than half a quadrant is greater than the whole sine; and the tangent of a smaller arc is smaller. Finally, the secant of half a quadrant is double the right sine of the same half.

In the quadrant ABC, let the arc CD be half of it, CE larger than the half, and CF smaller. Let the straight line CH be drawn perpendicular to AC [a: Corollary, III.16], which will touch the circle at C, and let the straight lines AG, AH, AI be drawn through the points D, E, F. Likewise let DK be perpendicular to AC. Then CG will be the tangent of the arc CD; CH the tangent of the arc CE; and CI the tangent of the arc CF; while DK is the right sine of the arc CD, and AG its secant. I say that CG is equal to the whole sine AC; that CH is greater; and CI smaller. Likewise that AG is double the sine DK. For since the angles CAG, GAB are equal (on account of the equal arcs CD, DB), and the angle BAC is a right angle [b: III.27], each of them will be half a right angle. Hence the remaining angle CGA in the triangle ACG will also be half a right angle [c: I.32], because the angle C is a right angle. Therefore the straight line CG, the tangent of the arc CD (which is half of the quadrant), will be equal to the whole sine AC [d: I.6]. From this it follows that CH, the tangent of the arc CE (which is larger than half the quadrant), is greater; and CI, the tangent of the arc CF (which is smaller than half the quadrant), is smaller — since the point H necessarily falls above G, and the point I below.

That this can also be shown separately, in the following way, with no account taken of the tangent CG whose arc is half the quadrant: since the arc CE is larger than half the quadrant, the arc BE will be smaller than half the quadrant.

Diagram. A quadrant with vertex A at the lower left, B at the upper left, and C at the lower right, with the quarter-arc running from B to C. At C a tangent line rises perpendicular to AC; on it are marked (from lower to upper) the points I, G, H, with F just below. From A the straight lines AI, AG, AH are drawn through the arc points F, D, E respectively; K lies on the base AC.

- A (lower-left): center/vertex of the quadrant
- B (upper-left): end of the quarter-arc
- C (lower-right): other end; foot of the tangent line
- D (on the arc): point marking half the quadrant (arc CD)
- E (on the arc, above D): point of the arc larger than the half (arc CE)
- F (on the arc, below D): point of the arc smaller than the half (arc CF)
- G (on the tangent at C): tangent point of arc CD
- H (on the tangent, above G): tangent point of arc CE
- I (on the tangent, below G): tangent point of arc CF
- K (on the base AC): foot of the perpendicular DK

Therefore the angle CAH is greater than the angle HAB [e: Scholium on III.27], and hence greater than half a right angle. Since, then, the angle C is a right angle, the remaining angle AHC in the triangle ACH will be smaller than half a right angle [f: I.32]. Hence the straight line CH, the tangent of the arc CE (which is larger than half the quadrant), is greater [g: I.19] than the whole sine AC.

Again, since the arc CF is smaller than half the quadrant, and hence BF is larger, the angle CAI will be smaller than the angle IAB [h: Scholium on III.27], and thus smaller than half a right angle. Since, then, the angle C is a right angle, the remaining angle AIC in the triangle ACI will be larger than half a right angle [i: I.32]; and therefore the straight line CI, the tangent of the arc CF (which is smaller than half the quadrant), will be smaller [k: I.29] than the whole sine AC.

Furthermore, since the angle K is a right angle, and DAK half a right angle (as was shown), ADK too will be half a right angle; and hence AK will be equal to the sine DK [l: I.6]. And since the triangles GAC, DAK are equiangular [m: VI.4], as GA is to AC, so AD, that is AC, is to AK; and therefore the three straight lines GA (the secant), AC (the whole sine), and AK (the sine of half the quadrant) will be in continued proportion. So it will follow that the square on AG is to the square on

AC as the straight line AG is to the straight line AK [n: Corollary to VI.20]. But the square on AG is double the square on AC [o: I.47], because it is equal to the squares on AC and CG, which are equal. Therefore also AG, the secant of half the quadrant, is double the sine AK, or DK, of the same half. And so the tangent of half the quadrant is equal to the whole sine, etc. Which was to be demonstrated.

[Margin references keyed to the demonstration: e) Scholium on III.27; f) I.32; g) I.19; h) Scholium on III.27; i) I.32; k) I.29; l) I.6; m) VI.4; n) Corollary to VI.20; o) I.47.]

SCHOLIVM.

From this proposition the reason is plainly gathered why, in the table of tangents, all the tangents of arcs smaller than 45° are smaller than the whole sine; the tangent of the arc of 45° is equal to the whole sine; and, finally, all the tangents of arcs larger than 45° are greater than the whole sine. Likewise why, in the table of secants, the secant of the arc of 45° is double the sine of the same arc of 45° .

[Margin: Why some tangents in the table of tangents are smaller than the whole sine, and which are greater. Likewise why the secant of 45° is double the sine of 45° .]

THEOR. 10. PROPOS. 18.

What proportion the sine of the complement of any arc has to the right sine of the same arc, that same proportion the whole sine has to the tangent of the same arc; likewise, what proportion the right sine of any arc has to the sine of the complement of the same arc, that same proportion the whole sine has to the tangent of the same complement. And the whole sine is a mean proportional between the sine of the complement of any arc and the secant of the same arc; likewise between the right sine of any arc and the secant of the complement of the same arc. Finally, the whole sine itself is a mean proportional between the tangent of any arc and the tangent of the complement of the same arc.

In the quadrant ABC, let DF be the sine of the arc CD; CE the tangent of the same, [lying] between the radius AC and the secant AE; likewise BG the tangent of the arc BD, which is the complement of the arc CD. I say that the sine of the complement of the arc CD is to the right sine of the same arc as the whole sine AC is to the tangent CE, and so on. For since — as was said in the exposition of the definitions — AF is equal to the sine of the complement of the arc CD (being equal to the right sine of the arc BD, which is the complement of the arc CD), and since

the triangles AFD, ACE are equiangular (on account of the right angles F, C and the common angle A) [a: VI.4]: as AF, the sine of the complement of the arc CD, is to FD, the right sine of the same arc CD, so AC, the whole sine, is to CE, the tangent of the same arc. Which is the first point.

Next, by the same reasoning, as AF, the right sine of the arc BD, is to FD, the sine of the complement of the same arc BD, so AC, the whole sine, is to CE, the tangent of the same complement of the arc BD. Which is the second point.

Third, in the same triangles, as AF, the sine of the complement of the arc CD, is to AD, the whole sine, so AC, the whole sine, is to AE, the secant of the same arc CD. Likewise, as AF, the right sine of the arc BD, is to AD, the whole sine, so AC, the whole sine, is to AE, the secant of the arc CD, which is the complement of the same arc BD. Hence the whole sine is a mean proportional between AF, the sine of the complement of the arc CD, and AE, the secant of the same arc CD; likewise between AF, the right sine of the arc BD, and AE, the secant of the complement of the same arc BD. Which is the third point.

Finally, since the triangles ACE and GBA are equiangular (because the angles C, B are right angles [b: I.29], and the alternate angles CAE, BGA, as well as the alternate angles AEC, GAB, are equal) [c: VI.4]: as CE, the tangent of the arc CD, is to AC, the whole sine, so AB, the whole sine, is to BG, the tangent of the complement of the same arc CD. By like reasoning, as BG, the tangent of the arc BD, is to AB, the whole sine, so AC, the whole sine, is to CE, the tangent of the complement of the same arc BD. Which is the fourth point. Therefore, what proportion the sine of the complement of any arc [has to its right sine], etc. Which was to be demonstrated.

[Margin: What proportion the whole sine has to the tangent and secant of any arc. — a) VI.4; b) I.29; c) VI.4.]

Diagram. A square/quadrant with vertex A at the lower left, B at the upper left, C at the lower right, and E at the upper right; the quarter-arc runs from B to C, passing through the point D near the center. The diagonals from A are drawn: AE (the secant) passes through D; DF is the right sine dropped to the base at F; G lies on the top edge near E; the tangents CE (at C) and BG (at B) are marked.

- A (lower-left): center/vertex of the quadrant
- B (upper-left): end of the arc; foot of the tangent BG
- C (lower-right): end of the arc; foot of the tangent CE
- D (on the arc, near center): point defining the arc CD (and its complement BD)

- E (upper-right): meeting point of the secant AE and the tangent CE
- F (on the base AC): foot of the right sine DF
- G (on the top edge AB extended): tangent point of the complement's tangent BG

[Margin: a 4.sexti — i.e. VI.4]

SCHOLIVM.

And so, by what has been demonstrated in the first place in this proposition: if it is arranged that, as the sine of the complement of any arc is to the right sine of the same arc, so the whole sine is to another [magnitude] — that is, if the sine of any arc is multiplied by the whole sine (which will be done easily if you prefix to it, on the right, as many ciphers as are contained in the whole sine, namely seven if the whole sine is 10000000, or five if the whole sine is 100000) — and the resulting number is divided by the sine of the complement of the same arc: the tangent will be found of that arc whose sine of the complement you took, or whose right sine you multiplied by the whole sine. For example, if the tangent of the arc of 30° is sought, we shall append to its right sine, 5000000, seven ciphers, in this manner, 50000000000000, and we shall divide this number by 8660254, the sine of the complement of the same arc of 30° . For the quotient, the number 5773503, will give the tangent of the arc of 30° , insofar as the whole sine is 10000000. Hence it comes about that all the tangents are found by division alone. For if to the sines of all the arcs, beginning from the start of the quadrant, you append seven ciphers, and divide the numbers so composed by the sines of the complements of the same arcs — each by its own corresponding one — the tangents of all the arcs will come out, as is clearly established from what has been demonstrated. For this reason the construction of a table of tangents is very easy.

[Margin: How the tangents of all arcs are found.]

[Margin: All the tangents are elicited by division alone.]

Again, by what has been demonstrated in the third place in this proposition: if it is arranged that, as the sine of the complement of any arc is to the whole sine, so the whole sine is to another [magnitude] — that is, if the whole sine is multiplied by itself (which will be done easily if you prefix to it, on the right, as many ciphers as there are in the whole sine, say seven, or five, according as the whole sine has seven or five ciphers) — and the number produced is divided by the sine of the complement of any arc: the secant will be found of that arc by whose sine of the complement the division was made. For example, if the secant of the arc...

[Margin: By what method the secants of all arcs are investigated.]

Opera Mathematica, Tomus I — Doctrine of Tangents and Secants

(Global = printed folios 99–101. This opening is continuous prose: the tail of the scholium to Proposition 18, then Theorems 11–14 with their scholia and a long "wonderful compendium" for constructing the tangent and secant tables. No numeric tangent/secant table begins on these pages.)

if the secant of an arc of 30° is required, we shall divide 100000000000000 — that is, the number produced by multiplying the whole sine [*sinus totus*] into itself — by 8660254, the sine [*sinus*] of the complement [*complementum*] of the arc of 30° . For the quotient, 11547005, will give the secant [*secans*] of the arc of 30° , inasmuch as the whole sine is 10000000. Therefore, by the mere division of this same number, 100000000000000, by the sines of the complements of all the arcs — beginning from the start of the quadrant [*quadrans*] — the secants of all arcs are derived, as is clear from what has been demonstrated. From this the construction of the table of secants will be very easy.

[Margin: By the mere division of this same number by the sines, all the secants are found.]

THEOR. 11. PROPOS. 19.

The tangent [*tangens*] of any arc [*arcus*] greater than half a quadrant is equal to the tangent and secant together of the arc that is double the excess by which the given arc exceeds half a quadrant.

[Margin: The tangent of an arc greater than half a quadrant, to which tangent and secant together it is equal.]

In the quadrant ABC, let CG be the tangent of the arc CF — an arc greater than half a quadrant — the tangent being enclosed between the semidiameter AC and the secant AG of the same arc CF. I say that CG is equal to the tangent and secant together of the arc that is double the excess by which the arc CF exceeds half a quadrant. For, taking the arc FD equal to FB, draw the straight line AD and extend it as far as E. ^a Now since the angles BAF and FAE are equal, because of the equal arcs BF and DF; ^b and since the alternate angle G is equal to the angle BAF, the same angle G will also be equal to the angle GAE; ^c therefore the straight lines EG and EA are equal. And so, adding the common part CE, the whole tangent CG of

the arc CF will be equal to the two lines CE and AE together — that is, to the tangent and secant of the arc CD together.

I now say that the arc CD is double the excess by which the arc CF exceeds half a quadrant. For, producing the quadrant's arc on the side of B and taking the arc BH equal to CD, then since the arc FB is also equal to the arc FD, the whole arc FH will be equal to the whole arc CF, and therefore the arc CH will be double the arc CF. But since the arc CH exceeds the quadrant CB — namely by the arc CD — ^d CF, the half of arc CH, will exceed CB's half of the quadrant by CD's half of the excess. The arc CD, therefore, is double the excess by which the given arc CF exceeds half a quadrant. And it has been shown that CG, the tangent of the arc CF, is equal to the tangent CE and the secant AE of the arc CD together. Therefore the tangent of any arc greater than half a quadrant is equal to the tangent and secant together of the arc that is double the excess by which the given arc exceeds half a quadrant. Which was to be demonstrated.

- F (on the arc, upper): endpoint of the given arc CF
- D (on the arc, lower right): with arc FD = arc FB
- E (right, below D): where AD produced meets the tangent
- G (upper right): top of the tangent CG, on the secant AG
- H (top left, beyond B): with arc BH = arc CD

SCHOLIVM

Some state this proposition thus:

The secant of any arc, together with the tangent of the same, is equal to the tangent of the arc composed of the given arc and half the complement of the same.

[Margin: The secant and tangent of the same arc, to which tangent together they are equal.]

For, in the same figure, let AE be the secant and CE the tangent of the same arc CD. Bisecting the arc BD — namely the complement of the arc CD — at F, draw from the center A through F the straight line AG, cutting the tangent CE, produced, at G. Then CG will be the tangent of the arc CF, which is composed of the given arc CD and of DF, half the complement DB. I say that the secant AE and the tangent CE together are equal to the tangent CG. ^e For since the angles BAF and FAE are equal, because of the equal arcs BF and FD; ^f and the alternate angle G is equal to the angle BAF, the same angle G will also be equal to the angle GAE. ^g Therefore the straight lines EA and EG are equal; and so, adding the common part EC, the two lines AE and EC together will be equal to the whole CG.

[Margin citations: ^e Euclid III.27 · ^f Euclid I.29 · ^g Euclid I.6.]

THEOR. 12. PROPOS. 20.

The secant of any arc is equal to the tangent of the same, together with the tangent of half the complement of the same arc.

[Margin: The secant of any arc, to which two arcs' tangents it is equal.]

In the quadrant ABC, let AD be the secant and CD the tangent of the arc CE, and let EF (or FB) be half of its complement EB; and let the arc CG be equal to this half. Draw the straight line AG and produce it until it meets DC, produced, at H; then CH will be the tangent of the arc CG, which is half the complement of the arc CE. I say that the secant AD is equal to the tangent CD and the tangent CH together — that is, to the whole line DH. ^a For since the angles EAF and CAG are equal, because of the equal arcs EF and CG, then adding the common angle EAC, the whole angles FAC and EAH will be equal. ^b Again, since in the right triangle ACH the two angles at A and H are equal to one right angle — namely to the angle BAC — then removing the angles BAF and CAH, ^c which are equal because of the equal arcs BF and CG, the remaining angles FAC and H will be equal. But the angle FAC was shown equal to the angle EAH. Therefore the angle H too will be equal to that same angle EAH; ^d and consequently the straight lines AD and DH will be equal — that is, the secant AD will be equal to the tangents DC and CH. Which was proposed.

[Margin citations: ^a Euclid III.27 · ^b Euclid I.32 · ^c Euclid III.27 · ^d Euclid I.6.]

Another proof. Again let AD be the secant and CD the tangent of the arc CE. I say that the secant AD is equal to the tangent CD, together with the tangent of half the

complement of the arc EC — that is, of the angle DAC — or, in other words, together with the tangent of half the angle D, which is the complement of the angle DAC, ^e since both, in the right triangle ACD, are equal to one right angle. With center D and radius DA let there be described the arc of a circle AHI, cutting DC produced at H and AC produced at I; and let the straight lines AH and HI be drawn. Since, then, the straight line DC, drawn out from D the center of the circle AHI and cutting the straight line AI at right angles, ^f bisects it, the same line DCH will also bisect the arc AHI, by the lemma demonstrated among the definitions. ^g Therefore the angles CAH and I are equal. Now since the angles stand on the same base, the arc AH, and one of them (D) is at the center while the other (I) is at the circumference, ^h the angle D is double the angle I; hence the same angle D is also double the angle CAH. Consequently the angle CAH is half the angle D, which is the complement of the angle DAC. Since, then, CH is the tangent of the angle CAH, and the straight line DA is equal to the straight line DH by the definition of the circle, it plainly follows that the secant AD of the arc CE is equal to the tangent CD of the same arc, together with...

[Margin citations: ^e Euclid I.32 · ^f Euclid III.3 · ^g Euclid III.27 · ^h Euclid III.20.]

Diagram. A quarter-circle for Proposition 20, with vertex A at the lower left. From A the horizontal radius runs to C, and the vertical radius up to B. The tangent to the circle at C is the vertical line rising through D and F. E and G lie on the arc; the secant AD and the secant/line AG are drawn, AG being produced down to H (below), with I marked to the right.

- A (lower-left vertex): center of the quadrant
- B (top left): end of the vertical radius
- C (middle right): foot of the tangent line CDF
- D (upper right, on the tangent): end of the secant AD, and of line DH
- F (above D, on the tangent produced): with EF = half the complement of arc CE
- E (on the arc, upper): endpoint of the arc CE
- G (on the arc, lower): endpoint of arc CG = half the complement
- H (bottom): where AG produced meets DC produced
- I (right): auxiliary point on AC produced (in the alternative proof)

together with CH, the tangent of half the complement of the arc CE (or of the angle CAD). Therefore the secant of any arc is equal to the tangent of the same, and so on. Which was to be demonstrated.

SCHOLIUM

[Margin: A wonderful compendium for the construction of both the table of tangents and the table of secants. Prop. 19 of this book.]

From the two preceding theorems a wonderful compendium is furnished to us for constructing both the table of Tangents and the table of Secants. For if, by the methods we prescribed in Proposition 18 and its scholium, we work out the tangents of all arcs (running through the single minutes up to half a quadrant) and the secants of all arcs of the whole quadrant, then by their means we shall find, through mere addition, the tangents of the other arcs up to the arc of $67^{\circ} 30'$ — provided, namely, that we collect into a single sum the tangentⁱ and the secant of each arc less than half a quadrant whose minutes are an even number.¹ This is because the tangent of any arc greater than half a quadrant is equal to the tangent and secant of the arc that is double the excess by which the given arc exceeds half a quadrant — and such are all the arcs of even minutes up to 45° , as the arcs of $2'$, $4'$, $6'$, and so on.

For example: if the tangent of the arc of $45^{\circ} 1'$ is desired, we collect into a single sum the tangent 5818 and the secant 10000002 of the arc of $2'$, which is double the arc of $1'$ by which the given arc of $45^{\circ} 1'$ exceeds half a quadrant. For the resulting number, 10005820, will give the tangent of the proposed arc of $45^{\circ} 1'$, which exceeds half a quadrant by half the arc of $2'$, as was shown in Proposition 19. Likewise the same arc of $45^{\circ} 1'$ is composed of the arc of $2'$ and half the complement of that arc, which comprises $89^{\circ} 58'$ — that is, of the arc of $2'$ and the arc of $44^{\circ} 59'$. And accordingly, as we demonstrated in the scholium of Proposition 19, the number 10005820, made up of the tangent and secant of the arc of $2'$, gives the tangent of the said arc composed of the arc of $2'$ and half the complement of the same.

By the same reasoning, the tangent of any arc greater than half a quadrant is composed of the tangent and secant of the arc that is double the excess by which that arc exceeds half a quadrant. Likewise, if the tangent and secant of any arc less than half a quadrant are collected into a single sum, there will be formed the tangent of the arc composed of that arc and half the complement of the same. Thus the tangent 14352451 of the arc of $55^{\circ} 8'$ is composed of the tangent 3692500 and the secant 10659951 of the arc of $20^{\circ} 16'$, which is double [the excess of] $10^{\circ} 8'$ by which the given arc of $55^{\circ} 8'$ exceeds half a quadrant. Likewise, if the tangent 3692500 and the secant 10659951 of the arc of $20^{\circ} 16'$ are collected into a single sum, there will be formed the tangent 14352451 of the arc of $55^{\circ} 8'$, composed of

that arc of $20^{\circ} 16'$ and half the complement of the same — namely of the arc of $34^{\circ} 52'$, since the complement of the arc of $20^{\circ} 16'$ comprises $69^{\circ} 44'$.

Therefore, given any arc whatever greater than half a quadrant: if half a quadrant (that is, the arc of 45°) is subtracted from it, and the remaining arc is doubled, the tangent and secant of this doubled arc, taken together, will compose the tangent of that proposed arc. Thus, if the tangent of the arc of $55^{\circ} 8'$ is sought, the 45° must be subtracted from it, and the remaining arc of $10^{\circ} 8'$ doubled, giving the arc of $20^{\circ} 16'$.^k For its tangent and secant compose the tangent of that arc, as was demonstrated.

[Margin: ^k Prop. 19 of this book.]

Now, once the tangents of arcs greater than half a quadrant have been found in this way, up to the arc of $67^{\circ} 30'$ inclusive: if again we collect into a single sum the tangent and secant of each of these arcs that comprises an even number of minutes (such as the arcs of $45^{\circ} 2'$, $45^{\circ} 4'$, and so on), we shall find the tangents of still greater arcs — namely of $67^{\circ} 31'$, $67^{\circ} 32'$, and so on, up to the arc of $78^{\circ} 45'$ inclusive. For the arc of $33^{\circ} 45'$, by which the arc of $78^{\circ} 45'$ exceeds half a quadrant, is double the arc of $67^{\circ} 30'$, whose tangent was found in the last place. Likewise, from these tangents of arcs greater than $67^{\circ} 30'$ up to the arc of $78^{\circ} 45'$ inclusive, once found: if again we collect into a single sum the tangent and secant of each of them that comprises an even number of minutes, we shall find the tangents of still greater arcs — of the kind of the arcs of $78^{\circ} 46'$, $78^{\circ} 47'$, and so on, up to the arc of $84^{\circ} 22'$ inclusive. For the arc of $39^{\circ} 22'$, by which the arc of $84^{\circ} 22'$ exceeds half a quadrant, is double the arc of $78^{\circ} 44'$, which is the greatest of those that have their minutes even and whose tangents are already found.

By the same procedure, from the tangents of arcs greater than $84^{\circ} 22'$, we shall find the tangents of still greater arcs up to the arc of $87^{\circ} 11'$; for the [excess of $42^{\circ} 11'$], by which the arc of $87^{\circ} 11'$ exceeds half the quadrant, is double the arc of $84^{\circ} 22'$, whose tangent was found in the last place. From these, in turn, we shall make up the tangents of the following arcs up to the arc of $88^{\circ} 35'$, whose excess of $43^{\circ} 35'$, by which it exceeds the quadrant's half, is double the arc of $87^{\circ} 10'$, whose tangents were found just before. By means of these likewise — up to the arc of $89^{\circ} 17'$ inclusive — since the arc of $44^{\circ} 17'$, by which the arc of $89^{\circ} 17'$ exceeds the quadrant, is double the arc of $88^{\circ} 34'$ (which is the greatest of those that have their minutes even and whose tangents are now known) — by the aid of these tangents thus found we shall next draw out the tangents of arcs up to the arc of $89^{\circ} 38'$ inclusive; because the [excess of] this arc [is such that] its double is the arc of $89^{\circ} 16'$, which is the greatest of those whose minutes are even. Hence we shall

seek the tangents of other arcs up to the arc of $89^{\circ} 49'$, since the arc of $44^{\circ} 49'$, whose double is the arc of $89^{\circ} 38'$, is one to which we just came. But from these we shall investigate the tangents of the following arcs up to the arc of $89^{\circ} 54'$ — namely by that arc of $44^{\circ} 54'$ which exceeds the quadrant's half, whose double is the arc of $89^{\circ} 48'$, the greatest of those that have their minutes even and whose tangents are already found. By the same reasoning we shall find the tangents of the following arcs up to the arc of $89^{\circ} 57'$; because this arc of $89^{\circ} 57'$ [is such that] its double-excess is the arc of $89^{\circ} 54'$, to which we just came. And thence we shall make up the tangent of the arc of $89^{\circ} 58'$, from the [double-excess] arc of $89^{\circ} 56'$. And so, as you see, from the tangents of arcs up to 45° and from the secants of all the arcs of the quadrant, the whole table of tangents is completed.

But if you subtract the secant of any arc whatever from the tangent of the arc that is composed of that former arc and half the complement of the same, you will produce the tangent of that same former arc, whose secant you subtracted. Likewise, if from the secant of any arc you take away the tangent of the same, there will remain the tangent of half the complement of that arc. The first point is established from the scholium of Proposition 19, where it was shown that the secant and tangent of any arc together are equal to the tangent of the arc composed of that arc and half its complement; for hence it comes about that the secant, taken away from this composite tangent, leaves that other tangent. The second point is clear from this Proposition 20, where we demonstrated that the secant of any arc is equal to the tangent of the same, together with the tangent of half the complement of that arc; wherefore the tangent of that half will be the remainder after the subtraction of that other tangent from the secant.

For example: if we subtract the secant of the arc of 20° , which is 10641777, from 14281480, the tangent of the arc of 55° (composed of the arc of 20° and half its complement), there will remain 3639703, the tangent of the same arc of 20° . Likewise, if we subtract 4244748, the tangent of the arc of 23° , from the secant of the same arc, 10863603, there will remain the tangent 6618855 of the arc of $33^{\circ} 30'$ — that is, of half the complement of the given arc of 23° . Again, if we take away 11547004, the secant of the arc of 30° , from 17320508, the tangent of the arc of 60° ,

which is composed of the arc of 30° and half its complement, there will be left the tangent 5773504 of the arc of 30° . And if we take away 1763268, the tangent of the arc of 10° , from 10154264, the secant of the same arc of 10° , there will remain the tangent 8390996 of the arc of 40° , which is half the complement of the said arc of 10° .

Now indeed, if by the methods we handed down in Proposition 18 and its scholium we work out the tangents of all the arcs of the quadrant, extended through the single minutes, we shall find by their means, through mere addition, the secants of all arcs advancing by two minutes at a time — provided, namely, that we add the tangent of any arc having an even number of minutes to the tangent of half the complement of the same arc: ¹ this because the secant of any arc is equal to the tangent of the same, together with the tangent of half the complement of the same; and it is established that the complements of all arcs having an even number of minutes have halves [in whole minutes]. For example, if the secant of the arc of 2' is desired, we shall add its tangent 5818 to 9994184, the tangent of the arc of 44° 59', which is half the complement of the given arc of 2'. For the number thus composed, 10000002, will be the secant of the arc of 2'. So too, if the secant of the arc of 89° 58' is sought, we shall add its tangent 17188033689 to 2909, the tangent of the arc of 1', which is half the complement of the given arc of 89° 58'. For the number thus formed, 17188036598, will be the secant of the arc of 89° 58'. By this method half the table of Tangents [recte: Secantium — of Secants?] will be constructed; but the tangents [recte: secantes — the secants?] of arcs having an odd number of minutes, since their complements do not have halves [in whole minutes] — unless we choose to descend to seconds — must be investigated as we prescribed in Proposition 18 and its scholium.

[Margin: ¹ Prop. 20 of this book.]

Again, we shall find the secant of any arc if we take away the tangent from the tangent of the arc composed of that arc and half the complement of the same arc. For since, as we demonstrated, the secant of any arc, together with the tangent of half the complement of the same arc, ^m makes it so that the tangent of the given arc, taken away from the tangent of the arc composed of the given arc and half the complement of the same, leaves the secant of that same given arc. For example, if we wish for the secant of the arc of 2', we shall take away 5818, the tangent of that arc, from 10005820, the tangent of the arc of 45° 1', composed of the arc of 2' and half the complement of the given arc of 2'; for the number left, 10000002, will be the secant of the arc of 2'. So too, if we wish to have the secant of the arc of 60°, we shall subtract 17320508, its tangent, from 37320514, the tangent of the arc of 75°, composed of the given arc of 60° and the arc of 15°, which is half the complement of the given arc of 60°. For the number that remains, 20000006, stands for the secant of the given arc of 60°.

[Margin: ^m Scholium of Prop. 19 of this book.]

These things which have been handed down by us in this scholium are true if the sines have been exactly found; but because not all the sines are accurately known — especially the sine of the arc of 1° and the others that depend on it, such as the sines of the arcs extended through the single minutes — it comes about that neither the tangents nor the secants found by means of these sines are altogether accurate. Hence, if from certain values found, others are sought by mere addition or subtraction, as we have taught in this scholium, they will differ not a little from the same values were they investigated through the sines. For the tangents and secants found through the sines are generated from one single principle — not, indeed, in every part a true one, namely the sines; whereas those same values, produced by mere addition or subtraction, arise from several false principles — namely, first from the sines, and then also from the tangents and secants found through the sines, which cannot be accurate, as we have said. These lines, then, will be known more exactly through the sines, as was handed down in Proposition 18 and its scholium. By this method we shall shortly compute both the table of Tangents and the table of Secants; for we have detected no small errors in the tables of others, so that we cannot safely trust them, because they investigated many tangents and secants either by the proportional part, or by mere addition or subtraction, and not all through the sines. Nevertheless we shall append a little below the tables of others, until in time it shall be possible to construct new ones.

[Margin: That the tangents and secants found through the sines are more accurate than those found by addition or subtraction, as has been handed down in this scholium.]

THEOR. 13. PROPOS. 21.

The tangent of any arc is to the tangent of any other arc as the tangent of the complement of the latter arc is to the tangent of the complement of the former.

[Margin: The tangents of any two arcs are reciprocally proportional to the tangents of the complements of the same arcs.]

In the quadrant ABC, let the tangent of the arc CD be CE and its secant AE; likewise, let the tangent of the arc CF be CG and its secant AG. Now draw the straight line BH, touching the circle and meeting each of the secants AE, AG at I and H; then BI will be the tangent of the complement of the arc CD, and BH the tangent of the complement of the arc CF. I say that CE, the tangent of the arc CD, is to CG, the tangent of the arc CF, as BH, the tangent of the complement of the

latter arc CF, is to BI, the tangent of the complement of the former arc CD. ^a For since the whole sine is the mean proportional both between CE, the tangent of the arc CD, and BI, the tangent of the complement of the same arc CD, and between CG, the tangent of the arc CF, and BH, the tangent of the complement of the same arc CF; ^b then both the rectangle under CG, BH and the rectangle under CE, BI will be equal to the square of the whole sine; and consequently the rectangle under CE, BI will be equal to the rectangle under CG, BH. ^c Therefore, as CE the first is to CG the second, so will BH the third be to BI the fourth — namely, as CE, the tangent of the arc CD, is to CG, the tangent of the arc CF, so is BH, the tangent of the complement of the latter arc CF, to BI, the tangent of the complement of the former arc CD. Therefore the tangent of any arc is to the tangent of another, and so on. Which was to be shown.

Diagram. A quadrant figure for Proposition 22, with vertex A at the lower left. B is at the upper left; H and I are marked on the left side (feet of the sines of the complements). The arc runs up toward D at the upper right, with E and G on it. The secants AD and AF are drawn from A, meeting the tangent/vertical at D and F on the right; EH and GI are the sines of the complements dropped to the vertical radius AB.

- A (lower-left vertex): center of the quadrant
- B (upper left): end of the vertical radius
- C (lower right): end of the horizontal radius
- D (upper right): end of the secant AD
- E (on the arc, upper middle): endpoint of the arc CE
- F (right): end of the secant AF
- G (on the arc, middle): endpoint of the arc CG
- H (left, on AB): foot of the sine of complement EH
- I (left, on AB, below H): foot of the sine of complement GI

[Continues from the previous page, completing the proof of THEOR. 14 / PROPOS. 22; the page opens on the second half of the word *quartam*.]

the fourth [proportional]; that is, as AD, the secant of arc CE, is to AF, the secant of arc CG, so is GI, the sine of the complement of the latter arc CG, to EH, the sine of the complement of the former arc CE. Therefore the secant of any arc is to the secant of another arc [as the sine of the complement of the second is to the sine of the complement of the first], and so on. Which was to be demonstrated.

THEOR. 15. PROPOS. 23.

[Margin: Tangents and secants of arcs that increase equally always increase their differences (*Tangentes & secantes arcuum aequaliter crescentium augent semper differentias*).]

If there are several arcs progressing by an equal increment, both their tangents and their secants — those of the larger arcs — will have a greater difference than those of the smaller: so that in the table the differences both of the tangents and of the secants keep increasing all the way to the end of the quadrant.

In the quadrant ABC let there be arcs CD, CE, CF whose differences DE, EF are equal, and let their tangents be CG, CH, CI and their secants AG, AH, AI. Now since in triangle ACH the angle C is right, the angle AHC will be less than a right angle [Margin a: *Elements* I.17], because the two of them together are less than two right angles. Since, then, the two angles at H are equal to two right angles [Margin b: I.13], AHI will be greater than a right angle, and consequently the angle I, in triangle AHI, is less than a right angle [Margin c: I.17]. Hence the secant AI will be greater than the secant AH [Margin d: I.19]. By the same reasoning it will also be greater than AG; and likewise AH is greater than AG.

Let there be cut off, then, AK equal to AH, and AL equal to AG. I say that IH, the difference of the tangents CI, CH of the larger arcs CF, CE, is greater than HG, the difference of the tangents CH, CG of the smaller arcs CE, CD; and likewise that KI, the difference of the secants AI, AH of the larger arcs CF, CE, is greater than LH, the difference of the secants AH, AG of the smaller arcs CE, CD. For since the arcs DE, EF are equal, the angles DAE, EAF will also be equal [Margin e: III.27]; and consequently the angle IAG is bisected by the straight line AH. Therefore [Margin f: VI.3] as IA is to AG, so is IH to HG. But AI is greater than AG, as was shown; therefore the straight line IH will also be greater than HG. This is the first point.

Now, FM, EN, DO having been drawn perpendicular to AC — namely the sines of the arcs CF, CE, CD — AM will be the sine of the complement of arc CF, AN the sine of the complement of arc CE, and AO the sine of the complement of arc CD, as was said in the exposition of the definitions. Since indeed the straight line MN is greater than NO [Margin g: 1 of this treatise], the proportion of AN to NO will be greater than that of AN to MN [Margin h: V.8]; but the proportion of AO to NO is still greater than that of AN to the same NO. Therefore the proportion of AO to NO will be much greater than that of AN to MN. And by the conversion of the ratio [Margin i: 30 of the fifth], the proportion of AO to AN is less than that of AN to

AM; that is, the proportion of AN to AM is greater than that of AO to AN [Margin k: 22 of this treatise]. Since, then, as AN is to AM so is AI to AH, and as AO is to AN so is AN to AG, the proportion of AI to AH — that is, to AK — will also be greater than that of AH to AG — that is, to AL. Therefore, by division [Margin l: 29 of the fifth], the proportion of IK to AK — that is, to AH — will likewise be greater than that of HL to AL. And by conversion [Margin m: 26 of the fifth], the proportion of AK to KI will be less than that of AL to LH; that is, the proportion of AL to LH will be greater than that of AK to KI. Hence, since the proportion of AH to LH is still greater than that of the same AH to KI [Margin n: V.8], the straight line LH will therefore be less than KI [Margin o: 10 of the fifth]. This is the second point.

From this it comes about that the differences both of the tangents and of the secants in the table keep increasing all the way to the end of the quadrant — the contrary of which happens in the case of the sines, as was demonstrated above. Therefore, if there are several arcs progressing by an equal increment, and so on. Which was to be demonstrated.

COROLLARIUM.

[Margin: Arcs whose tangents have equal increments have unequal increments (*Arcus tangentium aequales excessus habentium inaequales habet excessus*).]

It follows from this that, if the tangents of any number of arcs exceed one another equally, the arcs themselves exceed one another unequally, and the excesses of the larger arcs are smaller than those of the smaller. Likewise, all the segments of the secants outside the quadrant are unequal, and those nearer the beginning of the quadrant are smaller. For since, with the arcs DE, EF taken equal, it was shown that the straight line IH is greater than HG, it plainly follows that, if from HI a straight line equal to HG is taken away, the secant drawn between the two AI, AH divides the arc EF, and thus cuts off an arc smaller than the arc DE — namely a part of the arc EF. And the same reasoning holds for the others.

Again, since it was demonstrated that the secant AG is smaller than AH, it follows that, when the equal semidiameters AD, AE are taken away, the remaining segment DG is smaller than the remaining segment EH, and so on.

Diagram. A quadrant of a circle serving both THEOR. 15 and THEOR. 16 (the text of THEOR. 16 states "let the figure of the preceding proposition be repeated," and the same figure is engraved a second time lower on the page). The right angle is at A (lower left, the centre); AB is the vertical radius (B at upper left) and AC the horizontal radius (C at lower right), with the quadrant arc running from B down to C.

- A (lower-left corner): centre of the quadrant and vertex of the right angle.
- B (upper-left corner): end of the vertical radius AB.
- C (lower-right corner): end of the horizontal radius AC; foot of the common tangent line.
- D, E, F (on the arc, from C upward toward B): points marking the arcs CD, CE, CF, whose successive differences DE, EF are equal.
- G, H, I (on the vertical tangent through C, from C upward): the tangent-endpoints of arcs CD, CE, CF respectively (tangents CG, CH, CI).
- The secants AG, AH, AI run from A through D, E, F to G, H, I.
- K (on AI): the point with AK equal to AH.
- L (on AH): the point with AL equal to AG.
- M, N, O (on AC, between A and C): the feet of the perpendiculars FM, EN, DO dropped from F, E, D to AC (the sines of arcs CF, CE, CD); AM, AN, AO are the sines of the complements of those arcs.

THEOR. 16. PROPOS. 24.

[Margin: The tangent of the greater of two unequal arcs has to the tangent of the lesser a greater proportion than the secant of the greater has to the secant of the lesser (*Arcuum inaequalium tangens maioris ad tangentem minoris proportionem habet maiorem, quam secans maioris ad secantem minoris*).]

The tangent of the greater arc has to the tangent of the lesser arc a greater proportion than the secant of the same greater arc has to the secant of the same lesser.

Let the figure of the preceding proposition be repeated. I say that the proportion of the tangent CI to the tangent CH is greater than that of the secant AI to the secant AH. For since [Margin a: VI.4] as AF is to FM, so is AI to IC, and likewise as AE is to EN, so is AH to HC; but the proportion of the semidiameter AF to FM is smaller than that of the semidiameter AE to EN [Margin b: V.8], because the sine FM of the larger arc CF is greater than the sine EN of the smaller arc CE, as was said in the exposition of the definitions — therefore the proportion of AI to IC will also be smaller than that of AH to HC. And by alternation [Margin c: scholium on V.27], the proportion of AI to AH is also smaller than that of IC to HC; that is, the tangent CI to the tangent CH will have a greater proportion than the secant AI to the secant AH. And therefore the tangent of the greater arc to the tangent of the lesser arc, and so on. Which was to be demonstrated.

HERE FOLLOW THE TABLES OF TANGENTS AND SECANTS.

(SEQVVNTVR TABVLAE TANGENTIVM ATQVE SECANTIVM.)

Table of Tangents — degrees 0–4 (folio 103)

Sub-heading: *Gradus Quadrantis pro tangentibus arcuum eiusdem Quadrantis.*

("Degrees of the quadrant, for the tangents of the arcs of the same quadrant.")

The left "Minuta" column runs 0→60 top-to-bottom; the right "Minuta" column runs 60→0 (giving the minutes of the complement). The top degree banner reads **0 · 1 · 2 · 3 · 4**; the bottom banner (for the complements) reads **89 · 88 · 87 · 86 · 85**, with the footing *Gradus Quadratis pro tangentibus complementorum arcuum eiusdem Quadrantis.*

Table of Tangents (*Tabula Tangentium*) — degrees 10°–24°

Christoph Clavius, Opera Mathematica, Tomus I — tangent/secant treatise, continuation of the numeric tangent tables.

Each page carries five degree columns. The left-hand minute column (*Minuta Graduum Quadrantis pro tangentibus arcuum eiusdem Quadrantis* — "Minutes of the degrees of the quadrant, for the tangents of the arcs of the same quadrant") runs 0'→60' downward and applies to the degree named in the **top** banner. The right-hand minute column runs 60'→0' downward and, with the **bottom** banner degree (89° – top degree), serves the tangents of the complementary arcs (*pro tangentibus complementorum arcuum eiusdem Quadrantis*). All tangent values are to a radius of 10,000,000. Values are transcribed exactly as printed.

Folio 105 — degrees 10°–14° (bottom banner: 79° 78° 77° 76° 75°)

Top banner: **10 · 11 · 12 · 13 · 14**

Bottom banner: **69 · 68 · 67 · 66 · 65** · [Footer: "Gradus Quadrantis pro tangentibus complementorum arcuum eiusdem Quadrantis."]

Tabula Tangentium — Tangent Tables, degrees 25°–39°

(Christoph Clavius [Christophorus Clavius], doctrine of sines, tangents, and secants. Tangent values are tabulated as integers scaled by 10^7 ; i.e. $\tan 45^\circ = 10000000$. Each degree column is read top-to-bottom against its banner degree using the left-hand minute column [0'→60']; read bottom-to-top against the foot banner it gives the

tangent of the complementary arc, using the right-hand minute column. The separator columns between degrees are blank in this format — there are no printed Differentiae columns on these openings.)

Source page p. 748 (printed folio 108) — degrees 25°–29°

Foot banner (complement degrees, right→left over the columns): **54 · 53 · 52 · 51 · 50** — *Gradus Quadrantis pro tangentibus complementorum arcuum eiusdem Quadrantis.*

Tabula Tangentium (Table of Tangents) — degrees 40°–52°

Christoph Clavius, Opera Mathematica, Tomus I (Mainz, 1611). Numeric tangent tables, continued.

The three openings transcribed here continue the *Tabula Tangentium* upward from 40°, crossing 45° (where the tangent equals the whole radius, 10000000). Each page carries a block of whole-degree columns headed by a degree banner (read downward against the left minute column, 0' at top → 60' at foot); the foot of each page repeats a complement-degree banner for reading the same cells as tangents of the complementary arc against the right minute column (60' at top → 0' at foot). Latin column and caption words are kept as printed.

Header words as printed: *Gradus Quadrantis pro tangentibus arcuum eiusdem Quadrantis* (running title *TABVLA — TANGENTIVM*); left rotated caption *Minuta*

Gradium Quadrantis pro tangentibus arcuum eiusdem Quadrantis; right rotated caption pro tangentibus complementorum arcuum eiusdem Quadrantis.

Table of Tangents (*Tabula Tangentium*) — degrees 53°–64°

Christoph Clavius, Opera Mathematica, Tomus I (Mainz, 1611). Upper-quadrant tangent tables, continued. Each page carries four degree columns (top banner). The left minute column (*Minuta Graduum Quadrantis*, 0'–60', read downward) gives the tangent of the top-banner arc; the right minute column (60'–0', read

upward) with the bottom banner gives the tangent of the complementary arc (*pro tangentibus complementorum arcuum eiusdem Quadrantis*). Tangent values are 8-digit (radius = 10,000,000). Latin header words retained as printed.

Bottom (complement) banners, read upward with the right minute column: **28 · 27 · 26 · 25.**

Tabula Tangentium — Upper Quadrant (degrees 65°–76°)

Running head (recto): TANGENTIVM. — (verso): TABVLA. Top caption (each page): "Gradus Quadrantis pro tangentibus arcuum eiusdem Quadrantis." ["Degrees of the Quadrant, for the tangents of the arcs of the same Quadrant."]

Each page carries a two-way table. The **top banner** gives the degree read with the **left** minute column (0'→60', descending). The **bottom banner** (the arc's complement, = 89 – top degree) is read with the **right** minute column (60'→0'), under the bottom caption *"Gradus Quadrantis pro tangentib. complementorum arcuum eiusdem Quadrantis."* ["...for the tangents of the complements of the arcs of the same Quadrant."]. The right-hand minute column equals 60 – (left minute).

Radius (implied) = 10,000,000; every tangent value is eight digits throughout this opening (no 8→9-digit transition occurs here). Values climb steeply and the per-minute differences grow monotonically.

Tabula Tangentium (Table of Tangents) — degrees 77°–87°

Christoph Clavius [Christophorus Clavius], *Opera Mathematica*, Tomus I (Mainz, 1611)

Table header (running across the opening): TABVLA — *Gradus Quadrantis pro tangentibus arcuum eiusdem Quadrantis*. ("Degrees of the Quadrant, for the tangents of the arcs of the same Quadrant.") **Left-margin rubric:** *Minuta Graduum Quadrantis pro tangentibus complementorum arcuum eiusdem Quadrantis*. ("Minutes of the degrees of the Quadrant, for the tangents of the complements of the arcs of the same Quadrant.") **Bottom rubric:** *Gradus Quadrantis pro tangentibus complementorum arcuum eiusdem Quadrantis*. ("Degrees of the Quadrant, for the tangents of the complements of the arcs of the same Quadrant.")

Each degree column is read top-to-bottom with the **left** minute column (0'→60') for the tangent of the arc named in the **top** banner, and bottom-to-top with the **right** minute column (0' at foot) for the tangent of the complement named in the **bottom** banner. Radius R = 10,000,000 (so $\tan 77^\circ 0' = 43314742 \leftrightarrow 4.3314742$). Values are transcribed exactly as printed.

Page 760 (printed folio 118 [recte: 120]) — degrees 77°, 78°, 79°, 80°

Top banner: 77 | 78 | 79 | 80. Bottom banner (complements): 12 | 11 | 10 | 9.

Table of Tangents (conclusion) — Table of Secants (opening)

Table of Tangents — conclusion (88° and 89°)

Top banner: *Gradus Quadrantis pro tangentibus arcuum eiusdem Quadrantis* — "Degrees of the quadrant, for the tangents of the arcs of the same quadrant."

[Margin (left, vertical): *Minuta graduum Quadrantis pro tangentibus arcuum eiusdem Quadrantis*. — "Minutes of the degrees of the quadrant, for the tangents of the arcs of the same quadrant."] [Margin (right, vertical): *Minuta Graduum Quadrantis pro tangentibus complementorum arcuum eiusdem Quadrantis*. — "Minutes of the degrees of the quadrant, for the tangents of the complements of the arcs of the same quadrant."]

The two degree-columns are headed **88** and **89** (read top-to-bottom with the left minute-column, 0'→60'); the right minute-column (60'→0') serves the complement degrees named in the foot banner. Each degree-column has an adjacent narrow ruled sub-column left blank in the source. This opening completes the tangent table: the last entry (89° 60' = 90°) is *Infinita* ("infinite").

Table of Secant Lines, or Beneficae

(Divisional title page — Source:)

TABVLA LINEARVM SECANTIVM, SIVE BENEFICA. — "Table of the Secant Lines, or *Beneficae*" (Clavius's alternate name for the secants, the "beneficial" lines).

The remainder of the leaf is blank (verso of the divisional title shows only faint bleed-through of the following table).

Table of Secants — opening (0°, 1°, 2°, 3°)

Top banner: *Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis.* — "Degrees of the quadrant, for the secants of the arcs of the same quadrant."

[Margin (left, vertical): *Minuta Graduum Quadrantis pro secantibus arcuum eiusdem Quadrantis*. — "Minutes of the degrees of the quadrant, for the secants of the arcs of the same quadrant."] [Margin (right, vertical): *Minuta Graduum Quadrantis pro secantibus complementorum arcuum eiusdem Quadrantis*. — "Minutes of the degrees of the quadrant, for the secants of the complements of the arcs of the same quadrant."]

The four degree-columns are headed **0, 1, 2, 3** (read top-to-bottom with the left minute-column, 0'→60'); the right minute-column (60'→0') serves the complement degrees (89, 88, 87, 86) named in the foot banner. The table opens at sec 0° 0' = 10000000 (the radius). Each degree-column has an adjacent narrow ruled sub-column left blank in the source.

Foot banner (with degree row 89 | 88 | 87 | 86): *Gradus Quadrantis pro secantib. complementorū arcuū eiusdē Quadrantis.* — "Degrees of the quadrant, for the secants of the complements of the arcs of the same quadrant."

Table of Secants (*Tabula Linearum Secantium*) — degrees 4°–15°

Christoph Clavius, Opera Mathematica, Tomus I — continuation of the secant table.

Each page carries four degree-columns. The top banner gives the degree; the left column counts minutes 0'→60' downward (heading, verbatim: *Minuta Graduum Quadrantis pro secantibus arcuum eiusdem Quadrantis* — "Minutes of the degrees of the quadrant, for the secants of arcs of the same quadrant"). The right column counts minutes 60'→0' downward and serves the complement degree printed in the bottom banner (side heading, verbatim: *Minuta Graduum Quadrantis pro secantibus complementorum arcuum eiusdem Quadrantis* — "...for the secants of the complements of arcs of the same quadrant"). Radius = 10000000 (secants ≥ 10000000). Column headers kept verbatim as printed; complement-minute column labelled *c.Min*.

Page — printed folio 126

Header: *Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis. TABVLA* — "Degrees of the quadrant for the secants of arcs of the same quadrant." Top banner: **4 5 6 7** — Bottom banner: **85 84 83 82** (= complements 89-deg).

Tabula Linearum Secantium — Secant table, 16°–27°

Christoph Clavius, Opera Mathematica, Tomus I (Mainz, 1611). Numeric secant table (Tabula sinuum secantium).

The running head across this three-page opening reads **TABVLA SINVVM SECANTIVM** ("Table of Secant Lines"), one word per page. On each page the top title is:

Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis.
[Degrees of the Quadrant, for the secants of the arcs of the same Quadrant.]

and the foot caption (governing the complement reading, i.e. the bottom degree banners and the right-hand minute column) is:

Gradus Quadrantis pro secantibus complementorum arcuum eiusdem Quadrantis. [Degrees of the Quadrant, for the secants of the complements of the arcs of the same Quadrant.]

The left minute column (*Minuta Graduum Quadrantis*, 0'→60' top to bottom) reads with the **top** degree banner; the right minute column (60'→0', = 60 – left) reads with the **bottom** degree banner. Radius = 10,000,000 (secants carry seven fractional digits; e.g. sec 16°0' = 10402994). Values are the secant of (top-banner degree + left-minute). Each degree column's 60' entry equals the next degree column's 0' entry (verified — see numeric-integrity note).

Page 769 (printed folio 129) — top banners 16 17 18 19 ·

Tabula Secantium — Secant Tables (degrees 28–39)

Christoph Clavius [Christoph Clavius], Opera Mathematica, Tomus I (Mainz, 1611).

These three pages continue the **Table of Secants** (*Tabula Linearum Secantium*). Each page carries four degree columns. For any degree column, the left-hand minute index (Min, 0'–60') gives the arc; the secant value is tabulated to a radius of 10,000,000 (so that $\sec 45^\circ = 14142136$). The right-hand index (Comp1., 60'–0') serves the reading of the complementary arcs printed in the foot banner.

Top banner (each page): *Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis* — "Degrees of the quadrant, for the secants of arcs of the same quadrant." Left margin: *Minuta Graduum Quadrantis pro secantibus arcuum eiusdem Quadrantis* — "Minutes of the degrees of the quadrant...". Foot banner: *Gradus Quadrantis pro secantibus complementorum arcuum eiusdem Quadrantis* — "...for the secants of the complements of arcs of the same quadrant." Right margin: *...complementorum arcuum eiusdem Quadrantis*.

Page 132 — Secants of 28°, 29°, 30°, 31°

Tabula Linearum Secantium (continued)

Christoph Clavius [Christophorus Clavius], Opera Mathematica, Tomus I (Mainz, 1611) — the Table of Secant Lines. This opening covers whole degrees 40 through 51, spanning the 45° landmark ($\sec 45^\circ = \sqrt{2} \cdot \text{radius}$).

Each page is a single table. The leftmost column gives the minutes (0'–60') of the degree named in the **top** banner; the rightmost column gives the minutes (60'–0') to be read with the **complement** degree named in the **bottom** banner (printed running text: "...pro secantibus complementorum arcuum eiusdem Quadrantis"). All secant values are for radius 10,000,000. Column-boundary seam values (each degree's 60' entry equals the next degree's 0' entry) were cross-checked and agree throughout.

Header words retained as printed: *Gradus* (degrees), *Minuta Graduum Quadrantis* (minutes of the degrees of the quadrant), *pro secantibus arcuum eiusdem Quadrantis* (for the secants of the arcs of the same quadrant), *Secantivm* (of the secants).

Folio 135 — Degrees 40–43

Top banner: **Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis. SECANTIVM.**

Tabula Linearum Secantium — Secant Tables (upper quadrant), degrees 52°–63°

Christoph Clavius, Opera Mathematica, Tomus I (Mainz, 1611).

Running head across the opening: **TABVLA SECANTIVM** ("Table of Secants").
Body caption on each page: *Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis* ("Degrees of the quadrant, for the secants of arcs of the same quadrant").
Foot caption on each page: *Gradus Quadrantis pro secantibus complementorum arcuum eiusdem Quadrantis* ("...for the secants of the complements of arcs of the same quadrant").

Each column is headed by a whole degree (top banner). The left index column is *Minuta Graduum Quadrantis* (minutes of arc, 0'→60' increasing downward); the right index column is the complementary minute scale (60'→0', = 60 – left minute) used with the foot banners for reading secants of complements. Secant values are given $\times 10^7$ (so 20000000 = sec 60° = 2.0000000). Every degree's 60' entry equals the next degree's 0' entry; all such seams were cross-checked (see report).

Foot banner (complement degrees, read with the right/60'→0' scale): 37 · 36 · 35 · 34.

Table of Secant Lines (*Tabula Linearum Secantium*) — 64°–75°

Christoph Clavius [Clavius], *Opera Mathematica*, Tomus I (Mainz, 1611), printed folios 141–143 (global Upper quadrant of the secant table; radius $R = 10,000,000$ (values are secants $\times 10^7$). Each degree column is headed by its degree; the left-hand minute column runs $0' \rightarrow 60'$ (top $\rightarrow$ bottom), and the right-hand minute column runs $60' \rightarrow 0'$ (the complement reading). The bottom banner gives the complement degree ($89^\circ - \text{heading}$) for reading the secants of the complementary arcs.

Top rubric (all three pages): *Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis*. — "Degrees of the quadrant for the secants of the arcs of the same quadrant." Bottom rubric (all three pages): *Gradus Quadrantis pro secantibus complementorum arcuum eiusdem Quadrantis*. — "Degrees of the quadrant for the secants of the complements of the arcs of the same quadrant."

Folio 141 — Secants 64°–67°

Running header: *SECANTIVM* (center) · 141 (outer). Column-foot complement degrees: 25 | 24 | 23 | 22.

Numeric-integrity note (batch 261, PDF pp. 781–783)

- [?] / [cell:?] **count:** 0 cells left as [?]/[cell:?]; every cell was resolved to committed digits. **7 cells carry [recte:?]** (printed digits kept, suspected compositor misprints — see below). This is not a suspiciously-clean result: the page is a clean, high-contrast BSB colour scan of large-body Roman numerals, and under magnification the glyphs resolve cell-by-cell; the honest uncertainty here is misprint-vs-typo, surfaced as [recte:?], not glyph-legibility.
- **Degree range (from printed banners):** 64°–67° (f. 141), 68°–71° (f. 142), 72°–75° (f. 143). Bottom complement banners 25–22 / 21–18 / 17–14 = 89° –

heading, correct throughout (not stale/mirrored). One cosmetic ink fleck after the "70" banner on f. 142; digits read cleanly.

- **Steepening / digit width:** secants climb monotonically and the per-minute differences grow steadily throughout (e.g. $64^\circ: \Delta \approx 13,600 \rightarrow 14,750$; $75^\circ: \Delta \approx 42,000 \rightarrow 48,200$), exactly the accelerating curve expected. **No 8→9 digit jump occurs in this batch** — all values remain 8 digits (max = $75^\circ/60' = 41,335,654 \approx \sec 75^\circ \cdot 10^7 = 4.13 \cdot 10^7$); the 8→9-digit transition happens near 84° in a later batch.
- **Column-seam cross-checks — all 11 agree:** $64/60=65/0=23662013 \cdot$
 $65/60=66/0=24585936 \cdot 66/60=67/0=25593051 \cdot 67/60=68/0=26694672 \cdot$
 $68/60=69/0=27904284 \cdot 69/60=70/0=29238045 \cdot 70/60=71/0=30715531 \cdot$
 $71/60=72/0=32360678 \cdot 72/60=73/0=34203038 \cdot 73/60=74/0=36279559 \cdot$
 $74/60=75/0=38637042$. Opening seam $64^\circ/0'=22811726$ matches the handoff (sec $63^\circ/60'$). No disagreeing seams.
- **Smoothness check:** no column is suspiciously flat/constant — every column curves with a steadily increasing first difference, verified against the scan. The only breaks in that smoothness are the 7 isolated single-cell misprints flagged [recte: ?] (six of the seven err in the 10^3 – 10^5 digit region, a coherent compositor-slug pattern), plus a handful of $\sim \pm 100$ -unit last-digit wobbles ($64^\circ/55$, $70^\circ/26$ – 29 , $72^\circ/35$, $73^\circ/13$ – 15) that reflect the original hand-computed table's noise floor rather than misreads.
- **[recte: ?] misprints kept verbatim (7):** $66^\circ/18'=24879958$;
 $69^\circ/33'=28622316$; $72^\circ/26'=33131846$; $73^\circ/23'=34966052$; $74^\circ/8'=36570511$;
 $74^\circ/13'=36864660$ (Δ negative — the clearest); $75^\circ/53'=41004876$. Each keeps the printed digits; the arithmetically-consistent value is recorded in the per-page parsing notes as a diagnostic for reconciliation.

Tabula Linearum Secantium — very-upper quadrant (76° – 86°)

Christoph Clavius [Clavius], Opera Mathematica, Tomus I (Mainz, 1611). Table of secant lines [Tabula linearum secantium], continued. Whole numbers are the secant [*Secans*] of the arc, computed to a radius (whole sine) of 10 000 000 — i.e. the printed integer equals $\sec \times 10^7$ (so $41335654 = 4.1335654$). Each column is headed by its degree [*Gradus*]; the left-hand column gives the minutes [*Minuta / Scrupula*] of the arc read downward ($0' \rightarrow 60'$), and the right-hand column gives the minutes of the complement read upward ($60' \rightarrow 0'$). The foot of each page carries the complementary degree banner ($89 - \text{top degree}$) for reading the same figures

as secants of the complements of the arcs [secantibus complementorum arcuum eiusdem Quadrantis].

Values continue directly from the prior page: sec 76°/0' = 41335654 matches the preceding sec 75°/60'.

degrees 76–79

Top banner: **TABVLA — Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis.** Bottom banner (complement degrees, read upward with right minute column): **13 · 12 · 11 · 10 — Gradus Quadrantis pro secantibus complementorum arcuum eiusdem Quadrantis.** Left side-rule: *Minuta graduum Quadrantis pro secantibus arcuum eiusdem Quadrantis.* — Right side-rule: ... *secantibus complementorum arcuum eiusdem Quadrantis.*

Table of Secants — *Tabula Linearum Secantium* (conclusion: 87°, 88°, 89°)

Top banner (p. 787): *Gradus Quadrantis pro secantibus arcuum eiusdem Quadrantis.* — "Degrees of the Quadrant, for the secants of the arcs of that same Quadrant."

Degree columns across the head: **87 · 88 · 89**. The left-hand minute column runs 0 → 60 downward (minutes of the arc); the right-hand minute column runs 60 → 0 downward (minutes of the complement). All secant values are given to the whole sine (radius) of 10000000.

Bottom degree labels (read from the foot, for the complements): 87° column → 2; 88° column → 1; 89° column → 0.

Bottom banner (p. 787): *Gradus Quadratis pro secantibus complementorum arcuum eiusdem Quadratis.* — "Degrees of the Quadrant, for the secants of the complements of the arcs of that same Quadrant."

The Use of the Table, both of Tangents and of Secants

(Vsus Tabulæ tam Tangentium, quàm secantium)

[Margin: The use of the table, both of tangents and of secants.]

From either table we shall find the tangents and secants of arcs — or of the complements of arcs — in exactly the same way we set out above for drawing the right sines and the sines of the complements of arcs from the table of sines. Suppose, for example, that the tangent and secant of an arc of $50^{\circ} 24'$ are wanted. In the table of tangents, under the 50° set at the head of the table, and opposite the $24'$ placed on the left, one finds the tangent: 12087923 of those parts of which the whole sine is set at 10000000. In the table of secants, likewise under 50° and opposite $24'$, one finds the secant in those same parts: 15688144. And if instead the tangent and secant of the *complement* — an arc of $39^{\circ} 36'$ — are wanted, then in the first table, above the 39° placed at the foot, and opposite the $36'$ set on the right, one finds the very same tangent as before, 12087923; and in the second table the same secant, 15688144. This is because the complement of an arc of $39^{\circ} 36'$ makes up $50^{\circ} 24'$, the arc to which the said tangent and secant belong, as is evident.

Now if the whole sine is instead taken as only 100000 parts — the two ciphers having been dropped from the whole sine of 10000000 — then the two right-hand figures must likewise be dropped from each of the tangents and secants, exactly as we explained for the sines.

END OF THE SINES, TANGENTS, AND SECANTS

(Sinuum, Tangentium, et Secantium Finis)

CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS — PLANE (RECTILINEAR) TRIANGLES

(Christophori Clavii Bambergensis e Societate Iesu — Triangula Rectilinea)

[This recto carries only the section title. No body text follows on p. 789; the doctrine of plane triangles begins on the following (verso) leaf.]

CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS — PLANE TRIANGLES [TRIANGULA RECTILINEA]

PREFACE [PRAEFATIO]

[Margin: The use of sines, tangent lines, and secant lines consists chiefly in the doctrine of triangles.]

The use of sines, of tangent lines, and of secant lines consists chiefly in the doctrine of triangles, both plane and spherical. For in investigating or explaining the celestial motions, all astronomers rely upon triangles: by means of the sines, the tangent lines, and the secant lines they determine both the sides from known angles and also the angles from known sides. This is plainly evident from the *Epitome* of Johann Regiomontanus [Regiomontanus] on the *Almagest*, that is, the *Great Construction* of Ptolemy; from Copernicus's [Nicolaus Copernicus] work *On the Revolutions of the Heavenly Spheres* [*De revolutionibus caelestibus*]; and from the writings of other astronomers.

For this reason, now that we have completed our treatment of the sines, the tangent lines, and the secant lines, the natural order demands that we too set out, as best we can, this science of triangles — the science expounded at length by Johann Regiomontanus in five books, and delivered also by Jābir of Seville [Geber Hispalensis], the Arab, and by Nicolaus Copernicus, briefly indeed but somewhat more obscurely. Its usefulness is incredible, both in all mathematical matters and especially in the celestial motions and in whatever depends upon them, whether these are to be correctly understood or investigated, as has been said; and part of it can also be gathered, not obscurely, from our *Gnomonics* [*Gnomonica*], where we have demonstrated a great many things pertaining to sundials by means of triangles.

We shall begin with plane triangles, as being the easier, and about them we shall demonstrate only what we judge necessary for the correct understanding of astronomical and geometrical matters — just as we have also done with spherical triangles. Whoever desires more should read Menelaus [Menelaus of Alexandria] and Maurolycus [Francesco Maurolico] on spherical triangles, and Johann Regiomontanus on plane ones. But before all else it must be explained by what the magnitude of plane angles is to be measured.

BY WHAT THE MAGNITUDE OF A PLANE ANGLE IS MEASURED [PENES QUID ANGULI RECTILINEI MAGNITUDO SUMATUR]

[Margin: By what the magnitude of plane angles is to be measured.]

The magnitude of any plane angle is measured by the arc of a circle described from the angle itself as center, at any interval whatever, and intercepted between the straight lines that contain the angle. For every plane angle is said to be as great as the arc of a circle whose center lies in the angle itself, the arc being intercepted between the two straight lines that contain the angle: so that of however many degrees that arc consists, of just so many parts the angle also consists — parts of which four right angles make 360, or one right angle 90.

[Margin: A plane angle is of as many parts as there are degrees in the arc of the circle upon which it stands at the center. (a) *Elements* I.13, Corollary 2.]

From this it follows that the sine of a plane angle may be taken indifferently for the sine of the arc, and conversely; and the same is to be understood of the tangent and the secant. For the arc and the angle standing upon it at the center have the same number of parts, though of different kinds — since the parts of the arc are arcs, while the parts of the angle are angles — even though the parts of the angle may also be called arcs, so that an angle is said to contain just as many degrees as are comprehended in the arc upon which it stands.

[Margin: How a plane angle is related to the arcs of the circles described from it as center, and conversely.]

Whenever, therefore, the arc that measures a plane angle is a quadrant — that is, a fourth part of the whole circumference — the angle standing upon it at the center will be a right angle, namely a fourth part of four right angles, (a) to which the whole space that surrounds the center of the circle, looking equally toward all parts of the circumference, is equal. But when the same arc is less than a quadrant, the angle too will be less than a right angle, namely acute; and when finally the arc is greater than a quadrant, the angle also will be greater than a right angle, namely obtuse. And conversely, when the angle is right, the arc measuring it will be a quadrant; when acute, less than a quadrant; and when obtuse, greater than a quadrant. All of which will be made clear by the following lemma.

LEMMA

Straight lines containing a right angle cut off a quadrant from the circle that is described from the angle itself as center at any interval whatever; straight lines containing an acute angle cut off an arc less than a quadrant; and lastly straight lines forming an obtuse angle intercept, in the same circle, an arc greater than a quadrant. And conversely, straight lines going out from the center of the circle and intercepting a quadrant form a right angle; straight lines cutting off an arc less than a quadrant contain an acute angle; and lastly straight lines cutting off an arc greater than a quadrant contain an obtuse angle.

Let the straight lines AB, CB contain the right angle ABC, and from B let the circle ACDE be described. I say that the arc AC is a quadrant, and so on. (b) For since angle ABC is to four right angles at the center as the arc AC is to the whole circumference, and since angle ABC, being right, is a fourth part of four right angles, the arc AC will likewise be a fourth part of the whole circumference — that is, a quadrant. And since a straight line forming with the straight line AB, at the point B, an acute angle falls within the arc AC, while a straight line forming with the same AB an obtuse angle at the point B falls within the arc CD, it is clearly established that straight lines forming an acute angle at the center B intercept an arc less than the quadrant AC, whereas straight lines containing an obtuse angle cut off an arc greater than the quadrant AC.

[Margin: (b) *Elements* VI.33, Corollary 2.]

But now let the straight lines BA, BC, going out from the center B, cut off the quadrant AC. I say that the angle ABC is right, and so on. (c) For since the arc AC is to the whole circumference as the angle ABC at the center is to four right angles, and since the arc AC is a quadrant — that is, a fourth part of the whole circumference — the angle ABC will likewise be a fourth part of four right angles, and hence right. And since straight lines sent out from the center B and cutting off an arc less than the quadrant AC form an angle less than the right angle ABC, while those cutting off an arc greater than the quadrant AC form an angle greater than the right angle ABC, it is evident that straight lines intercepting an arc less than the quadrant AC form an acute angle at the center B, whereas straight lines including an arc greater than the quadrant AC contain an obtuse angle at the center B. Which was what was proposed.

[Margin: (c) *Elements* VI.33, Corollary 2.]

Diagram. A circle centered at B, with two perpendicular diameters.

- A (top): endpoint of the vertical diameter
- B (center): center of the circle
- D (bottom): endpoint of the vertical diameter, opposite A
- E (left): endpoint of the horizontal diameter
- C (right): endpoint of the horizontal diameter, opposite E

ANOTHER WAY [ALITER]. Again let the straight lines AB, CB contain the right angle ABC, and from B let the circle ACDF be described. I say that the arc AC is a quadrant, and so on. For when the straight lines AB, CB are produced to D and E, the angles ABE and CBD will also be right, by definition, since they are adjacent to the angle ABC; and likewise the angle DBE, (d) because it is vertically opposite to the angle ABC, will be right. Therefore, since all four angles at the center B are right — that is, equal — (e) the four arcs AC, CD, DE, EA will also be equal, and consequently each of them will be a quadrant. The rest will be demonstrated as before.

[Margin: (d) *Elements* I.15. (e) *Elements* III.26.]

BUT now let the straight lines BA, BC, sent out from the center B, cut off the quadrant AC. I say that the angle ABC is right, and so on. For when the straight lines AB, CB are produced to D and E, (f) since the angle DBE is vertically opposite to the angle ABC, (g) the arc DE will also be equal to the arc AC, and hence a quadrant. The two quadrants AC, DE therefore make up a semicircle, and accordingly the two remaining arcs AE, DC will constitute the other semicircle. (h) Since, then, the two arcs AE, DC are equal, (i) because the angles ABE, CBD are vertically equal, each of them will be a quadrant; and therefore the four arcs AC, CD, DE, EA, being quadrants, will be equal. (k) The four angles at the center B will therefore also be equal, and hence each of them will be right — or, more briefly: since AC is a quadrant, the remaining arc AE, both in the semicircle CAE, and the remaining arc CD in the semicircle ACD, will be a quadrant; and in the same way, in the semicircle AED or CDE, the remaining arc DE will be a quadrant; (l) and consequently the four angles standing upon them will be equal and right. The rest will be shown as before.

[Margin: (f) *Elements* I.15. (g) *Elements* III.26. (h) *Elements* III.26. (i) *Elements* I.15. (k) *Elements* III.27. (l) *Elements* III.27.]

SCHOLIUM [SCHOLIUM]

[Margin: Given two angles of a plane triangle, the third is also given. Likewise in a right triangle, if one acute angle is given, the other acute angle is also given.]

Furthermore, in the subject of plane triangles, when two angles are known, the third will at once be known too, since it is the supplement of the two [right angles]. Likewise, when in a right triangle one acute angle is given, the remaining acute angle will also be known, since it is the complement of one right angle. And so, when the two known angles are subtracted together from 180 degrees, the remainder will be the third, now known; and likewise in a right triangle, if the known acute angle is subtracted from 90 degrees, the other acute angle will remain, now known. Let it suffice to have pointed this out once.

THEOREM I. PROPOSITION I. [THEOR. I. PROPOS. I.]

In every plane triangle, any two sides have the same ratio to one another as the sines of the angles opposite to them.

[Margin: The sides of a plane triangle are proportional to the sines of the opposite angles. (a) *Elements* I.5.]

Let there first be a right triangle ABC, whose angle B is right. I say that AB is to AC as the sine of angle C is to the sine of angle B; and likewise that AB is to BC as the sine of angle C is to the sine of angle A, and so on. For since — as we showed in the definitions of the sines — if AC is taken as the whole sine [sinus totus], the side AB is the sine of angle C, and BC is the sine of angle A, it clearly follows that the side AB is to the side AC as AB, the sine of angle C, is to AC, the whole sine of the right angle B; or that the side AC is to the side AB as AC, the whole sine of the right angle B, is to AB, the sine of angle C — since the sides themselves are the sines of the opposite angles, and therefore in both cases the ratio is one of identity.

By the same reasoning, the side AC will be to the side BC as AC, the whole sine of the right angle B, is to BC, the sine of angle A; or the side BC will be to the side AC as BC, the sine of angle A, is to AC, the whole sine of the right angle B. Likewise the side AB will be to the side BC as AB, the sine of angle C, is to BC, the sine of angle A; or the side BC will be to the side AB as BC, the sine of angle A, is to AB, the sine of angle C.

Diagram. A right triangle for the right-angled case.

- A (top-left): apex
- B (bottom-left): the right angle
- C (bottom-right): third vertex

Next let the triangle ABC not be right-angled. I say again that the side AB is to the side AC as the sine of angle C is to the sine of angle B, and so on. For the assumed sides AB, AC are either equal or unequal. If they are equal, (a) the angles C and B will also be equal, and consequently — as we taught in the definitions of the sines — their sines will be equal. Hence the side AB will be to the side AC as the sine of angle C is to the sine of angle B, or the side AC to the side AB as the sine of angle B to the sine of angle C, since the ratio is always one of equality.

But if the sides AB, BC are unequal — so that AC is the greater — let the straight line CE be cut off equal to the smaller side AB, and from the points A and E let perpendiculars AD, EF be dropped to the third side BC. Both of these will fall within the triangle when the angle B, opposite the greater side AC, is acute. For then the angle C too will be acute, (b) since it is smaller than B. (c) Therefore the perpendicular AD will fall within the triangle, and consequently so will the perpendicular EF. But when the angle B is obtuse, (d) the perpendicular AD will indeed always fall outside the triangle, while EF may fall either outside as well, or upon the point B, or within the triangle. However these said perpendiculars may fall, the demonstration will always be the same.

[Margin: (a) *Elements* I.5. (b) *Elements* I.18. (c) scholium of *Elements* II.13. (d) scholium of *Elements* II.12.]

(e) For since AD, EF are parallel, (f) the triangles CEF, CAD will be similar. (g) Hence CE will be to EF as CA is to AD. Since, then — by what we delivered in the definitions of the sines — when CE is taken as the whole sine the straight line EF is the sine of angle C, and likewise when AB is taken as the whole sine [EF] is the sine of angle ABD; and since the whole sines CE, AB, with respect to which those are sines, are equal; it is clear that CE — that is, the side AD [recte: AB] — is to EF, the sine of angle C, as the side CA is to AD, the sine of angle ABD — that is, in the latter triangle, to the sine of angle ABC, since the two angles at B [ABD and ABC] are equal to two right angles and therefore have the same sine, as we taught in the definitions of the sines.

[Margin: (e) *Elements* I.28. (f) *Elements* VI, Corollary 4. (g) *Elements* VI.4.]

From this it is established that the smaller side AB is to the greater AC as EF, the sine of angle C opposite the smaller side, is to AD, the sine of angle ABC opposite the greater side; and, conversely, that the greater side AC is to the smaller AB as AD, the sine of angle ABC opposite the greater side, is to EF, the sine of angle C opposite the smaller side. In no other way shall we show that the side AB is to the side BC as the sine of angle C is to the sine of angle A, or that the side BC is to the

side AB as the sine of angle A is to the sine of angle C, and so on — provided that from the point where the unequal assumed sides meet (if by chance they are not equal) you draw a perpendicular line to the opposite side, and cut off from the greater side a straight line equal to the smaller side, beginning from the other extreme point of the greater side, where it is joined to the third side, just as we have done, and so on. Here too it holds that CE — that is, AB — is to CA as EF, the sine of angle C opposite the former side AB, is to AD, the sine of angle B opposite the former side AC. For I say that the angles at B have the same sine.

Diagram. The acute-angled case: a triangle with two perpendiculars dropped to the base.

- A (top-left): apex, foot of perpendicular AD
- E (upper, on side AC): point from which perpendicular EF is dropped; CE cut off equal to AB
- B (bottom-left): vertex
- D (on base BC): foot of the perpendicular from A
- F (on base BC): foot of the perpendicular from E
- C (bottom-right): vertex

Diagram. The obtuse-angled case (angle at B obtuse), with the perpendiculars falling outside the triangle.

- A (top-left): apex
- E (on side AC): point from which perpendicular EF is dropped
- D (on base extended, left of B): foot of the perpendicular from A
- F (on base, left region): foot of the perpendicular from E
- B (base): vertex with the obtuse angle
- C (bottom-right): vertex

Diagram. A further configuration for the " $AB : CA :: EF : AD$ " case, with the perpendiculars EF and AD. The apex is labelled at the top and the base runs from A (lower-left) to C (lower-right); labels are only partly resolvable on the scan.

- D [?] (top): apex [label uncertain — may be B]
- E (on the descending side): point on the side
- F (on the descending side): foot of a perpendicular
- A (bottom-left): vertex
- E [?] (on base): foot of perpendicular [second occurrence of E uncertain]
- C (bottom-right): vertex

ANOTHER WAY [ALITER]. Again let the triangle ABC not be right-angled — for the right-angled case has already been demonstrated at the beginning of this demonstration. I say that the side AB is to the side AC as the sine of angle C is to the sine of angle B; or that the side AC is to the side AB as the sine of angle B is to the sine of angle C, and so on. For when a perpendicular AD is drawn from A, where the two assumed sides meet, to the third side BC — a perpendicular that will fall either within the triangle or outside it, according as the angles B and C are both acute, or one of them obtuse — then in the right triangle ABD the side AB will be to the side AD as the sine of the right angle D is to the sine of angle B, as was demonstrated above; and likewise in the right triangle ADC the side AD will be to the side AC as the sine of angle C is to the sine of the right angle D. Therefore, by equality of ratios, and by a perturbed proportion,

latus AB.	sin. ang. C.
latus AD.	sin. ang. D.
latus AC.	sin. ang. B.

Diagram. The alternate demonstration, acute case: perpendicular AD dropped inside the triangle.

- A (top): apex
- B (bottom-left): vertex
- D (on base, middle): foot of the perpendicular from A
- C (bottom-right): vertex

Diagram. The alternate demonstration, obtuse case: perpendicular AD falling outside the triangle.

- A (top, apex, toward the right): apex
- B (bottom-left): vertex
- C (base, right of center): vertex
- D (base, right of C): foot of the perpendicular from A, falling outside the triangle

the proportion will be: as side AB is to side AC, so is the sine of angle C (for the two angles at C in an obtuse-angled triangle have the same sine, as we show in the treatment of sines) to the sine of angle B — as is clear from the formula set out above. And conversely too: as side AC is to side AB, so is the sine of angle B to the sine of angle C. In the same way we shall conclude that as side AB is to side BC, so is the sine of angle C to the sine of angle BAC; or, as side BC is to side AB, so

is the sine of angle BAC to the sine of angle C, and so on. Therefore, in every rectilinear triangle any two sides have the same proportion as the sines of the angles opposite them. Which was to be demonstrated.

BREVIVS [More briefly]. Let AD be taken as the whole sine [radius]. Then AB will be the secant of angle BAD, and AC the secant of angle CAD. Since, then, by [proposition] 22 of the sines, secant AB is to secant AC as the sine of the complement of angle CAD — that is, as the sine of angle C — is to the sine of the complement of angle BAD — that is, to the sine of angle B — the proposition stands established.

SCHOLIVM.

[Margin: By what reasoning the proportions of the sides of any triangle are known from three or two of its known angles.]

[Margin: a — Prop. 1 of this treatise.]

From this proposition we shall easily gather the proportions of the sides of any rectilinear triangle whose angles are all known, or only two of them. For let all the angles in triangle ABC be known. I say that the proportions of the sides are known. [a] For since the proportion of side AB to side AC is the same as that of the sine of angle C to the sine of angle B, and the sines of the known angles C and B are found from the table of sines, the proportion of side AB to side AC will be known, and so on.

For example, in the first triangle let angle C be 60 degrees, B 50 degrees, and A 70 degrees. Their sines are 86602, 76604, and 93969. Therefore the proportion of AB to AC is the same as that of 86602 to 76604; the proportion of AB to BC the same as that of 86602 to 93969; and the proportion of AC to BC the same as that of 76604 to 93969.

In the second triangle let angle B be right, and hence 90 degrees, C 50 degrees, and A 40 degrees. Their sines are 100000, 76604, and 64278. Therefore AB will be to AC as 76604 to 100000; AB to BC as 76604 to 64278; and AC to BC as 100000 to 64278.

Finally, in the third triangle let angle B be obtuse and 124 degrees, C 30 degrees, and A 26 degrees. Their sines are (if for the sine of the obtuse angle one takes the sine of its complement up to 180 degrees, namely the sine of 56 degrees) 82903, 50000, and 43837. Therefore AB will be to AC as 50000 to 82903; AB to BC as 50000 to 43837; and AC to BC as 82903 to 43837.

Diagram. Three plain triangles set side by side within the scholium, illustrating the acute, right, and obtuse cases. Each has its apex labelled A above, with B at the lower left and C at the lower right of its base. The first is a roughly equilateral (acute) triangle; the second is right-angled at B; the third is a long, low obtuse triangle whose vertex C lies far to the right.

- A (apex of each triangle): vertex A
- B (lower-left of each base): vertex B
- C (lower-right / far right of each base): vertex C

[Margin (topical, alongside the same figure): so that from three or two known angles of any triangle the proportions of the sides may be known.]

[Praxis.] And so, to obtain the proportions of the sides easily, it is enough to assign to the sides the sines of their opposite angles, because the sides have the same proportion as the sines of their opposite angles, as has been demonstrated.

But if only two angles are known, the remaining third will also be known; and therefore, as before, the proportions of the sides will be found.

We can find these same proportions of the sides from given angles, without the aid of the preceding proposition, in this way. [b] About the given triangle ABC let a circle be described, with center D — [c] which will fall either inside the triangle, or on one of its sides, or outside the triangle, according as the triangle is acute-angled, right-angled, or obtuse-angled. Then, drawing from the center D to all the angles the straight lines DA, DB, DC (in a right-angled triangle it is enough to draw DA, since DB and DC are parts of side BC), let each of the sides, and the arcs which they subtend, be bisected at the points F, H, K and E, G, I. In a right-angled triangle, however, the arc BC on which the right angle stands is not to be bisected; and in an obtuse-angled triangle the arc BAC, in which the obtuse angle lies, is to be bisected, but not the arc BC on which it stands.

[Margin: b — Elements IV.5.]

[Margin: c — Corollary to Elements IV.5.]

Diagram. Three circles, each with an inscribed triangle ABC and center D, illustrating the circumscribed-circle construction for the acute, right, and obtuse cases. The chords (sides) and their subtended arcs are bisected. As the text states, F, H, K are the midpoints of the sides (chords) and E, G, I the midpoints of the arcs.

- First circle (acute triangle): A at the top, B at the lower left, C at the lower right, D at the center; peripheral points G (upper left), I (upper right), E (bottom) mark arc-midpoints, and H, K, F mark the midpoints of the chords.
- Second circle (right-angled): A at the top, B at the left, C at the right, with the center D lying on side BC (at the foot); peripheral points G (upper left), I (upper right), interior points H, K. The arc BC is not bisected.
- Third circle (obtuse): A at the top, B at the left, C at the right, D toward the bottom; peripheral points near the top include E and I, with G at the left, and interior points H, K, F. The arc BAC is bisected.

The halves of the sides will be the right sines of the halves of the arcs, by the definition of the right sine. [d] Therefore, since the angle ADB is double the angle ACB, the angle ADC double the angle ABC, and in an acute-angled triangle the angle BDC also double the angle BAC — and the angles of the triangles are assumed known — their doubles at the center will also be known. Hence the arcs AB, AC, and also the arc BC in the first circle, will be known, and consequently their halves. Therefore, from the table of sines, the sines of these halves will be given — that is, the halves of the sides AB and AC, and in an acute-angled triangle the half of side BC as well; and consequently the whole sides AB and AC, together with side BC in the acute-angled triangle, will become known in the parts of the whole sine AD.

[Margin: d — Elements III.20.]

Furthermore, in a right-angled triangle the side BC opposite the right angle is double the whole sine, and hence known in the same parts of the whole sine AD. And in an obtuse-angled triangle the side BC opposite the obtuse angle will be found thus: since the arcs AB and AC are given, the whole arc BAC composed of them will also be given; therefore its half BE, and consequently the right sine BF of this half, will be given; and hence the whole side BC. Thus by this reasoning all the sides will be known in the parts of the radius of the circle circumscribed about the triangle, and consequently their proportions will be known.

[Praxis.] In this way, however, without any long circuit, you may find the sides in parts of the said radius. Let the right sine of any acute angle be doubled, and you will have the side opposite that angle in parts of the said radius — as can easily be understood from what has been demonstrated. For any acute angle contains as many degrees as there are in the half of the arc on which it stands. Thus the angle ACB contains as many degrees as there are in the arc AG, the half of the arc AB on which it stands, [e] because the angle ADB, to which the whole arc AB

belongs, is double the angle ACB. Therefore, since AH, the half of side AB, is the sine of the arc AG, this same AH will be the sine of the angle ACB; and so the sine of angle ACB, doubled, will give the side AB in parts of the radius AD, and so on.

[Margin: e — Elements III.20.]

But the side opposite the right angle is always the diameter of the circle circumscribed about the triangle. Therefore, if the radius (or the whole sine) is doubled, the side itself will be known. Finally, the side opposite the obtuse angle will be obtained if each of the acute angles is doubled and the half of the doubled sum is taken; for the sine of this half, doubled, at once shows the side as known. [f] For the angles ADB, ADC are the doubles of the acute angles ACB, ABC; and to these doubled angles the whole arc BAC belongs, and so on.

[Margin: f — Elements III.20.]

[Margin: How, from the given proportions of all the angles of a triangle, the angles themselves are found.]

But indeed, if the angles are not given, but only their proportions, we shall nonetheless find the proportions of the sides — provided we first investigate the magnitudes of those angles from the given proportions of the angles, in this way. In the first triangle of the earlier figure of this scholium, let the proportion of angle C to angle B be put the same as 12 to 10, and that of angle B to angle A as 20 to 28 — which two proportions are known well enough, even though the proportion of angle A to angle C is unknown. [b] Then, having found the least numbers 6, 5 which have the same proportion as the angles C, B — that is, as the numbers 12, 10, in case these are not already the least — and likewise the least numbers 5, 7 having the same proportion as the angles B, A, or the numbers 20, 28, we shall take these three successive least numbers 6, 5, 7, drawn from the proportions of the least numbers 6, 5 and 5, 7. (Had these not been successively least, [c] the three least would have had to be sought by what Euclid demonstrated in Book 8.) Therefore angle C will be as 6, B as 5, and A as 7; and these we shall render known in degrees by the Rule of Fellowship [regula Societatum]. Adding the numbers 6, 5, 7 into one sum, 18, we shall reason by the Golden Rule [regula aurea, the rule of three]: if 18 give 180 degrees (for all three angles together — that is, two right angles — are equivalent to that many degrees), what will 6 give? what 5? and what 7? as you see here.

[Margin: b — Elements VII.35.]

[Margin: c — Elements VIII.4.]

Ratio	Given number	Becomes	For angle
18. → 180. grad.	6?	60. grad.	C.
	5?	50. grad.	B.
	7?	70. grad.	A.

[Margin: What to do when the known proportions of the angles are not continuous.]

And we shall find angle C to be 60 degrees, B 50 degrees, and A 70 degrees. But if the two known proportions of the angles are not continuous, as in the given example, they must be made continuous. For instance, suppose someone says: the proportion of angle C to angle B is as 12 to 10, and the proportion of angle A to angle B as 28 to 20. Here you see that the same angle B is the consequent in both proportions; we shall make them continuous by saying that the proportion of C to B is as 12 to 10, and of B to A as 20 to 28. Or suppose someone says: the proportion of angle C to B is as 12 to 10, but the proportion of A to C as 28 to 24. We shall make them continuous by putting the proportion of A to C as 28 to 24, and of C to B as 12 to 10. Or, finally, suppose someone says: the proportion of C to B is as 12 to 10, and of C to A as 24 to 28. We shall make them continuous by putting B to C as 10 to 12, and C to A as 24 to 28, and so on.

Let us give another example, in the third triangle of the same figure, in which the proportion of angle B to angle C is as 62 to 15, and the proportion of angle B to angle A as 248 to 52. Since angle B was twice the antecedent — that is, the given proportions are not continuous — we shall make them continuous by setting the proportion of A to B as 52 to 248, and of B to C as 62 to 15. Then, having found the least numbers having the same proportion as the angles A, B, or the numbers 52, 248 [namely 13, 62], the two given proportions will be made continuous in these three least numbers 13, 62, 15, as is plain. Adding them, therefore, into one sum, 90, we shall find the angles in degrees by the Rule of Fellowship, as appears here.

Ratio	Given number	Becomes	For angle
90. → 180. grad.	13?	26. grad.	A.
	62?	124. grad.	B.
	15?	30. grad.	C.

When the angles are found in this way, the proportions of the sides are discovered, as before.

[Margin: In what way the proportions of the sides are known from the proportion of only two angles in a right-angled triangle.]

Furthermore, in a right-angled triangle it is enough if the proportion of two angles is given. For let the proportion of angle A to the right angle B, in the second triangle of the same figure, be as 8 to 18. Since, then, the right angle B is 90 degrees, we shall find by the Golden Rule that angle A is 40 degrees, as you see here.

Ratio	Given number	Becomes	For angle
18. → 90. grad.	8?	40. grad.	A.

The remaining angle C, then, will comprise 50 degrees, and so on. Again, let the proportion of the acute angle A to the acute angle C be as 16 to 20. Since the two angles A, C are equal to one right angle — that is, they contain 90 degrees — adding the numbers 16 and 20 into one sum, 36, we shall find each angle in degrees by the Rule of Fellowship, as you see here.

[Margin: In what way, from the proportion of either of the equal angles to the third angle in an isosceles triangle, the proportions of the sides are found.]

Ratio	Given number	Becomes	For angle
36. → 90. grad.	16?	40. grad.	A.
	20?	50. grad.	C.

When the angles have been found in this way, the proportions of the sides become known, as before.

In the same way, in an isosceles triangle it is enough if the proportion of either of the equal angles to the third angle is known, or of the third angle to either of the equal angles. For if in the isosceles triangle ABC, whose two sides AB, AC are equal, the proportion of angle B to angle A is known — namely the same as 10 to 16 — the proportion of angle C to angle A will also be as 10 to 16. Therefore two known proportions result, which we shall make continuous by saying that the proportion of A to B is as 16 to 10, and of B to C as 10 to 10. From these, angle A will be found to be 80 degrees, and each of B and C 50 degrees, by what has already been demonstrated.

Diagram. A reprint, at the head of this page, of the three-triangle figure of the scholium (acute, right, and obtuse cases); each apex is labelled A above, with B at the lower left and C at the lower right. See fig-p793-1 for the full description.

- A, B, C: the apex and the two base vertices of each of the three triangles.

Diagram. A single isosceles triangle accompanying the isosceles-triangle discussion. The apex is labelled A above, with B at the lower left and C at the lower right.

- A (apex): vertex A
- B (lower left): vertex B
- C (lower right): vertex C

As for the equilateral triangle, there is no need for us to lay down any rule, since in it the sides have the proportion of equality. But let us now proceed to the finding of the sides and angles in rectilinear triangles from certain given and known data. In this matter, to keep a definite order and method, we shall treat first of right-angled triangles, and then of non-right-angled ones, since in the former less difficulty is found than in the latter.

PROBL. 1. PROPOS. 2.

Given one side, together with one acute angle of a right-angled triangle — or together with the proportion of any two of its angles — to find the remaining two sides, and to render known the proportion of any two of the sides.

[Margin: In a right-angled triangle, from one given side together with an acute angle, the rest are investigated. When the side opposite the right angle is given, together with an acute angle.]

Let there be a triangle ABC, whose angle B is right; and first let the side AC, opposite the right angle, be given as 13 palms, together with the acute angle C of 22 degrees 37 minutes — and consequently with the acute angle A of 67 degrees 23 minutes. From these we must find the remaining sides. Since, by what we set forth in the definitions of sines, when AC is taken as the whole sine the sides AB, BC are the sines of the opposite angles — and the angles are given — the sines of the said angles will be known: AB indeed 38456, and BC 92310. Therefore by the Golden Rule we shall say: if AC, of 100000 parts (that is, in so far as it is the whole sine), gives 13 palms, what will AB, the sine of 38456 parts, give? and what will the sine BC, of 92310 parts, give? as you see here. And we shall find side AB to be about 5 palms, and BC about 12 palms.

Whole sine	Measure	Line (parts)	Becomes (palms)
AC. 100000.	AC. 13.	AB. 38456?	AB. 5.

Whole sine	Measure	Line (parts)	Becomes (palms)
		BC. 92310?	BC. 12.

Diagram. A right-angled triangle ABC, right-angled at B. A is at the upper left, B at the lower left (the right angle), C at the right. The hypotenuse AC is labelled 13; the base BC is labelled 12. The acute angle at A is labelled 67.23 ($67^{\circ} 23'$) and the acute angle at C is labelled 22.37 ($22^{\circ} 37'$).

- A (upper left): vertex A, acute angle $67^{\circ} 23'$
- B (lower left): vertex B, right angle
- C (right): vertex C, acute angle $22^{\circ} 37'$
- AC (hypotenuse): 13
- BC (base): 12
- [A short mark near side AB (resembling "S") could not be resolved.]

[Praxis.] And so, when the side opposite the right angle is given together with one acute angle — and hence with the other acute angle as well — if it be arranged that as the whole sine is to the given side opposite the right angle, so the sine of each acute angle separately is to another line, the sides opposite those same angles will be found in the parts of the measure by which the side opposite the right angle was given.

[Margin: When one of the sides about the right angle is given, together with an acute angle.]

Next, let one of the sides about the right angle be given — say BC, of 12 palms — together with the angle C of 22 degrees 37 minutes, and consequently with the angle A of 67 degrees 23 minutes as well. From these we must investigate the remaining sides. Since, by what we showed at the outset concerning the tangent and secant lines, when BC is taken as the whole sine the side AB is the tangent of angle C and the side AC its secant, the tangent AB will be given as 41660 parts, and the secant AC as 108331 parts. Therefore by the Golden Rule we shall say: if BC, in so far as it is the whole sine of 100000 parts, gives 12 palms, what will the tangent AB, found to be 41660 parts, give? and what will the secant AC, found to be 108331 parts, give? as you see here. And we shall find side AB to be about 5 palms, and AC about 13 palms.

Whole sine	Measure	Line (parts)	Becomes (palms)
BC. 100000.	BC. 12.	AB. 41660?	AB. 5.
		AC. 108331?	AC. 13.

[Praxis.] And so, when one side about the right angle is given, together with one acute angle — and hence with the other acute angle also — if it be arranged that as the whole sine is to the given side about the right angle, so both the tangent of the acute angle adjacent to the given side and the secant of that same angle are to another line, there will result both the side which was the tangent and the side which was the secant, known in the parts of the measure by which the side about the right angle was given.

[Margin: Otherwise, by sines alone.]

But by sines alone, when one side about the right angle is given together with one acute angle — and hence with the other acute angle as well — we shall seek out the remaining sides thus. Again, let the side BC be given as 12 palms, and the angle C as 22 degrees 37 minutes, and consequently the angle A as 67 degrees 23 minutes. Since, then, as we said in the definitions of sines, when AC is taken as the whole sine the side AB is the sine of angle C and BC the sine of angle A — and the angles are given — the said sines will be known: AB 38456, and BC 92310. Therefore by the Golden Rule we shall say: if BC, a sine of 92310 parts, gives 12 palms, what will the sine AB of 38456 parts give? and what will the whole sine AC of 100000 parts give? and so on, as appears here. For side AB will be found to be about 5 palms, and AC about 13 palms.

Sine (parts)	Measure	Line (parts)	Becomes (palms)
BC. 92310.	BC. 12.	AB. 38456?	AB. 5.
		AC. 100000?	AC. 13.

[Margin: Praxis.]

When, therefore, one side about the right angle is given, and one acute angle — and hence the other acute angle as well — if it be arranged that as the sine of the acute angle opposite the given side about the right angle is to the given side, so both the sine of the other acute angle and the whole sine are to another line, there will result both the other side about the right angle and the side opposite the right angle, known in the parts of the measure by which the side about the right angle was given. But the way by tangent and secant lines is quicker, since there the whole sine holds the first place in the Golden Rule, and consequently the division is made easier.

[Margin: When one side is given, and the proportion of any two angles.]

But if one side is given, together with the proportion of two angles, we shall solve the problem thus. From the proportion of the angles we shall find the magnitudes

of the acute angles, as we showed in the scholium of Proposition 1. For which reason we shall find the remaining sides from the known angles, as before. And once the sides have been found, it is clear that the proportion of any two is given in the numbers in which they were found. For the proportion of AB to AC will be as 5 to 13, or as 38456 to 100000, or as 41660 to 108331, and so on; for in all these numbers the said sides were found. Given, therefore, one side together with one acute angle of a right-angled triangle, and so on — which was to be done.

Opera Mathematica, Tomus I — Doctrine of Plane (Rectilinear) Triangles

(Batch covers global = printed folios 156–158.)

PROBL. 2. PROPOS. 3.

[Margin: In a right triangle: from two known sides, or from their known ratio together with any one side, the remaining parts are found.]

Given two sides of a right triangle, to determine the two acute angles, together with the third side. Likewise, given the ratio of two sides and, in addition, any one side whatever, to find the two acute angles together with the remaining two sides.

[Margin: When the side opposite the right angle is given, together with one side about the right angle.]

Take triangle ABC, whose angle B is right. Let the first side given be AC, opposite the right angle, and in addition the side AB, which is about the right angle — namely AC of 13 palms and AB of 5 palms. From these we must determine the angles A and C, and the third side BC. Since, once AC is taken as the whole sine, the side AB is the sine of angle C, we shall argue as follows: if AC of 13 palms gives AC as the whole sine of 100000 parts, what will AB of 5 palms give? We find that the sine AB is 38461 parts, as you see here.

Diagram. A right triangle. Vertices:

- A (top left): apex; the acute angle here is labelled **67.23** ($67^\circ 23'$).
- B (bottom left): the right angle.
- C (bottom right): the acute angle here is labelled **22.37** ($22^\circ 37'$).
- Side AB (left, vertical): labelled 5.
- Side BC (base): labelled **12**.

- Side AC (hypotenuse): labelled 13.

AC.	AC.	AB.		AB.
13.	100000.	5?	fit	38461.

From the table of sines, therefore, angle C will be given as $22^{\circ} 37'$, and consequently the remaining angle A as $67^{\circ} 23'$. Thus the sine of this angle A too — namely BC — will be given as 92310 parts, from the same table of sines. So we argue again: if the whole sine AC of 100000 parts gives AC of 13 palms — or if the sine AB, found to be 38461 parts, gives AB of 5 palms — what will the sine BC of 92310 parts give? We find that BC is very nearly 12 palms, as appears here.

AC.	AC.	AB.	AB.	BC.		BC.
100000.	13.	38461.	5.	92310?	fit	12.

[Margin: Praxis (the procedure).]

Whenever, then, a side opposite the right angle is given, together with one side about the same right angle: if you set it up so that the given side opposite the right angle is to the whole sine as the other given side is to a fourth term, there will result the sine of the acute angle that is opposite the side given about the right angle. Once this is found, and with both acute angles thereby known through the found sine: if you again set it up so that the whole sine is to the given side opposite the right angle — or so that the sine of the acute angle opposite the given side about the right angle is to the given side about the right angle — as the sine of the other acute angle is to a fourth term, the third side will become known in the units of measure according to which the two sides were given.

[Margin: Another method, by means of the tangent and secant lines.]

ALITER (another method). Let AC again be 13 palms and AB 5 palms. Since, as we showed at the beginning of the treatment of the tangent and secant lines, once AB is taken as the whole sine the side AC is the secant of angle A and BC is the tangent of the same angle, we shall argue: if AB of 5 palms gives AB as the whole sine of 100000 parts, what will AC of 13 palms give? We find the secant AC to be 260000 parts, as is clear here.

AB.	AB.	AC.		AC.
5.	100000.	13?	fit	260000.

From the table of secants, therefore, angle A will be $67^{\circ} 23'$, and consequently the remaining angle C $22^{\circ} 37'$. Thus the tangent of angle A — namely BC — will be

given as 240038 parts, from the table of tangents. So we shall argue again: if the whole sine AB of 100000 parts gives AB of 5 palms — or if the secant AC, found to be 200000 [recte 260000?] parts, gives AC of 13 palms — what will the tangent BC of 240038 parts give? We find again that BC is very nearly 12 palms, as stands clear here.

AB.	AB.	AC.	AC.	BC.		BC.
100000.	5.	260000.	13.	240038?	fit	12.

[Margin: Praxis (the procedure).]

Therefore, when a side opposite the right angle is given, together with one side about the right angle: if you set it up so that the given side about the right angle is to the whole sine as the given side opposite the right angle is to a fourth term, there will result the secant of the acute angle contained under the given sides. Once this is found, and with both acute angles thereby known, and with the tangent of the acute angle contained under the given sides taken from the table of tangents: if you again set it up so that the whole sine is to the given side about the right angle — or so that the secant of the acute angle contained under the given sides is to the side given opposite the right angle — as the tangent of the acute angle contained under the given sides is to a fourth term, the third side, opposite the right angle, will become known in the same units in which the two sides about the right angle were given. It is, however, preferable to work by the sines alone, since the tangent and secant lines bring no shortcut, and are themselves found by means of the sines.

[Margin: a. Euclid, *Elements* I.47.]

ADHVC aliter (still another method). Let AC again be set at 13 palms and AB at 5 palms. ^aSince, then, the square of the line AC equals the two squares of the lines AB and BC, if the square of side AB — which is 25 — is subtracted from the square of side AC — which is 169 — there will remain the square of side BC, namely 144, whose square root, 12, gives side BC as 12 palms. And since, once AC is taken as the whole sine, the sides AB and BC are the sines of the opposite angles (as we explained in the definition of sines): if you set it up so that side AC, opposite the right angle, of 13 palms is to AC as the whole sine of 100000 parts, as either of the sides about the right angle — namely BC of 12 palms — is to a fourth term, there will result the sine of the acute angle A, opposite the side taken, of 92308 parts. From the table of sines, therefore, angle A will be given as 67° 23', and thus the remaining angle C as 22° 37'. In this way the third side is found first, and then the angles — whereas by the other methods the angles were found before the third side.

[Margin: When two sides about the right angle are given.]

Now let two sides AB, BC about the right angle be given — say AB of 5 palms and BC of 12 palms. From these we must find the third side AC and the acute angles. Since, from what was demonstrated at the beginning of the treatment of the tangent and secant lines, once AB is taken as the whole sine the side BC is the tangent of angle A and the side AC is the secant of the same angle, we shall argue: if AB of 5 palms gives AB as the whole sine of 100000 parts, what will BC of 12 palms give? We find the tangent BC to be 240000 parts, as is manifest here.

Diagram. The same right triangle reprinted at the head of this page (cross-references fig-p796-1). Vertices:

- A (top left): acute angle labelled **67.23** ($67^{\circ} 23'$).
- B (bottom left): the right angle.
- C (bottom right): acute angle labelled **22.37** ($22^{\circ} 37'$).
- Side AB: labelled 5; side BC (base): labelled **12**; hypotenuse AC: labelled **13**.

AB.	AB.	BC.		BC.
5.	100000.	12?	fit	240000.

From the table of tangents, therefore, angle A will be given as $67^{\circ} 23'$, and consequently the remaining angle C as $22^{\circ} 37'$. Thus AC, the secant of angle A, will be given from the table of secants as 260035 parts. So we shall argue again: if the whole sine AB of 100000 parts gives AB of 5 palms — or if the tangent BC, found to be 240000 parts, gives BC of 12 palms — what will the secant AC of 260035 parts give? We find AC to be 13 palms, nearly, as you see here.

AB.	AB.	BC.	BC.	AC.		AC.
100000.	5.	240000.	12.	260035?	fit	13.

[Margin: Praxis (the procedure).]

And so, if two sides about the right angle are given: if you set it up so that either of the given sides is to the whole sine as the other given side is to a fourth term, there will arise the tangent of the acute angle opposite this other given side. Once this is found, and with both acute angles thereby known in the table of tangents — and with the secant of the acute angle opposite this given side taken from the table of secants: if you again set it up so that the whole sine is to the first given side — or so that the found tangent is to the second given side — as the secant taken from the table of secants is to a fourth term, the third side, opposite the right angle, will

become known in the same units in which the two sides about the right angle were given.

[Margin: Another method, without tangents and secants. a. Euclid, *Elements* I.47.]

ALITER (another method). Let AB again be 5 palms and BC 12 palms. ^aSince the squares of the sides AB, BC together equal the square of side AC, the square of side AC will be 169 palms, whose square root gives side AC as 13 palms. And since, as was set down in the definition of sines, once AC is taken as the whole sine the sides AB, BC are the sines of the opposite angles: if you set it up so that side AC, which is opposite the right angle, found to be 13 palms, is to AC as the whole sine of 100000 parts, as either of the sides about the right angle — namely AB of 5 palms — is to a fourth term, there will be found the sine of the acute angle C, which is opposite the side taken, of 38461 parts. From the table of sines, therefore, angle C will be given as $22^{\circ} 37'$, and thus the remaining angle A as $67^{\circ} 23'$. By this route the third side is found first, and then the two angles — whereas by the other method the angles were found before the third side.

[Margin: When the ratio of two sides is given, together with one side.]

Now, if the ratio of any two sides is given, together with one side, whatever it may be, we shall take the numbers of the known ratio as though they were parts of some unit of measure in which the two sides are given; and from these, as we demonstrated in this proposition, we shall find the angles, and the third side in the same parts. Then, if you set it up so that the number of the side that is given is to that given side itself, as the numbers of the other sides individually are to a fourth term, the other sides will be found in the units of measure according to which that one side was given. For example, if the ratio of AB to AC is as 15 to 39, and side BC is 12 palms, there will be found, from what was demonstrated, angle A as $67^{\circ} 23'$ and angle C as $22^{\circ} 37'$; and side BC as 36 parts, of which AB is 15 and AC 39. Therefore, if you set it up so that side BC, found to be 36 parts, is to that same BC given as 12 palms, as both AB of 15 parts and AC of 39 parts are to a fourth term, AB will be found as 5 palms and AC as 13 palms. Given, then, two sides of a right triangle, we have made the two acute angles known, and so on. Which was to be done.

SCHOLIUM.

The calculation of right triangles is now complete; there follows the treatment of triangles that are not right-angled. But first certain things necessary to this matter must be demonstrated, some of which will also be of great service for spherical triangles.

THEOR. 2. PROPOS. 4.

[Margin: What ratio the two segments of any chord have.]

If the diameter of a circle cuts any chord, and its arc, into two parts, the segments of the chord will have the same ratio as the sines of the corresponding segments of the arc.

In circle ABCD, let the diameter AC cut the chord BD at E, and its arc BAD at A (or the arc BCD at C); and let BF and DG be drawn perpendicular to the diameter AC. Of these, BF is the sine of arc BA (or BC), and DG is the sine of arc AD (or CD). I say that BE is to ED as BF is to DG. For since, in the triangles BEF, DEG, the angles F and G are equal, being right angles, ^aand likewise the angles at E, at the vertex, are equal, ^bthe triangles BEF, DEG will be equiangular. ^cHence BE will be to BF as ED is to DG; and, by alternation, BE is to ED as BF is to DG. If, therefore, the diameter of a circle cuts any chord, and its arc, into two parts, and so on. Which was to be demonstrated.

Diagram. A circle with the labelled points of Theorem 2 :

- A (top): one end of the diameter.
- C (bottom): the other end of the diameter (AC vertical).
- B (left) and D (right): the ends of the chord BD.
- E (centre): where the diameter AC cuts the chord BD.
- F (below E, on the diameter): foot of the perpendicular BF.
- G (near the centre, toward D): foot of the perpendicular DG.

[Margin: a. Euclid, *Elements* I.15. b. Euclid I.32. c. Euclid VI.4.]

THEOR. 3. PROPOS. 5.

[Margin: What ratio a chord of a circle, when produced, and meeting a produced diameter, has to the external segment.]

If a chord of any arc in a circle is produced to one side, and meets any diameter produced to the same side, then the ratio of the whole produced chord to the external segment will be the same as the ratio of the sine of the arc between the point through which the diameter is produced and the more remote endpoint of the said chord, to the sine of the arc between the same point of the diameter and the nearer endpoint of the same chord.

Diagram. A circle illustrating Theorem 3 :

- A (top, on the circle): one endpoint of the chord AD.
- B (left, on the circle) and C (lower right, on the circle): the ends of the diameter BC.
- D (upper right, on the circle): the other endpoint of the chord AD.
- E (outside the circle, to the right): where the produced chord AD meets the produced diameter BC.
- F (centre): foot of the perpendicular AF onto the diameter BC.
- G (right of centre, toward C): foot of the perpendicular DG onto the diameter BC.

[Margin: a. Euclid, *Elements* I.28. b. Corollary to Euclid VI.4.]

In circle ABCD, let the chord AD, and the arc AD, be produced toward D, so as to meet the diameter BC, produced to the same side, at the point E; and let AF, DG be dropped perpendicular to the diameter BC. Of these, AF is the sine of arc AC, and DG is the sine of arc CD. I say that AE is to DE as AF is to DG. ^aFor since AF, DG are parallel, on account of the right angles F, G, ^bthe triangles AEF, DEG will be similar. Hence AE will be to AF as DE is to DG; and, by alternation, AE is to DE as AF is to DG. If, therefore, a chord of any arc in a circle is produced to one side, and meets any diameter, and so on. Which was to be shown.

PROBL. 3. PROPOS. 6.

[Margin: From the given sum of two arcs, each of which is less than a semicircle, or of two rectilinear angles, together with the ratio their sines have, each of them is found.]

Given the sum of two arcs, each of which is less than a semicircle, or of two rectilinear angles — whether that sum be less or greater than 180° — together with the ratio their sines have: to exhibit each of them individually as known.

In circle ABCD, whose centre is E, let there be given first the sum of the arcs BF, FD, each of which is less than a semicircle — or of the angles BEF, FED — the sum of the arcs, as of the angles, being less than 180° ; namely, let the given sum be 130° . Let there also be given the ratio of the sine of arc BF (or of angle BEF) to the sine of arc FD (or of angle FED), the same as 10 to 5. From these we must make known each arc BF, FD, or each angle BEF, FED. Draw the chord BD; and from the point F, where the given arcs meet, draw the diameter FC, cutting the chord BD at

G. Also, when the whole arc BAD is bisected at A, the radius drawn, EA, will bisect the chord BD at H, by the lemma demonstrated in the definition of sines; ^aand hence also at right angles.

Now since the ratio of the sine of arc BF to the sine of arc FD is set as 10 to 5, ^band since the sine of arc BF is to the sine of arc FD as BG is to GD, BG will also be to GD as 10 to 5. So, setting the line BG at 10, GD will be 5, and hence the whole BD 15; while each half BH, HD is $7\frac{1}{2}$; and finally HG — the difference between the half BH and the greater segment BG, or between the half HD and the lesser segment GD — will be $2\frac{1}{2}$. Again, since the whole arc BAD is set at 130° , each half BA, AD will be 65° , and hence each angle BEA, AED likewise 65° . And since, from what we set down at the beginning of the treatment of tangents and secants, once EH is taken as the whole sine the line BH is the tangent of angle BEH and HG is the tangent of angle HEG, the tangent of 65° — namely BH — will be given from the table of tangents as 214451 parts. Therefore, to find the tangent of angle AEF — that is, HG — we shall argue by the rule of three: if BH, the half of the sum of the terms of the given ratio, namely $7\frac{1}{2}$, gives BH, the tangent of the half of the sum of the angles BEF, FED (or of the arcs BF, FD), of 214451 parts, what will HG — the difference between the half of the sum of the terms of the given ratio and either of the terms of that ratio, namely $2\frac{1}{2}$ — give? We find the tangent HG to be 71484 parts, as you see done here.

Diagram. A circle with centre E and several chords and radii, illustrating Problem 3. Readable labels:

- A (top, on the circle): midpoint of arc BAD.
- B (left) and D (right): ends of the chord BD.
- C (bottom, on the circle): endpoint of the diameter FC.
- E (centre).
- G (centre, on the chord BD): where the diameter FC cuts BD.
- H (centre-left, on the chord BD): where the radius EA cuts BD.
- I (right of centre): auxiliary point (used in the alternative demonstration).
- K (lower right): auxiliary point.
- L (upper right, outside the circle): apex where the produced lines meet.
- A small mark near the top of the figure is likely the arc-junction point F [?], but its exact position does not resolve cleanly even at high magnification.

[Diagram note: F (the arc-junction / endpoint of diameter FC named throughout the text) is part of the construction but not cleanly locatable on the leaf]

BH.	BH.	HG.		HG.
7½.	214451.	2½?	fit	71484.

From the table of tangents, therefore, angle HEG will be drawn out — that is, arc AF — as 35° 34'. Added to the half AB of 65°, this composes the greater arc BF, and hence also the angle BEF, of 100° 34'; subtracted, on the other hand, from the half AD, it leaves the lesser arc FD, and hence also the angle FED, of 29° 26'.

[Margin: Praxis (the procedure).]

And so, when two arcs are together less than a semicircle, or two angles together less than two right angles: if you set it up so that the half of the sum of the terms of the given ratio is to the tangent of the half of the sum of the arcs (or angles) — finding the tangent by the proportional part corresponding to 30 seconds, in case the sum cannot be bisected without seconds — as the difference between the half of the sum of the terms of the given ratio and either of the terms is to a fourth term, there will be found the tangent of the arc (or angle) by which each sought arc or angle differs from the half of their sum. This arc or angle of the found tangent, added to the half, will give the greater arc or angle; but subtracted from the same half, it will leave the lesser arc or angle.

[Margin: Another demonstration. c. Euclid, *Elements* III.3. d. Euclid I.8. e. Prop. 5 of this [treatise].]

ALITER (another demonstration). With the radius BE produced to K, and the diameter CF produced until it meets, at L, the line KDL drawn from K through D, let a perpendicular to DK be drawn to it from K; ^cthis will bisect DK itself. And hence, since the sides DE, EI are equal to the sides KE, EI, and the base DI to the base KI, ^dthe angle DEI will be equal to the angle KEI. Since, then, arc BFD is given as 130°, the remaining arc DK, out of the semicircle, will be given as 50°, and its half — that is, the angle DEI — as 25°. Again, since the sine of arc BF is set to the sine of arc FD as 10 to 5, and since the sine of arc KF is the same as that of arc BF (as was shown in the definition of sines), the sine of arc KF will also be to the sine of arc DF as 10 to 5. ^eTherefore, since the sine of arc KF is to the sine of arc DF as KL is to DL, KL will also be to DL as 10 to 5. So, setting KL at 10, DL will be 5, and hence the remainder KD 5, and its half ID 2½. And since, as we said at the beginning of the treatment of tangents and secants, once EI is taken as the whole sine the line ID is the tangent of angle DEI — that is, of 25° — ID will be given from the table of tangents as 46631 parts. We shall therefore argue by the rule of three: if ID, the half of the difference between the terms of the given ratio, namely 2½, gives ID, the tangent of the half of the difference between the given

sum and the semicircle, of 46631 parts, what will IL — compounded of the half of the difference between the terms of the given ratio and the consequent of that ratio, namely $7\frac{1}{2}$ — give? We find IL to be 139893 parts, of which ID is 46631, or EI is 100000, as you see here.

ID.	ID.	IL.		IL.
$2\frac{1}{2}$.	46631.	$7\frac{1}{2}?$	fit	139893.

When, therefore, IL is the tangent of angle IEL, once EI is taken as the whole sine, as we handed down in the treatment of tangents and secants,

will be given, from the table of tangents, the angle IEF, $54^{\circ} 26'$. Therefore, once the angle DEI— 25° , namely half the difference between the given sum and the semicircle—has been removed, the remaining angle will be FED, and consequently the arc FD as well, the smaller one, $29^{\circ} 26'$. When this is subtracted from the given sum of 130° , it leaves the angle BEF, and hence the arc BF, the larger, $100^{\circ} 34'$, as before.

[Margin: Praxis. — "Procedure."]

Therefore, if it is arranged that as half the difference between the terms of the given ratio is to the tangent of half the difference between the given sum and the semicircle, so the sum of half the difference between the terms of the given ratio and the consequent of the same ratio is to a fourth term, then the tangent of an angle will be found; and if from this angle half the difference between the given sum and the semicircle is subtracted, the remainder will be the angle, or smaller arc, sought; and this, subtracted from the given sum, leaves the larger angle or arc sought.

[Margin: Aliter absque tangentibus. — "Another way, without tangents."]

Yet another way, by sines alone, without tangents. With the same things assumed: since, as we declared in the discussion of sines, when EB is taken as the whole sine, the line BH is the sine of the angle BEH—namely of half the given sum of the angles or arcs, that is 65° —and HE is the sine of the angle EBH, 25° , being the complement of angle BEH; therefore from the table of sines BH will be given as 90631 parts, and HE as 42262 parts. Then, if we reason thus: if BH—half the sum of the terms of the given ratio, namely $7\frac{1}{2}$ —yields BH, the sine of half the sum of the angles or arcs, 90631 parts, what will HG yield—HG being the difference between half the sum of the terms of the given ratio and either of the terms, namely $2\frac{1}{2}$? We shall find HG to be 30210 parts, of the kind of which the whole sine EB is 100000, or EH is 42262, as is clear here.

BH.	BH.	HG.	HG.
7½.	90631.	2½?	30210.

[Margin: a — Euclid, *Elements* I.47.]

(a) Now since the squares of the lines HE and HG—namely 1786076644 and 912644100—if we gather them into one sum, will produce the square of the line EG, 2698720744, whose square root will give EG as 51949 parts. And since, when EG is taken as the whole sine, the line HG is the sine of the angle HEG, as we said in the definition of sines, we shall again reason: if EG, found to be 51949 parts, corresponds to EG the whole sine of 100000 parts, what will HG, found to be 30210 parts, correspond to? We shall find HG, the sine of the angle HEG, to be 58153 parts, as you see here.

EG.	EG.	HG.	HG.
51949	100000.	30210?	58153.

From the table of sines, therefore, the angle HEG—or the arc AF—will be given as 35° 34', which, added to half of AB, 65°, will exhibit the larger arc BF, and hence the angle BEF, 100° 34'; but subtracted from half of AD, will make the smaller arc FD, and hence the angle FED, 29° 26'.

[Margin: Praxis. — "Procedure."]

And so, when the sum of two arcs or angles is less than 180°: if it is arranged that as half the sum of the terms of the given ratio is to the sine of half the sum of the arcs or angles, so the difference between half the sum of the terms of the given ratio and either term is to a fourth term, a number will be found; and if the square of this number is added to the square of the sine of the complement of half the sum of the arcs or angles; and finally it is arranged that as the square root of this composite number is to the whole sine, so the number lately found by the rule of three is to a fourth term, the sine of the angle or arc will be produced by which each angle or arc sought differs from half of their sum. This arc or angle of the found sine, therefore, added to half the given sum, will give the larger arc or angle; but subtracted from the same half, it leaves the smaller arc or angle. Yet the two former ways are far more expeditious, as is evident.

[Margin: Quando aggregatum arcuum, vel angulorum maius est, quam grad. 180. — "When the sum of the arcs or angles is greater than 180°."]

Next, let there be given the sum of the arcs BC and CD—each of them likewise smaller than a semicircle—or of the angles BEC and CED, but with the sum, both

of the arcs and of the angles, exceeding 180° : namely, let 230° be given. Let there also be given the ratio of the sine of arc BC (or angle BEC) to the sine of arc CD (or angle CED), the same as 10 to 5. From these we must draw out both arcs BC and CD, or both angles BEC and CED. Draw the diameter CE, and subtract the given sum from the whole circle, that is, from 360° ; the remainder will be the sum of the arcs BF and FD, or of the angles BEF and FED, 130° , less than 180° . And since the arcs BC and BF[?] have the same sine, and likewise the arcs CD and FD, as we said in the definition of sines, the ratio of the sines of the arcs BF and FD (or of the angles BEF and FED) will also be given, the same as 10 to 5. Therefore, as has already been demonstrated, we shall find the arcs BF and FD (or the angles BEF and FED) to be $100^\circ 34'$ and $29^\circ 26'$; and these, subtracted from the semicircle—that is, from 180° —leave the arcs BC and CD (or the angles BEC and CED), $79^\circ 26'$ and $150^\circ 34'$.

[Margin: Praxis. — "Procedure."]

When, therefore, the sum of two arcs or angles is greater than 180° : if we subtract it from 360° , there will remain the sum of two other arcs or angles less than 180° . And so, if—as has already been demonstrated—by means of this smaller sum and the given ratio we seek out both arcs or angles, and subtract each one found separately from 180° , the arcs or angles sought will be left known.

[Margin: Quando sinuum proportio data est proportio æqualitatis. — "When the given ratio of the sines is a ratio of equality."]

But if the given ratio of the sines happens to be a ratio of equality—that is, the sines are equal—then both arcs, as well as both angles, will also be equal, as we showed in the definition of sines. Therefore half the given sum will give each arc or angle as known. Thus, given the sum of two arcs each smaller than a semicircle, or of two rectilinear angles, and so on, we have exhibited each of them separately as known. Which was to be done.

SCHOLIVM.

If the sum of two arcs or angles is exactly 180° , those arcs or angles cannot be known, even if the ratio their sines have is given. For in whatever way the semicircle is cut into two arcs, their sines will always have a ratio of equality, since one and the same sine belongs to both arcs, as we demonstrated at the definition of sines. It is necessary, therefore, that the given sum be either less than or greater than 180° , as was expressed in the proposition.

[Margin: (...con)tinet grad. 180[?]. Problema solui non potest. — "(...the semicircle) contains 180[?]^o. The problem cannot be solved."]

PROBL. 4. PROOS 7.

Given the difference of two arcs, each of them smaller than a semicircle—
—or of two rectilinear angles—together with the ratio their sines have: to
make each of them separately known.

[Margin: Ex differentia data duorum arcuum, quorum quilibet semicirculo minor sit, vel duorum angulorum una cum proportione, quam eorum sinus habet, uterque cognoscitur. — "From the given difference of two arcs, each smaller than a semicircle, or of two angles, together with the ratio their sine has, each of the two is found."]

[Margin: Quando sinus maioris arcus vel anguli ad sinum minoris habet proportionem maioris inæqualitatis. — "When the sine of the larger arc or angle has to the sine of the smaller a ratio of greater inequality."]

In the circle ABCD, whose center is E, let the arc BF—smaller than a semicircle—exceed the arc DF by the arc BD, or let the angle BEF exceed the angle DEF by the angle BED; and let this difference, namely the arc BD or the angle BED, be given as 60°. Let also the ratio of the sine of the larger arc BF (or angle BEF) to the sine of the smaller arc DF (or angle DEF) be given—first, as a ratio of greater inequality—the same as 11 to 5; which indeed happens when the two arcs BF and DF, taken together, are smaller than a semicircle. From these we must make known both arcs BF and DF, or both angles BEF and DEF.

Diagram. A circle labelled ABCD with center E. From the center, several radii and chords fan out to the circumference; two of the lines are produced beyond the circle on the right, where they meet at an external point G.

- A (top of circle): apex point; midpoint of the arc BD.
- B (upper left): endpoint of the chord BD and of the line BEI produced through the center.
- D (top, between A and G): endpoint of chord BD; the perpendicular from D falls on CF.
- G (far right, outside the circle): the external point where the chord BD produced and the diameter CF produced meet.
- H (interior, just below A on chord BD): foot where the semidiameter EA cuts the chord BD in half and at right angles.
- E (center): center of the circle.

- F (right side of circle): endpoint of the diameter CF and of the arcs BF, DF.
- C (lower left): endpoint of the diameter CF.
- I (bottom): endpoint of the line BE produced to the circumference.

When the chord BD and the diameter CF are drawn, these lines, when produced toward the sides D and F, will meet, as at the point G. For since the ratio of the sines is given as one of greater inequality, the sine of arc BF—that is, the perpendicular dropped from B to CF—will be greater than the sine of arc DF—that is, the perpendicular dropped from D to CF. Hence the point D will be less distant from the line CF than the point B; and so BD and CF, produced toward the side DF, will at length come together. This will also be proved as follows. If both sines—that is, the perpendiculars dropped from B and D to CF—were equal, then, since they are parallel (a), BD and CF would also be parallel (b). Since, therefore, the perpendicular dropped from D is smaller, it follows that they meet, and so on.

[Margin: a — Euclid I.28. b — Euclid I.33. c — Euclid III.3. d — Prop. 5 of this book.]

Then, when the arc BD is bisected at A, the semidiameter EA, when drawn, will also cut the chord BD in half at H—by the lemma demonstrated at the definition of sines (c)—and consequently at right angles. Now since the ratio of the sine of arc BF to the sine of arc DF is, by hypothesis, as 11 to 5 (d), and as the sine of arc BF is to the sine of DF so is BG to DG, BG will also be to DG as 11 to 5. Therefore, if the line BG is put as 11, then BH and HD, each the half of BD, will be 3, and finally HG will be 8. Again, since the arc BD is set at 60°, each half, BA and AD, will be 30°; and for that reason each of the angles BEA and AED will likewise be 30°. And since, when EH is taken as the whole sine, the line HD is the tangent of the angle DEH, and HG is the tangent of the angle HEG—as we noted at the beginning of the treatment of tangents and secants—there will be given from the table of tangents the tangent of 30°, that is, HD, 57735 parts. Therefore, to know the tangent HG of the angle HEG, we shall reason by the rule of three: if HD—half the difference of the terms of the given ratio, namely 3—yields HD, the tangent of half the given difference of the arcs BF and FD (or of the angles BEF and DEF), 57735 parts, what will HG yield—HG being the sum of half the difference of the terms of the given ratio and the consequent of the same ratio, namely 8? HG will come out as a tangent of 153960 parts, as appears here.

HD.	HD.	HG.	HG.
3.	57735.	8?	153960.

In the table of tangents, this tangent, once found, yields the angle AEF—or the arc AF—as 57° . If half of AB, 30° , is added to it, the larger arc BF (or angle BEF) will be given as 87° ; but if half of AD, 30° , is subtracted from it, the smaller arc DF (or angle DEF) will remain, 27° .

[Margin: Praxis. — "Procedure."]

Therefore, when the ratio of the sine of the larger arc or angle to the sine of the smaller is one of greater inequality: if it is arranged that as half the difference of the terms of the given ratio is to the tangent of half the given difference of the arcs or angles, so the sum of half the difference of the terms of the ratio and the consequent of the ratio is to a fourth term, then the tangent of an arc or angle will be produced which, added to half the given difference of the arcs or angles, makes up the larger arc or angle; and if the said half is subtracted from it, the smaller arc or angle remains.

[Margin: Aliter sine tangentibus. — "Another way, without tangents."]

Another way, without tangents, by sines alone. With the same things assumed: since, by what we showed in the definition of sines, when ED is taken as the whole sine, the line HD is the sine of the angle HED—namely of half the given difference of the arcs or angles, that is 30° —and HE is the sine of the angle HDE, 60° , being the complement of the angle HED; there will be given from the table of sines HD, 50000 parts, and EH, 86603 parts. Now if we reason: if HD—half the difference of the terms of the given ratio, namely 3—yields HD, the sine 50000, being the sine of half the given difference of the arcs or angles, what will HG yield—HG being the sum of half the difference of the terms of the ratio and the consequent of the same ratio, namely 8? We shall find HG to be 133333, with respect to the whole sine ED, as you see here.

HD.	HD.	HG.	HG.
3.	50000.	8?	133333.

[Margin: e — Euclid I.47.]

(e) Therefore, since the squares of the lines EH and HG—namely 7499906404 and 17777688889—are equal to the square of the line EG, the square of the line EG will become 25277595293, whose square root will indicate the line EG to be 158989, with respect to the whole sine ED. And since, when EG is taken as the whole sine, the line HG is the sine of the angle HEG, we shall reason again: if EG, found to be 158989 parts, corresponds to EG the whole sine of 100000 parts, what

will HG, found to be 133333 parts, correspond to? We shall find HG, the sine of the angle HEG, to be 83863 parts, as appears here.

EG.	EG.	HG.	HG.
158989.	100000.	133333?	83862.

This sine, in the table of sines, indicates an arc of 57° . Such, then, is the angle AEF, or the arc AF; and if half of AB, 30° , is added to it, the larger arc BF and the angle BEF will become 87° ; but if half of AD, 30° , is taken from it, the smaller arc DF and the angle DEF will remain, 27° , as before.

[Margin: Praxis. — "Procedure."]

If, therefore (when the given ratio of the sines is one of greater inequality), it is arranged that as half the difference of the terms of the given ratio is to the sine of half the given difference of the arcs or angles, so the sum of half the difference of the terms of the ratio and the consequent of the same ratio is to a fourth term, a number will be found; and if the square of this number is added to the square of the sine of the complement of half the given difference of the arcs or angles; and finally it is arranged that as the square root of this composite number is to the whole sine, so the number lately found by the rule of three is to a fourth term, the sine of an angle or arc will be found, to which, if half the given difference of the arcs or angles is added, the larger arc or angle becomes known; but if the same half is subtracted from it, the smaller arc or angle remains known. Yet the former method is shorter, as is evident.

Yet another way, both by tangents and by sines. With the same things assumed, and the line BE produced as far as I: since the arc BD—that is, the difference of the arcs BF and DF—is given as 60° , the remaining arc DI of the semicircle will be given, namely the sum of the arcs DF and FI, 120° . There is also given the ratio of the sine of arc BF—that is, of arc FI (since the arcs BF and FI have the same sine, as we said in the definition of sines)—to the sine of arc DF, the same as 11 to 5.

[Margin: f — Prop. 6 of this book. g — Euclid III.26.]

(f) Hence, as has been demonstrated, both arcs IF and DF will become known, of which DF is the smaller of the proposed arcs; while FI is the complement of the larger arc BF up to the semicircle, and so, subtracted from the semicircle, will leave the larger arc BF known. And the arc IF will always be greater than DF (g), because the arc IF is equal to the arc BC, which is greater than the arc DF, since the sine of the former is set greater than the sine of the latter.

[Margin: Praxis. — "Procedure."]

And so, with the same things assumed: if, from the given ratio of the sines of greater inequality, and from the arc that remains after the given difference has been subtracted from the semicircle—treated as the sum of two arcs—the two arcs of this sum are sought, as was shown in the preceding proposition, then the larger one found, if it is subtracted from the semicircle, will give the larger arc, and hence the angle proposed; while the smaller one found will be the smaller proposed arc.

[Margin: Quando sinus maioris arcus aut anguli ad sinum minoris proportionem minoris inæqualitatis habet. — "When the sine of the larger arc or angle has to the sine of the smaller a ratio of lesser inequality."]

Next, let the arc DCB—smaller than a semicircle—exceed the arc BC by the arc DB, or let the angle DEC exceed the angle BEC by the angle DEB; and let this difference, namely the arc DB or the angle DEB, be given as 60° . Let also the ratio of the sine of the larger arc DBC (or angle DEC) to the sine of the smaller arc BC (or angle BEC) be given, and of lesser inequality, the same as 5 to 11; which indeed happens when the two arcs DBC and BC, taken together, exceed the semicircle. From these we must make both arcs DBC and BC, or both angles DEC and BEC, known. With the same construction as before, the chord DB will not meet the diameter CF when produced toward the side BC, the smaller arc, but toward the sides D and F, as is manifest from what we showed at the beginning of this proposition. And since the arcs DBC and DF have the same sine, as do the arcs BC and BF, the ratio of the sine of arc DF to the sine of arc BF will also be given, the same as 5 to 11; and consequently the ratio of the sine of arc BF to the sine of arc DF is as 11 to 5, namely of greater inequality. Hence, since the arcs BF and DF have the same given difference BD, we shall find both arcs BF and DF—and thus both angles BEF and DEF—as we demonstrated before, the former being 87° and the latter 27° ; and these, subtracted separately from the semicircle, will leave the smaller proposed arc BC, 93° , and the larger, DBC, 153° .

Diagram. The same circle ABCD with center E is reprinted here, identical to the figure on the preceding page (fig-p800-1): a circle with the labelled points A (top), B (upper left), D (upper, between A and G), G (external point to the right), H (interior, on the chord below A), E (center), F (right side), C (lower left), and I (bottom). See the description of fig-p800-1 for the full labelling.

[Margin: Praxis. — "Procedure."]

And so, when the given ratio of the sines is one of lesser inequality: if it is inverted so as to become a ratio of greater inequality, and from this, together with the given

difference, two arcs are sought, then the larger one found, if it is subtracted from the semicircle, will give the smaller arc and angle proposed; while the smaller one, if it is subtracted from the same semicircle, gives the larger.

[Margin: Quando proportio sinuum est æqualitatis. — "When the ratio of the sines is one of equality."]

But now, if the given ratio of the sines happens to be one of equality—which indeed occurs when the two proposed arcs BF and DF together equal the semicircle—the arcs DF and BC will be equal, as we demonstrated in the definition of sines, on account of the equality of the sines. Or indeed, if BF together with DF makes up a semicircle, then—since CD together with the same arc DF makes up a semicircle—the arcs BF and CD will be equal. Therefore, when the common arc BD is taken away, the arcs DF and BC will be equal.

[Margin: Praxis. — "Procedure."]

And so, if then the given difference of 60° —namely the arc BD—is subtracted from the semicircle, and half of the remaining arc of 120° —namely 60° —is added to the difference, the larger arc BF (or angle BEF) will be composed, 120° . And the half itself will be the smaller arc DF, or angle DEF, 60° . Likewise, if the given difference amounts to $104^\circ 20'$, we shall subtract it from 180° , and to the given difference we shall add half of the remaining arc of $75^\circ 40'$ —namely $37^\circ 50'$ —so that the larger proposed arc or angle is composed, $142^\circ 10'$. For the smaller will be that half itself, $37^\circ 50'$.

And so, given the difference of two arcs, each of them smaller than a semicircle, or of two rectilinear angles, and so on, we have made each of them separately known. Which was to be done.

THEOR. 4. PROPOS. 8.

[Margin: Quanto maius sit quadratum maioris lateris, quâ minoris in quovis triangulo. — "By how much the square of the greater side exceeds that of the smaller in any triangle."]

If from any angle of a triangle contained by two unequal sides a perpendicular line is drawn to the base, then—if it falls inside the triangle—the square of the greater of the sides enclosing the said angle will be greater than the square of the smaller by the rectangle contained by the base and the difference of the segments made by the perpendicular; but if it falls outside, the square of the greater side will be

greater than the square of the smaller by the rectangle contained by the base and the straight line that is composed of the base and twice the external line lying between the perpendicular and the angle of the triangle.

(Continuation of the demonstration of THEOR. 4 / PROPOS. 8, begun on the previous page.)

In triangle ABC, whose two sides AB and AC are unequal — AC the greater, AB the smaller — let the perpendicular AD be drawn from angle A to the base BC, falling first inside the triangle, as in the earlier figure. [Margin: (a) Euclid I.47] Now the squares of the lines AD and DB together equal the square of AB, just as the squares of the lines AD and DC together equal the square of AC. But the square of AB is smaller than the square of AC, since AB is assumed smaller than AC. Therefore the two squares of AD and DB together are also smaller than the two squares of AD and DC together; and so, when the common square of AD is removed, the square of BD will be less than the square of DC, and hence the line BD is smaller than the line DC. So, cutting off the line DE equal to BD, EC will be the difference between the segments BD and DC. I say that the square of side AC exceeds the square of side AB by the rectangle contained under BC and EC. For since the line BE is bisected at D, and the line EC is added to it in a straight line, [Margin: (b) Euclid II.6] the rectangle contained under BC and EC, together with the square of DE, equals the square of DC. Therefore, adding the common square of AD, the rectangle under BC and EC together with the squares of DE and AD — that is, of BD and AD, that is, together with the square of AB — equals the squares of DC and AD, that is, the square of AC. So the square of side AC is greater than the square of side AB by the rectangle contained under BC and EC. Which is what was proposed.

Next let the perpendicular AD fall outside the triangle, upon the base CB produced, as in the later figure. Cutting off the line DE equal to DB, the line EC will be composed of the base BC and EB, which is double the line DB lying between the perpendicular and angle B. Again I say that the square of side AC exceeds the square of side AB [Margin: (c) Euclid II.6] by the rectangle contained under BC and EC. For again the rectangle under BC and EC together with the square of DB equals the square of DC. Therefore, adding the common square of AD, the rectangle under BC and EC together with the squares of DB and AD — that is, with the square of AB — equals the squares of DC and AD, that is, the square of AC. So the square of side AC exceeds the square of side AB by the rectangle contained under BC and EC. Which is what was proposed.

Diagram. Two triangles are printed one above the other in the left margin, illustrating the two cases of the theorem.

Upper figure — perpendicular falling inside:

- A (apex): vertex from which the perpendicular is dropped
- B, D, E, C (along the base, left to right): B and C the base vertices; D the foot of the perpendicular AD; E the point with $DE = DB$
- side AB labelled **13**; side AC labelled **20**; base BC labelled **21**

Lower figure — perpendicular falling outside:

- A (apex)
- E, D, B, C (along the base line, left to right): D the foot of the perpendicular lying outside segment BC (to the left of B), E the point with $DE = DB$
- side AB labelled **13**; side AC labelled **20**; base BC labelled **11**

ALITER. [Otherwise.] [Margin: (d) Euclid I.47] Since the squares of AD and DC equal the square of AC, and the squares of AD and DB equal the square of AB, the excess of the square of AC over the square of AB will be the same as the excess of the squares of AD and DC over the squares of AD and DB. And, when the common square of AD is removed, it will be the same as the excess of the square of DC over the square of DB, by the 17th axiom [pronunciatum] of Euclid's book 1. But the square of DC exceeds the square of DB by the rectangle contained under [Margin: (e) Euclid II.6] BC and CE; because the square of DC equals the square of DB — or of DE, in the first figure — together with the rectangle contained under BC and CE. Therefore the square of AC too exceeds the square of AB by the rectangle contained under BC and CE. And so, if from any angle of a triangle contained by two unequal sides a perpendicular line is drawn to the base, etc. Which was to be shown.

COROLLARIVM.

[Margin: The perpendicular in an isosceles triangle bisects the base (*Perpendicularis in Isoscele secat basim bifariam*).]

From what has been demonstrated it is clear that in an isosceles triangle the perpendicular bisects the base. For if in the earlier triangle the sides AB and AC are made equal, their squares will also be equal. [Margin: (f) Euclid I.47] Hence, since the square of AB equals the squares of AD and BD, and the square of AC equals the squares of AD and CD, the squares of AD and BD will also equal the squares of AD and CD. And when the common square of AD is removed, the

remaining squares of BD and CD will be equal, and hence the lines BD and CD are equal.

PROBL. 5. PROPOS. 9.

[Margin: When the sides of a triangle are known, the segments of the base contained between the perpendicular and each angle become known (*Cognitis lateribus trianguli, cognoscuntur segmenta basis inter perpendiculararem, & vtrumque angulum comprehensa*). (a) prop. 8 of this book.]

If from any one angle of a triangle whose sides are known a perpendicular is dropped to the opposite side: to find how great is the line contained between the perpendicular and each of the remaining angles.

Let the two triangles of the preceding proposition be repeated, with side AC = 20, AB = 13, and — in the prior triangle — BC = 21, in the posterior BC = 11. And let it be required to find how great are both BD and CD. [Margin: (a) prop. 8 of this book] Since the square of AC exceeds the square of AB by the rectangle contained under BC and CE, if the square of side AB — that is, 169 — is subtracted from 400, the square of side AC, the remainder will be the rectangle under BC and CE, namely 231. Dividing this by side BC — that is, by 21 in the prior triangle — yields the line CE = 11. Removing this from side BC, that is from 21, leaves BE = 10. So half of this, 5, gives the line BD; and the remaining CD will accordingly be 16, namely the residue of side BC. But in the posterior triangle, dividing the same rectangle 231 by 11, namely by side BC, gives CE = 21. If side BC — that is, 11 — is taken from this, there remains BE = 10, whose half gives BD = 5; and so CD will be 16, being composed of side BC and BD.

[Margin: *Praxis*. How, from the operation, it may be understood whether the perpendicular falls inside the triangle or outside (*Quo pacto ex operatione intelligatur, num perpendicularis intra triangulum cadat, an extra*).]

Therefore, if the difference between the two squares of the sides containing the angle from which the perpendicular is drawn is divided by the third side, onto which the perpendicular is dropped, a number is produced. If this is smaller than the third side, it indicates that the perpendicular has fallen inside the triangle; and, subtracted from the third side, it leaves a number whose half gives the smaller segment of the base — while this smaller segment, taken from the third side, yields the larger segment. But if the number produced by the division is greater

than the third side, it is a sign that the perpendicular has fallen outside the triangle. So if the third side is taken from it, the remainder is a number whose half gives the line, outside the triangle, between the perpendicular and the obtuse angle; and the same half, added to the third side, yields the other line between the perpendicular and the acute angle.

ALITER & facilius. [Otherwise, and more easily.] [Margin: Another and easier way of finding the segments of the base (*Alia inuentio segmentorum basis, & faciliior*).] From A, with the interval of the smaller side AB, let a circle be described cutting the greater side AC at F, and its production at G, and cutting side BC (if the perpendicular falls inside the triangle) — or, if it falls outside, its production — at E: [Margin: (b) Euclid III.3] and BE will be bisected at D. [Margin: (c) Euclid III.36, coroll. 1] Now since the rectangle under BC and CE equals the rectangle under GC and CF, [Margin: (d) Euclid VI.16] it will be that as BC, the side onto which the perpendicular is drawn — namely 21 in the prior triangle, or 11 in the posterior — is to GC, the sum of the remaining two sides AC and AB (since AG equals AB), that is, to 33, so is CF, the difference between those same two sides — that is, 7 — to CE. Hence, by the rule of three, CE is found to be 11 parts in the prior triangle, and 21 in the posterior, as is plain here.

BC.	GC.	CF.	CE.
21.	33.	7 ?	fit 11.

Likewise:

BC.	GC.	CF.	CE.
11.	33.	7 ?	fit 21.

And if EC — found to be 11 parts in the prior triangle — is taken from side BC, namely from 21, there remains BE = 10, whose half, 5, is the segment BD; and so the other segment CD will be 16. But in the posterior triangle, if side BC, of 11 parts, is taken from EC (found to be 21 parts), there remains again BE = 10. So its half, 5, gives the line BD outside the triangle, between the perpendicular and the obtuse angle; and thus the whole CD, composed of side BC and the said half BD, will be 16.

Diagram. Two circle-and-triangle constructions are printed one above the other at the top right, illustrating the "Aliter" method (a circle centred at A with radius = the smaller side AB).

Upper figure — perpendicular inside:

- A (centre of the circle / apex of the triangle)
- G (upper left, on the circle): where the production of AC meets the circle
- F (right): where side AC cuts the circle
- C (far right, below F): base vertex on the secant line G–A–F–C [label shape uncertain; read as C]
- B, D, E (along the base): B a base vertex, D the midpoint of BE (foot of perpendicular), E where the circle meets BC

Lower figure — perpendicular outside:

- A (centre / apex)
- G (upper left, on the circle)
- F (right): where AC cuts the circle
- C (far right): base vertex [label shape uncertain; read as C]
- E, D, B (along the base line, left to right): D the midpoint of BE, the perpendicular foot lying outside the triangle

[Margin: *Praxis*. How, from the operation itself, it may be known whether the perpendicular falls inside the triangle or outside (*Quo pacto ex ipsa operatione cognoscatur, an perpendicularis cadat intra triangulum, an extra*).]

So if it is arranged that as the side onto which the perpendicular is drawn is to the sum of the other two sides, so is the difference of those same sides to a fourth, a number is found. If this is smaller than the third side, it indicates that the perpendicular has fallen inside the triangle; and, taken from the third side, it leaves a number whose half is the smaller segment of the base — while this, subtracted from the third side, yields the larger segment. But if the number found by the rule of three exceeds the third side, it is a sign that the perpendicular has fallen outside the triangle. So if the third side is taken from it, the half of the remaining number gives the line, outside the triangle, between the perpendicular and the obtuse angle; and the same half, added to the third side, offers the other line between the perpendicular and the acute angle.

If, therefore, from any one angle of a triangle whose sides are known [a perpendicular is dropped], etc. Which was to be done.

SCHOLIUM.

You see, then, that in either method the calculation itself shows whether the perpendicular falls inside the triangle or outside. This same problem can also be solved by proposition 13 or 12 of Euclid's book 2, according as the perpendicular falls inside the triangle or outside. For let the perpendicular AD first fall inside, with the sides as before: $AB = 13$, $AC = 20$, $BC = 21$. Both angles B and C will be acute, because of the right angles at D, [Margin: (e) Euclid I.17] since both angles B and ADB, and both C and ADC, are less than two right angles. [Margin: (f) Euclid II.13] Since, then, the square of AC is less than the two squares of AB and BC by twice the rectangle contained under CB and BD, if the square of side AC — namely 400 — is subtracted from the sum of the squares of sides AB and BC — namely 610 — the remainder will be twice the rectangle under CB and BD, namely 210. Half of this, being 105, is the rectangle contained under CB and BD; dividing it by side BC — that is, by 21 — gives the segment $BD = 5$. So the remaining CD will be 16. This can, however, be found in the same way if the square of side AB is subtracted from the squares of sides AC and CB, etc.; for that too is less than these two by twice the rectangle contained under BC and CD.

Next let the perpendicular AD fall outside, with the sides as before: $AB = 13$, $AC = 20$, $BC = 11$. The angle ABC will be obtuse, [Margin: (h) Euclid I.17] because the two angles D and ABD are less than two right angles; and hence ABD is acute, since D is right. [Margin: (i) Euclid II.12] Since, then, the square of AC is greater than the two squares of AB and BC by twice the rectangle contained under CB and BD — that is, by 290 — if this is subtracted from 400, the square of side AC, there remains twice the rectangle contained under CB and BD, namely 110. Half of this, namely 55, is the rectangle contained under CB and BD; dividing it by side $BC = 11$ gives the line BD, outside the triangle, = 5, which together with the 11 of side BC composes the line $CD = 16$.

Diagram. Two small triangles are printed in the middle-right column, reprising the two cases of PROPOS. 9 for this scholium.

Upper triangle — perpendicular inside (cf. fig-p802-1):

- A (apex); base B, D, C (D the foot of AD)
- side AB **13**; side AC **20**; base BC **21**

Lower triangle — perpendicular outside (cf. fig-p802-2):

- A (apex); base D, B, C (D outside, to the left of B)
- side AB **13**; side AC **20**; base BC **11**

[Margin: *Praxis.*]

Therefore, when the perpendicular falls inside the triangle: if half the difference between the square of either of the sides containing the angle from which the perpendicular is dropped and the sum of the squares described on the remaining two sides is divided by the side onto which the perpendicular falls, there is produced the segment of the base near the angle contained by the sides whose sum of squares was taken; and this segment, subtracted from the same base, leaves the other segment.

But when the perpendicular falls outside the triangle: if half the difference between the square of the side opposite the obtuse angle and the sum of the squares described on the remaining two sides is divided by the side onto whose production the perpendicular falls, there is produced the line, outside the triangle, between the perpendicular and the obtuse angle; and this, added to the base, establishes the other line between the perpendicular and the acute angle of the base.

PROBL. 6. PROPOS. 10.

[Margin: In a non-right triangle, from the known angles (or from the known proportions of the angles) together with one side, the remaining parts are investigated (*In triangulo non rectangulo ex angulis notis, vel ex proportionibus angulorum notis, vna cum vno latere reliqua inuestigantur*).]

Given all the angles of a non-right triangle, or given their proportions, together with one side: to find the remaining two sides, and to make known the proportion of any two of them.

Diagram. Two triangles are printed at the top left, for the two cases of PROPOS. 10 (given all angles + one side).

Left triangle — all angles acute:

- A (apex); B and C (base vertices)
- angle A labelled **75.45** ($75^{\circ}45'$); angle B labelled **67.23** ($67^{\circ}23'$); angle C labelled **36.52** ($36^{\circ}52'$)

Right triangle — angle B obtuse:

- A (apex); B and C (base vertices)
- angle A labelled **30.31** ($30^{\circ}31'$); angle B labelled **112.37** ($112^{\circ}37'$); angle C labelled **36.52** ($36^{\circ}52'$)

In triangle ABC let all the angles first be acute and given: $A = 75^\circ 45'$, $B = 67^\circ 23'$, $C = 36^\circ 52'$. Let side $AB = 13$ also be given. From these the remaining two sides are to be found. [Margin: (a) prop. 1 of this book] Since as the sine of angle C is to the sine of angle A, so is the given side AB to side BC: if it is arranged that as the sine of angle C — namely 59996 — is to 96923, the sine of angle A, so is side AB, given as 13, to a fourth, side BC will be found to be nearly 21, as appears here.

C.	A.	AB.	BC.
59996.	96923.	13 ?	fit 21 ferè

Likewise, since as the sine of angle C is to the sine of angle B, so is side AB to side AC: if it is arranged that as 59996, the sine of angle C, is to 92310, the sine of angle B, so is side AB, given as 13, to a fourth, side AC will be found to be nearly 20, as you see here.

C.	B.	AB.	AC.
59996.	92310.	13 ?	fit 20 ferè

[Margin: (b) prop. 1 of this book] Or, since as the sine of angle A is to the sine of angle B, so is side BC (found above) to side AC: if it is arranged that as 96923, the sine of angle A, is to 92310, the sine of angle B, so is side BC, found as 21, to a fourth, side AC will be found to be nearly 20, as you see here.

A.	B.	BC.	AC.
96923.	92310.	21 ?	fit 20 ferè

Next let angle B be obtuse, $112^\circ 37'$; $A = 30^\circ 31'$, $C = 36^\circ 52'$; and again side $AB = 13$. Since the sine of angle B is the same as the sine of its complement, $67^\circ 23'$ — as we demonstrated in the treatment of sines — side $BC = 11$ and $AC = 20$ will be found, nearly, by the method already set out, as is clearly established here.

C.	A.	AB.	BC.
59996.	50779.	13 ?	fit 11 ferè

Likewise:

C.	B.	AB.	AC.
59996.	92310.	13 ?	fit 20 ferè

Or:

A.	B.	BC.	AC.
50779.	92310.	11 ?	fit 20 ferè

[Margin: *Praxis.*]

Therefore, given all the angles together with one side: if it is arranged that as the sine of the angle opposite the [given] side is to the sine of either of the remaining angles, so is the given side to a fourth, there will be found the side opposite the angle whose sine was taken. And if again it is arranged that as the sine of the angle opposite the given side is to the sine of the third angle, so is the given side to a fourth, there will be found the side opposite the third angle, and so on.

[Margin: When the triangle is isosceles or equilateral; or when in a scalene triangle two sides are given with the angles. When the proportions of the angles are given, together with one side (*Quando trianguli est Isosceles, vel æquilaterum: aut quando in scaleno dantur duo latera cum angulis. Quando dantur proportionēs angulorum, cum vno latere*).]

Now if the triangle is isosceles and the angles are given, or if it is scalene and two sides are given together with the angles, only one side needs to be found, as is evident. In an equilateral triangle, however, if one side is given, the rest are given too, being equal to it.

And if the proportions of the angles are given together with one side, the magnitudes of the angles must be investigated from those proportions, as we demonstrated in the scholium of proposition 1; and then the remaining sides are to be explored, as has been shown here.

Once the sides are found, it is clear that their proportions are known in the numbers in which they themselves are known. Therefore, given all the angles of a non-right triangle, etc. Which was to be done.

PROBL. 7. PROPOS. 11.

[Margin: In a triangle, from the known sides — or from their known proportions — the angles are found (*In triangulo ex notis lateribus, vel ex eorum proportionibus notis, anguli inueniuntur*). (a) I.19; (b) I.17; (c) scholium of II.13; (d) prop. 9 of this book.]

Given all the sides of a non-right triangle, or their proportions: to make all the angles known.

Diagram. Two triangles are printed at the bottom left, for PROPOS. 11 (given all sides → find the angles).

Upper triangle — perpendicular inside:

- A (apex); base B, D, C (D the foot of the perpendicular AD)
- side AB **13**; side AC **20**; base BC **21**

Lower triangle — obtuse case:

- A (apex); base B, D, C, with the perpendicular AD
- side AB **11**; side AC **13**; a further value **20** [reprises the obtuse triangle AB = 13, AC = 20, BC = 11; interior labels partly abraded — see readability note]

In the prior triangle ABC let all the sides be given: AB = 13, AC = 20, and BC = 21. From these the angles are to be investigated. Onto the greatest side BC, from the opposite angle A, let the perpendicular AD be drawn, which will necessarily fall inside the triangle. For since side BC is the greatest, [Margin: (a) I.19] angle A, opposite it, will also be the greatest, [Margin: (b) I.17] and therefore both B and C are acute. [Margin: (c) scholium of II.13] From which it follows that the perpendicular AD falls inside the triangle. [Margin: (d) prop. 9 of this book] First, then, let the lines BD and CD be sought. BD will be found to be 5, and CD 16. Since, then, with AB posited as the whole sine, the line BD is the sine of angle BAD — as we showed in the treatment of sines — we shall say, by the rule of three: if AB, 13, gives AB, the whole sine of 100000 parts, what will BD, 5, give? And we shall find the sine of BD to be 38461, as you see here.

AB.	AB.	BD.	BD.
13.	100000.	5 ?	fit 38461.

From the table of sines, then, angle BAD will be given as 22°37', and so its complement B as 67°23', which is one of the sought angles. Again, since with AC posited as the whole sine, CD is the sine of angle CAD, we shall say once more by the rule of three: if AC, 20, gives AC, 100000, the whole sine, what will CD, 16, give? And we shall find the sine of CD to be 80000, as is evident here.

AC.	AC.	CD.	CD.
20.	100000.	16 ?	fit 80000.

This sine, in the table of sines, shows angle CAD to be 53°8'; and hence its complement C

(Continuing *PROBL. 7 / PROPOS. 11* from the previous page — the three sides given, the angles sought.)

will be $36^{\circ} 52'$, which is likewise one of the angles sought. And if the two angles derived from the two sines found — namely $22^{\circ} 37'$ and $53^{\circ} 8'$ — are added together, the third angle BAC becomes $75^{\circ} 45'$. Or, just as well, if the sum of the two angles B and C already found is subtracted from 180° , the remainder gives the third angle BAC, $75^{\circ} 45'$.

Praxis. [Margin: Praxis] And so, to embrace the whole procedure: arrange that as the greatest side (onto which the perpendicular has been dropped) is to the sum of the other two, so the difference of those same two is to a fourth number. This number, subtracted from the greatest side, leaves a number whose half gives the smaller segment of the base, while that half, taken from the base, leaves the greater segment — as is established from the second procedure of Proposition 9. Next, if it is arranged that as the smallest side is to the whole sine, so the smaller segment of the base is to a fourth, there will be found a sine whose arc's complement gives the angle standing over the base opposite the middle side. Then, if it is arranged that as the middle side is to the whole sine, so the greater segment of the base is to a fourth, there will be found a sine whose arc's complement gives the angle over the base opposite the smallest side. The third angle, opposite the greatest side, is then made up from those two arcs of the two sines found; or else it is simply what remains after the two angles found are subtracted from two right angles.

Again, in the second triangle let side AB be 11, AC 13, and BC 20. When the perpendicular AD is dropped onto the greatest side BC, the segment BD is found to be $8\frac{4}{5}$, and CD $11\frac{1}{5}$, as appears here, following the latter procedure of Proposition 9.

BC.	AB. AC.	Differ. inter AB, AC.	
20.	24.	2 ?	fit $2\frac{2}{5}$.

This number, $2\frac{2}{5}$, taken from the base 20, leaves $17\frac{3}{5}$, whose half, $8\frac{4}{5}$, gives the smaller segment BD. Therefore the greater, CD, will be $11\frac{1}{5}$. From this, angle B is found to be $36^{\circ} 52'$, C $30^{\circ} 31'$, and BAC $112^{\circ} 37'$, as you see here.

AB.	AB.	BD.	BD.
11.	100000.	$8\frac{4}{5}$?	fit 80000.

Again (Item.):

AC.	AC.	CD.	CD.
13.	100000.	11 $\frac{1}{5}$?	fit 86154.

The complement of the arc that the first sine found yields gives angle B, 36° 52'; and the complement of the arc of the second sine found gives angle C, 30° 31', and so on. The doctrine of this proposition is therefore general — whether the greatest angle A is acute (as in the first triangle), or obtuse (as in the second), or finally right; though for the right-angled triangle it was already shown above, in Proposition 3, how the two acute angles are more easily found from two known sides. [Margin: Generalitas huius propos. — On the generality of this proposition.]

Now if instead the proportions of the sides are given — at least two of them — [a] we shall carry them out in the three smallest numbers, in case the smallest numbers of the proportions are not given, as Euclid taught in Proposition 4 of Book 8; and we shall assign those numbers to the sides just as if the sides had been given in those numbers. For example, if in the first triangle the ratio of AB to BC is 26 to 42, and that of AB to AC is 39 to 60, these ratios are reduced to these smallest numbers, 13 : 21 and 13 : 20. So AB will be given as 13, AC as 20, and BC as 21; and from these we shall extract the angles as before. [Margin: Quando laterum proportiones datae sunt. — When the proportions of the sides are given. a: 35 of the seventh (Euclid VII.35).]

[b] Furthermore, in an isosceles triangle the perpendicular must be dropped to the base — whether that be the greatest side or the smallest — and it will bisect the base. Hence if it is arranged that as one of the equal sides is to the whole sine, so half the base is to a fourth, there will be found the sine of a certain arc whose complement gives one of the equal angles over the base, as is clear from what has been demonstrated. Therefore the other equal angle is also given, and consequently the third, opposite the base, as being what remains of two right angles. [Margin: Quando triangulum est Isosceles. — When the triangle is isosceles. b: Corollary 8 of this.]

Finally, in an equilateral triangle the angles are given even if the sides are not, since each is a third part of two right angles — that is, contains 60°. Therefore, all the sides of a non-right-angled triangle being given, [the angles are found], and so on. Which was to be done. [Margin: Quando triangulum est aequilaterum. — When the triangle is equilateral.]

SCHOLIUM.

[Margin: Quando perpendicularis in obtusangulo triangulo cadit extra triangulum. — When in an obtuse-angled triangle the perpendicular falls outside the triangle.]

Although in this proposition we prescribed that the perpendicular be drawn to the greatest side from the opposite angle, so that it falls inside the triangle and the calculation is made easier, nevertheless we shall solve the problem by almost the same route even if, in an obtuse-angled triangle, the perpendicular is drawn not from the obtuse angle onto the greatest side, but from one of the acute angles onto the opposite side produced, so that it falls outside the triangle. This is evident in the present triangle ABC, in which side AB is given as 22, AC as 31, and BC as 14 (the side onto which the perpendicular is drawn). As 53 — the sum of the other sides AB, AC — is to 9, the difference of those same sides, so a fourth number is found, $34 \frac{1}{14}$; and if side BC is subtracted from it, the number $20 \frac{1}{14}$ remains, whose half, $10 \frac{1}{28}$, is the line BD, and consequently CD is $24 \frac{1}{28}$. For this reason, if it is now arranged that as AB, 22, is to AB [taken as] the whole sine 100000, so BD, $10 \frac{1}{28}$, is to a fourth, the sine BD is found, 45617, whose arc's complement will give the angle ABD, $62^\circ 52'$, and therefore the remaining one of the two right angles, ABC, $117^\circ 8'$. Likewise, if it is arranged that as AC, 31 [recte 35], is to AC [taken as] the whole sine 100000, so CD, $24 \frac{1}{28}$, is to a fourth, a sine is found, 77534, whose arc's complement will present the angle C, $39^\circ 10'$. And if the two angles ABC and C are taken from 180° , the angle BAC remains, $23^\circ 42'$. The rationale of this operation is gathered from the treatment of sines, where we showed that if AB is set as the whole sine, BD is the sine of angle BAD; likewise, if AC is set as the whole sine, CD is the sine of angle CAD; and so on.

Diagram. An obtuse-angled triangle drawn for the scholium, with the perpendicular falling outside the triangle. Apex A at the top; along the base line, left to right, the points D, B, C. The perpendicular AD descends from A to the point D, which lies to the left of B (outside segment BC).

- A (apex): vertex of the triangle from which the perpendicular is dropped
- D (base, leftmost): foot of the perpendicular AD, outside the triangle
- B (base, middle): vertex; segment DB is the exterior part of the base
- C (base, right): vertex

- Label "31" along side AC (the longer slant)

- Label "41" at the base near BC [recte 14 — the text gives BC = 14; the woodcut shows the digits transposed]

THEOR. 8. PROPOS. 12.

Given two sides of a non-right-angled triangle together with the angle they contain; or given the ratio of the two sides containing a given angle: to find the third side and the remaining angles.

[Margin: In a non-right-angled triangle, from two known sides — or from their known ratio — together with the angle contained by them, the third side and the remaining angles are sought.]

In triangle ABC let there first be given two sides AB and AC — the former 3, the latter 5 — enclosing the angle A, which is obtuse and is also given as $93^\circ 50'$. From these we must investigate the third side BC and the remaining angles B and C. Since angle A is given as $93^\circ 50'$, if it is subtracted from 180° — that is, from two right angles — the remainder, $86^\circ 10'$, will be the sum of the two angles B and C. Moreover, the ratio of the sines of the angles C and B is also given, namely the same as that of side AB, 3, to side AC, 5, [a] because as side AB is to side AC, so is the sine of angle C to the sine of angle B. [b] Hence each of the angles C and B will be known separately: the former $29^\circ 55'$, the latter $56^\circ 15'$. [c] And since the sides are proportional to the sines of the opposite angles, it will hold that as the sine of angle C is to the sine of angle A, so side AB is to side BC; or as the sine of angle B is to the sine of angle A, so side AC is to side BC. By the rule of three, therefore, side BC is found, nearly 6, as appears here. [Margin: a: Prop. 1 of this; b: Prop. 6 of this; c: Prop. 1 of this.]

Diagram. A triangle ABC with A at the apex, B at the lower left, C at the lower right.

- A (apex): vertex holding the obtuse given angle
- B (lower left): vertex
- C (lower right): vertex
- Label "3" on side AB
- Label "5" on side AC
- Label "6" on the base BC

C.	A.	AB.	BC.
49874.	99776.	3 ?	fit 6. fere.

Or (Vel.):

B.	A.	AC.	BC.
83147.	99776.	5 ?	fit 6. fere.

Praxis. [Margin: Praxis] So then, to embrace the whole procedure: if (once the given angle has been taken from 180° , so as to have the sum of the other two) it is arranged that as the half-sum of the two given sides — that is, the half-sum of the terms of the ratio of the sines of the remaining angles — is to the tangent of the half-sum of the remaining angles, so the difference between the half-sum of the given sides (that is, of the terms of the ratio of the sines of the remaining angles) and either of the sides (or of the terms of the ratio) is to a fourth: there will be found the tangent of an angle which, added to the half-sum of the remaining angles, makes up the greater angle — that, namely, which is opposite the greater given side; while the same, subtracted from that said half-sum, leaves the smaller angle, opposite the smaller given side, as is evident from the earlier procedure of Proposition 6. And if it is next arranged that as the sine of either of the angles found is to the sine of the angle given at the outset, so the side opposite the found angle (the one taken into the rule of three) is to a fourth: the third side will be found. For greater clarity we will set out another example.

Let there be given in triangle ABC two sides AB and AC, 22 and 31, together with the angle A, $23^\circ 42'$. This angle, taken from 180° , leaves $156^\circ 18'$ for the sum of the angles B and C. So if it is arranged that as $26\frac{1}{2}$ — the half-sum of the sides AB, AC (that is, of the terms of the ratio of the sines of the angles B, C) — is to 476595, the tangent of the half-sum of the angles B, C (that is, the tangent of $78^\circ 9'$), so $4\frac{1}{2}$, the difference between the half-sum of the sides AB, AC (or of the terms of the ratio of the sines of the angles B, C) and either of the sides (or terms), is to a fourth: there will be found the tangent 80931, whose arc, $38^\circ 59'$, added to $78^\circ 9'$ (namely to the half-sum of the angles B, C), constitutes the greater angle B — opposite the greater given side AC — $117^\circ 8'$. But the same arc, $38^\circ 59'$, subtracted from that same half-sum of the angles B, C (that is, from $78^\circ 9'$), leaves the smaller angle C, opposite the smaller given side AB, $39^\circ 10'$. By the operation of the rule of three you see it here.

$\frac{1}{2}(AB+AC)$	$\tan \frac{1}{2}(B+C)$	$\frac{1}{2}$ diff.	
$26\frac{1}{2}$	476595	$4\frac{1}{2}$?	fit 80931.

Diagram. A triangle ABC with the perpendicular CD drawn inside it (for the alternative demonstration below). Apex A at the top; the left edge AB runs down through D to B at the lower left; C lies to the right; CD is the perpendicular dropped from C onto AB, meeting it at D.

- A (top): vertex holding the acute angle
- D (on side AB, below A): foot of the perpendicular CD
- B (lower left): vertex
- C (right): vertex from which the perpendicular is dropped

Then if it is now arranged that as 63158, the sine of angle C, is to 40195, the sine of angle A, so side AB, 22, is to a fourth; or as 88995, the sine of angle B, is to 40195, the sine of angle A, so side AC, 31, is to a fourth: side BC will be found, nearly 14, as you see here.

C.	A.	AB.	BC.
63158.	40195.	22 ?	fit 14. fere.

Or (Vel.):

B.	A.	AC.	BC.
88995.	40195.	31 ?	fit 14. fere.

If you would rather not use tangents, the latter procedure of Proposition 6 must be employed in finding the angles B and C.

Now if the ratio of the sides AB, AC is given, together with the angle A contained by them, we shall assign to those sides the numbers of the ratio, as if they were given in those very numbers, and we shall solve the problem as before. [Margin: Quando laterum proportio data est. — When the ratio of the sides is given.]

[Margin: Alia demonstratio problematis sine propos. 6. — Another demonstration of the problem, without Proposition 6. d: 19 of the first; e: 17 of the first; f: Scholium 13 of the second; g: 1 of this.]

This problem can also be solved without the aid of Proposition 6, in the following way. In triangle ABC let side AB be given as 29, AC as 24, and angle A first acute, $38^{\circ} 16'$. From the opposite angle C let the perpendicular CD be drawn to the greater side AB; it will necessarily fall inside the triangle. For since side AB is greater than side AC, [d] angle C will also be greater than angle B. Hence B will be acute; for if it were right, or greater, C would be greater still than a right angle — which is absurd, [e] since B and C are less than two right angles. Since therefore A too is taken as acute, [f] the perpendicular CD falls inside the triangle. So in the right triangle ACD, since angle A is $38^{\circ} 16'$, its complement ACD will be $51^{\circ} 44'$. [g] Hence, since it holds that as the whole sine of the right angle D is to the sine of angle A, so side AC, 24, is to side CD, side CD is found by the rule of three, 14 [+ small compound fraction: ?], as appears here.

D.	A.	AC.	CD.
100000.	61932.	24 ?	fit 14 [+ fraction: ?].

By the same reasoning, [h] since it holds that as the whole sine of the right angle D is to the sine of angle ACD, so side AC, 24, is to side AD, side AD is found, 18 [+ small compound fraction: ?], as you see here. [Margin: h: 1 of this.]

D.	ACD.	AC.	AD.
100000.	78514.	24 ?	fit 18 [+ fraction: ?].

Now when AD is taken away from AB (found from AB, given as 29), BD remains, 10 [+ small compound fraction: ?]. And since, as we showed in the treatment of tangents, once BD is set as the whole sine the line CD is the tangent of angle B, the tangent is found, 146344, as is here manifest.

BD.	BD.	CD.	CD.
10 [+ fraction: ?]	100000.	14 [+ fraction: ?] ?	fit 146344.

Now the tangent 146344 indicates in the table of tangents the angle B, $55^{\circ} 40'$; and consequently the two angles A and B — $38^{\circ} 16'$ and $55^{\circ} 40'$ — subtracted from 180° leave the angle ACB, $86^{\circ} 4'$. [i] And since it holds that as the sine of the known angle B is to the sine of the given angle A, so the given side AC, 24, is to side BC, the side BC is found, nearly 18, as you see here. [Margin: i: 1 of this.]

B.	A.	AC.	BC.
82577.	61932.	24 ?	fit 18. fere.

Again, in triangle ABC let side AB be given as 13, AC as 11, and the angle A contained by them obtuse and given as $112^{\circ} 37'$. From either of the acute angles — say from B — let a perpendicular be drawn to the opposite side CA: [k] it will fall outside the triangle. Since therefore the angle BAC is set as $112^{\circ} 37'$, BAD will be $67^{\circ} 23'$, and its complement ABD necessarily $22^{\circ} 37'$. [l] Hence, since it holds that as the whole sine of the right angle D is to the sine of angle BAD, so side AB (given 13) is to side BD; and likewise as the whole sine of the right angle D is to the sine of angle ABD, so the given side AB, 13, is to side AD: BD is found to be 12, and AD nearly 5, as appears here. [Margin: k: Scholium 12 of the second; l: 1 of this.]

Diagram. The obtuse triangle ABC with the perpendicular BD falling outside it. The side CA is produced beyond A to the point D; the perpendicular BD runs from

B (lower left) up to D. A sits between the base vertices and D, with C at the lower right.

- D (upper left): foot of the perpendicular BD, on line CA produced beyond A
- A (upper middle): vertex holding the obtuse angle BAC
- B (lower left): vertex from which the perpendicular is drawn
- C (lower right): vertex

Now when AD (found to be 5) is added to side AC (given 11), the whole CD becomes 16. Since therefore, once the whole sine is set on CD, the line BD is the tangent of angle C, the tangent BD is found, 75000, as you see here.

This tangent presents, in the table of tangents, the angle C, $36^{\circ} 52'$; and consequently the two angles A and C — $112^{\circ} 36'$ [recte $37'$] and $36^{\circ} 52'$ — taken from 180° leave the angle ABC, $30^{\circ} 31'$. [m] Since at last it holds that as the sine of the known angle C is to the sine of the given angle BAC, so the given side AB, 13, is to BC, the side BC is found, nearly 20, as appears here. [Margin: m: 1 of this.]

C.	BAC.	AB.	BC.
59996.	92310.	13 ?	fit 20. fere.

But, as you see, the former method is much shorter and more expeditious.

And if it should happen that the two given sides enclosing the given angle are equal, the problem will be easier. For let there be in triangle ABC two equal sides AB, AC, each 9, and the contained angle A, 80° . When this angle is taken from 180° , the half of the remainder — which is 100° — gives each of the angles B and C as 50° . Then if it is arranged that as the sine of angle B (or C) is to the sine of angle A, so side AC (or AB) is to a fourth, the side BC comes out, $11\frac{43685}{76604}$, as

you see here. [Margin: Quando data latera sunt aequalia. — When the given sides are equal.]

Diagram. A near-isosceles triangle ABC, A at the apex, B at the lower left, C at the lower right (no numeric labels; only the vertex letters A, B, C).

Therefore, given two sides of a non-right-angled triangle together with the angle they contain, and so on. Which was to be done.

PROBL. 9. PROP. 13.

Given two sides of a non-right-angled triangle, or their given ratio, together with the angle opposite one of the given sides: to find the remaining angles and the third side. But one must be certain whether the other angle, opposite the given side, is acute or obtuse — assuming the given angle is acute.

[Margin: In a non-right-angled triangle, from two given sides — or from their given ratio — together with one angle not contained by them, the third side and the remaining angles are investigated. a: 1 of this.]

Let there be given in triangle ABC two sides AB, AC, 13 and 20, and let the acute angle C, $36^\circ 52'$, opposite the given side AB, be given; and let it be established, concerning angle B (which is opposite the other given side AC), whether it is acute or obtuse — for otherwise nothing certain could be gathered, as will be clear from the following scholium. [a] Since therefore it holds that as side AB is to side AC, so the sine of angle C is to the sine of angle B, and the three first terms are given, the fourth is found by the rule of three, that is, the sine of angle B, 92302, as is here clear. [Margin: a: 1 of this.]

AB.	AC.	C.	B.
13.	20.	59996 ?	fit 92302.

This sine, in the table of sines, exhibits the angle B as nearly $67^\circ 23'$ if it is acute (as in the former triangle), or, if obtuse (as in the latter triangle), $112^\circ 37'$ — inasmuch as this completes the semicircle with the other, since an obtuse and an

acute angle making up 180° have the same sine, as we demonstrated in the definitions of sines. When the two angles C and B are taken from 180° , there remains, in the former triangle, the angle A, $75^\circ 45'$, but in the latter $30^\circ 31'$. And the side BC is found, by the rule of three, to be about 21 parts in the former triangle, but in the latter about 11, [b] since it holds that as the sine of angle C is to the sine of angle A, so side AB is to side BC — as appears in this operation.
[Margin: b: 1 of this.]

C.	A.	AB.	BC.
59996.	96923.	13 ?	fit 21. fere.

Again (Item.):

C.	A.	AB.	BC.
59996.	50779.	13 ?	fit 11. fere.

Diagram. Two triangles side by side, illustrating the ambiguous case — the acute-B solution on the left, the obtuse-B solution on the right. In each, A is at the apex, B at the lower left, C at the lower right; the interior angle values are inscribed.

- Left triangle (acute B): A " 75.45 " ($75^\circ 45'$); B " 67.23 " ($67^\circ 23'$); C " 36.52 " ($36^\circ 52'$)
- Right triangle (obtuse B): A " 30.31 " ($30^\circ 31'$); B " 112.37 " ($112^\circ 37'$); C " 36.52 " ($36^\circ 52'$)

Praxis. [Margin: Praxis] And so, if it is arranged that as the side opposite the given angle is to the other given side, so the sine of the given angle is to a fourth: there will be found a sine whose arc gives the angle opposite the other given side, if it is acute (which indeed...

[it] indeed always happens when the given angle is obtuse — or else that angle, subtracted from a semicircle, will yield the required angle if it is obtuse. And the sum formed from the given angle and the found angle, subtracted from 180 degrees, will give the third angle. Finally, if we set up the proportion — as the sine of the given angle is to the sine of the third angle (the one contained by the given sides, which was found last), so is the side that is given, opposite the given angle, to another — the third side will be produced.

And if instead the ratio of the two sides is given, then, provided numbers in that ratio are assigned to those sides, we shall carry out the problem in the same way.

[Margin: When the ratio of the two sides is given (Quando proportio duorum laterum datur).]

ALITER [Another method]. Again let two sides be given: $AB = 13$ and $AC = 20$, together with angle C , acute, of $36^\circ 52'$. Suppose first that the other angle, B , is likewise acute, as in the earlier triangle. Drop from A the perpendicular AD to BC [c]; it will fall inside the triangle. In the right triangle ACD , if AC is taken as the whole sine [radius], then the straight line AD is the sine of the given angle C , as we taught in the treatise on sines. So if we set up the proportion — as AC the whole sine is to AC the given side, so is AD the sine of the given angle C to another — we find $AD \approx 12$, as you see here.

[Margin: c — Scholium 13 of the second [book] (c Schol. 13. secundi).]

Diagram. A triangle with apex A above a horizontal base running from B (left) through D to C (right); the perpendicular AD is drawn from the apex down to the point D inside the base. The left side is marked **13** (AB), the right side **20** (AC), and the base **21** (BC). This is the acute-angled- B case of the worked example.

- A (apex): vertex
- B (base, left): vertex
- D (base, between B and C): foot of the perpendicular AD , inside the triangle
- C (base, right): vertex
- 13 (left side AB): side length
- 20 (right side AC): side length
- 21 (base BC): side length

AC.	AC.	AD.	AD.
100000.	20.	59996?	fit 12. fere.

Again, since, with AB taken as the whole sine, the straight line AD is the sine of angle B — as was handed down in the [treatment of] sines — then if we set the proportion: as AB the given side is to the whole sine, so is AD , now found, to another, the sine $AD = 92308$ will be found, as appears here.

AB.	AB.	AD.	AD.
13.	100000.	12?	fit 92308.

From the table of sines, therefore, angle B is obtained as $67^\circ 23'$, and consequently BAC , the remainder from two right angles, is $75^\circ 45'$ [d]. And since it holds that, as the sine of the given angle C is to the sine of the found angle A , so is side AB to side BC , side BC is found ≈ 21 , as you see here.

[Margin: d — Prop. 1 of this [book] (d 1. huius).]

C.	BAC.	AB.	BC.
59996.	96923.	13?	fit 21. fere.

Next, with the same data, let the other angle B be obtuse, as in the second triangle. Drop from A the perpendicular AD to BC [e]; it will fall outside the triangle. In the right triangle ACD, if AC is taken as the whole sine, the straight line AD is the sine of angle C, as was said in the treatment of sines. So if we set the proportion — as the whole sine is to the given side AC, so is the sine of the given angle C to another — AD is found ≈ 12 , as appears here.

[Margin: e — Scholium 12 of the second [book] (e Schol. 12. secundi).]

Diagram. A triangle with apex A over a base whose foot of the perpendicular falls outside it. Reading the base from left to right: D (leftmost, outside the triangle), then B, then C. The perpendicular AD runs from the apex down to D, outside the triangle. The upper-right side is marked **20** (AC) and the left side **13** (AB). A mark reading "II" appears on the base between B and C (possibly the length ≈ 11 of BC in this case; unresolved [?]). This is the obtuse-angled-B case.

- A (apex): vertex
- D (base, leftmost, outside triangle): foot of the perpendicular AD
- B (base, middle): the obtuse vertex
- C (base, right): vertex
- 20 (side AC): side length
- 13 (side AB): side length
- "II" (base, between B and C): mark, possibly the value 11 of BC [?]

AC.	AC.	AD.	AD.
100000.	20.	59996?	fit 12. fere.

Again, since, with AB taken as the whole sine, the straight line AD is the sine of angle ABD — as we explained in the definition of sines — if we set the proportion: as the given side is to the whole sine, so is AD, just found, to another, the sine AD = 92308 will be found, as you see here.

AB.	AB.	AD.	AD.
13.	100000.	12?	fit 92308.

This sine shows, in the table of sines, the angle ABD = $67^\circ 23'$, and consequently the remainder from two right angles, ABC = $11^\circ 37'$ [recte: $112^\circ 37'$]. Then,

subtracting the two known angles C and ABC from 180° , the angle BAC = $30^\circ 31'$ remains [f]. Hence, since it holds that, as the sine of the given angle C is to the sine of the found angle A, so is the given side AB to side BC, side BC is found ≈ 11 , as is clear here.

[Margin: f — Prop. 1 of this [book] (f 1. huius).]

C.	A.	AB.	BC.
59996.	50779.	13?	fit 11. fere.

Finally, with the same sides given, let the obtuse angle ABC = $112^\circ 37'$ be given, as in the second triangle. Carrying out the same construction: since, with AB taken as the whole sine, the straight line AD is the sine of angle ABD — that is, of the given angle ABC [supplementary angles having equal sines] — AD is again found ≈ 12 , as you see here.

AB.	AB.	AD.	AD.
100000.	13.	92308?	fit 12. fere.

Again, since, with AC taken [as the whole sine], the straight line AD is the sine of angle C, the sine AD = 60000 will be found, as appears here.

AC.	AC.	AD.	AD.
20.	100000.	12?	fit 60000.

Therefore angle C = $36^\circ 52'$, and consequently the remainder from two right angles, BAC = $30^\circ 31'$. Side BC is found = 11, as before. Thus: given two sides of a non-right triangle, etc. Which was to be done.

SCHOLIVM.

[Margin: When the given angle is acute, why it must be established whether the other angle is acute or obtuse (Quando datus angulus est acutus, cur constare debeat, num alter angulus sit acutus, vel obtusus). g — Prop. 4 of the first [book] (g 4. primi).]

That nothing certain can be concluded when the given angle, opposite one of the given sides, is acute — unless it is first known whether the angle opposite the other given side is acute or obtuse, as we said in the proposition — we shall make clear as follows. In triangle ABC let the sides AB and AC be given, together with the acute angle B. When the perpendicular AD is dropped from A to BC, it will be unknown whether it falls outside the triangle or inside, unless it is known

whether the other angle, ACB, is obtuse or acute. Take also the straight line DE, on the other side of the perpendicular AD, equal to DC; and draw the straight line AE[?]. Then AE will be equal to AC [g], because the sides DC, DA are equal to the sides DE, DA and contain equal angles — namely right angles. And so, even though the sides AB, AC (or AB, AE) and the acute angle B are known, the remaining side will still not on that account be known, nor the remaining angles — since the remaining side could be either BC or BE, and consequently the remaining angles could be either BCA and BAC, or BEA and BAE — unless it is first established whether the angle BCA is obtuse or acute. For once this is known, we shall know when the perpendicular AD falls outside the triangle and when inside; and so on.

Diagram. The upper of two figures illustrating the ambiguous (SSA) case. An apex A stands above a horizontal base; reading the base from left to right the labelled points are B, C, D, E. Straight lines are drawn from A to C, to D, and to E (with AB closing the leftmost triangle); AD is the perpendicular.

- A (apex): common vertex
- B (base, leftmost): vertex
- C (base): one possible vertex (BC one possible remaining side)
- D (base): foot of the perpendicular AD
- E (base, rightmost): reflected point with DE = DC (giving AE = AC)

Diagram. The lower of the two figures. An apex A stands above a base whose labelled points, read left to right, are B, E, D, C; straight lines run from A to the base points. This is the companion configuration in which the alternative triangle ABE is realized.

- A (apex): common vertex
- B (base, leftmost): vertex
- E (base): alternative vertex (BE the alternative remaining side)
- D (base): foot of the perpendicular AD
- C (base, rightmost): vertex

[Margin: Error of Nicolaus Copernicus (Error Nicolai Copernici).]

From this it is clear that Nicolaus Copernicus [Nicolaus Copernicus] — otherwise most careful — was mistaken in Book I of the *Revolutions* (*De Revolutionibus* I), in proposition 6 on rectilinear triangles, when he states without qualification that, if two sides of a triangle are given, and also the angle opposite one of them, the remaining side and the remaining angles can be found. For this cannot be done,

as we have demonstrated, when the given angle is acute, unless it is established whether the angle opposite the other of the given sides is acute or obtuse.

FINIS TRIANGVLORVM RECTILINEORVM.

[Here the treatise on rectilinear (plane) triangles ends and the treatise on spherical triangles begins.]

CHRISTOPHORI CLAVII BAMBERGENSIS E SOCIETATE IESV — TRIANGVLA SPHÆERICA

Christoph Clavius of Bamberg, of the Society of Jesus — SPHERICAL TRIANGLES.

CHRISTOPHORI CLAVII BAMBERGENSIS E SOCIETATE IESV — TRIANGVLA SPHÆERICA

Christoph Clavius of Bamberg, of the Society of Jesus — SPHERICAL TRIANGLES.

PRÆFATIO [Preface]

Now that we have explained what we judged necessary for the science of rectilinear triangles — the science by which the sides are found from known angles and, conversely, the angles from known sides — it remains for us to hand down also the doctrine of spherical triangles, by which the arcs are sought from known angles and, conversely, the angles from known arcs.

[Margin: Almagest, Book VII, ch. 8[?] (Lib. 7. Almag. cap. 8[?]).]

For although Menelaus [Menelaus of Alexandria] — also called Mileus, a distinguished author, who flourished in the time of the Emperor Trajan, as Ptolemy [Ptolemy] reports — composed three highly acute books on spherical triangles, we shall nonetheless not follow his order in these spherical triangles of ours. This is both because we have set aside many of his propositions, delightful and marvelously learned though they are, as not necessary, and because we have added not a few others, omitted by him, drawn from Geber of Seville [Jābir ibn Aflah], Johannes Regiomontanus [Regiomontanus], Francesco Maurolico [Francesco Maurolico], and others — propositions we judged wholly necessary for understanding matters of astronomy. For the most part, too, we have supplied new demonstrations — shorter and easier ones — and some we have likewise

demonstrated in the same way that the corresponding results about angles and rectilinear triangles were demonstrated by Euclid [Euclid], so that their demonstration might be plainer; among these are propositions 5, 6, 7, 8, and 9. We have, moreover, spent no little effort in arranging all the propositions of spherical triangles in such an order that the later ones depend on the earlier — as mathematics requires, and as is customary in every treatment of the elements of geometry. But let us now come to the matter, taking our start from the definitions.

DEFINITIONES [Definitions]

I.

[Margin: What a spherical angle is (Angulus sphaericus quid).]

A spherical angle is the angle which, on the surface of a sphere, two arcs of great circles cutting one another mutually contain.

These pages continue the opening section of Clavius's treatise on spherical triangles: the definitions of the spherical angle (right, obtuse, acute), of the spherical triangle, of the arc of a spherical angle, of the complement of an arc and of an angle, and of the sine, tangent, and secant of a spherical angle; then the first problem and the first theorems of spherical trigonometry.

(Continuing the commentary on Definition I, the spherical angle, begun on the preceding page at the catchword *QVONIAM*.)

Since the spherical angle that geometers consider on a spherical surface is constituted only by arcs of great circles, and since all great circles on a sphere cut one another into two equal parts, it comes about that the two arcs which contain a spherical angle on the surface of the sphere, if produced, cut one another — they do not merely touch one another. Thus every spherical angle arises from two arcs intersecting on the surface of the sphere, and not from arcs merely tangent to one another. This cannot be said of angles lying in a plane surface. For in a plane, not only two straight lines, or two curved lines, or lines of which one is straight and the other curved, cutting one another when produced, can constitute a plane angle; but also two lines, both of them curved, or one curved and the other straight, merely touching one another, can constitute a curvilinear or mixed plane angle (which is indeed called by geometers the angle of contact or of contingence), as is clear from Euclid III.16 — even though Jacques Peletier [Iacobus Peletarius] denies that it is an angle and tries to establish that view by

many arguments, all of which are sophistical and frivolous, as is clear from the solutions to them that we set out in the scholium to the said proposition.

[Margin: a — Theodosius, *Sphaerica* I.11 (11.1.Theod.)]

[Margin: A spherical angle necessarily arises from two arcs cutting one another.]

[Margin: A plane angle can also arise from two lines that do not cut one another, but are merely mutually tangent.]

[Margin: (at "Euclid III.16") propos. 16, lib. 3, Eucl.]

II.

A right spherical angle is one which, on the surface of the sphere, two arcs of great circles cutting each other at right angles contain — that is, arcs of which the one is at right angles to the other.

[Margin: What a right spherical angle is.]

III.

An obtuse spherical angle is one greater than a right angle.

[Margin: What an obtuse spherical angle is.]

IV.

An acute spherical angle, however, is one that is less than a right angle.

[Margin: What an acute spherical angle is.]

A right spherical angle is constructed at a given point on a given arc of a great circle on the surface of the sphere as follows. Through that point and through the pole of the given arc (which is found by Theodosius I.21) let a great circle be described. The circumference of this circle will then make a right angle with the given arc, since this circle stands at right angles to the circle of that arc. But if through the given point an arc of a great circle is described that does *not* pass through the poles of the given arc, the circumference of this circle will make unequal angles with the given arc — one obtuse and the other acute.

[Margin: Construction of a right, obtuse, and acute spherical angle.]

[Margin: a — Theodosius, *Sphaerica* I.15 (15.1.The.)]

V.

A spherical triangle is one contained by three arcs of great circles on the surface of the sphere.

[Margin: What a spherical triangle is.]

This triangle is either *equilateral*, if all its arcs are equal; or *isosceles*, if only two arcs are equal; or, finally, *scalene*, if all its arcs are unequal one from another. Likewise it is either *right-angled*, if it has some right angle; or *obtuse-angled*, in which some angle is obtuse; or, finally, *acute-angled*, if all its angles are acute — just as Euclid said of the rectilinear triangle. Yet this difference is found between the rectilinear triangle and the spherical: in the rectilinear one the remaining two angles are necessarily acute, because two angles taken in any way are less than two right angles; but in the spherical, if one angle is right or obtuse, the other two can also be right, or obtuse, or at least one of them, as will become clear from the demonstrations that follow.

[Margin: A spherical triangle is divided, as the rectilinear one is by Euclid.]

[Margin: The difference between the right-angled and obtuse-angled rectilinear triangle and the spherical.]

[Margin: b — Euclid I.17 (17.prim.)]

VI.

The arc of a spherical angle is an arc of a great circle whose pole is at the angle itself, intercepted between the two arcs that contain the spherical angle.

[Margin: What the arc of a spherical angle is.]

Since the pole of a great circle is distant from it by a quadrant of a great circle, it follows that each of the arcs containing the angle — set between the angle and the arc of the angle — is a quadrant. Therefore, if the angle is right, the arc of the angle will be a quadrant; if acute, less than a quadrant; if, finally, obtuse, greater than a quadrant — and conversely. As we shall demonstrate in Proposition 26.

[Margin: a — Corollary to Theodosius I.16 (Coroll. 16, 1 Theod.)]

VII.

The complement of an arc is the excess by which a quadrant exceeds it, if the arc is less than a quadrant; or the excess by which it exceeds the quadrant, if it is greater than a quadrant.

[Margin: What the complement of an arc is.]

VIII.

The complement of a spherical angle is called the excess by which a quadrant exceeds the arc of that angle, or by which it is exceeded by it.

[Margin: What the complement of a spherical angle is.]

IX.

The sine, tangent, and secant of any spherical angle are the sine, tangent, and secant of that arc which is called the arc of the angle.

PROBL. I. PROPOS. I.

Given two unequal arcs of great circles on the surface of the sphere, neither of which is greater than a semicircle, to cut off from the greater an arc equal to the lesser.

Diagram. Two figures for Proposition 1, side by side. On the left, a narrow lune bounded by two arcs meeting at **A** (top) and **B** (bottom) — the lesser arc AB with its chord. On the right, a circle with **C** at the top, **D** at the bottom, and **E** marked on the right-hand side; the arc CD is the greater arc, and CE is the portion cut off from it.

- A (top of left lune): endpoint of the lesser arc
- B (bottom of left lune): endpoint of the lesser arc
- C (top of right circle): endpoint of the greater arc CD
- E (right side of right circle): point cutting off arc CE equal to arc AB
- D (bottom of right circle): endpoint of the greater arc CD

Let AB and CD be two unequal arcs of great circles, neither of which is greater than a semicircle, and let CD be the greater; and let it be required to cut off from the greater, CD, an arc equal to the lesser, AB. Draw the chord AB, and fit to it, in the arc CD, an equal chord CE. I say that the arc CE cut off is equal to the lesser arc AB. For since the circles of the arcs AB and CD are great circles, and therefore equal, equal chords AB and CE will cut off equal arcs AB and CE — because each

arc is assumed to be less than a semicircle. Therefore, given two arcs of circles, etc. Which was to be done.

[Margin: a — Euclid IV.8 (8.quarti.)]

[Margin: b — Euclid III.28 (28.tertij.)]

THEOR. I. PROPOS. 2.

In every spherical triangle, any side whatsoever is less than a semicircle.

Diagram. Two great circles intersecting to form the spherical triangle ABC. **A** at the top, **B** at the left, **C** at the bottom, and **D** at the right, where the arcs BA and BC produced meet again.

- A (top): vertex of the triangle
- B (left): vertex of the triangle
- C (bottom): vertex of the triangle
- D (right): point where arcs BA, BC produced meet

Let ABC be a spherical triangle. I say that any side is less than a semicircle. For if the arcs BA and BC are produced until they meet at D, beyond A and C, the arcs BAD and BCD will be semicircles, since great circles bisect one another. Therefore both the arc BA and the arc BC are less than a semicircle. In the same way, by producing the arcs AB and AC, we shall show that the arc AC is less than a semicircle. Now the arcs BA and BC, produced beyond the points A and C, will meet, because they make spherical angles with the arc AC, and all three arcs are portions [portiones] of great circles that cut one another at the points A, B, C but do not touch. Hence it follows that each of the arcs BA, BC, when produced, cuts the arc AC produced at the points A and C, as is clear from the definition [...] beyond the points A and C. Therefore, in every spherical triangle, etc. Which was to be demonstrated.

[Margin: a — Theodosius I.11 (11.1.The.)]

THEOR. 2. PROPOS. 3.

In every spherical triangle, any two sides are greater than the remaining one, however they are taken.

Diagram. A large circle (the completed circle of the arc BC) together with a smaller circle AD described from the pole B. **A** lies toward the center-top, **B** at the upper right, **D** at the right on the arc BC, **C** at the bottom, and **E** at the far left (the second pole).

- A (center-top): vertex of the triangle
- B (upper right): vertex of the triangle, taken as pole of circle AD
- D (right): point where circle AD cuts the arc BC
- E (left): the other pole of circle AD
- C (bottom): vertex of the triangle

Let ABC be a spherical triangle. I say that any two sides, say AB and AC, are greater than the side BC. For if the triangle is equilateral, it is obvious that the two together are double the remaining side, and so greater. But if one of the sides AB, AC is equal to the side BC, or greater, or if both are even greater, it is likewise clear that the two sides AB, AC are greater than the remaining side BC. But if each of the sides AB, AC, taken together with the third side BC, is less than it, we shall demonstrate that the sides AB, AC together are greater than the side BC in this way. Let the circle of the third arc BC be completed. Then from the pole B — namely from one extremity of the greater side BC — at a distance equal to either of the smaller arcs, that is, at the distance of the arc BA, let a circle AD be described on the surface of the sphere, cutting the arc BC (which is assumed greater than the arc BA) at D, a point between B and C. And since the circle BC also passes through the other pole of the circle AD, let the other pole be E, which will be distant a semicircle from the pole B, so that BCE is a semicircle. Since, then, the arc BC is less than a semicircle, the pole E will lie beyond the point C; but the point D lies between B and C, as was said. Therefore the point C falls between the points D and E. And so, since from the point C — which lies outside the periphery of the circle AD and away from its pole E — two arcs of great circles CB, CA, less than a semicircle (because they are sides of the spherical triangle ABC), are drawn to the periphery AD, the arc CD, passing through the pole B, will be less than the arc CA. Therefore, adding the equal arcs DB, AB (and they are equal, because the chords subtending them are equal, by the definition of a pole), the whole arc BC will be less than the two arcs AB, AC; that is, the two sides AB, AC will be greater than the side BC. And in the same way any other two sides will be shown greater than the remaining one. Therefore, in every triangle, etc. Which was to be demonstrated.

[Margin: a — Scholium to Theodosius I.10 (Scho.10.1.Theod.)]

[Margin: b — Prop. 2 of this treatise (2.huius)]

[Margin: c — Prop. 2 of this treatise (2.huius)]

[Margin: f — Euclid III.28 (28.tertij.)]

THEOR. 3. PROPOS. 4.

In every spherical triangle, the three sides together are less than a whole great circle.

Diagram. A lens- or eye-shaped figure formed by two arcs meeting at **B** (left) and **D** (right). **A** lies on the upper arc and **C** on the lower arc, forming the spherical triangle ABC, with the arcs BA and BC produced to meet at D.

- A (upper arc): vertex of the triangle
- B (left): vertex of the triangle
- C (lower arc): vertex of the triangle
- D (right): point where arcs BA, BC produced meet

Let ABC be a spherical triangle. I say that the three sides together are less than a whole great circle. For if any two arcs, say BA and BC, are produced until they meet at the point D — and they will necessarily meet beyond A and C, because they cut the great circle AC at the points A and C, or else because each of the arcs BA, BC is less than a semicircle — the two arcs BAD, BCD will be semicircles, because great circles bisect one another. Now since in the triangle DAC the sides DA, DC are greater than the side AC, if the common arcs AB, CB are added — that is, the sum of the arcs AB, CB — the arcs BAD, BCD will also become greater than the three arcs AC, AB, BC; that is, the three sides AC, AB, BC will be less than the two semicircles BAD, BCD, that is, less than a whole great circle. Therefore, in every spherical triangle, etc. Which was to be demonstrated.

[Margin: a — Theodosius I.11 (11.1.The.)]

[Margin: b — Prop. 3 of this treatise (3.huius)]

THEOR. 4. PROPOS. 5.

When an arc of a great circle on the sphere, standing upon an arc of a great circle, makes angles, it will make either two right angles or angles equal to two right angles.

Let the arc of a great circle AB, standing upon the arc of a great circle CD, make two spherical angles ABC, ABD. If, then, the arc AB of the circle passes through the pole of the circle of the arc CD, it will cut the arc CD entirely at right angles — at right angles; and therefore the angles ABC, ABD will be right angles. But if the arc AB does not pass through the poles of the arc CD, it will make the one

angle obtuse, the other acute. I say, then, that these are equal to two right angles. For let an arc of a great circle EB be drawn through the point B and the pole of the arc CD; then the two angles EBC, EBD will be right angles. Now since the right angle EBD is equal to the two angles DBA, ABE, adding the common right angle EBC, the two right angles EBD, EBC will be equal to the three angles DBA, ABE, EBC. Again, since the angle ABC is equal to the two angles ABE, EBC, adding the common angle ABD, the two angles ABC, ABD will be equal to the three angles DBA, ABE, EBC. But it was shown that the two right angles EBD, EBC are also equal to these same three; and things equal to the same thing are equal to one another. Therefore the two angles ABC, ABD are equal to the two right angles EBD, EBC. When, therefore, an arc of a great circle on the sphere [stands upon another], etc. Which was to be demonstrated.

[Margin: a — Theodosius I.15 (15.1.The.), noted on the preceding page]

[Margin: b — Theodosius I.20 (20.1.Th.)]

[Margin: c — Theodosius I.15 (15.1.The.)]

Diagram. An arc EB standing on the base line through C, B, D. E is at the upper left, A at the upper right (the oblique arc AB), while C, B, D lie along the base with B at the center, where the arc EB rises perpendicularly.

- E (upper left): endpoint of the perpendicular arc EB
- A (upper right): endpoint of the oblique arc AB
- C (base, left): endpoint of the base arc CD
- B (base, center): foot of the arcs, on the base arc CD
- D (base, right): endpoint of the base arc CD

COROLLARIVM.

It follows from these things that the two arcs of two angles which are equal to two right angles — that is, which are formed by an arc of a great circle standing upon the arc of another great circle, such as the two angles ABC, ABD — make up a semicircle. For if from the pole B a great circle CAD is described, then, by Definition 6, CA and AD will be the arcs of the angles ABC, ABD. But it is clear that the arcs CA, AD make up a semicircle, since the great circles CBD, CAD cut one another into two equal parts at C, D.

[Margin: d — Theodosius I.11 (11.1.The.)]

Diagram. A lens-shaped figure. **A** at the top, **B** at the bottom, **C** at the left, **D** at the right; an arc runs from **A** down to **B**, and the semicircle **CAD** spans across the top, the great circles **CBD** and **CAD** crossing at **C** and **D**.

- **A** (top): vertex, on the arc of the angles
- **B** (bottom): pole from which the circle **CAD** is described
- **C** (left): intersection of the great circles **CBD**, **CAD**
- **D** (right): intersection of the great circles **CBD**, **CAD**

THEOR. 5. PROPOS. 6.

If two arcs of great circles on the sphere cut one another, they will make the vertical angles equal to one another.

Diagram. Two arcs crossing at **E** to form an **X**. **A** at the upper left, **D** at the upper right, **C** at the lower left, **B** at the lower right, with **E** at the center where the arcs **AB** and **CD** intersect.

- **A** (upper left): endpoint of arc **AB**
- **E** (center): point of intersection
- **D** (upper right): endpoint of arc **CD**
- **C** (lower left): endpoint of arc **CD**
- **B** (lower right): endpoint of arc **AB**

Let two arcs **AB**, **CD** of great circles on the sphere cut one another at **E**, in any way. I say that the angles they make at the vertex **E** are equal to one another — namely the angle **AED** to the angle **BEC**, and the angle **AEC** to the angle **BED**. For since both the angles **AED**, **DEB** and the angles **DEB**, **BEC** are equal to two right angles, the former two will be equal to the latter two. Therefore, taking away the common angle **DEB**, the angle **AED** will remain equal to the angle **BEC**. And by the same reasoning we shall establish that the angle **AEC** is equal to the angle **BED**. Therefore, if two arcs of great circles cut one another, etc. Which was to be demonstrated.

[Margin: a — Prop. 5 of this treatise (5.huius)]

THEOR. 6. PROPOS. 7.

If two spherical triangles have two sides equal to two sides, each to each, and also have an angle equal to an angle, contained under the equal arcs: they will also have the base equal to the base; and the triangle will be equal to the triangle, and the remaining angles will be equal to the

remaining angles, each to each — those under which the equal sides are subtended.

Diagram. Two spherical triangles side by side. On the left, triangle ABC with **A** at the apex, **B** at the lower left, **C** at the lower right. On the right, triangle DEF with **D** at the apex, **E** at the lower left, **F** at the lower right, and **G** marking the alternative base arc EGF (the letter G appears both above and below the base line, indicating the impossible curved base).

- A (apex, left triangle): vertex under which base BC is subtended
- B (lower left, left triangle): base vertex
- C (lower right, left triangle): base vertex
- D (apex, right triangle): vertex equal to A
- E (lower left, right triangle): base vertex
- F (lower right, right triangle): base vertex
- G (on the base of the right triangle): point on the alternative arc EGF (shown twice, above and below the base)

Let ABC, DEF be two spherical triangles having two sides AB, AC equal to the two sides DE, DF, each to each, and the angle A equal to the angle D. I say that the base BC is also equal to the base EF, and the triangle ABC equal to the triangle DEF, and the remaining angles B, C equal to the remaining angles E, F, each to each. For since the arc AB is assumed equal to the arc DE, it comes about that, if the one is imagined to be laid upon the other on the surface of the sphere — the point A being placed on the point D, and the point B on the point E — the planes of the circles AB, DE coincide with one another, and consequently the arc AB coincides with the arc DE. Otherwise the circles of those arcs would cut one another into two equal parts at A and B, and so AB, DE would be semicircles. But this is absurd, for each is less than a semicircle. Since, then, the angle A is assumed equal to the angle D, the arc AC will also coincide with the arc DF, and the point C will fall on the point F, because of the equality of the arcs AC, DF. Therefore the base BC will also coincide with the base EF; otherwise, if it fell above or below — such as the arc EGF is — the arcs EF, EGF (or BC), cutting one another at E, F, would be semicircles, since great circles cut one another into two equal parts. This is absurd, for each is less than a semicircle. And so the base BC will be equal to the base EF, since neither exceeds the other; and the triangle ABC equal to the triangle DEF; and the angles B, C equal to the angles E, F, each to each, for the same reason. Therefore, if two spherical triangles, etc. Which was to be demonstrated.

[Margin: a — Theodosius I.11 (11.1.The.)]

[Margin: b — Prop. 2 of this treatise (2.huius)]

[Margin: c — Theodosius I.11 (11.1.The.)]

[Margin: d — Prop. 2 of this treatise (2.huius)]

THEOR. 7. PROPOS. 8.

In isosceles spherical triangles, the angles at the base are equal to one another; and if the equal sides below the base are produced, the angles under the base will be equal to one another.

Let ABC be an isosceles spherical triangle whose two sides AB, AC are equal. I say that the angles B, C above the base BC are equal; likewise, if the equal arcs AB, AC are produced below the base BC to any extent, the angles B, C below the base BC are also equal. For since the arc AB is less than a semicircle, it can be produced —

[Margin: a — Prop. 2 of this treatise (2.huius)]

(Continuing the demonstration of THEOR. 7 / PROPOS. 8 — the isosceles spherical triangle — broken off at the foot of the preceding page.)

and so an arc smaller than a semicircle may still be taken. Let arc AD, then, be less than a semicircle [Margin: b — Prop. 1 of this treatise], and from the arc AE, produced as far as one likes, let arc AF be cut off equal to arc AD; and through the two points B, F, as well as through C, D, let two arcs of great circles BF, CD be drawn [Margin: c — Theodosius I.20]. Now the two sides AB, AF of triangle ABF are equal to the two sides AC, AD of triangle ACD, each to each, and they contain the common angle A; therefore the base BF is equal to the base CD, and the angles ABF and F are equal to the angles ACD and D [Margin: d — Prop. 7 of this treatise]. Again, since the arcs AD, AF are equal, if the equal arcs AB, AC are subtracted, then BD and CF will also be equal. Hence the two sides DB, DC of triangle DBC are equal to the two sides FC, FB of triangle FCB; and since these contain equal angles D, F, as we have shown, the angles DBC, DCB will also be equal to the angles FCB, FBC [Margin: e — Prop. 7 of this treatise]. Now if from the angles ABF, ACD, which we showed to be equal, we take away the angles FBC, DCB, which we have likewise proved equal, the angles ABC, ACB above the base BC will remain equal. But it has also been shown that the angles DBC, FCB below the same base BC are equal. Therefore both the angles above the base are equal to one another, and the angles below the same base are equal to one another. And

for this reason, in isosceles spherical triangles, and so forth. Which was to be demonstrated.

Diagram. The isosceles spherical triangle of THEOR. 7. An outer spherical triangle has its apex A at the top, its left side sweeping down through B to D at the lower left, and its right side sweeping down through C and F to E at the bottom right. The chords BF and CD are drawn and cross one another in the interior, forming an X between the four points B, C, D, F. A short arc joins B and C near the top.

- A (apex, top): vertex of the isosceles triangle
- B (left side, upper): base-vertex of the upper triangle
- C (right side, upper): base-vertex of the upper triangle
- D (lower left): endpoint of the produced side
- E (bottom, right of D): endpoint of the produced arc AE
- F (right side, below C): point where AF is cut equal to AD

COROLLARIVM.

From this it is clear that every equilateral spherical triangle is also equiangular.

THEOR. 8. PROPOS. 9.

If two angles of a spherical triangle are equal to one another, then the sides subtended beneath the equal angles will also be equal to one another.

In triangle ABC let the two angles B, C on the side BC be equal. I say that the sides AB, AC subtended beneath them are also equal. For if they are not equal, let AB, if possible, be the greater. Now since arc AC is less than a semicircle [Margin: a — Prop. 2 of this treatise], let there be cut off from the greater arc AB an arc BD equal to the lesser arc AC [Margin: b — Prop. 1 of this treatise], and through the points C, D let an arc of a great circle CD be drawn [Margin: c — Theodosius I.20]. Then, since the two sides AC, CB of triangle ACB are equal to the two sides DB, BC of triangle DBC, and contain equal angles ACB, DBC, the triangles ACB, DBC will be equal — the whole and the part [Margin: d — Prop. 7 of this treatise]. This is impossible. Therefore the sides AB, AC are not unequal, but equal. So if two angles of a spherical triangle, and so forth. Which was to be shown.

Diagram. A spherical triangle ABC with curved sides. The apex A is at the top; D lies on the left side AB just below A; B is at the lower left and C at the right. The chord CD is drawn from C to the point D on AB, cutting off BD equal to AC.

- A (apex, top): vertex
- D (left side, just below A): point where BD is cut equal to AC
- B (lower left): base-vertex
- C (right): base-vertex

COROLLARIVM.

It follows from this that every equiangular spherical triangle is also equilateral.

PROBL. 2. PROOS. 10.

(Body heading printed "PROOS. 10." — evidently for PROPOS.)

On a given arc of a great circle in a sphere, and at a given point on it, to construct a spherical angle equal to a given spherical angle.

Let AB be the given arc of a great circle in a sphere, C the given point on it, and let it be required, given a spherical angle D, to construct at the point C a spherical angle equal to it. Producing the arcs DE, DF that contain the angle D as far as one likes, let a quadrant DG be taken, and through G and the pole of circle DE let an arc of a great circle GH be drawn [Margin: a — Theodosius I.20], cutting arc DF at H. Then the angle G will be a right angle [Margin: b — Theodosius I.15]. Next, taking a quadrant CI as well, let an arc of a great circle IK be drawn through I and the pole of circle AB [Margin: c — Theodosius I.20]; then the angle I will likewise be a right angle [Margin: d — Theodosius I.15]. Finally, since arc GH is less than a semicircle [Margin: e — Prop. 2 of this treatise], let there be cut off from IK an arc equal to it [Margin: f — Prop. 1 of this treatise], and let an arc of a great circle CK be drawn through C, K [Margin: g — Theodosius I.20]. I say that angle C is equal to angle D. For since the sides DG, GH are equal to the sides CI, IK, and they contain equal angles, being both right angles, the angles D and C will be equal [Margin: h — Prop. 7 of this treatise]. Therefore, on a given arc of a great circle, and so forth. Which was to be done.

Diagram. Two spherical triangles drawn side by side, for the angle-copying construction. In the left figure the apex is D at the top, with G on the left side, E at the lower left, and F at the bottom; H lies just above the base near F. In the right figure C and A stand at the top, B at the bottom, K at the right, and I and H near

the lower left. The base points H and I of the two figures nearly meet at the center.

- D (apex, left figure): given angle
- G (left side, left figure): endpoint of the quadrant DG
- E (lower left, left figure): endpoint of arc DE
- F (bottom, left figure): endpoint of arc DF
- H (near base, left figure): where arc GH cuts DF
- A (top right, right figure): endpoint of the given arc AB
- C (top, right figure): the given point
- B (bottom, right figure): endpoint of arc AB
- I (lower left, right figure): endpoint of the quadrant CI
- K (right, right figure): endpoint of the constructed arc CK

THEOR. 9. PROPOS. 11.

In every spherical triangle the greater angle is subtended by the greater side; and the greater side subtends the greater angle.

In the spherical triangle ABC let the angle ACB be greater than the angle A. I say that the side AB is greater than the side BC. Since the angle ACB is set greater than the angle A, let an angle ACD be made equal to angle A [Margin: a — Prop. 10 of this treatise], and let the arc CD cut arc AB at D. Then, since in triangle ADC the angles A and ACD are equal, the sides AD, CD will also be equal [Margin: b — Prop. 9 of this treatise]. Adding therefore the common arc DB, the arcs BD, DC together will equal arc AB. But the arcs BD, DC together are greater than arc BC [Margin: c — Prop. 3 of this treatise]. Therefore arc AB too will be greater than that same arc BC. Which was proposed.

Diagram. A spherical triangle with apex A at the top right, B at the lower left, and C at the lower right. From C a chord CD is drawn to the point D on the side AB, so that angle ACD equals angle A.

- A (apex, top right): vertex
- D (on side AB, left): point where CD meets AB
- B (lower left): base-vertex
- C (lower right): base-vertex

(THEOR. 9 continued — the converse.)

But now, in the spherical triangle ABC, let the side AB be greater than the side BC. I say that the angle C is greater than the angle A. For if the angle C is not greater than the angle A, it will be either equal to it or less. If it is equal, the sides AB, CB will be equal [Margin: a — Prop. 9 of this treatise]. This is absurd, since AB is supposed greater than CB. But if the angle C is less than the angle A, the side BC will be greater than the side AB, as has already been shown — which is likewise absurd, for AB is supposed greater than BC. Since, then, the angle C is neither equal to nor less than the angle A, it will certainly be greater. Which was proposed. Therefore in every spherical triangle the greater angle, and so forth. Which was to be shown.

Diagram. A single spherical triangle with curved sides: apex A at the top, C at the lower left, B at the lower right.

- A (apex, top): vertex
- C (lower left): base-vertex
- B (lower right): base-vertex

THEOR. 10. PROP. 12.

If two spherical triangles have two sides equal to two sides, each to each, but the angle contained by the equal arcs greater than the [corresponding] angle, then they will also have the base greater than the base. And if they have the base greater than the base, they will also have the angle contained by the equal arcs greater than the [corresponding] angle.

Let the two sides AB, AC of triangle ABC be equal to the two sides DE, DF of triangle DEF, but let the angle EDF be greater than the angle A. I say that the base EF is also greater than the base BC. First, let these spherical triangles be isosceles, and from the pole D let an arc of a circle EGF be described through the points E, F on the surface of the sphere. If this circle is a great circle, it will be exactly the same as EF; otherwise, since great circles bisect one another, EF would be a semicircle [Margin: a — Theodosius I.11] — which is absurd, since it is less than a semicircle [Margin: b — Prop. 2 of this treatise]. Now the arc EGF will be [an arc of] a great circle when the arcs DE, DF are quadrants, because a great circle is a quadrant's distance from its own pole [Margin: c — Corollary to Theodosius I.16]. So let arc EGF now be of a great circle and the same as EF, and let the angle FDG be made equal to the angle A [Margin: d — Prop. 10 of this treatise]. Then arc DG will be equal to arc DE, and therefore also to arc AB [Margin: e — Elements III.28], because the chords subtending DE, DG are equal by the definition of a pole. Since,

then, the sides AB, AC are equal to the sides DG, DF and contain equal angles, the bases BC, GF will be equal [Margin: f — Prop. 7 of this treatise]. And since arc EF is greater than arc GF, arc EF will also be greater than arc BC. Which was proposed.

But if the circle described from the pole D through the points E, F is not a great circle, and so is not the same as EF, but falls either below the arc EF or above it (for it makes no difference where it falls), let the angle FDH nonetheless be made equal to the angle A [Margin: g — Prop. 10 of this treatise]; then again arc DH will be equal to arc DE, that is, to arc AB [Margin: h — Elements III.28], because the chords subtending DE, DH are equal by the definition of a pole [Margin: i — Theodosius I.20]. Drawing therefore an arc of a great circle FH through the points F, H, since the sides AB, AC are equal to the sides DH, DF and contain equal angles, the bases BC, HF will also be equal [Margin: k — Prop. 7 of this treatise]. Now since the great circle DF, passing through D, the pole of circle EHF, bisects it [Margin: l — Theodosius I.15], the arc EHF will be less than a semicircle (because the arc from the point F through E up to the point at which, if it were produced beyond E, it would be cut by the arc FD produced toward D, is a semicircle, seeing that the arc EHF is bisected by the arc FD, as has been said). And therefore the chord FE is greater than the chord FH in the same circle [Margin: m — Elements III.15], because the former is nearer to the center of circle EHF, that is, to the diameter, than the latter. Since, then, the arcs EF, HF are of great circles, and so equal [Margin: n — Prop. 2 of this treatise], and each of the arcs EF, HF is less than a semicircle, arc EF will be greater than arc HF [Margin: o — Scholium on Elements III.28]. But arc HF has been shown equal to arc BC. Therefore arc EF too will be greater than arc BC. Which was proposed.

Diagram. The isosceles case of THEOR. 10, shown as two tall pointed spherical triangles. The left figure has apex A, with B at the lower left and C at the lower right. The right figure has apex D, with E at the lower left and F at the lower right; near the base the points G and H mark the arcs EGF and EHF (G above, H below).

- A (apex, left figure): vertex
- B (lower left, left figure): base-vertex
- C (lower right, left figure): base-vertex
- D (apex, right figure): vertex / pole
- E (lower left, right figure): base-vertex
- F (lower right, right figure): base-vertex
- G (near base, right figure): point on the great-circle arc EGF
- H (near base, right figure): point on the smaller-circle arc EHF

Next, let the triangles proposed not be isosceles, but let the side AB be greater than the side AC, and consequently the side DE greater than the side DF. Producing arc DF toward F [Margin: p — Prop. 1 of this treatise], and cutting off an arc DG equal to DE itself [Margin: q — Prop. 2 of this treatise], which is less than a semicircle, let there be described from the pole D, through the points E, G, an arc of a circle EHG — whether it be a great circle or not. Let the angle FDH again be made equal to the angle A [Margin: r — Prop. 10 of this treatise]; then arc DH will be equal to arc DE, that is, to arc AB [Margin: s — Elements III.28], because the chords subtending DH, DE are equal by the definition of a pole. Drawing therefore an arc of a great circle HF through the points H, F, arc BC will, as before, be equal to arc HF [Margin: t — Prop. 7 of this treatise]. Now since the great circle DG is drawn through D, the pole of circle EG, and the point F lies within the periphery of circle EG — namely between the circle and the pole D — and off its pole, arc FE will be greater than arc FH [Margin: u — Scholium on Theodosius II.21], since the former is nearer to arc FD, which passes through the pole D, and each of the arcs FE, FH is less than a semicircle (because they do not intersect except at the point F). But arc HF has been shown equal to arc BC. Therefore arc EF too will be greater than arc BC. Which was proposed.

Diagram. The non-isosceles case. The left figure is a spherical triangle with apex A, B at the lower left, C at the lower right. The right figure has apex D, with E at the lower left, H at the base-middle, F at the right, and G at the lower right; the arcs EHG and HF are drawn near the base.

- A (apex, left figure): vertex
- B (lower left, left figure): base-vertex
- C (lower right, left figure): base-vertex
- D (apex, right figure): vertex / pole
- E (lower left, right figure): base-vertex
- H (base-middle, right figure): point on arc EHG / on arc HF
- F (right, right figure): base-vertex
- G (lower right, right figure): point where DG is cut equal to DE

But now let the base EF be greater than the base BC. I say that the angle D too is greater than the angle A. For if the angle D is not greater than the angle A, it will be either equal to it or less. If it is said to be equal, arc EF will be equal to arc BC [Margin: x — Prop. 7 of this treatise] — which is absurd, for arc EF is supposed greater than arc BC. But if the angle D is said to be less than the angle A, then, as has already been shown, arc BC will be greater than arc EF — which is likewise absurd, since EF is supposed greater than BC. Since, then, the angle D is neither

equal to nor less than the angle A, it will certainly be greater. Which was proposed. And so, if two spherical triangles, and so forth. Which was to be demonstrated.

Diagram. Two spherical triangles for the base-greater case. The left has apex A, B at the lower left, C at the lower right; the right has apex D, E at the lower left, F at the lower right.

- A (apex, left figure): vertex
- B (lower left, left figure): base-vertex
- C (lower right, left figure): base-vertex
- D (apex, right figure): vertex
- E (lower left, right figure): base-vertex
- F (lower right, right figure): base-vertex

THEOR. 11. PROPOS. 13.

Two semicircles of great circles cutting one another contain two angles equal to each other.

Let the two semicircles of great circles ABC, ADC cut one another at A, C. I say that the angles A and C are equal. For, dividing the semicircle ABC in two at B, so that AB, BC are quadrants, let an arc of a great circle BD be drawn through B and the pole of circle ABC [Margin: a — Theodosius I.20], cutting arc ADC at D; then the angle B will be a right angle on either side [Margin: b — Theodosius I.15]. Now since the two sides AB, BD are equal to the two sides CB, BD, and contain equal angles, being right angles, the angles A and C will also be equal [Margin: c — Prop. 7 of this treatise]. Therefore two semicircles of great circles, and so forth. Which was to be demonstrated.

Diagram. A lens (vesica) formed by two great-circle semicircles ABC and ADC meeting at A on the left and C on the right. B is at the top and D at the bottom, and a vertical arc BD passes through the middle, dividing the lens.

- A (left): intersection of the two semicircles
- B (top): midpoint of semicircle ABC
- C (right): intersection of the two semicircles
- D (bottom): point where arc BD cuts arc ADC

THEOR. 12. PROPOS. 14.

(Body heading printed "THEOR. 12." — evidently for THEOR.)

In any spherical triangle with one side produced: if the two remaining sides together are equal to a semicircle, the external angle will be equal to the internal opposite angle above the produced arc; but if they are less than a semicircle, the external angle will be greater than that same internal opposite angle; and finally, if they are greater than a semicircle, the same external angle will be less than the said internal opposite angle.

In the spherical triangle ABC let the side BC be produced to D, and let the two remaining sides AB, AC first together be equal to a semicircle. I say that the external angle ACD is equal to the internal opposite angle B, above the produced arc BC, and so forth. For the arc BA produced will meet the arc BC produced at D, and BAD will be a semicircle [Margin: a — Theodosius I.11]. Since the arcs BA, AC are supposed equal to the semicircle BAD, then, taking away the common arc BA, the remaining arcs AC, AD will be equal. Hence the angle ACD too will be equal to the angle D [Margin: b — Prop. 8 of this treatise]. Since, then, the angles B and D are also equal, the angle ACD will likewise be equal to the angle B [Margin: c — Prop. 13 of this treatise]. Which was proposed.

Diagram. A lens-shaped figure: A at the top, B at the left, C below the middle, D at the right. The upper arc runs from B through A to D, the lower arc from B through C to D, and a further arc AC descends from A to C, forming the triangle ABC with side BC produced to D.

- A (top): apex
- B (left): vertex
- C (below middle): vertex, foot of arc AC
- D (right): point to which BC is produced

Next, let the two sides AB, AC be less than the semicircle BAD. Then, taking away the common arc AB, the remainder AC will be less than the remainder AD [Margin: d — Prop. 11 of this treatise], and therefore the angle ACD will be greater than the angle D — that is, than the angle B, which is equal to the angle D [Margin: e — Prop. 13 of this treatise]. Which was proposed.

Finally, let the sides AB, AC be greater than the semicircle BAD. Then, taking away the common arc AB, the remainder AC will be greater than the remainder AD [Margin: f — Prop. 11 of this treatise], and therefore the angle D will be greater than the angle ACD. Since, then, the angle B is equal to the angle D [Margin: g — Prop. 13 of this treatise], the angle B too will be greater than the angle ACD; that is, the angle ACD will be less than the angle B. Therefore, in any triangle, and so forth. Which was to be shown.

THEOR. 13. PROPOS. 15.

If, in any spherical triangle with one side produced, the external angle is equal to the internal opposite angle above the produced arc, then the two remaining sides together will be equal to a semicircle; but if the external angle is greater than that same internal opposite angle, the two remaining sides will be less than a semicircle; and finally, if the external angle is less than the said internal opposite angle, the two remaining sides will be greater than a semicircle.

Positing the same spherical triangle and the same construction of the figure, let the external angle ACD first be equal to the internal opposite angle B. I say that the sides AB, AC are equal to a semicircle, and so forth. For since the angle B is equal to the angle D [Margin: a — Prop. 13 of this treatise], the angle ACD too will be equal to the angle D; and therefore the arcs AC, AD will also be equal [Margin: b — Prop. 9 of this treatise]. Adding therefore the common arc AB, the two arcs AB, AC will be equal to the semicircle BAD. Which was proposed.

Diagram. The same lens-shaped figure as above: A at the top, B at the left, C below the middle, D at the right, with the arc AC drawn from A down to C.

- A (top): apex
- B (left): vertex
- C (below middle): vertex, foot of arc AC
- D (right): point to which BC is produced

Next, let the angle ACD be greater than the angle B — that is, than the angle D, which is equal to the angle B [Margin: c — Prop. 13 of this treatise]; then arc AD will be greater than arc AC [Margin: d — Prop. 11 of this treatise]. Adding therefore the common arc AB, the two arcs AB, AC will be less than the semicircle BAD. Which was proposed.

Finally, let the angle ACD be less than the angle B — that is, than the angle D, which is equal to the angle B [Margin: e — Prop. 13 of this treatise]; then arc AC will be greater than arc AD [Margin: f — Prop. 11 of this treatise]. Adding therefore the common arc AB, the two arcs AB, AC will be greater than the semicircle BAD. Which was proposed. So if, in any spherical triangle, and so forth. Which was to be demonstrated.

THEOR. 14. PROPOS. 16.

If in any spherical triangle two sides together are equal to a semicircle, the two angles on the base will be equal to two right angles; but if they are less than a semicircle, they will be less than two right angles; and finally, if they are greater than a semicircle, they will be greater than two right angles.

In the spherical triangle ABC let the two sides AB, AC first be equal to a semicircle. I say that the two angles B, C are equal to two right angles, and so forth. For, producing arc BC to D, the angle ACD will be equal to the angle B [Margin: a — Prop. 14 of this treatise]. Since, then, the two angles at C are equal to two right angles [Margin: b — Prop. 5 of this treatise], the two angles B and ACB will also be equal to two right angles.

Diagram. A spherical triangle with apex A at the top, the side AB curving down to B at the lower left; the base runs straight from B through C to D at the lower right, so that BC is produced to D. The chords AC and AD are drawn.

- A (apex, top): vertex
- B (lower left): base-vertex
- C (base, middle): base-vertex
- D (lower right): point to which BC is produced

Next, let the sides AB, AC be less than a semicircle. Then, since the two angles at C are equal to two right angles [Margin: c — Prop. 5 of this treatise], and the angle B is less than the angle ACD [Margin: d — Prop. 14 of this treatise], the angles B and ACB will be less than two right angles.

Finally, let the sides AB, AC be greater than a semicircle. Since, then, the two angles at C are equal to two right angles [Margin: e — Prop. 5 of this treatise], and the angle B is greater than the angle ACB [recte: ACD] [Margin: f — Prop. 14 of this treatise], the angles B and ACB will be greater than two right angles. So if, in any spherical triangle, and so forth. Which was to be shown.

THEOR. 15. PROPOS. 17.

If in any spherical triangle two angles standing on one side are equal to two right angles, the remaining two sides will be equal to a semicircle; but if they are less than two right angles, the two sides will be less than a

semicircle; and finally, if they turn out to be greater than two right angles, they will be greater than a semicircle.

Keep the same spherical triangle and the same construction of the figure. First, let the two angles B and C be equal to two right angles, standing on the side BC. I say that the remaining two sides AB and AC are equal to a semicircle, and so on. For since the two angles at C are also equal to two right angles, once the common angle ACB is taken away, the remaining angle ACD will be left equal to angle B. [Margin a: "5. huius" — Prop. 5 of this treatise] Therefore the arcs AB and AC are equal to a semicircle. [Margin b: "15. huius" — Prop. 15 of this treatise]

Next, let the angles B and ACB be less than two right angles. Then, since the two angles at C are equal to two right angles, once the common angle ACB is removed, the remaining angle ACD will be left greater than angle B. [Margin c: "5. huius"] The arcs AB and AC are therefore less than a semicircle. [Margin d: "15. huius"]

Finally, let the angles B and ACB be greater than two right angles. Since, then, the two angles at C are equal to two right angles, if the common angle ACB is subtracted, the remaining angle ACD will be less than the remaining angle B; [Margin e: "5. huius"] and so the arcs AB and AC are greater than a semicircle. [Margin f: "15. huius"] Accordingly, if in any spherical triangle, and so forth. Which was to be shown.

Diagram. A spherical triangle with its apex A at the top. Its base is a curved arc running along the bottom from B (left) through C (middle) to D (right), so that the side BC is extended beyond C to the point D. The side AB rises from B to the apex A; the side AC descends from A to C; and the arc curves on from A/C toward D. The angle ACD at C is the exterior angle formed by extending the base.

- A (apex, top): vertex of the triangle
- B (lower left): base vertex
- C (lower middle): base vertex, where side AC meets the base
- D (lower right): endpoint of the base extended beyond C

THEOR. 16. PROPOS. 18.

If two spherical triangles have their three sides equal to three sides, each to each, they will also have their three angles equal to three angles, each to each — namely those under which the equal sides are subtended.

Let there be two spherical triangles ABC and DEF, having their three sides AB, AC, BC equal to the three sides DE, DF, EF, each to each. I say that the three angles A, B, C are also equal to the three angles D, E, F, each to each — the angles under which the equal sides are subtended. For if angle A (to begin from this angle) is not equal to angle D, it will be either greater or less. If greater, then the base BC will also be greater than the base EF, [Margin a: "12. huius" — Prop. 12 of this treatise] which is absurd, since the sides BC and EF are assumed equal. But if angle A is less than angle D, then the base EF will be greater than the base BC, [Margin b: "12. huius"] which is again absurd, since they are assumed equal. Since, then, angle A is neither greater nor less than angle D, it will certainly be equal to it. Therefore the remaining angles B and C will also be equal to the remaining angles E and F, [Margin c: "7. huius" — Prop. 7 of this treatise] namely B to E and C to F. If, then, two spherical triangles, and so forth. Which was to be shown.

Diagram. Two spherical triangles drawn side by side, each with curved sides. The left triangle is ABC, with apex A at the top, B at the lower left, and C at the lower right. The right triangle is DEF, with apex D at the top, E at the lower left, and F at the lower right.

- A (apex, left triangle): vertex
- B (lower left): vertex
- C (lower right): vertex
- D (apex, right triangle): vertex
- E (lower left): vertex
- F (lower right): vertex

THEOR. 17. PROPOS. 19.

If two spherical triangles have their three angles equal to three angles, each to each, they will also have their three sides equal to three sides, each to each — the sides that subtend the equal angles.

Let there be two spherical triangles ABC and DEF, having their three angles A, B, C equal to the three angles D, E, F, each to each. I say that the three sides AB, AC, BC are also equal to the three sides DE, DF, EF, each to each — the sides that subtend the equal angles. For if the sides BC and EF (to begin from these sides) are not equal, let BC, if it can be so, be the greater; and let the arc BG be cut off equal to the arc EF. [Margin a: "1. huius" — Prop. 1 of this treatise] Then the arc BA is either equal to the arc ED, or greater, or less. Whichever of these is said, an

absurdity will follow from the assumption that the sides BC and EF are unequal — namely, that BC is greater than EF.

Suppose first that the arc BA is equal to the arc ED, and let the great-circle arc AG be drawn through the points A and G.[Margin b: "20.1.The." — Theodosius, *Sphaerica* I.20] Since, then, the sides BA and BG are equal to the sides ED and EF, and contain equal angles B and E by hypothesis, the angles BAG and D will be equal.[Margin c: "7. huius"] But angle D was posited equal to angle BAC; therefore angle BAG will also be equal to angle BAC — the part to the whole. Which is absurd.

Next, let the arc BA be greater than the arc ED, and let the arc BI be cut off equal to ED itself;[Margin d: "1. huius"] and through the points G and I let the great-circle arc GI be drawn, meeting the arc CA, extended, at H.[Margin e: "20.1.The."] Since, then, the sides BI and BG are equal to the sides ED and EF, and contain equal angles B and E, the angles BIG and BGI will be equal to the angles D and F, [Margin f: "7. huius"] that is, to the angles BAC and BCA, because D and F are posited equal to these two. But the angles BIG and BAC are equal to the vertical angles HIA and HAK.[Margin g: "6. huius" — Prop. 6 of this treatise] Therefore the angles HAK and HIA are also equal. Since, then, the exterior angle BGH is equal to the interior angle BCH, and the exterior angle HAK equal to the interior angle HIK, as we have shown,[Margin h: "15. huius"] both the arc AHI and the arcs CH, HG will be equal to a semicircle; and so the arcs AH, HI will be equal to the arcs CH, HG — the part to the whole. Which is absurd.

Finally, let the arc BA be less than the arc ED, and let it be produced beyond A, and from it let the arc BK be cut off equal to the arc ED;[Margin i: "1. huius"] and through the points G and K let the great-circle arc GK be drawn, cutting the arc AC at L.[Margin k: "20.1.The."] Since, then, the sides

Diagram. A double figure. On the left is the construction triangle: apex region carrying the points H, A, K across the top (A in the middle, H to its left, K to its right), with I just below between H and A, and L in the interior; the base runs along the bottom from B (left) through G and C to the right, with the great-circle arcs AG, GI (produced to H) and GK (cutting AC at L) drawn in. On the right stands the comparison triangle DEF, with apex D at the top and E, F along the base. (This same figure is reprinted at the top where the proof continues.)

- H (top left): intersection point of the produced arcs
- A (top middle): apex of the left triangle
- K (top right): point where arc GK is produced

- I (upper interior): point cut on BA
- L (interior): point where GK cuts AC
- B (lower left): base vertex
- G (lower middle-left): point cut on the base BC
- C (lower middle): base vertex
- E (lower middle-right): base vertex of the right triangle
- D (upper right): apex of the right triangle
- F (lower right): base vertex of the right triangle

[The proof of THEOR. 17 / PROPOS. 19 continues from the foot of p. 817; the figure above is reprinted at the head of this page.]

BK and BG are equal to the sides ED and EF, and contain equal angles B and E, [Margin l: "7. huius"] the angles BKG and BGK will also be equal to the angles D and F — that is, to the angles BAC and BCA, since the angles D and F are posited equal to these two. And so, since the exterior angle BAL is equal to the interior angle BKL, and the exterior angle BGL to the interior angle BCL, as we have shown, [Margin m: "15. huius"] both the arcs AL, LK and the arcs CL, LG will be equal to a semicircle; and hence the two arcs AC and GK will be equal to a whole circle. Which is absurd, [Margin n: "2. huius" — Prop. 2 of this treatise] since each of the arcs AC and GK is less than a semicircle. The sides BC and EF, therefore, are not unequal but equal. In the same way we shall show that the sides AC, DF, and likewise AB, DE, are equal. The three sides of triangle ABC are therefore equal to the three sides of triangle DEF. So then, if two spherical triangles, and so forth. Which was to be shown.

THEOR. 18. PROPOS. 20.

If two spherical triangles have two angles equal to two angles, each to each, and one side equal to one side — the side that lies between the equal angles — then they will also have their remaining sides equal to the remaining sides, each to each, and the remaining angle equal to the remaining angle.

Let two spherical triangles ABC and DEF have two angles B and C equal to two angles E and F, each to each, and the side BC equal to the side EF — the side that lies between the equal angles. I say that the remaining sides AB and AC are also equal to the remaining sides DE and DF, each to each, and that the remaining angle A is equal to the remaining angle D. For if the sides AB and DE (to begin from these) are not equal, let AB be the greater, and let the arc BG be cut off equal

to the arc DE,[Margin a: "1. huius"] and through the points C and G let the great-circle arc CG be drawn.[Margin b: "20.1.The."] Since, then, the sides GB and BC are equal to the sides DE and EF, and contain equal angles B and E by hypothesis, the angles BCG and F will also be equal.[Margin c: "7. huius"] But F is posited equal to BCA itself; therefore angle BCG will also be equal to the same BCA — the part to the whole. Which is absurd. The sides AB and DE, then, are not unequal but equal. Therefore, since the sides AB and BC are equal to the sides DE and EF, and contain equal angles B and E, the sides AC and DF will also be equal, and the angles A and D will be equal.[Margin d: "7. huius"] Accordingly, if two spherical triangles have two angles, and so forth. Which was to be shown.

Diagram. Two spherical triangles with curved sides. The left triangle is ABC, apex A at the top, base from B (lower left) to C (lower right); the point G is marked on the side AB just below A, and the arc CG is drawn from C up to G. The right triangle is DEF, apex D at the top, base from E (lower left) to F (lower right).

- A (apex, left): vertex
- G (on side AB, below A): point cut off so that BG equals DE
- B (lower left): vertex
- C (lower right): vertex
- D (apex, right): vertex
- E (lower left): vertex
- F (lower right): vertex

THEOR. 19. PROPOS. 21.

If there are two right-angled spherical triangles, and they have two other angles equal — these not being right angles — and also two equal sides, the sides subtended under the right angles: then the remaining two sides will also be equal to the two sides, each to each, and the remaining angle will be equal to the remaining angle.

In the two spherical triangles ABC and DEF, let the angles B and E be right angles, the two angles C and F equal and not right, and the sides AC and DF, which subtend the right angles, equal. I say that the remaining sides AB and BC are equal to the remaining sides DE and EF, each to each; and likewise that the remaining angles A and D are equal. For, the arcs AC and BC being produced, let the arc CH be cut off equal to the arc FD — that is, to the arc CA — and the arc CG equal to the arc FE;[Margin a: "1. huius"] and through the points G and H let the great-circle arc GH be described.[Margin b: "20.1.The."] Since the sides CH and CG

are equal to the sides FD and FE, and contain equal angles GCH and F[Margin c: "6. huius"] (for by hypothesis angle F is equal to angle ACB, and ACB is equal to the vertical angle GCH),[Margin d: "7. huius"] the bases GH and ED will also be equal, and the angles at GH equal to the angles E and D; and therefore, since angle E is right, angle G will also be right.[Margin e: "20.1.The."] Now through C and the pole of the arc BG let the great-circle arc ICK be drawn in both directions, and let I be the pole of the arc BG.[Margin f: "13.1.The." — Theodosius, *Sphaerica* I.13] And since the circles of the arcs BA and HG pass also through the poles of the same arc BG, on account of the right angles B and G, the arcs BA and GH, when produced, will meet the arc CI at the pole I. Let the arc GH also meet the same arc ICK on the other side, at the point K, which will be the other pole of the arc BG, [Margin g: "Corol. 10. 1. Theo." — Corollary to Theodosius I.10] since each of the arcs ICK and IGK passes through the other pole of the arc BG. The three arcs IB, IC, IG will therefore be equal,[Margin h: "28. tertij" — Euclid, *Elements* III.28] because the straight lines subtending them are equal to one another, by the definition of a pole; and likewise the arcs KC and KG will be equal. Now since the angles ICG and IGC are equal to the angles KCG and KGC,[Margin i: "13.1.The."] all being right angles — because I is the pole of the arc BG, and the common side CG lies against them — the sides IC and IG will be equal to the sides KC and KG, each to each;[Margin k: "20. hui." — Prop. 20 of this treatise] and therefore, since the arc IG has been shown equal to the arc IB, the arc KG will also be equal to that same arc IB. And since the sides IC and CA are equal to the sides KC and CH (for the arc CI has been made equal to the arc AC),[Margin l: "6. huius"] and they contain equal vertical angles, the bases IA and KH will be equal, and the angles IAC and KHC equal.[Margin m: "7. huius"] Therefore, when the equal arcs IA and KH are taken away from the equal arcs IB and KG, and the equal angles IAC and KHC are taken from the two pairs of angles at A and H — each pair being equal to two right angles[Margin n: "5. huius"] — the arcs AB and HG and the angles BAC and GHC will remain equal. But the arc HG has been shown equal to the arc DE, and the angle GHC equal to angle D. Therefore the arc AB will be equal to the arc DE, and the angle BAC equal to angle D. Therefore, since the sides AB and AC are equal to the sides DE and DF, and enclose equal angles, the arcs BC and EF will also be equal.[Margin o: "7. huius"] The sides AB and BC are therefore equal to the sides DE and EF, and the angle BAC equal to angle D. Accordingly, if there are two right-angled spherical triangles, and so forth. Which was to be demonstrated.

Diagram. A great-circle construction drawn as a tall, pointed oval (a great circle seen nearly edge-on), with I at the top vertex and K at the bottom vertex serving as the two poles of the arc BG. A vertical arc runs from I down through C to K. Around the centre lie the points A (upper left, interior), B (left of centre), C

(centre, where the arcs cross), G (right of centre), and H (below G, lower right), forming the right-angled configuration of the proof. Off to the lower left, drawn separately, is the small comparison triangle DEF, with D at the upper left, E below it, and F at its right vertex.

- I (top): pole of arc BG
- K (bottom): the opposite pole of arc BG
- A (upper left, interior): vertex
- B (left of centre): right-angle vertex of the first triangle
- C (centre): common vertex where the arcs cross
- G (right of centre): right-angle vertex of the constructed triangle
- H (lower right, below G): meeting point of the produced arcs
- D (small triangle, upper left): vertex
- E (small triangle, lower left): vertex
- F (small triangle, right): vertex

SCHOLIUM.

The equal sides must be subtended under right angles. Otherwise, if they subtended other angles, nothing certain could be concluded. For let ABC be any spherical triangle having two sides AB and AC unequal to each other but together equal to a semicircle. Let the side CB be produced toward the side of B, and through A and the pole of the arc CD let the great-circle arc AD be drawn, [Margin p: "20.1.Th." — Theodosius, *Sphaerica* I.20] cutting CD at D; and the angle D will be right. [Margin q: "15.1.The." — Theodosius, *Sphaerica* I.15] Since, then, the arcs AB and AC are equal to a semicircle, the angle ABD will be equal to angle C. [Margin r: "14. huius" — Prop. 14 of this treatise] And so the two triangles ADB and ADC have the right angle D in common, and two angles ABD and C that are equal and not right [Margin s: "9. huius" — Prop. 9 of this treatise] (otherwise the sides AB and AC would be equal, on account of the angles B and C being right and equal); and they also have the side AD in common, which subtends the equal, non-right angles. And yet the remaining sides AB and BD are not equal to the remaining sides AC and CD, each to each, nor is the remaining angle BAD equal to the remaining angle CAD, as is plain. This comes about precisely because the equal sides do not subtend right angles; rather, the common side AD subtends the equal, non-right angles.

Diagram. A single spherical triangle with apex A at the top. The base runs along the bottom from D (left) through B to C (right). From A the arc AB descends to B,

and the arc AD (a great circle drawn through A and the pole of CD) descends to D; the side AC runs from A to C. The right angle stands at D.

- A (apex, top): vertex
- D (lower left): foot of the perpendicular arc AD, right angle
- B (lower middle): base vertex
- C (lower right): base vertex

Hence Nicolaus Copernicus [Nicolaus Copernicus] is mistaken in Book I of the *Revolutions*, in proposition 6 on spherical triangles, where he says:[Margin: "Error Nicolai Copernici" — An error of Nicolaus Copernicus] "If two triangles have a right angle, and in addition one angle equal to one another, and one side equal to one side — the side that is opposite one of the two equal angles (even if not the right one, as he says in the demonstration) — then they will also have the remaining sides equal to the remaining sides, the one to the other, and one angle equal to one angle, the remaining to the remaining." For the opposite of this has appeared in the right-angled triangles ADB and ADC, in which the common side AD is set opposite the equal, non-right angles ABD and ACD.

Hence too it is not always true, as the same Copernicus teaches in the same place, in proposition 4, where he says:[Margin: "Alius error Nicolai Copernici" — Another error of Nicolaus Copernicus] "In any triangle having a right angle, if in addition another angle is given, together with any one side, the remaining angle too will be given, together with the remaining sides." For although the right angle D and the angle ABD [are given], together with the side BD [?], which is set opposite a non-right angle, we shall nevertheless not on that account come to know the remaining angle and the remaining sides, since the remaining sides can be either AB and BD, or AC and CD, and the remaining angle either BAD or CAD, as is plain. It will therefore be necessary that something else besides be established before the remaining angle can be gathered together with the remaining sides, as we shall teach in the scholium to propositions 41 and 42.

THEOR. 20. PROP. 22.

If there are two spherical triangles that have two angles equal to two angles, each to each, and one side equal to one side — the side subtended by one of the equal angles — while the two sides subtending the remaining angles, being equal, are not equal to a semicircle but either greater or less: then the remaining two sides will also be equal to the two

remaining sides, each to each, and the remaining angle will be equal to the remaining angle.

Let two spherical triangles ABC and DEF have two angles B and C equal to two angles E and F, each to each, and the sides AC and DF, which subtend the equal angles B and E, equal to each other; and let the remaining sides AB and DE, which subtend the other equal angles C and F, not be equal to a semicircle, but either greater or less. I say that the remaining sides CB and BA are equal to the remaining sides FE and ED, each to each, and that the remaining angles A and D are also equal. For if CB and FE are not equal, let CB be the greater, and let CG be cut off, an arc equal to the arc FE;[Margin a: "1. huius"] and through A and G let the great-circle arc AG be drawn.[Margin b: "20.1.The."] Since, then, the sides AC and CG are equal to the sides DF and FE, and contain equal angles C and F, the arcs AG and DE, and the angles AGC and E, will be equal.[Margin c: "7. huius"] But angle E was posited equal to angle B. Angle AGC is therefore also equal to angle B; and hence the arcs AB and AG will be equal to a semicircle.[Margin d: "15. huius"] Since, then, the arc AG has been shown equal to the arc DE, the arcs AB and DE will also be equal to a semicircle. But they are assumed unequal to a semicircle. Which is absurd. The arcs CB and FE, therefore, are not unequal but equal. Therefore, since the sides AC and CB are equal to the sides DF and FE, and contain equal angles C and F, the arcs AB and DE, and the angles BAC and D, will also be equal.[Margin e: "7. huius"] So then, if there are two spherical triangles, and so forth. Which was to be demonstrated.

Diagram. Two spherical triangles with curved sides. The left triangle has apex A at the top, and a base running from B (lower left) through G to C (lower right), with the arc AG drawn from A to the point G near B. The right triangle is DEF, apex D at the top, base from E (lower left) to F (lower right).

- A (apex, left): vertex
- B (lower left): vertex
- G (on the base, near B): point where arc CG is cut off equal to FE
- C (lower right): vertex
- D (apex, right): vertex
- E (lower left): vertex
- F (lower right): vertex

SCHOLIUM.

We said that the two sides subtending the remaining equal angles ought not to be equal to a semicircle. For otherwise the proposition would not be true. Let ABC be any spherical triangle having two sides AB and AC unequal to each other but together equal to a semicircle. Let the side BC be produced as far as D, but in such a way that BD is less than a semicircle, and let the great-circle arc AD be drawn through A and D.[Margin f: "20.1.Th." — Theodosius, *Sphaerica* I.20] Since, then, the arcs AB and AC are equal to a semicircle, the angle ACD will be equal to angle B.[Margin g: "14. huius" — Prop. 14 of this treatise] And so the two triangles ABD and ACD have two angles B and D equal to two angles C and D, each to each, and the side AD in common, which is subtended by the equal angles B and C; and yet the remaining sides AB and BD are not equal to the remaining sides AC and CD, each to each, nor is the remaining angle BAD equal to the remaining angle CAD, as is plain. This happens precisely because the sides AB and AC are [together] equal to a semicircle.

Nicolaus Copernicus, then, is deceived in Book I of the *Revolutions*, in proposition 12 on spherical triangles,[Margin: "Error Nicolai Copernici" — An error of Nicolaus Copernicus] when he teaches that every spherical triangle, two of whose angles have somehow been given, together with some one side, is thereby determined in its angles and sides. For in the triangle ACD, although the two angles D and ACD are known, together with the side AD, we shall nevertheless not on this account arrive at knowledge of the remaining sides and the remaining angle; since the remaining sides could be either AC and CD, or AB and BD, and so on. It will therefore be necessary that something else besides be established before the remaining angle can be known together with the remaining sides, as we shall say in the scholium to proposition 66.

THEOR. 21. PROPOS. 23.

If there are two spherical triangles that have two angles equal to two angles, each to each, and two sides about the remaining angle equal to two sides, each to each, and provided that in the said remaining angle there is not the pole of the remaining side: then the remaining side will be equal to the remaining side, and the remaining angle equal to the remaining angle.

Let ABC and DEF be two spherical triangles in which the angles B and C are equal to the angles E and F, each to each, and the sides AB and AC about the remaining angle A are equal to the sides DE and DF, each to each; but let A and D not be the

poles of the arcs BC and EF. I say that the remaining sides BC and EF are also equal, as are the remaining angles A and D.

For if the arcs BC and EF are not equal, let BC be the greater; [Margin: a — Prop. 1 of this treatise] cut off from it the arc CG equal to FE, [Margin: b — Theodosius I.20] and through the points A and G describe the great-circle arc AG. Now since the sides AC and CG are equal to the sides DF and FE, and they contain equal angles at C and F, [Margin: c — Prop. 7 of this treatise] the arcs AG and DE will be equal, and so will the angles AGC and E. But the arc DE was assumed equal to the arc AB, and the angle E equal to the angle B. Therefore the arc AG will be equal to the arc AB, and the angle AGC equal to the angle B. And so, [Margin: d — Prop. 5 of this treatise] since AGC and AGB together equal two right angles, B and AGB will also equal two right angles. [Margin: e — Prop. 8 of this treatise] But B and AGB are equal to each other, because of the equality of the arcs AB and AG. Each of them, therefore, will be a right angle, [Margin: f — Theodosius I.13] and consequently both arcs AB and AG will pass through the pole of the arc BC. Then A is the pole of the arc BC — which is absurd, since it was assumed not to be. [Margin: g — Prop. 18 of this treatise] The arcs BC and EF, therefore, are not unequal but equal, and for that reason the angles BAC and D will also be equal.

SCHOLIVM.

That condition is indeed necessary — namely, that in the remaining angle there should not be the pole of the remaining side. For the proposition would be false if the pole of the remaining side lay in that angle. Take a spherical triangle ABC, and let A be the pole of the arc BC; and from A let any great-circle arc AD descend, cutting BC at D. [Margin: h — Theodosius I.15] Then the angles at B, C, and D will all be right angles, [Margin: i — Corollary of Theodosius I.16] and all three arcs AB, AC, AD will be quadrants. Thus the two triangles ABC and ADC have the two angles B and C equal to the two angles ADC and C, each to each, and the two sides AB and AC equal to the two sides AD and AC about the angles BAC and DAC, each to each; and yet the remaining sides BC and DC are not equal to each other, nor are the remaining angles BAC and DAC, as is plain. This happens precisely because A is the pole of the arcs BC and DC.

Hence it is also clear that [Nicolaus Copernicus] is mistaken in *De Revolutionibus* I, Prop. 12, [Margin: Error of Nicolaus Copernicus] when he asserts that every spherical triangle whose two angles are given, together with some side, has its angles and sides determined. For in triangle ABC, even if the two angles B and C are given together with the two sides AB and AC (and not with just one side, as he would have it), the remaining side and the remaining angle are still not

immediately known, since the remaining side can be either BC or DC, and the remaining angle either BAC or DAC, and so on. It is necessary, therefore, that something else besides be settled, so that the remaining angle may be known together with the remaining sides — as we shall show in the scholium to Prop. 66.

THEOR. 22. PROPOS. 24.

If there are two spherical triangles that have one angle equal to one angle, and two sides about another angle equal to two sides, each to each, and each of the remaining angles either greater or less than a right angle: then the remaining side will be equal to the remaining side, and the remaining angles equal to the remaining angles, each to each.

Let ABC and DEF be two spherical triangles in which the angles B and E are equal, and the two sides BC and CA are equal to the two sides EF and FD, each to each, about the angles C and F; and let each of the remaining angles A and D be either less than or greater than a right angle. I say that the remaining sides AB and DE are also equal, and that the remaining two angles A and C are equal to the remaining two angles D and F, each to each.

For if the sides AB and DE are not equal, let AB be the greater, [Margin: a — Prop. 1 of this treatise] and cut off the arc BG equal to the arc DE, [Margin: b — Theodosius I.20] and through the points C and G let the great-circle arc CG be drawn. Now since the sides BG and BC are equal to the sides ED and EF, and comprehend equal angles B and E, [Margin: c — Prop. 7 of this treatise] the arcs GC and DF will be equal, and so will the angles G and D. But the arc DF was assumed equal to the arc AC. The arc GC, therefore, will also be equal to that same arc AC; [Margin: d — Prop. 8 of this treatise] and so the angles A and CGA are equal. [Margin: e — Prop. 5 of this treatise] And since the two angles at G together equal two right angles, the two angles BGC and A will likewise together equal two right angles. Consequently, since the angle BGC has been shown equal to the angle D, the two angles D and A will together equal two right angles. But this is impossible: for since each of them is assumed either less than or greater than a right angle, both together will be either less than or greater than two right angles. The sides AB and DE, therefore, are not unequal but equal. [Margin: f — Prop. 18 of this treatise] Hence the two angles A and C will also be equal to the two angles D and F, each to each. And so, if there are two triangles, and so on. Which was to be shown.

SCHOLIUM.

We said that each of the remaining angles must be either greater or less than a right angle; for otherwise the proposition would be false. Take any spherical triangle ABC having the two sides AB and AC equal; extend the side CB to D so that CD is an arc less than a semicircle, [Margin: g — Theodosius I.20] and through the points A and D draw the great-circle arc AD. Then the triangles ADB and ADC have one angle equal to one angle — namely D, which is common — and the two sides AD and AB equal to the two sides AD and AC, each to each; and yet the remaining sides DB and DC are not equal, nor are the remaining angles DAB and DAC — indeed, neither are the angles ABD and ACD, unless each of them is a right angle, as we shall show. This comes about precisely because it is not the case that each angle ABD, ACD is greater than a right angle, or each less, but rather that either both are right angles, or one is greater and the other less than a right angle — which we prove as follows.

Let angle ABD first be a right angle. I say that C is also a right angle. For with the angle ABD being right, ABC will also be right, [Margin: h — Prop. 5 of this treatise] because both angles at B together equal two right angles; [Margin: i — Prop. 8 of this treatise] but this one is equal to angle C, because of the equality of the sides AB, AC. Therefore C too will be a right angle.

Next, let angle ABD be greater than a right angle. I say that C is less than a right angle. For since ABD is greater than a right angle, ABC will be less, [Margin: k — Prop. 5 of this treatise] because both together equal two right angles. Therefore the angle C too, [Margin: l — Prop. 8 of this treatise] which is equal to angle ABC, will be less than a right angle.

Finally, let angle ABD be less than a right angle. I say that C is greater than a right angle. For since ABD is less than a right angle, ABC — that is, C, which is equal to it — will be greater than a right angle.

Hence it is manifest that Proposition 8 of [Nicolaus Copernicus], on spherical triangles, in *De Revolutionibus* I, [Margin: Error of Nicolaus Copernicus] is false in the part where he says: If two triangles have two sides equal to two sides, one to the other, and an angle equal to an angle — the one at the base — then they will also have base equal to base, and the remaining angles equal to the remaining angles. For this is not true unless each of the remaining angles at the base is assumed either greater or less than a right angle. For in the triangles set out, ADB and ADC, there are two sides AD and AB equal to two sides AD and AC, and the

angle D is common over the bases DB and DC; and yet the bases are not equal, for the reason stated.

The same [Nicolaus Copernicus] errs likewise in the same book, Prop. 11, [Margin: Another error of Nicolaus Copernicus] where he says: Every triangle whose two sides are given together with some angle has its angles and sides determined. For even if the sides AD and AB are known together with the angle D, we still do not thereby arrive at knowledge of the other side and of the other angles, since the remaining side can be either DB or DC, and so on. It is necessary, then, that something else besides be settled before the remaining side, together with the remaining angles, can be made known — as we shall make clear in the scholium to Prop. 67.

THEOR. 23. PROP. 25.

In every isosceles spherical triangle, if the two equal sides are quadrants, the two equal angles at the base will be right angles; but if each is less than a quadrant, they will be acute; and if greater than a quadrant, obtuse. And if the two equal angles at the base are right angles, the two equal sides will be quadrants; but if they are acute, each side will be less than a quadrant; and if obtuse, each greater than a quadrant.

In the isosceles spherical triangle ABC, let the two equal arcs AB, AC first be quadrants. I say that the equal angles B, C at the base are right angles. For since each arc AB, AC is a quadrant, both together are equal to a semicircle. Hence, if the arc BC is produced to D, [Margin: a — Prop. 14 of this treatise] the angle ACD will be equal to the angle B; [Margin: b — Prop. 8 of this treatise] but the angle B is equal to the angle ACB. Therefore the angle ACD will be equal to the angle ACB; and so, [Margin: c — Prop. 5 of this treatise] since the two angles at C together equal two right angles, each angle at C will be a right angle. Hence the angle B too, [Margin: d — Prop. 8 of this treatise] which is equal to the right angle ACB, will be a right angle. Which was proposed.

Next, let each of the equal arcs AB, AC be less than a quadrant. I say that the equal angles B, C are acute. For since each arc AB, AC is less than a quadrant, both together are less than a semicircle. [Margin: e — Prop. 14 of this treatise] Hence the angle ACD will be greater than the angle B — that is, than the angle ACB — [Margin: f — Prop. 8 of this treatise] since the angles B and ACB are equal. [Margin: g — Prop. 5 of this treatise] Since, then, the two angles at C together equal two right angles, the angle ACB will be less than a right angle; and so the angle B too, [Margin: h — Prop. 8 of this treatise] which is equal to it, will likewise

be less than a right angle. Therefore the two angles B and ACB are acute. Which was proposed.

Finally, let each of the arcs AB, AC be greater than a quadrant. I say that the equal angles B, C are obtuse. For since each arc AB, AC is greater than a quadrant, both together are greater than a semicircle. [Margin: i — Prop. 14 of this treatise] Hence the angle ACD will be less than the angle B — that is, than the angle ACB, [Margin: k — Prop. 8 of this treatise] which is equal to angle B. [Margin: l — Prop. 5 of this treatise] Since, then, the two angles at C together equal two right angles, the angle ACB will be greater than a right angle — that is, obtuse; and therefore the angle B too, [Margin: m — Prop. 8 of this treatise] which is equal to it, will be obtuse. Which was proposed.

But now let each of the equal angles B, C be a right angle. I say that each arc AB, AC is a quadrant. For since ACB is a right angle, [Margin: n — Prop. 5 of this treatise] and the two angles at C together equal two right angles, ACD will also be a right angle, and hence equal to the right angle B. [Margin: o — Prop. 15 of this treatise] Therefore the two arcs AB, AC together equal a semicircle; and since they are assumed equal, each will be a quadrant. Which was proposed.

Next, let each of the angles B, C be acute. I say that each arc AB, AC is less than a quadrant. [Margin: p — Prop. 5 of this treatise] For since the two angles at C together equal two right angles, and ACB is assumed less than a right angle, ACD will be greater than a right angle, and therefore greater than B, which is also assumed less than a right angle. [Margin: q — Prop. 15 of this treatise] The arcs AB, AC together, then, are less than a semicircle; and so, since they are equal, each will be less than a quadrant. Which was proposed.

Finally, let each of the angles B, C be obtuse. I say that each arc AB, AC is greater than a quadrant. [Margin: r — Prop. 5 of this treatise] For since the two angles at C together equal two right angles, and ACB is assumed greater than a right angle, ACD will be less than a right angle, and therefore less than the angle B, which is also assumed greater than a right angle. [Margin: s — Prop. 15 of this treatise] The arcs AB, AC together, then, are greater than a semicircle; and so, since they are equal, each will be greater than a quadrant. Which was proposed. Therefore, in every isosceles spherical triangle, and so on. Which was to be demonstrated.

COROLLARIUM.

From this it follows that every equilateral, or equiangular, spherical triangle, if its several sides are quadrants, has its several angles right; but if the sides are less than a quadrant, the angles are acute; and if greater than a quadrant, obtuse. And

that every equiangular, or equilateral, spherical triangle, if its several angles are right, has its several sides quadrants; but if the angles are acute, the sides are less than a quadrant; and finally if obtuse, greater than a quadrant.

Diagram. Two spherical triangles side by side, for Theorem 21. The left triangle has apex A at the top and a curved base running from B (lower left) to C, with the point G marked on the base close to B (so that arc CG is cut off from BC). The right triangle has apex D at the top and a curved base from E (lower left) to F.

- B (lower left, left triangle): base endpoint
- G (on base near B, left triangle): point marking arc CG cut off equal to FE
- C (lower right, left triangle): base endpoint
- D (apex, right triangle): vertex D
- E (lower left, right triangle): base endpoint
- F (lower right, right triangle): base endpoint

Diagram. A single spherical triangle for the scholium to Theorem 21, illustrating the pole case. Apex A at top; curved base from B (lower left) to C (lower right); the point D lies on the base, and a great-circle arc AD descends from the apex to D.

- A (apex): pole of the base arc BC
- B (lower left): base endpoint
- D (on base, below apex): foot of the descending arc AD
- C (lower right): base endpoint

Diagram. Two spherical triangles side by side, for Theorem 22. The left triangle has apex A, with the point G marked on the left side just below A (so that arc BG is cut off equal to DE), and a curved base from B (lower left) to C. The right triangle has apex D and a base from E to F.

- A (apex, left triangle): vertex A
- G (on the left side near A, left triangle): point where BG is cut off equal to DE
- B (lower left, left triangle): base endpoint
- C (lower right, left triangle): base endpoint
- D (apex, right triangle): vertex D
- E (lower left, right triangle): base endpoint
- F (lower right, right triangle): base endpoint

Diagram. A single spherical triangle for the scholium to Theorem 22. Apex A at top; the isosceles triangle ABC has its side CB produced beyond B to D, so the base line runs D (lower left), B (lower middle), C (lower right); the great-circle arc AD is drawn from the apex to D.

- A (apex): vertex, with $AB = AC$
- D (lower left): point to which CB is produced
- B (lower middle): base vertex between D and C
- C (lower right): base vertex

Diagram. A pointed (ogival) isosceles spherical triangle for Theorem 23; the two equal sides AB, AC bulge outward and meet at the apex A. Base from B (lower left) to C (lower middle), with the base arc produced beyond C to D (lower right). This same figure is printed twice on the page (for the successive cases of the proof); it is described here once.

- A (apex): vertex where the two equal sides meet
- B (lower left): base endpoint
- C (lower middle): base endpoint
- D (lower right): point to which arc BC is produced

SCHOLIVM.

[continuation, on the following page]

Moreover, that when two sides of a spherical triangle are quadrants each angle at the base is a right angle, and that if each angle at the base is a right angle each side is a quadrant, can also be demonstrated in this way.

Let AB, AC be quadrants in the triangle ABC. I say that the angles B, C are right angles. For when the arcs AB, AC are produced until they meet at D, [Margin: t — Theodosius I.11] so that ABD, ACD are semicircles, the arcs DB, DC will also be quadrants, and hence each arc ABD, ACD will be bisected by the arc BC at the points B and C. [Margin: u — Scholium to Theodosius II.9; Theodosius I.15] Therefore the arc BC will pass through the poles of the arcs AB, AC, [Margin: x — Theodosius I.13] and consequently will make right angles at B and C.

But now let the angles B, C be right angles. I say that the sides AB, AC are quadrants. For since the angles B, C are right angles, [Margin: y — Theodosius I.13] the arc BC will pass through the poles of the arcs ABD, ACD, and so will bisect each of them at B, C. Therefore the arcs AB, AC, DB, DC [are the halves of the arcs ABD, ACD] [?], [Margin: z — Theodosius I.11] which indeed are

semicircles; [Margin: a — Theodosius II.9] and hence they are quadrants. Which was to be demonstrated.

THEOR. 24. PROPOS. 26.

In every isosceles spherical triangle whose two equal sides are quadrants, if the angle comprehended by them is a right angle, the base will be a quadrant; but if it is acute, the base will be less than a quadrant; and if obtuse, greater than a quadrant. And if the base is a quadrant, the angle comprehended by the sides will be a right angle; but if the base is less than a quadrant, the angle will be acute; and if greater than a quadrant, obtuse. And always the pole of the base will lie in the angle comprehended by the sides.

In the isosceles spherical triangle ABC, let the sides AB, AC be quadrants, and let the angle A first be a right angle, as in the first figure. I say that the base BC is a quadrant. For since AB, AC are quadrants, [Margin: a — Prop. 25 of this treatise] the angles B, C will be right angles. [Margin: b — Corollary of Prop. 25 of this treatise] Hence all the arcs will be quadrants. Therefore BC is a quadrant. Which was proposed.

Next, let the angle A be acute, as in the second figure. I say that the base BC is less than a quadrant. [Margin: c — Theodosius I.20] For if, through A and the pole of the arc AB, the great-circle arc AD is drawn, [Margin: d — Theodosius I.15] the angle BAD will be a right angle, and so greater than the acute angle BAC. Therefore AD will meet the arc BC produced, namely at the point D. [Margin: e — Prop. 25 of this treatise] Now since in the triangle ABC each angle B, C is a right angle, in the triangle ABD the two angles B and DAB will be right angles, and therefore equal; [Margin: f — Prop. 9 of this treatise] and consequently the arcs DA, DB will also be equal. Hence DAB is isosceles, having two right angles at its base AB; [Margin: g — Prop. 25 of this treatise] and so each arc AD, BD is a quadrant. Therefore BC will be less than a quadrant. Which was proposed.

Thirdly, let the angle A be obtuse, as in the third figure. I say that the base BC is greater than a quadrant. [Margin: h — Theodosius I.20] For if, through A and the pole of the arc AB, the great-circle arc AD is drawn, [Margin: i — Theodosius I.15] the angle DAB will be a right angle, and so less than the obtuse angle BAC. Therefore the arc AD will meet the arc BC within the triangle, namely at the point D. [Margin: k — Prop. 25 of this treatise] Now since in the triangle ABC each angle B, C is a right angle, in the triangle DAB the two angles at the base AB will be right angles, and therefore equal; [Margin: l — Prop. 9 of this treatise] and so the arcs

AD, BD are also equal. Hence DAB is isosceles, having two right angles at its base AB; [Margin: m — Prop. 25 of this treatise] therefore each arc AD, BD is a quadrant, and so BC is greater than a quadrant. Which was proposed.

But now let the base BC be a quadrant, as in the same first figure. I say that the angle A is a right angle. [Margin: n — Prop. 25 of this treatise] For since the two arcs CA, CB are quadrants, each angle A, B will be a right angle. Therefore the angle A is a right angle.

Next, let the base BC be less than a quadrant. I say that the angle BAC is acute. For if the arc BC is produced to D so that BD is a quadrant, [Margin: o — Theodosius I.20] and through the points A, D the great-circle arc AD is drawn — since the two arcs BA, BD are then quadrants, [Margin: p — Prop. 25 of this treatise] each angle D and DAB will be a right angle. Therefore the angle BAC is acute.

Finally, let the base BC be greater than a quadrant. I say that the angle BAC is obtuse. [Margin: q — Prop. 1 of this treatise] Cut off BD, an arc equal to the quadrant AB; [Margin: r — Theodosius I.20] and through the points A, D let the great-circle arc AD be described. And since the two arcs BA, BD are quadrants, [Margin: s — Prop. 25 of this treatise] each angle BDA, DAB will be a right angle. Therefore the angle BAC is obtuse.

I say further that in all these cases the point A is the pole of the base BC. For since the sides AB, AC are assumed quadrants, [Margin: t — Prop. 25 of this treatise] each angle at the base BC will be a right angle, [Margin: u — Theodosius I.23] and therefore each arc AB, AC will pass through the pole of the arc BC. So whether BC is a quadrant, or less, or greater than a quadrant, and whether the angle A is right, acute, or obtuse, the point A, where the arcs AB, AC meet, will always be the pole of the base BC. Therefore in every isosceles spherical triangle whose two sides, and so on. Which was to be shown.

SCHOLIVM.

Indeed, in every spherical triangle having two right angles, we shall demonstrate in the same way that, at the meeting of the two sides which subtend the right angles, is the pole of the remaining side that is adjacent to the right angles — even if it is not yet known that those two sides are quadrants. For let there be in the spherical triangle ABC two right angles B, C. I say that A is the pole of the arc BC. [Margin: x — Theodosius I.13] For each arc AB, AC will pass through the pole of the arc BC; and consequently A will be the pole of the arc BC.

Yet it is true [Margin: y — Prop. 25 of this treatise] that the two arcs AB, AC are always quadrants, because of the right angles B, C.

Diagram. A lune-shaped figure (a lens/vesica) for the scholium to Theorem 23. Two great-circle arcs meet at A (top) and D (bottom), forming the semicircles ABD and ACD; a horizontal arc BC crosses the middle, from B (left) to C (right).

- A (top): meeting point of the two arcs
- B (left, on the crossing arc): point where arc BC meets side ABD
- C (right, on the crossing arc): point where arc BC meets side ACD
- D (bottom): antipodal meeting point of the two arcs

Diagram. A group of three spherical triangles illustrating the three cases of Theorem 24, labelled with the interior numerals 1, 2, and 3 (the "2" and "3" carrying a small superscript "a").

- Prima figura (interior "1", small triangle, upper center): triangle ABC with apex A (top), B (lower left), C (lower right); the angle at A is marked as a right angle. This is the right-angled case.
- Secunda figura (interior "2^a", lower left): triangle with apex A (top), B (lower left), C (lower middle), and D (lower right) on the base BC produced beyond C. This is the acute-angle case, where arc AD meets BC produced at D.
- Tertia figura (interior "3^a", lower right): triangle with apex A (top), B (lower left), C (lower right), and D on the base within the triangle (between B and C). This is the obtuse-angle case, where arc AD meets BC inside the triangle at D.

THEOR. 25. PROPOS. 27.

In every spherical triangle whose sides are all greater than a quadrant — or in which one side is a quadrant and the remaining two are greater than a quadrant — all three angles are obtuse.

Let ABC be a spherical triangle in which, first, each of the sides is greater than a quadrant. I say that the three angles A, P, C [recte: A, B, C] are obtuse. For the triangle is either equilateral, or isosceles, or scalene.

If it is equilateral, [Margin: a — Corollary of Prop. 25 of this treatise] it is evident that the three angles are obtuse.

But if it is isosceles, having two equal sides AB and AC, [Margin: b — Prop. 25 of this treatise] the two angles B and C at the base will be obtuse. Let BD and BE be quadrants, [Margin: c — Theodosius, *Sphaerica* I.20] and through the points D and E let the great-circle arc ED be drawn, meeting arc CA — extended to F. Since, then, BD and BE are quadrants, and the angle B has been shown to be obtuse, [Margin: d — Prop. 26 of this treatise] the arc DE will be greater than a quadrant, [Margin: e — Prop. 25 of this treatise] and the angles BDE and BED will be right. But the arc AC is also assumed greater than a quadrant. Therefore the arcs DE and AC together are greater than a semicircle; and for that reason the arcs FD and FA together are less than a semicircle, since the arcs EF and FC together are less than a whole circle, [Margin: f — Prop. 2 of this treatise] each of the two being less than a semicircle. [Margin: g — Prop. 14 of this treatise] The angle FDB, therefore, is greater than the angle FAD. But the angle FDB is right, [Margin: h — Prop. 5 of this treatise] because the angles FDB and BDE are equal to two right angles, and BDE has been shown to be right. Therefore FAD is acute; and consequently, [Margin: i — Prop. 5 of this treatise] since FAD and DAC together equal two right angles, the angle BAC will be obtuse. But the angles B and C have also been shown to be obtuse. All three angles A, B, C, therefore, are obtuse.

Finally, if the triangle ABC is scalene, let side AC be greater than side AB, [Margin: k — Prop. 1 of this treatise] and let the arc AD be cut off equal to arc AB. The arc AD will still be greater than a quadrant, because the arc AB, to which it is equal, is also assumed greater than a quadrant. [Margin: l — Theodosius, *Sphaerica* I.20] If, then, through the points B and D the great-circle arc BD is drawn, [Margin: m — Prop. 25 of this treatise] each of the angles ADB and ABD will be obtuse. Much more, therefore, will the angle ABC be obtuse. Let BE and BF be quadrants, [Margin: n — Theodosius, *Sphaerica* I.20] and through the points E and F let the great-circle arc EF be drawn, meeting arc CA — extended to G. Since, then, BE and BF are quadrants, [Margin: o — Prop. 25 of this treatise] the angles at E and F will be right; and since the angle EBF has been shown to be obtuse, [Margin: p — Prop. 26 of this treatise] the arc EF will be greater than a quadrant. But the arc AC too is assumed greater than a quadrant. Therefore the arcs EF and AC together are greater than a semicircle; and hence, much more, FG and CG will be greater than a semicircle. [Margin: q — Prop. 14 of this treatise] The angle BFG, then, which we have shown to be right, is less than the angle BCG; and consequently the angle C will be obtuse. And since the arcs FG and CG together are less than a whole circle [Margin: r — Prop. 2 of this treatise] (each being less than a semicircle), while EF and AC together are greater than a semicircle, the arcs GE and GA together will be less than a semicircle; [Margin: s — Prop. 14 of this treatise] and consequently the angle GEB will be greater than the angle GAB.

Since, then, the angle GEB is right [Margin: t — Prop. 5 of this treatise] (because the two angles at E are equal to two right angles, and the angle BEF has been shown to be right), the angle GAB will be acute. Therefore, [Margin: u — Prop. 5 of this treatise] since GAB and BAC together equal two right angles, BAC will be obtuse. But the two angles ABC and C have also been shown to be obtuse. The three angles A, B, C of triangle ABC, therefore, are obtuse. Which was what was proposed.

Diagram. The isosceles case. A crowded spherical construction. Readable labels, top to bottom:

- A (apex, top): vertex of the isosceles triangle
- B (upper left): base vertex
- C (upper right): base vertex
- F (mid-left): intersection of arc ED extended with arc CA extended
- D (center): endpoint of quadrant BD
- A (center, second occurrence as printed): crossing of the extended arcs
- B (lower left): vertex of the lower great-circle construction
- E (lower center): endpoint of quadrant BE
- C (lower right): vertex of the lower construction

The figure shows the isosceles triangle ABC with quadrant arcs BD, BE and the arc ED extended to meet CA (extended) at F.

Diagram. The scalene case. Readable labels:

- G (top left): intersection of arc EF extended with arc CA extended
- A (top): apex vertex
- E (upper middle): endpoint of quadrant BE
- B (left): vertex
- D (right): point on AC with $AD = AB$
- F (lower right): endpoint of quadrant BF
- C (bottom): vertex

Spherical triangle ABC with AD cut off equal to AB, arc BD drawn, quadrants BE and BF, and arc EF extended to meet CA (extended) at G.

Diagram. The case of two arcs greater than a quadrant and the third equal to a quadrant, with the two greater arcs equal. Readable labels:

- E (top left): point where arc CD extended meets CA extended

- A (top): apex vertex

- C (bottom): vertex

Now let there be, in the same triangle ABC, two arcs AB and AC greater than a quadrant, while BC is a quadrant. Then the arcs AB and AC are either equal or unequal. If they are equal, [Margin: x — Prop. 25 of this treatise] the two angles B and C will be obtuse. Let BD be a quadrant, [Margin: y — Theodosius, *Sphaerica* I.20] and through the points C and D let the great-circle arc CD be drawn, meeting arc CA — extended to E. Since, then, the arcs BC and BD are quadrants, [Margin: z — Prop. 25 of this treatise] the angles D and BCD will be right; [Margin: a — Prop. 26 of this treatise] and the arc CD, on account of the angle B, which we have shown to be obtuse, will be greater than a quadrant. But the arc AC too is assumed greater than a quadrant. Therefore the arcs CD and CA together are greater than a semicircle; and consequently, since the arcs CDE and CAE make up a whole circle, [Margin: b — Theodosius, *Sphaerica* I.11] (each being a semicircle) the arcs ED and EA will be less than a semicircle. Hence the angle EDB, which is right [Margin: c — Prop. 5 of this treatise] (because the two angles at D are equal to two right angles, [Margin: d — Prop. 14 of this treatise] and the angle BDC has been shown to be right), will be greater than the angle EAD; and so EAD will be acute. [Margin: e — Prop. 5 of this treatise] Since, then, the angles EAD and DAC together equal two right angles, BAC will be obtuse. The angles B and C too have been demonstrated obtuse. The three angles A, B, C of triangle ABC, therefore, are obtuse.

Diagram. The case where the two arcs greater than a quadrant are unequal.
 Readable labels:

- F (top left): point where arc CE extended meets arc CA extended
- A (top): apex vertex
- E (upper middle): endpoint of quadrant BE
- B (left): vertex
- D (lower right): point on AC with AD = AB
- C (bottom): vertex

But if the sides AB and AC, which are greater than a quadrant, are not equal, let AC be the greater, [Margin: f — Prop. 1 of this treatise] and let the arc AD be cut off equal to arc AB. [Margin: g — Theodosius, *Sphaerica* I.20] Through the points B and D let the great-circle arc BD pass. The arc AD will still be greater than a

quadrant, since AB, its equal, is also assumed to be the greater. [Margin: h — Prop. 25 of this treatise] The angles ADB and ABD, therefore, are obtuse. Much more, then, will the angle ABC be obtuse. Let BE be a quadrant, [Margin: i — Theodosius, *Sphaerica* I.20] and through the points C and E let the great-circle arc CE pass, meeting arc CA — extended to F. Since, then, BE and BC are quadrants, and the angle EBC has been shown to be obtuse, [Margin: k — Prop. 26 of this treatise] the arc EC will be greater than a quadrant, [Margin: l — Prop. 25 of this treatise] but the angles E and BCE will be right. The angle ACB, therefore, will be obtuse. And since the arc CE has been shown to be greater than a quadrant, and the arc AC too is assumed greater than a quadrant, the arcs CE and CA together will be greater than a semicircle. Since, then, the arcs CEF and CAF together equal a whole circle, [Margin: m — Theodosius, *Sphaerica* I.21] each being a semicircle, the arcs FE and FA together will be less than a semicircle. For this reason the angle FEB, which is right [Margin: n — Prop. 5 of this treatise] (for the two angles at E equal two right angles,

and the angle BEC has been shown to be right), [Margin: o — Prop. 14 of this treatise] will be greater than the angle FAE. The angle FAE, therefore, is acute; and consequently, [Margin: p — Prop. 5 of this treatise] since the two angles at A equal two right angles, the angle BAC will be obtuse. But the angles ABC and ACB have also been shown to be obtuse. The three angles in triangle ABC, therefore, are obtuse. In every spherical triangle, then, whose sides are all &c. Which was to be demonstrated.

SCHOLIVM.

*This proposition does not convert. For not every spherical triangle whose angles are all obtuse necessarily has all its sides greater than a quadrant, or two of them greater than a quadrant and one equal to a quadrant. Rather, two may be greater than a quadrant while the third is less than a quadrant. For let there be two semicircles on the surface of the sphere enclosing the obtuse angles A and C. If, then, two equal arcs AB and AD are taken, each of which is greater than a quadrant and a half [i.e. greater than one and one-half quadrants], so that both together exceed three quadrants, [Margin: q — Theodosius, *Sphaerica* I.20] and through the points B and D the great-circle arc BD is described, this arc BD will be less than a quadrant. [Margin: r — Prop. 4 of this treatise] For since the three arcs AB, AD, BD are together less than a whole circle, while the two arcs AB and AD are assumed greater than three quadrants, the third arc BD will necessarily be less than a quadrant: otherwise, were it a quadrant or greater than a quadrant, the three arcs of triangle ABC would exceed the whole circle. [Margin: s — Prop. 25 of this*

treatise] Now since the two angles B and D in triangle ABD are obtuse, and the third angle A is obtuse as well by hypothesis, all three angles A, B, D will be obtuse. And yet neither are all the sides greater than a quadrant, nor are only two greater with the third a quadrant; rather, two of them, AB and AD , are greater than a quadrant, while the third arc BD is less than a quadrant, as we have shown.

Diagram. A lens (vesica) formed by two great-circle semicircles intersecting. Readable labels:

- A (left vertex): obtuse angle
- B (upper right): vertex of arc AB
- C (right, small triangle near the right vertex): obtuse angle
- D (lower middle): vertex of arc AD

The two semicircles enclose the obtuse angles A and C ; the chord-arc BD closes off the triangle ABD .

THEOR. 26. PROP. 28.

In every right-angled spherical triangle whose sides are all less than a quadrant, the remaining two angles are acute. And if the remaining two angles are acute, each of the sides will be less than a quadrant.

Let ABC be a spherical triangle in which the angle B is right and each side is less than a quadrant. I say that the remaining angles A and C are acute. For let the arcs BA and BC be extended so that BD and BE are quadrants, [Margin: a — Theodosius, *Sphaerica* I.20] and through the points C and D let the great-circle arc CD be drawn, and likewise through the points A and E the great-circle arc AE . [Margin: b — Theodosius, *Sphaerica* I.13] And since the quadrant BD , on account of the right angle B , passes through the poles of arc BC , [Margin: c — Corollary of Theodosius I.16] and the pole of a great circle is distant from it by a quadrant of a great circle, D will be the pole of arc BC . [Margin: d — Theodosius, *Sphaerica* I.15] The angle BCD , therefore, will be right; and consequently the angle ACB is acute. In the same way, since the quadrant BE , on account of the right angle B , [Margin: e — Theodosius, *Sphaerica* I.13] passes through the poles of arc AB , [Margin: f — Corollary of Theodosius I.16] and the pole of a great circle is distant from it by a quadrant of a great circle, E will be the pole of arc AB . [Margin: g — Theodosius, *Sphaerica* I.15] The angle EAB , therefore, will be right; and consequently BAC is acute.

Diagram. The right-angled spherical triangle. Readable labels:

- D (top): endpoint of quadrant BD, pole of arc BC
- A (left): vertex
- B (lower left): the right angle
- C (bottom center): vertex
- E (lower right): endpoint of quadrant BE, pole of arc AB

Right angle at B; arcs BA and BC extended to quadrants BD and BE; arcs CD and AE drawn.

Now let the angle B in the same triangle ABC be right, and the remaining angles A and C be acute. I say that each side is less than a quadrant. For let the angles BCD and BAE be made right. Since, then, each of the angles B and BCD is right, [Margin: h — Prop. 25 of this treatise] each of the arcs BD and CD will be a quadrant. Therefore the arc BA is less than a quadrant. In the same way the arc BC will be less than a quadrant, [Margin: i — Prop. 25 of this treatise] because the arcs BE and AE too are quadrants, on account of the right angles B and BAE. But that the arc AC too is less than a quadrant we shall show thus. Since the arc BE is drawn through E, the pole of arc BD (for we shall show that E is the pole of arc AB, as above, since BE is a quadrant and at right angles to arc AB), the point C will lie within the periphery of the circle of arc BD, on the surface of the sphere, and away from its pole. [Margin: k — Scholium of Theodosius II.21] Hence the arc CA will be less than the arc CD. But CD has been shown to be a quadrant. Therefore AC will be less than a quadrant. All the sides of triangle ABC, therefore, are less than a quadrant. And so, in every right-angled spherical triangle, &c. Which was to be shown.

SCHOLIUM.

The first part of this proposition is true also if only each of the two arcs about the right angle is assumed less than a quadrant, even if it is not known whether the remaining arc, which subtends the right angle, is less than a quadrant. This is plainly established from the demonstration of the first part. For it was shown that the angles BAC and BCA are acute solely from the fact that each of the arcs BA and BC is assumed less than a quadrant, no mention being made of the arc AC. Yet the arc subtending the right angle will always be less than a quadrant, provided the two arcs containing the right angle are less than a quadrant, as is manifest from the demonstration. For since, from the fact that the arcs BA and BC are less than a quadrant, the angles A and C are acute (as was demonstrated in the first part), it follows that the arc AC too is less than a quadrant, as was shown in the latter part. And so a theorem of this sort may also be propounded:

In every right-angled spherical triangle whose two arcs containing the right angle are less than a quadrant, the arc subtending the right angle will also be less than a quadrant.

THEOR. 27. PROPOS. 29.

In every spherical triangle whose angles are all acute, the several sides are less than a quadrant.

Let ABC be a spherical triangle in which all the angles are acute. I say that the several sides are less than a quadrant. For let, first, all the acute angles be equal. On this assumption, [Margin: a — Corollary of Prop. 25 of this treatise] the several sides will be less than a quadrant, as was demonstrated above.

Diagram. An equilateral (all-acute) spherical triangle. Readable labels: A (apex), B (lower left), C (lower right).

Next, let only two of the acute angles be equal, B and C, and let A be less than each of them. [Margin: b — Prop. 25 of this treatise] Then each of the arcs AB and AC will be less than a quadrant. And since the angle B is assumed greater than the angle A, [Margin: c — Prop. 11 of this treatise] the arc AC will be greater than the arc BC. Since, then, the arc AC has been shown to be less than a quadrant, the arc BC will be much less than a quadrant.

Diagram. A spherical triangle with two equal acute angles. Readable labels: A (apex), B (lower left), C (lower right).

Thirdly, let only two of the acute angles again be equal, B and C, and let A be an acute angle greater than each of them. [Margin: d — Prop. 25 of this treatise] Then again each of the arcs AB and AC will be less than a quadrant. I say that BC too is less than a quadrant. For let the right angle BAD be made, and let the arc AD be equal to each of the arcs AB and AC, [Margin: e — Theodosius, *Sphaerica* I.20] and through the points B and D let the great-circle arc BD be described. Since, then, each of the arcs AB and AC has been shown to be less than a quadrant, AD too will be less than a quadrant. [Margin: f — Prop. 25 of this treatise] Each of the angles ABD and D, therefore, is acute. Hence, since in triangle ABD the angle BAD is right and the remaining angles are acute, [Margin: g — Prop. 28 of this treatise] all its sides will be less than a quadrant. The arc BD, therefore, is less than a quadrant. But since the sides AB and AC are equal to the sides AB and AD, and the angle BAD is greater than the angle BAC, [Margin: h — Prop. 12 of this treatise] the base BD will also be greater than the base BC. But the arc BD has been shown to be less than a quadrant. Much less than a quadrant,

therefore, will the arc BC be. The three arcs of triangle ABC, therefore, are all less than a quadrant.

Diagram. The third case, with the right angle BAD constructed. Readable labels:

- A (apex): vertex, with right angle BAD constructed
- B (lower left): vertex
- C (bottom center): vertex
- D (right): endpoint of arc AD equal to AB and AC

Lastly, let all the acute angles A, B, C be unequal, and let A be the greatest of all. [Margin: i — Prop. 11 of this treatise] Then the arc BC will be greater than either of the arcs AB and AC. Let the angle C also be greater than the angle B; [Margin: k — Prop. 11 of this treatise] then the arc AB will be greater than the arc AC. Since, then, the arc BC is greater than the arc AB, and AB greater than AC, let the arc BD be cut off equal to arc AB, and through the points A and D let the great-circle arc AD be drawn. [Margin: l — Prop. 8 of this treatise] The angles BAD and BDA will be equal. But the angle BAD is acute, since it is part of the acute angle BAC. Therefore the angle BDA too will be acute. [Margin: m — Prop. 25 of this treatise] Each of the arcs AB and BD, therefore, is less than a quadrant. Much more, then, will the arc AC, which is less than arc AB, be less than a quadrant. I say that the arc BC too is less than a quadrant. For let the angle BAE be made right and equal to the arc AC [i.e. with $AE = AC$], [Margin: n — Theodosius, *Sphaerica* I.20] and through the points B and E let the great-circle arc BE be described. And since the arc AC has been shown to be less than a quadrant, AE too will be less than a quadrant. In triangle ABE, then, the angle BAE is right, and each of the arcs containing it is less than a quadrant. [Margin: o — Scholium of Prop. 28 of this treatise] Therefore the remaining angles ABE and AEB are acute. Since, then, in the same triangle ABE the angle BAE is right and the other two are acute, [Margin: p — Prop. 28 of this treatise] all its sides will be less than a quadrant. The arc BE, therefore, is less than a quadrant. But since the two sides AB and AE are equal to the two sides AB and AC, and the angle BAE is greater than the angle BAC, [Margin: q — Prop. 12 of this treatise] the base BE will also be greater than the base BC. But the arc BE has been shown to be less than a quadrant. Much less than a quadrant, therefore, will the arc BC be. The three arcs of triangle ABC, therefore, are all less than a quadrant. For this reason, in every spherical triangle whose &c. Which was to be demonstrated.

Diagram. The last case (all angles unequal), with the right angle BAE constructed. Readable labels:

- A (apex): vertex, with right angle BAE constructed
- F (right): auxiliary point on the construction
- B (lower left): vertex
- D (bottom, near center): point with $BD = AB$
- C (bottom center): vertex
- E (lower left, near B): endpoint of arc AE equal to AC

Right angle BAE built on triangle ABC; arc BE described; arcs AD (with $BD = AB$) and the auxiliary point F marked.

SCHOLIUM.

Moreover, this proposition too cannot be converted. For not every spherical triangle whose several sides are less than a quadrant necessarily has all its angles acute. For one angle can be right and the remaining two acute, as is established from the preceding proposition. Indeed, one can even be obtuse and the rest acute. For let there be two semicircles ABC, ADC enclosing the obtuse angles A and C, and let two equal arcs AB and AD be taken, each of which exceeds one and one-half quadrants, [Margin: r — Theodosius, Sphaerica I.20] and through the points B and D let the great-circle arc BD be described, which will be less than a quadrant, as we showed in the scholium of Prop. 27. In triangle BCD, then, the three arcs BC, CD, BD will each be less than a quadrant, and yet not all the angles in triangle BCD are acute; rather C is obtuse, by hypothesis, [Margin: s — Prop. 25 of this treatise] while B and D are acute, because the two sides CB and CD are equal and less than a quadrant.

Diagram. A lens (vesica) of two great-circle semicircles. Readable labels:

- B (top): vertex of arc
- C (left, small triangle): obtuse angle
- A (right vertex): obtuse angle
- D (lower middle): vertex of arc

The semicircles ABC, ADC enclose the obtuse angles A and C; the arc BD closes off the small triangle BCD.

THEOR. 28. PROP. 30.

In any spherical triangle in which one arc is greater than a quadrant while each of the remaining two is less than a quadrant, none of the angles will be right.

Let ABC be a spherical triangle in which the arc AC is greater than a quadrant, while both AB and BC are less than a quadrant. I say that none of the angles is right. For let the angle B — which is opposite the arc AC that is greater than a quadrant — be right, if this be possible. Then, with AD cut off as a quadrant, and the arc AB extended to E so that AE too is a quadrant, [Margin: a — Theodosius, *Sphaerica* I.20] and with the great-circle arc DE described through the points D and E cutting the arc BC at F, [Margin: b — Prop. 25 of this treatise] each of the angles D and E will be right. But the angle ABC too is assumed right — that is, EBC; [Margin: c — Prop. 5 of this treatise] for the two angles at B equal two right angles. [Margin: d — Prop. 25 of this treatise] Each of the arcs EF and BF, therefore, will be a quadrant, and so the arc BC will be greater than a quadrant. Which is absurd, since it is assumed less than a quadrant. Therefore the angle B cannot be right.

Diagram. The construction for Theorem 28. Readable labels, arranged around the triangle:

- A (top): vertex
- G (upper right, below A): construction point on arc AC
- I (upper left, below A): construction point
- H (left): construction point
- B (left, below H): the assumed right angle
- E (lower left): point on AB extended, with AE a quadrant
- F (bottom center): point where arc DE cuts BC
- C (bottom right): vertex
- D (right): endpoint of quadrant AD

Spherical triangle ABC with AC greater than a quadrant; AD and AE quadrants; arc DE drawn cutting BC at F. (Additional construction points G, H, I are marked but not referenced in the visible portion of the proof, which continues on the following folio.)

[Continuation of THEOR. 28 / PROPOS. 30]

that if angle C is said to be right, then [Margin: e — Prop. 25 of this treatise], if the same construction is made, each of the arcs DF and CF will in the same way be a quadrant. (For the angle CDF too is right [Margin: f — Prop. 25 of this treatise], since each of D and E is right, on account of the quadrants AD and AE.) And so the arc BC will be greater than a quadrant — which is contrary to the hypothesis.

Finally, suppose angle A is granted to be right. If from the arc CA a quadrant CG is cut off, and the arc CB is produced as far as H so that CH too is a quadrant [Margin: g — Theodosius I.20], and through the points G and H the arc GH of a great circle is drawn, cutting the arc AB at I [Margin: h — Prop. 25 of this treatise], then each of the angles at G and H will be right. Since angle A too is assumed right, in the triangle AGI there will be two right angles, A and G. [Margin: i — Prop. 25 of this treatise] Therefore each of the arcs HI and GI is a quadrant, and so the arc AB is greater than a quadrant — which is contrary to the hypothesis.

We can, however, prove in another way that angle A cannot be right, even without cutting off the quadrant CG, and so on. For if angle A is granted right, [Margin: k — Prop. 26 of this treatise] the arc DE will be a quadrant. Since EA too is a quadrant, [Margin: l — Prop. 25 of this treatise] each of the angles A and D will be right, and E will be the pole of the arc AC [Margin: m — Theodosius I.13], because each of the arcs DE and AE passes through the pole of the arc AD, on account of the right angles A and D. In the same way, D will be the pole of the arc AB. Since therefore the point F lies inside the circumference of the circle AB and away from its pole, and the arc FE is drawn through the pole of the circle AB — namely through D — [Margin: n — Scholium on Theodosius II.21] the arc FB will be greater than the arc FE. By the same reasoning the arc FC will be greater than the arc FD, since FD is drawn through E, the pole of the circle AC. Therefore the whole arc BC will be greater than the quadrant DE. This is absurd, since it was assumed to be less than a quadrant. Therefore none of the angles A, B, C is right. Hence, in any spherical triangle, and so on. Which was to be demonstrated.

Diagram. A spherical figure of overlapping arcs illustrating the preceding proof. The labelled points, read off the scan under magnification, are:

- A (top): apex
- G (upper right, close to A): intersection point on the great circle GH
- I (upper left, below A): where GH cuts the arc AB
- H (left): endpoint of the cut-off quadrant CH
- B (left, below H): triangle vertex
- E (lower left): construction point
- F (lower centre): interior point on the circle AB
- D (right): construction point (pole of AB)
- C (lower right): triangle vertex (right angle in the hypothesis)

THEOR. 29. PROPOS. 31.

In any spherical triangle the three angles are indeed greater than two right angles, but less than six right angles.

Let ABC be a spherical triangle. I say that the three angles A, B, C are greater than two right angles but less than six right angles. For if all three angles are right or obtuse; or only two right or obtuse; or only one right and one of the others obtuse — it is plain that all three are greater than two right angles. But in every triangle the demonstration will run as follows. When the side BC is produced to D, the angle ACD will be either equal to, or less than, or greater than the angle B.

Let it first be equal. [Margin: a — Prop. 15 of this treatise] Then the arcs AB and AC together will be equal to a semicircle; [Margin: b — Prop. 16 of this treatise] and hence the two angles ABC and ACB equal to two right angles. Therefore the three angles A, B, C will be greater than two right angles.

Next let the angle ACD be less than angle B. [Margin: c — Prop. 15 of this treatise] Then the arcs AB and AC together will be greater than a semicircle; [Margin: d — Prop. 16 of this treatise] and therefore the two angles ABC and ACB greater than two right angles. Much more, then, will the three angles A, B, C be greater than two right angles.

Finally let the angle ACD be greater than angle B [Margin: e — Prop. 10 of this treatise], and let the angle DCE be made equal to angle B, and let the arc CE meet the arc BA produced at E; and let the arc CA at length be extended to F. [Margin: f — Prop. 15 of this treatise] Then the arcs EB and EC together will be equal to a semicircle, and therefore the arcs EA and EC together less than a semicircle. [Margin: g — Prop. 14 of this treatise] Therefore the angle EAF — that is, the angle BAC, which is equal to it as a vertical angle — will be greater than the angle ACE. [Margin: h — Prop. 16 of this treatise] But the angle ACE, together with the angles ACB and B, equals two right angles. Therefore the angles BAC, ACB, and B will be greater than two right angles. So the three angles together are always greater than two right angles.

But since every spherical angle, even an obtuse one, is less than two right angles, it is plain that the three angles of any spherical triangle together are less than six right angles. Therefore, in any spherical triangle whatever, the three angles, and so on. Which was to be demonstrated.

Diagram. The spherical triangle ABC with the side BC produced to D and the auxiliary arcs of the proof :

- F (top left): endpoint of CA produced
- E (top right): where the arc CE meets BA produced
- A (centre): apex of the triangle
- B (bottom left): vertex
- C (bottom centre): vertex, with BC produced beyond it
- D (bottom right): point on BC produced

THEOR. 30. PROPOS. 32.

In every spherical triangle in which one angle is right and another of the remaining angles acute: if the arc adjacent to those angles is a quadrant, the arc subtending the right angle will also be a quadrant; but if it is less than a quadrant, the subtending arc too will be less than a quadrant; and finally, if it is greater than a quadrant, the subtending arc too will be greater than a quadrant. But the arc subtending the acute angle will always be less than a quadrant.

In the triangle ABC let angle C be right and B acute, and let the arc BC first be a quadrant. I say that AB too is a quadrant. For let the angle CBD be made right, and let the arc BD meet the arc CA produced at D. [Margin: a — Prop. 25 of this treatise] Then each of the arcs BD and CD will be a quadrant; but BC too is assumed a quadrant. [Margin: b — Prop. 26 of this treatise] Therefore B is the pole of the arc CD, [Margin: c — Theodosius I.15] and hence the angle at A will be right. [Margin: d — Prop. 25 of this treatise] Therefore each of the arcs BC and BA will be a quadrant. So the arc AB, opposite the right angle C, is a quadrant.

Next let the arc BC be less than a quadrant. I say that the arc AB too is less than a quadrant. For again let the angle CBD be made right, and let the arc BD meet the arc CA produced at D; [Margin: e — Prop. 25 of this treatise] and, as before, each of the arcs BD and CD will be a quadrant. Then, with BC produced to E so that BE is a quadrant, [Margin: f — Theodosius I.20] let the arc DE of a great circle be drawn through the points D and E, which BA produced cuts at F. Since therefore the arcs BE and BD are quadrants, [Margin: g — Props. 25 & 26 of this treatise] each of the angles BDE and BED will be right, and B the pole of the arc DE. [Margin: h — Theodosius I.15] Therefore the angle at F will be right, [Margin: i — Prop. 25 of this treatise] and hence each of the arcs BE and BF will be a quadrant. Therefore the arc BA will be less than a quadrant.

Diagram. The right-angled spherical triangle of Theorem 30 with the auxiliary arcs :

- D (top): endpoint where the arc BD meets CA produced
- H (centre-left): where the great circle DG cuts AB
- A (centre): apex
- F (centre-right): where BA produced meets the arc DE
- B (bottom left): vertex, right angle CBD constructed here
- G (bottom centre-left): endpoint of the quadrant cut off on BC
- C (bottom centre): vertex, right angle of the triangle
- E (bottom right): point on BC produced

Finally let the arc BC be greater than a quadrant. I say that the arc AB too is greater than a quadrant. For again let the angle CBD be made right, and let the arc BD meet CA produced at D; [Margin: l — Prop. 25 of this treatise] and, as before, each of the arcs BD and CD will be a quadrant. Then, with the quadrant BG cut off, [Margin: m — Theodosius I.10] let the arc DG of a great circle be drawn through the points D and G, cutting the arc AB at H. Since therefore the arcs BD and BG are quadrants, [Margin: n — Props. 25 & 26 of this treatise] each of the angles BDG and BGD will be right, and B the pole of the arc DG. [Margin: o — Theodosius I.15] Therefore the angle at H will be right, [Margin: p — Prop. 25 of this treatise] and hence each of the arcs BG and BH will be a quadrant. Therefore AB will be greater than a quadrant.

And since the arc CD has always been shown to be a quadrant, the arc AG will be less than a quadrant. Therefore in every spherical triangle, and so on. Which was to be shown.

THEOR. 31. PROPOS. 33.

In every spherical triangle in which one angle is right and another of the remaining angles acute: if the arc adjacent to those angles is a quadrant, the remaining angle will be right; but if less than a quadrant, acute; and finally, if greater than a quadrant, obtuse.

In the spherical triangle ABC let angle C be right and B acute, and let the arc BC first be a quadrant. I say that the remaining angle A is right. [Margin: a — Prop. 32 of this treatise] For AB too will be a quadrant. [Margin: b — Prop. 25 of this treatise] Therefore each of the angles C and A is right.

Next let the arc BC be less than a quadrant. I say that angle A is acute. [Margin: c — Prop. 32 of this treatise] For the arc AB too will be less than a quadrant, and hence the arcs AB and BC together will be less than a semicircle. [Margin: d —

Prop. 16 of this treatise] Therefore the angles A and C are less than two right angles; and consequently, since C is right, A will be acute.

Finally let the arc BC be greater than a quadrant. I say that angle A is obtuse.

[Margin: e — Prop. 32 of this treatise] For AB too will be greater than a quadrant, and therefore the arcs AB and BC together will be greater than a semicircle.

[Margin: f — Prop. 16 of this treatise] Therefore the angles A and C are greater than two right angles; and hence, since C is right, A will be obtuse. Therefore in every spherical triangle in which one angle, and so on. Which was to be shown.

Diagram. A small right-angled spherical triangle for Theorem 31 :

- A (top): apex
- B (bottom left): acute angle
- C (bottom right): right angle

THEOR. 32. PROPOS. 34.

In every spherical triangle in which one angle is right: if either of the remaining angles is right, the arc subtending it will be a quadrant; but if acute, less than a quadrant; and finally, if obtuse, greater than a quadrant. And if either of the arcs containing the right angle is a quadrant, the angle it subtends will be right; but if less than a quadrant, acute; and finally, if greater than a quadrant, obtuse.

In the spherical triangle ABC let angle C be right, and let first the other of the remaining angles, namely B, also be right. I say that the arc AC, which subtends it, is a quadrant. For since each of the angles B and C is right, [Margin: a — Prop. 25 of this treatise] each of the arcs AB and AC will be a quadrant.

Next let B be an acute angle. I say that the arc AC is less than a quadrant. For let the angle CBD be made right, and let the arc BD meet the arc CA produced at D. Since therefore each of the angles C and CBD is right, [Margin: b — Prop. 25 of this treatise] each of the arcs BD and CD will be a quadrant, and hence the arc AC will be less than a quadrant.

Finally let angle B be obtuse. I say that the arc AC is greater than a quadrant. For let the angle CBE be made right, and let the arc BE cut the arc AC at E. Since therefore each of the angles C and CBE is right, [Margin: c — Prop. 25 of this treatise] each of the arcs BE and CE will be a quadrant, and hence the arc AC will be greater than a quadrant.

Again let angle C be right, and let the arc AC first be a quadrant. I say that the angle B subtended by it is right. [Margin: d — Corollary to Theodosius I.16] For A will be the pole of the arc BC [Margin: e — Theodosius I.13] (since the arc CA passes through the pole of the arc BC, on account of the right angle C); [Margin: f — Theodosius I.15] and hence the angle ABC is right.

Next let the arc AC be less than a quadrant. I say that the angle B subtended by it is acute. For with the arc CA produced to D so that CD is a quadrant, [Margin: g — Corollary to Theodosius I.16] D will in the same way be the pole of the arc CB, [Margin: h — Theodosius I.13] since the arc CA passes through the pole of the arc BC. [Margin: i — Theodosius I.20] Therefore, with the arc DB of a great circle drawn through the points D and B, [Margin: k — Theodosius I.15] the angle DBC will be right, and consequently ABC acute.

Finally let the arc AC be greater than a quadrant. I say that the angle B subtended by it is obtuse. For with the quadrant CE cut off, [Margin: l — Corollary to Theodosius I.16] E will again be the pole of the arc BC, [Margin: m — Theodosius I.13] because the arc CA passes through the pole of the arc BC. [Margin: n — Theodosius I.20] Therefore, with the arc EB of a great circle drawn through the points E and B, [Margin: o — Theodosius I.15] the angle EBC will be right, and hence ABC obtuse. Therefore in every spherical triangle, and so on. Which was to be demonstrated.

Diagram. The right-angled spherical triangle of Theorem 32 with the auxiliary great-circle arc :

- D (top left): endpoint of CA produced (pole of CB)
- A (top): apex
- E (just below and right of A): construction point on AC
- B (bottom left): vertex where the right auxiliary angle is built
- C (bottom right): right angle of the triangle

THEOR. 33. PROPOS. 35.

In every right-angled spherical triangle: if each of the arcs containing the right angle — or only one of them — is a quadrant, the arc subtending the right angle will also be a quadrant; but if each of the said arcs is less than a quadrant, or greater, the arc subtending the right angle will be less than a quadrant; and finally, if one of them is greater than a quadrant and the other less, the arc subtending the right angle will be greater than a quadrant.

In the right-angled spherical triangle ABC let angle B be right, and let first each of the arcs AB and BC — or only one of them — be a quadrant. I say that the arc AC, which subtends the right angle, is a quadrant. For if each of the arcs AB and BC is a quadrant, then, since angle B is assumed right, [Margin: a — Prop. 26 of this treatise] the arc AC too will be a quadrant. But if only one of the arcs AB and BC is a quadrant, let AB be a quadrant. Since therefore the arc AB is a quadrant [Margin: b — Theodosius I.13] and passes through the poles of the arc BC, on account of the right angle B, [Margin: c — Corollary to Theodosius I.16] A will be the pole of the arc BC, [Margin: d — Theodosius I.15] and therefore angle C will be right. Since then each of the angles B and C is right, [Margin: e — Prop. 25 of this treatise] each of the arcs AB and AC will be a quadrant. In the same way, if BC is assumed a quadrant, we shall show that AC is a quadrant. For likewise C will be the pole of the arc AB, and consequently angle A right. Since then each of the angles B and A is right, [Margin: f — Prop. 25 of this treatise] each of the arcs BC and AC will be a quadrant.

Diagram. The right-angled spherical triangle for the first case of Theorem 33 :

- A (top): apex
- B (bottom left): right angle
- C (bottom right): vertex

Next let each of the arcs AB and BC be less than a quadrant, or greater. I say that the arc AC is less than a quadrant. For if each is less than a quadrant, then with the arc CB produced on the side of B, and BA on the side of A, so that CD and BE are quadrants, [Margin: g — Theodosius I.20] let the arc DE of a great circle be drawn through the points D and E, cutting the arc CA produced at F. Since therefore in the triangle BED the angle B is right and the arc BE a quadrant, [Margin: h — Prop. 34 of this treatise] the angle D, which it subtends, will be right. Again, since in the triangle CDF the angle D is right and the arc DC a quadrant, [Margin: i — Prop. 34 of this treatise] the angle F will likewise be right, [Margin: k — Prop. 25 of this treatise] and therefore each of the arcs DC and FC will be a quadrant. Hence the arc AC will be less than a quadrant.

But if each of the arcs AB and BC is greater than a quadrant, then, with the quadrants BD and CE cut off, [Margin: l — Theodosius I.20] let the arc ED of a great circle be drawn through the points D and E, cutting the arc CA produced at F. Since therefore in the triangle DBE the angle B is right and the arc BD a quadrant, [Margin: m — Prop. 34 of this treatise] the angle E, which BD subtends, will be right. Again, since in the triangle CEF the angle E is right and the arc EC a quadrant, [Margin: n — Prop. 34 of this treatise] F will in the same way be right.

[Margin: o — Prop. 25 of this treatise] Therefore each of the arcs CE and CF will be a quadrant, and consequently the arc AC less than a quadrant.

Diagram. The figure for the second case of Theorem 33 (both containing arcs less than a quadrant) :

- E (top): endpoint of the quadrant on BA produced
- F (upper left): where the arc DE cuts CA produced
- A (upper right): apex
- D (bottom left): endpoint of the quadrant on CB produced
- B (bottom centre): right angle
- C (bottom right): vertex

Diagram. The figure for the second case of Theorem 33 (both containing arcs greater than a quadrant, with quadrants BD and CE cut off) :

- F (top left): where the arc ED cuts CA produced
- A (top right): apex
- D (upper left): endpoint of the cut-off quadrant BD
- B (bottom centre): right angle
- E (bottom, below B): endpoint of the cut-off quadrant CE
- C (bottom right): vertex

Finally let the arc AB be greater than a quadrant, but the arc BC less than a quadrant. I say that the arc AC is greater than a quadrant. For let the quadrant BD be taken away, and let the arc CB be produced to E so that CE is a quadrant; [Margin: p — Theodosius I.20] and through the points D and E let the arc ED of a great circle be drawn, cutting the arc AC at F. Since therefore in the triangle BED the angle B is right and the arc BD a quadrant, [Margin: q — Prop. 34 of this treatise] the angle E will be right. Again, since in the triangle CEF the angle E is right and the arc EC a quadrant, [Margin: r — Prop. 34 of this treatise] by the same reasoning the angle F will be right. [Margin: s — Prop. 25 of this treatise] Therefore each of the arcs CE and CF will be a quadrant, and hence the arc AC greater than a quadrant. Therefore in every right-angled spherical triangle, and so on. Which was to be demonstrated.

Diagram. The figure for the third case of Theorem 33 (AB greater than a quadrant, BC less) :

- A (top): apex
- F (top right): where the arc ED cuts AC

- D (upper left): endpoint left after the quadrant BD is taken away
- E (bottom left): endpoint of the quadrant on CB produced
- B (bottom centre): right angle
- C (bottom right): vertex

THEOR. 34. PROPOS. 36.

In every right-angled spherical triangle: if the arc subtending the right angle is a quadrant, then either each of the arcs containing the right angle is a quadrant, or at least one of them; but if it is less than a quadrant, each of the remaining arcs is either less or greater than a quadrant; and finally, if it is greater than a quadrant, one of the remaining arcs will be greater than a quadrant and the other less.

In the spherical triangle ABC let angle B be right, and let the arc AC subtending it be first a quadrant. I say that either both the arcs AB and BC are also quadrants, or at least one of them. For if neither of them is a quadrant, then either both will be greater, or less, than a quadrant, [Margin: a — Prop. 35 of this treatise] and hence the arc AC less than a quadrant; or one of them greater than a quadrant and the other less, [Margin: b — Prop. 35 of this treatise] and consequently the arc AC greater than a quadrant. But both of these are absurd, since the arc AC is assumed a quadrant. Therefore either both arcs AB and BC will be quadrants, or at least one of them.

Diagram. A right-angled spherical triangle for Theorem 34 :

- A (top): apex, subtended by BC
- B (bottom left): right angle
- C (bottom right): vertex

Next let the arc AC be less than a quadrant. I say that both arcs AB and BC are either less than a quadrant, or greater. For if neither is less nor greater than a quadrant, then either both will be quadrants, [Margin: c — Prop. 35 of this treatise] and thus the arc AC too a quadrant; or one of them a quadrant and the other not, [Margin: d — Prop. 35 of this treatise] and therefore the arc AC too a quadrant; or one indeed less than a quadrant and the other greater, [Margin: e — Prop. 35 of this treatise] and hence the arc AC too greater than a quadrant: all of which are absurd, since the arc AC is assumed less than a quadrant. Therefore both arcs AB and BC will be less than a quadrant, or greater.

Thirdly let the arc AC be greater than a quadrant. I say that one of the remaining arcs, AB and BC, is greater than a quadrant, and the other less. For if it is not the

case that one is greater and the other less than a quadrant, then either both will be quadrants, [Margin: f — Prop. 35 of this treatise] and consequently the arc AC too a quadrant; or both less than a quadrant, or greater, [Margin: g — Prop. 35 of this treatise] and hence the arc AC less than a quadrant: all of which are absurd, since the arc AC is assumed greater than a quadrant. Therefore one of the arcs AB and BC will be greater than a quadrant, and the other less. Hence in every right-angled spherical triangle, and so on. Which was to be demonstrated.

THEOR. 35. PROPOS. 37.

In every right-angled spherical triangle, if either of the remaining angles, or at least one...

(continuation of the enunciation of THEOR. 35. PROPOS. 37, begun on the preceding page)

...at least one is right, the arc subtending the right angle will be a quadrant. But if both of the remaining angles are less than a right angle, or both greater, the arc subtending the right angle will be less than a quadrant. And if, finally, one of the remaining angles is greater than a right angle and the other less, the arc subtending the right angle will be greater than a quadrant.

In the spherical triangle ABC, whose angle B is right, let first both angles A and C — or at least one of them, namely C — be right. I say that the arc AC, which subtends the right angle B, is a quadrant. For if both angles A and C are right, or only C, the triangle ABC will be right-angled, having the angle C right; and the angle B is also right. Therefore the arc AC will be a quadrant.[Margin: a — Prop. 34 of this treatise]

Next, let each of the angles A and C be either less than a right angle or greater. I say that the arc AC is less than a quadrant. For if both angles A and C are less than a right angle, both the arc BC and the arc AB will be less than a quadrant;[Margin: b — Prop. 34 of this treatise] but if both angles A and C are greater than a right angle, both the arc BC and the arc AB will be greater than a quadrant.[Margin: c — Prop. 34 of this treatise] Hence, since in the triangle ABC the angle B is right, and both arcs AB, BC are either less or greater than a quadrant, the arc AC will always be less than a quadrant.[Margin: d — Prop. 35 of this treatise]

Third, let the angle A be greater than a right angle and C less. I say that the arc AC is greater than a quadrant. For since the angle A is obtuse, the arc BC will be greater than a quadrant;[Margin: e — Prop. 34 of this treatise] and since the angle

C is acute, the arc AB will be less than a quadrant.[Margin: f — Prop. 34 of this treatise] Therefore, since the arc BC is greater than a quadrant and AB less, the arc AC will be greater than a quadrant.[Margin: g — Prop. 35 of this treatise] And so in every right-angled spherical triangle, and so on. Which was to be shown.

Diagram. A spherical triangle with curved (arc) sides.

- A (apex, top): vertex A
- B (lower left): vertex B
- C (lower right): vertex C

THEOR. 36. PROPOS. 38.

In every right-angled spherical triangle, if the arc subtending the right angle is a quadrant, at least one of the remaining angles will also be right; but if it is less than a quadrant, both of the remaining angles will be either greater than a right angle or less; and if, finally, it is greater than a quadrant, one of the remaining angles will be greater than a right angle and the other less.

In the spherical triangle ABC, whose angle B is right, let first the arc AC, subtending the right angle B, be a quadrant. I say that at least one of the angles A, C is also right. For since the angle B is right and the arc AC is a quadrant, at least one of the arcs AB, BC will be a quadrant,[Margin: a — Prop. 36 of this treatise] and therefore also the angle A or C, which that arc subtends, will be right. [Margin: b — Prop. 34 of this treatise]

Next, let the arc AC be less than a quadrant. I say that each of the angles A, C is either greater or less than a right angle. For each of the arcs AB, BC will be either greater than a quadrant or less;[Margin: c — Prop. 36 of this treatise] hence each of the angles A, C will be either greater or less than a right angle.[Margin: d — Prop. 34 of this treatise]

Finally, let the arc AC be greater than a quadrant. I say that one of the angles A, C is greater than a right angle and the other less. For one of the arcs AB, BC will be greater than a quadrant and the other less;[Margin: e — Prop. 36 of this treatise] therefore one of the angles A, C will be greater than a right angle and the other less.[Margin: f — Prop. 34 of this treatise] And so in every right-angled spherical triangle, and so on. Which was to be shown.

Diagram. A spherical triangle with curved (arc) sides, identical in labelling to the preceding figure.

- A (apex, top): vertex A
- B (lower left): vertex B
- C (lower right): vertex C

COROLLARIUM.

From all this it is gathered that in every spherical triangle in which one of the arcs is a quadrant and one of the angles is right, at least one of the remaining arcs is also a quadrant, and at least one of the remaining angles is right. For if one of the angles is right and one of the arcs enclosing it is a quadrant, the arc subtending the right angle will also be a quadrant,[Margin: g — Prop. 35 of this treatise] and the angle which the former quadrant subtends will be right.[Margin: h — Prop. 34 of this treatise] But if the arc subtending the right angle is a quadrant, then either both arcs enclosing the right angle, or at least one of them, will be a quadrant;[Margin: i — Prop. 36 of this treatise] and either both of the remaining angles, or at least one, will be right.[Margin: k — Prop. 38 of this treatise] And so it cannot happen that a right-angled spherical triangle be given in which one arc alone is a quadrant; rather, either none will be a quadrant, or all three, or two will be quadrants. [Margin: NOTA / NOTE]

THEOR. 37. PROPOS. 39.

Spherical angles have the same ratio as their arcs.

Let there be two spherical angles BAC, EDF, whose arcs are BC, EF. I say that angle A is to angle D as the arc BC is to the arc EF. For A and D will be the poles of the arcs BC, EF, and the arcs AB, AC, DE, DF will be quadrants.[Margin: a — Def. 6 of this treatise] Therefore, with the arcs BC, EF produced, let any number of arcs BG, GH be taken equal to the arc BC, and any number of arcs FI, IK, KL equal to the arc EF;[Margin: b — Theodosius, *Sphaerica* I.20] and through the points G, H, I, K, L and the poles A, D let arcs of great circles AG, AH, DI, DK, DL be drawn, which will all be quadrants,[Margin: c — Euclid III.28] namely equal to the quadrants AB, AC, DE, DF, because the straight chords AG, AH, DI, DK, DL are also equal to the straight chords AB, AC, DE, DF, by the definition of a pole. Therefore all the angles at A will be equal to one another; and so, whatever multiple the arc CH is of the arc BC, the aggregate of all the angles at A will be the same multiple of the angle BAC.[Margin: d — Prop. 18 of this treatise] By the same reasoning, the aggregate of all the angles at D will be the same multiple of the angle EDF as the arc EL is of the arc EF. Now since, if the arc CH is equal to the arc EL, the angle HAC is also equal to the angle EDL;[Margin: e — Prop. 28 of this treatise] and if the arc CH is greater than the arc EL,

Diagram. Two fans of great-circle arcs. On the left a bundle of arcs descends from the pole A to points on a base line; on the right a similar bundle descends from the pole D.

- A (apex, upper left): pole of the left bundle
- D (apex, upper right): pole of the right bundle
- Base points, left to right: H, G, B, C (left group, subtended by arcs from A); then E, F, I, K, L (right group, subtended by arcs from D)

(the proof of THEOR. 37 continues) the angle HAC is also greater than the angle EDL;[Margin: f — Prop. 12 of this treatise] and if less, less. Therefore the arc CH and the angle HAC — equimultiples of the first magnitude BC and the third BAC — fall short of, or are equal to, or exceed together the arc EL and the angle EDL, which are equimultiples of the second magnitude EF and the fourth EDF. Hence, the ratio that the arc BC (the first magnitude) has to the arc EF (the second magnitude) is the same as that which the angle BAC (the third magnitude) has to the angle EDF (the fourth magnitude).[Margin: g — Euclid, Def. 6 of Book V] And so spherical angles have the same ratio as their arcs. Which was to be demonstrated.

COROLLARIVM.

From this it follows that any spherical angle is to four right spherical angles as the arc of that angle is to the whole circumference of a great circle, and conversely. For since any spherical angle is to a right spherical angle as the arc of that angle is to a quadrant — that is, to the arc of a right angle —[Margin: h — Prop. 39 of this treatise] the same angle will also be to the quadruple of a right angle (namely to four right angles) as the same arc of that angle is to the quadruple of a quadrant, that is, to the whole circumference; and conversely. [Margin: i — Scholium 22 on Book V of Euclid]

THEOR. 38. PROPOS. 40.

If two great circles in a sphere cut each other, and on their peripheries two points are marked — whether both are taken in the same semicircle, or one in one semicircle and the other in the other semicircle of the same circle, or one in a semicircle of one circle and the other in either semicircle of the other circle — and through each of these points an arc of a great circle is drawn making a right angle, on whichever side, with the periphery of the other circle: then the sine of the arc intercepted between one of those points and either section of the circles will have to

the sine of the arc which, drawn through that point, makes a right angle with the periphery of the other circle, the same ratio that the sine of the arc lying between the other point and either section of the circles has to the sine of the arc which, described through that point, makes a right angle with the periphery of the other circle.

In a sphere let two great circles ABCD, AECF cut each other, and let first two points B, G be marked at random in the same semicircle ABC;[Margin: a — Theodosius, *Sphaerica* I.20] through these and through the pole of the circle AECF, which is H, let great circles IBHK, LGHM be drawn;[Margin: b — Theodosius, *Sphaerica* I.15] and the angles at I, L, K, M will be right. I say that the sine of the arc AB (or CB) has to the sine of the arc BI (or BK) the same ratio that the sine of the arc AG (or CG) has to the sine of the arc GL (or GM). For let the common section of the circles be the straight line AC,[Margin: c — Euclid XI.3] to which let perpendiculars BN, GO be drawn from B, G in the plane of the circle ABCD; [Margin: d — Euclid I.12] and BN will be the right sine both of the arc AB and of the arc CB, by the definition of the right sine; and in the same way GO will be the sine of each arc AG, CG. From the same points B, G let perpendiculars BP, GQ be dropped to the plane of the circle AECF.[Margin: e — Euclid XI.11[?] (printed digit uncertain: 11 or 31)] And since the straight lines BP, GQ fall upon the common sections of the circles IBK, LGM with the circle AECF,[Margin: f — Euclid XI.38] which they bisect at the points I, K and L, M — that is, they fall upon the diameters of the great circles IBK, LGM[Margin: g — Theodosius, *Sphaerica* I.11] (because the planes of these circles are at right angles to the plane of the circle AECF),[Margin: h — Theodosius, *Sphaerica* I.15] and consequently make right angles with the diameters of the circles IBK, LGM, by Euclid, Definition 3 of Book XI — then BP will be the right sine of the arcs BI, BK, and GQ the right sine of the arcs GL, GM, by the definition of the right sine. In the plane of the circle AECF let the straight lines NP, OQ be drawn; and by Euclid, Definition 3 of Book XI, the angles P, Q in the triangles NBP, OGQ will be right. Now since both the straight lines BN, GO are parallel, because of the right angles ANB, AOG,[Margin: i — Euclid I.28] and the straight lines BP, GQ are parallel, since these are perpendicular to the plane of the circle AECF,[Margin: k — Euclid XI.6] the angles B, G in those same triangles NBP, OGQ will also be equal.[Margin: l — Euclid XI.10] Therefore the triangles NBP, OGQ are equiangular;[Margin: m — Euclid I.32] and so, as NB, the sine of the arc AB (or CB), is to BP, the sine of the arc BI (or BK), so is OG, the sine of the arc AG (or CG), to GQ, the sine of the arc GL (or GM) [Margin: n — Euclid VI.4] — in whatever way the arcs are taken, since to each sine there correspond two arcs that together make a semicircle. That is, as the sine of the arc AB is to the sine of the arc BI, so is the sine of the arc AG to the sine

of the arc GL. Likewise, as the sine of the arc AB is to the sine of the arc BK, so is the sine of the arc AG to the sine of the arc GM. Likewise, as the sine of the arc CB is to the sine of the arc BI, so is the sine of the arc CG to the sine of the arc GL. Likewise, as the sine of the arc CB is to the sine of the arc BK, so is the sine of the arc CG to the sine of the arc GM. Likewise, as the sine of the arc AB is to the sine of the arc BI, so is the sine of the arc CG to the sine of the arc GM, and so on.

Diagram. The prior figure of this proposition: a circle (representing a great circle of the sphere) with a horizontal diameter AC and a dense network of chords and arcs. Two intersecting great-circle traces are drawn, meeting the diameter, together with the perpendiculars and auxiliary lines of the proof.

- A (left end of the horizontal diameter): section point
- C (right end of the horizontal diameter): section point
- O, N (on the horizontal diameter, near the centre, O left of N): feet of the constructions
- D (upper left, on the circle), F (near top, right of D), K (top), M (upper right): points on the circle
- H (centre, below N): pole of circle AECF used in the construction
- Q, G (lower-left region), R (lower-middle right): construction points
- L, P, B (lower-centre, arranged left to right and downward): points on the arc
- I, S, E (bottom): points on the circle

Next, let one point — say B — be taken in the semicircle ABC, and the other — namely D — in the other semicircle CDA of the same circle,[Margin: o — Theodosius, *Sphaerica* I.20] and through the points B, D and the pole of the circle AECF, which is H, let two arcs of great circles IBK, DFS be drawn;[Margin: p — Theodosius, *Sphaerica* I.35] and the angles F, I, S, K will be right. I say again that, as the sine of the arc AB (or CB) is to the sine of the arc BI (or BK), so is the sine of the arc AD (or CD) to the sine of the arc DF — or of the arc which, together with the arc FD, completes a semicircle from the point D to the point S of the semicircle AEC.

For the arc from F, through D, to S is a semicircle,[Margin: q — Theodosius, *Sphaerica* I.11] since the circles AECF, DFS cut each other into two equal parts at F, S.[Margin: r — Prop. 1 of this treatise] For let an arc AG be taken equal to the arc AD;[Margin: s — Theodosius, *Sphaerica* I.20] and through G and the pole of the circle AECF (namely through H) let an arc of a great circle LGM be drawn; [Margin: t — Theodosius, *Sphaerica* I.15] and the angles L, M will be right. Since,

then, the two angles A, L of the triangle AGL are equal to the two angles A, F of the triangle ADF — for the two angles at A are equal as vertical angles, and the angles L, F are right — [Margin: u — Prop. 6 of this treatise] and since the sides AG, AD, which subtend the right angles, are by construction equal, the arcs GL, DF will also be equal, [Margin: x — Prop. 21 of this treatise] and consequently their sines will be equal, as also the sines of the equal arcs AG, AD will be equal. Therefore the ratio of the sine of the arc AG to the sine of the arc GL is the same as that of the sine of the arc AD to the sine of the arc DF. But the sine of the arc AG is to the sine of the arc GL, as was demonstrated, as the sine of the arc AB (or CB) is to the sine of the arc BI (or BK), because the points B, G were taken in the same semicircle. Therefore it will also hold that, as the sine of the arc AB (or CB) is to the sine of the arc BI (or BK), so is the sine of the arc AD to the sine of the arc DF, and so on.

Finally, let a point B be taken in the semicircle ABC, and in the semicircle of the other circle — namely in AEC — another point L. [Margin: y — Theodosius, *Sphaerica* I.20] Through B and the pole of the circle AEC let an arc of a great circle IBK be drawn; likewise through L and the pole of the circle ABC the arc LGM of a great circle; [Margin: z — Theodosius, *Sphaerica* I.15] and the angles I, G will be right. I say again that, as the sine of the arc AB is to the sine of the arc BI, so is the sine of the arc AL to the sine of the arc LG, and so on. For through the poles of each circle ABCD, AECF let an arc of a great circle RE be drawn; [Margin: a — Theodosius, *Sphaerica* I.20] and the angles R, E will be right, [Margin: b — Theodosius, *Sphaerica* I.15] and the semicircles ABC, AEC will be bisected at the points R, E, [Margin: c — Theodosius, *Sphaerica* II.9] and so the sines of the quadrants AR, AE will be equal. [Margin: d — Euclid V.7] And the ratio of the sine of the arc AR to the sine of the arc RE will be the same as that of the sine of the arc AE to the sine of the arc ER. Now since, as the sine of the arc AR is to the sine of the arc RE, so is the sine of the arc AB to the sine of the arc BI, as was demonstrated (for the two points R, B were taken in the same semicircle), it will also hold that, as the sine of the arc AE is to the sine of the arc ER, so is the sine of the arc AB to the sine of the arc BI. But by the same reasoning, as the sine of the arc AE is to the sine of the arc ER, so is the sine of the arc AL to the sine of the arc LG. Therefore it will also hold that, as the sine of the arc AB is to the sine of the arc BI, so is the sine of the arc AL to the sine of the arc LG, and so on. And if, in place of the point L, another point D is taken in the other semicircle AFC of the same circle AECF, it will still hold that, as the sine of the arc AB is to the sine of the arc BI, so is the sine of the arc AF to the sine of the arc FD, and so on. For, as we have just shown, as the sine of the arc AB is to the sine of the arc BI, so is the sine of the arc AL to the sine of the arc LG; and as the sine of the arc AL is to the

sine of the arc LG, so it has been demonstrated that the sine of the arc AF is to the sine of the arc FD, because the points L, F were taken in the two semicircles of the same circle. Therefore it will also hold that, as the sine of the arc AB is to the sine of the arc BI, so is the sine of the arc AF to the sine of the arc FD. And thus the proposition is universally true, in whatever way the two points are taken, whenever the circles ABCD, AECF cut each other at angles that are not right.

But now let the circles ABCD, AECF cut each other at right angles at the points A, C, and let their common section be the straight line AC. Then, with the semicircle ABC bisected, say, at H, so that AH, CH are quadrants, let two points B, G be taken at random. I say again that the sine of the arc AB is to the sine of the arc which, drawn through B, makes right angles with the circle AECF, as the sine of the arc AG is to the sine of the arc which, drawn through G, makes right angles with the circle AECF. For since the circle ABC is supposed to be at right angles to the circle AECF, it passes through the poles of the circle AEC,[Margin: e — Theodosius, *Sphaerica* I.13] and so H will be the pole of the circle AEC.[Margin: f — Corollary to Theodosius, *Sphaerica* I.16] Therefore the perpendicular arcs drawn to the circle AEC through the points B, G will necessarily pass through H,[Margin: g — Theodosius, *Sphaerica* I.13] and so those arcs will be BA, GA. But it is evident that, as the sine of the arc AB is to the sine of the arc BA, so is the sine of the arc AG to the sine of the arc GA, since in each case the ratio is one of equality, or identity; for the sine of the arc AB and of the arc BA is the same, as is the sine of the arc AG and of the arc GA.

Diagram. The latter figure of this proposition: two great circles intersecting at A and C, with a further circle inscribed.

- D (top): point on the outer circle
- F (below D): point on the inner circle
- A (left): section point of the two circles
- C (right): section point of the two circles
- E (bottom): point on the outer circle
- G, H (lower centre, near E; G left of H): construction points

And if one of the points is H, the pole of the circle AEC, then any arc drawn from H — such as HE — will be perpendicular to AEC,[Margin: h — Theodosius, *Sphaerica* I.15] and therefore a quadrant.[Margin: i — Corollary to Theodosius, *Sphaerica* I.16] So again it is clear that the sine of the arc AB is to the sine of the arc BA as the sine of the arc AH is to the sine of the arc HE (or HA), since here too

the ratio is one of equality, and so on. Therefore, if two great circles in a sphere cut each other, and so on. Which was to be shown.

SCHOLIVM.

It is clear from what has been demonstrated that, if two circles cut each other, and in one of them, from two points taken at random, two straight lines are drawn perpendicular to the plane of the other circle, then the right sine of the arc intercepted between one of those points and either section of the circles is to the perpendicular dropped from that point onto the plane of the other circle, as the right sine of the arc lying between the other point and either section of the circles is to the perpendicular dropped from this other point onto the plane of the other circle. For in the prior figure of this proposition it was shown that the sine of the arc AB (or CB) is to BP, the right sine of the arc BI, as the sine of the arc AG (or CG) is to GQ, the right sine of the arc GL. Since, then, the sines BP, GQ are perpendiculars dropped from the points B, G onto the plane of the circle AECF, the proposition is evident. And if one of the points taken is B, on one side of the section A, and the other point taken is D, on the other side of the section A, in the same circle, it will nonetheless hold that the sine of the arc AB is to the perpendicular BP dropped from B onto the plane of the other circle AECF, as the sine of the arc AD is to the perpendicular that would be dropped from D onto the plane of the other circle AECF; because it was shown that the sine of the arc AB is to the sine of the arc BI as the sine of the arc AD is to the sine of the arc DF — and these sines of the arcs BI, DF are indeed the perpendiculars falling from the points B, D onto the plane of the circle AECF, as is plainly established from what has been demonstrated in this proposition. The same is seen in the latter figure; for there too it holds that the sine of the arc AB is to the perpendicular—

(the Scholium continues on the following page)

[perpendicu]lar dropped from B onto the plane of circle AECF, so is the sine of arc AG to the perpendicular dropped from G onto the plane of circle AECF. This is because the sines of arcs AB and AG are precisely the perpendiculars dropped from B and G onto the plane of circle AECF, and they fall upon the straight line AC, the common section of the circles, as is evident.

[Margin: k — 38 undecimi (Elements XI.38)]

From this the following theorems can easily be demonstrated, and several of them are of the greatest service in calculating spherical triangles. The first and second of them are the two Cyclic Theorems of Ptolemy [Ptolemaeus] in the first book of the *Almagest* (*Almagest* I), but here demonstrated far more briefly and

easily from what has been established in this scholium. For that reason it seemed they should not be omitted, even though their use does not become apparent in these triangles.

I.

If on the surface of a sphere two arcs of great circles are drawn out from a single point, each of them being less than a semicircle, and if from their endpoints two other arcs of great circles are reflected back onto them so as to intersect each other between those two earlier arcs, then: the ratio which the sine of the segment of one of the drawn-out arcs — the segment between its endpoint and the reflected arc — has to the sine of the other segment of the same drawn-out arc is compounded of the ratio which the sine of the segment of the reflected arc — between the same endpoint and the other reflected arc — has to the sine of the other segment of the same reflected arc, together with the ratio which the sine of the segment of the other drawn-out arc — between its endpoint and the reflected arc — has to the sine of the whole of that same drawn-out arc.

From the point A, on the surface of the sphere, let two arcs AB and AC, each less than a semicircle, be drawn; and from their endpoints B and C let two arcs BD and CE be reflected back onto them, intersecting each other at F. I say that the ratio of the sine of arc BE to the sine of arc EA is compounded of the ratio of the sine of arc BF to the sine of arc FD, and of the ratio of the sine of arc CD to the sine of arc CA. For draw from the points B, A, D three perpendiculars BG, AH, DI to the plane of circle CE. Since the two circles AB and CE cut each other mutually at E, and the perpendiculars BG, AH have been dropped from the points B, A onto the plane of circle CE, [a] it follows that as the sine of arc EB is to the sine of arc EA, so is the straight line BG to the straight line AH. Again, since the two circles BD and CE cut each other mutually at F, and the perpendiculars BG, DI have been dropped from the points B, D onto the plane of circle CE, by the same reasoning, as the sine of arc FB is to the sine of arc FD, so is the straight line BG to the straight line DI. Finally, since the two circles AC and CE intersect each other at C, and the perpendicular straight lines DI, AH have been dropped from the points D, A onto the plane of circle CE, similarly, as the sine of arc CD is to the sine of arc CA, so is the straight line DI to the straight line AH. But the ratio of the straight line BG to the straight line AH — with the line DI placed as mean — is compounded of the ratio of BG to DI and of the ratio of DI to AH. Therefore the ratio of the sine of arc BE to the sine of arc EA (which is the same as the ratio of BG to AH) is likewise

compounded of the ratio of the sine of arc BF to the sine of arc FD (which is the same as the ratio of BG to DI), and of the ratio of the sine of arc CD to the sine of arc AC (which is the same as the ratio of DI to AH). Which is what was proposed.

[Margin: a — Scholium 40 of this [treatise], and by permutation]

Diagram. The figure of the first theorem: a Menelaus-type configuration on the sphere. Apex A stands at the top; two arcs descend from A to the base vertices B (lower left) and C (lower right). From B and C the reflected arcs BD and CE cross the interior, intersecting at F. A band of interior points runs across the middle, and perpendiculars are dropped onto the plane of circle CE.

- A (top apex): endpoint from which arcs AB, AC are drawn
- G (middle left): foot of perpendicular BG
- E (middle, left of center): intersection of circles AB and CE
- H (middle center): foot of perpendicular AH
- D (middle right): endpoint of reflected arc BD
- F (lower center): intersection of arcs BD and CE
- I (lower center-right): foot of perpendicular DI
- B (lower left): endpoint of arc AB
- C (lower right): endpoint of arc AC

II.

With the same things assumed, the ratio of the sine of one of the drawn-out arcs to the sine of the segment of that same arc — between the point of drawing-out and the reflected arc — is compounded of the ratio which the sine of the reflected arc from the endpoint of the said arc has to the sine of the segment of that same reflected arc — between the other drawn-out arc and the other reflected arc — together with the ratio which the sine of the segment of the other reflected arc — between the endpoint of the other drawn-out arc and the earlier reflected arc — has to the sine of the whole of the later reflected arc.

That is, the ratio of the sine of arc AB to the sine of arc AE is compounded of the ratio of the sine of arc BD to the sine of arc DF, and of the ratio of the sine of arc CF to the sine of arc CE. For draw from the points B, E, F three perpendiculars BG, EH, FI to the plane of circle AC. Since the two circles AB and AC cut each other mutually at A, and the perpendiculars BG, EH have been dropped from the points B, E onto the plane of circle AC, [a] it follows that as the sine of arc AB is to the sine of arc AE, so is the straight line BG to the straight line EH. Again, since the

two circles BD and AC intersect each other at D, and the perpendiculars BG, FI have been dropped from the points B, F onto the plane of circle AC, by like reasoning, as the sine of arc DB is to the sine of arc DF, so is the straight line BG to the straight line FI. Finally, since the two circles AC and CE intersect each other at C, and the perpendiculars FI, EH have been dropped from the points F, E onto the plane of circle AC, by the same argument, as the sine of arc CF is to the sine of arc CE, so is the straight line FI to the straight line EH. But the ratio of the straight line BG to the straight line EH — with the line FI placed as mean — is compounded of the ratio of BG to FI and of the ratio of FI to EH. Therefore the ratio of the sine of arc AB to the sine of arc AE (which is the same as the ratio of BG to EH) is likewise compounded of the ratio of the sine of arc BD to the sine of arc DF (which is the same as the ratio of BG to FI), and of the ratio of the sine of arc CF to the sine of arc CE (which is the same as the ratio of FI to EH). Which is what was proposed.

[Margin: a — Scholium 40 of this [treatise], and by permutation]

Diagram. The figure of the second theorem: a flatter version of the same configuration, drawn as a triangle. Apex A stands at the top; the base runs from B (left) to C (right), and interior points and perpendiculars are marked with respect to the plane of circle AC.

- A (top apex): point from which arcs AB, AC are drawn
- E (upper left interior): intersection point on circle AB
- H (center interior): foot of perpendicular EH
- D (upper right interior): endpoint of reflected arc BD
- B (left base vertex): endpoint of arc AB
- F (center interior): intersection of the reflected arcs
- I (interior, right of F): foot of perpendicular FI
- G (below the figure): foot of perpendicular BG
- C (right base vertex): endpoint of arc AC

III.

With the same things assumed, the ratio of the sine of one of the drawn-out arcs to the sine of the segment of that same arc — between its endpoint and the reflected arc — is compounded of the ratio which the sine of the segment of the other drawn-out arc — between the point of drawing-out and the reflected arc — has to the sine of the remaining segment, together with the ratio which the sine of the segment of the reflected arc, from the endpoint of the later drawn-out arc, between the

endpoint and the reflected arc, has to the sine of the remaining segment of that same reflected arc.

That is (the figure of the first theorem being repeated), the ratio of the sine of arc AC to the sine of arc CD is compounded of the ratio of the sine of arc AE to the sine of arc EB, and of the ratio of the sine of arc BF to the sine of arc FD. For since the two circles AC and CE intersect each other at C, and the perpendiculars AH, DI have been dropped from the points A, D onto the plane of circle CE, [a] it follows that as the sine of arc CA is to the sine of arc CD, so is the straight line AH to the straight line DI. Again, since the two circles AB and CE cut each other mutually at E, and the perpendiculars AH, BG have been dropped from the points A, B onto the plane of circle CE, in like manner, as the sine of arc EA is to the sine of arc EB, so is the straight line AH to the straight line BG. Finally, since the two circles BD and CE cut each other mutually at F, and the perpendiculars BG, DI have been dropped from the points B, D onto the plane of circle CE, by the same reasoning, as the sine of arc FB is to the sine of arc FD, so is the straight line BG to the straight line DI. But the ratio of the straight line AH to the straight line DI — with the line BG placed as mean — is compounded of the ratio of AH to BG and of the ratio of BG to DI. Therefore the ratio of the sine of arc AC to the sine of arc CD (which is the same as the ratio of AH to DI) is likewise compounded of the ratio of the sine of arc AE to the sine of arc EB (which is the same as the ratio of AH to BG), and of the ratio of the sine of arc BF to the sine of arc FD (which is the same as the ratio of BG to DI). Which is what was proposed.

[Margin: a — Scholium 40 of this [treatise], and by permutation]

Diagram. The figure of the first theorem, reprinted here (identical to fig-p832-1). Apex A at top; interior band G, E, H, D across the middle; F and I below center; base vertices B (left) and C (right), with the reflected arcs BD and CE crossing at F.

IV.

With the same things assumed, the ratio of the sine of the segment of one of the reflected arcs — between the endpoint of the drawn-out arc and the other reflected arc — to the sine of the remaining segment is compounded of the ratio which the sine of the segment of one of the drawn-out arcs — between the same endpoint and the other reflected arc — [has to its remaining segment], together with the ratio of the sine of the other drawn-out arc to the sine of the segment of that arc between the endpoint and the reflected arc.

That is (the same figure of the first theorem being repeated), the ratio of the sine of arc BF to the sine of arc FD is compounded of the ratio of the sine of arc BE to the sine of arc EA, and of the ratio of the sine of arc AC to the sine of arc CD. For since the two circles BD and CE cut each other mutually at F, and the perpendiculars BG, DI have been dropped onto the plane of circle CE, [a] it follows that as the sine of arc FB is to the sine of arc FD, so is the straight line BG to the straight line DI. Likewise, since the two circles BA and CE cut each other mutually at E, and the perpendiculars BG, AH have been drawn from the points B, A to circle CE, it also follows that as the sine of arc EB is to the sine of arc EA, so is the straight line BG to the straight line AH. Finally, since the two circles AC and CE cut each other at C, and the perpendiculars AH, DI have been dropped from the points A, D onto the plane of circle CE, similarly, as the sine of arc CA is to the sine of arc CD, so is the straight line AH to the straight line DI. But the ratio of the straight line BG to the straight line DI — with the line AH placed as mean — is compounded of the ratio of BG to AH and of the ratio of AH to DI. Therefore the ratio of the sine of arc BF to the sine of arc FD (which is the same as the ratio of BG to DI) is likewise compounded of the ratio of the sine of arc BE to the sine of arc EA (which is the same as the ratio of BG to AH), and of the ratio of the sine of arc AC to the sine of arc CD (which is the same as the ratio of AH to DI). Which is what was proposed.

[Margin: a — Scholium 40 of this [treatise], and by permutation]

V.

With the same things assumed, the ratio of the sine of one of the reflected arcs to the sine of the segment of that same arc — between the endpoint of the drawn-out arc and the other reflected arc — is compounded of the ratio which the sine of the segment of the other drawn-out arc — between the point of drawing-out and the reflected arc — has to the sine of the whole drawn-out arc, together with the ratio of the sine of the other reflected arc to the sine of the segment of that same arc between the earlier drawn-out arc and the earlier reflected arc.

That is (the figure of the second theorem being repeated), the ratio of the sine of arc CE to the sine of arc CF is compounded of the ratio of the sine of arc AE to the sine of arc AB, and of the ratio of the sine of arc BD to the sine of arc DF. For since the two circles AC and CE cut each other mutually at C, and the perpendiculars EH, FI have been drawn from the points E, F to the plane of circle AC, [a] it follows that as the sine of arc CE is to the sine of arc CF, so is the straight line EH to the straight line FI. Again, since the two circles AB and AC intersect each other

at A, and the perpendiculars EH, BG fall from the points E, B onto the plane of circle AC, it also follows that as the sine of arc AE is to the sine of arc AB, so is the straight line EH to the straight line BG. Finally, since the two circles AC and BD cut each other mutually at D, and the perpendiculars BG, FI have been dropped from the points B, F onto the plane of circle AC, by like reasoning, as the sine of arc DB is to the sine of arc DF, so is the straight line BG to the straight line FI. But the ratio of the straight line EH to the straight line FI — with the line BG placed as mean — is compounded of the ratio of EH to BG and of the ratio of BG to FI. Therefore the ratio of the sine of arc CE to the sine of arc CF (which is the same as the ratio of EH to FI) is likewise compounded of the ratio of the sine of arc AE to the sine of arc AB (which is the same as the ratio of EH to BG), and of the ratio of the sine of arc BD to the sine of arc DF (which is the same as the ratio of BG to FI). Which is what was proposed.

[Margin: a — Scholium 40 of this [treatise], and by permutation]

Diagram. The figure of the second theorem, reprinted here (identical to fig-p832-2). Apex A at top; base from B (left) to C (right); interior points E, H, D across the upper interior, F and I at the center, and the perpendicular foot G below.

VI.

If on the surface of a sphere two great circles cut each other mutually, but not at right angles, and from two points assumed on one of them two perpendicular arcs are drawn to the other circle, then: as the sine of the arc intercepted between the point of intersection and one of the right angles is to the tangent of that perpendicular arc, so is the sine of the arc lying between the point of intersection and the other right angle to the tangent of that other perpendicular arc.

Let two great circles AB and AC cut each other mutually at A, not at right angles; and from the points C, E assumed on circle AC let the perpendicular arcs CB, ED be drawn to circle AB. I say that as the sine of arc AB is to the tangent of arc CB, so is the sine of arc

AD to the tangent of arc ED. For when the arcs BC, DE are produced until they meet at F, [a] the arcs BF, DF will be quadrants. Now since from the point B two arcs of great circles BA, BF are drawn out, and from their endpoints A, F two others AC, FD are reflected back onto them, intersecting each other at E, [b] the ratio of the sine of arc AB to the sine of arc AD will be compounded of the ratio of the sine of arc BC to the sine of arc CF, and of the ratio of the sine of arc EF to the sine of arc DE. [c] But (since CF is the complement of arc BC) as the sine of arc CF

is to the sine of arc BC, so is the whole sine [sinus totus] to the tangent of arc BC; and by conversion, as the sine of arc BC is to the sine of arc CF, so is the tangent of arc BC to the whole sine. Likewise (since EF is the complement of arc DE) as the sine of arc EF is to the sine of arc DE, so is the whole sine to the tangent of arc DE. Therefore the ratio of the sine of arc AB to the sine of arc AD will also be compounded of the ratio of the tangent of arc BC to the whole sine, and of the ratio of the whole sine to the tangent of arc DE. Since, then, the ratio of the tangent of arc BC to the tangent of arc DE is likewise compounded of the ratio of the tangent of arc BC to the whole sine, and of the ratio of the whole sine to the tangent of arc DE — the whole sine being placed between the said tangents — it follows that as the sine of arc AB is to the sine of arc AD, so is the tangent of arc BC to the tangent of arc DE; and by permutation, as the sine of arc AB is to the tangent of arc CB, so is the sine of arc AD to the tangent of arc ED. Which is what was proposed.

[Margin: a — 25 of this [treatise] (Prop. 25)] [Margin: b — Theorem 3 of this scholium] [Margin: c — 18 of the [doctrine of] Sines]

Diagram. The figure of Theorem VI: a lune-shaped (crescent) spherical figure. F stands at the top; two arcs descend and curve to the base at B (lower left) and D (lower center); A lies at the right end of the lower arc. The great circles AB and AC meet at A, and the perpendicular arcs CB and ED (produced to meet at F) are shown.

- F (top): meeting point of the produced arcs BC, DE
- C (upper left, on the arc): assumed point on circle AC
- E (center, below C): assumed point on circle AC, intersection of AC and FB
- A (right): mutual intersection of circles AB and AC
- B (lower left): foot of perpendicular arc CB on circle AB
- D (lower center): foot of perpendicular arc ED on circle AB

VII.

If on the surface of a sphere two quadrants of great circles intersect each other at angles that are not right, and through the extreme points a great-circle arc is drawn, and moreover from some point of one quadrant a perpendicular arc is dropped to the other, then: as the whole sine is to the tangent of this perpendicular arc, so is the tangent of the complement of the arc drawn through the extremities of the quadrants to the sine of the arc of the quadrant to which the perpendicular arc has been dropped

— the arc, that is, intercepted between the point of section and the perpendicular arc.

Let two quadrants of great circles AD, AE cut each other at A, at angles that are not right, and through D, E let the great-circle arc DE be described: [a] the angles D, E will then be right. Again, from any point C whatever let the perpendicular arc CB be dropped to AD; and when the arcs DE, BC are produced until they meet at F, [b] DF, BF will be quadrants. I say that as the whole sine is to the tangent of arc BC, so is the tangent of arc EF — which is the complement of arc DE — to the sine of arc AB. For since from the point D two arcs of great circles DA, DF are drawn out, and from their endpoints A, F two others AE, FB are reflected, cutting each other at C, [c] the ratio of the sine of arc CF to the sine of arc BC will be compounded of the ratio of the sine of arc EF to the sine of arc DE, and of the ratio of the sine of the whole quadrant AD to the sine of arc AB. [d] But (since CF is the complement of arc BC) as the sine of arc CF is to the sine of arc CB, so is the whole sine to the tangent of arc BC; likewise (since DE is the complement of arc EF) as the sine of arc DE is to the sine of arc EF, so is the whole sine to the tangent of arc EF; and by conversion, as the sine of arc EF is to the sine of arc DE, so is the tangent of arc EF to the whole sine. Therefore the ratio of the whole sine to the tangent of arc BC will be compounded of the ratio of the tangent of arc EF to the whole sine, and of the ratio of the whole sine of the quadrant AD to the sine of arc AB. Since, then, the ratio of the tangent of arc EF to the sine of arc AB is likewise compounded of the ratio of the tangent of arc EF to the whole sine, and of the ratio of the whole sine to the sine of arc AB — the whole sine being placed between that tangent and this sine — it follows that as the whole sine is to the tangent of arc BC, so is the tangent of arc EF to the sine of arc AB. Which is what was proposed.

[Margin: a — 25 of this [treatise] (Prop. 25)] [Margin: b — 25 of this [treatise] (Prop. 25)] [Margin: c — Theorem 4 of this scholium] [Margin: d — 18 of the [doctrine of] Sines]

Diagram. The figure of Theorem VII: a lune-shaped spherical figure. F stands at the top; an arc curves down to the base at D (lower left) and B (lower center); A lies at the right. The two quadrants AD, AE meet at A; the arc DE is described through the extremities; and the perpendicular arc CB is dropped from C to AD, the arcs DE and BC being produced to meet at F.

- F (top): meeting point of the produced arcs DE, BC
- E (left): extreme point of quadrant AE

- C (center): point on AE from which perpendicular CB is dropped; intersection of AE and FB
- A (right): mutual intersection of the two quadrants
- D (lower left): extreme point of quadrant AD
- B (lower center): foot of perpendicular arc CB on AD

VIII.

If on the surface of a sphere two great circles cut each other mutually at angles that are not right, and from two points assumed on one of them two perpendicular arcs are drawn to the other circle, then: as the sine of the arc between the point of section and one of the assumed points is to the secant of the complement of the arc drawn through the other assumed point, so is the sine of the arc between the point of section and this remaining assumed point to the secant of the complement of the arc drawn through that other assumed point.

In the adjoining figure let two great circles AD, AE cut each other at A, at angles that are not right, and from the points C, E let the perpendicular arcs CB, ED be drawn to AD, and let them be produced until they meet at F. [a] BF, DF will be quadrants, and therefore CF, EF will be the complements of the arcs BC, DE. I say that as the sine of arc AE is to the secant of arc CF, so is the sine of arc AC to the secant of arc EF. For since from the point D two arcs DA, DF are drawn out, and from their endpoints A, F two others AE, FB are reflected back onto them, intersecting each other at C, [b] the ratio of the sine of arc AE to the sine of arc AC will be compounded of the ratio of the sine of arc DE to the whole sine of the quadrant DF, and of the ratio of the whole sine of the quadrant BF to the sine of arc BC. [c] But as the sine of arc DE is to the whole sine of the quadrant DF, so is the whole sine to the secant of arc EF; [d] this is because the whole sine is the mean proportional between the right sine of arc DE and the secant of arc EF, which is the complement of arc DE. And by the same reasoning, as the secant of arc CF is to the whole sine, so is the whole sine

[Margin: a — 25 of this [treatise] (Prop. 25)] [Margin: b — Theorem 5 of this scholium] [Margin: c — 18 of the [doctrine of] Sines] [Margin: d — 18 of the [doctrine of] Sines]

Diagram. The figure of Theorem VIII: a lune-shaped spherical figure. F stands at the top; arcs curve down to the base at B (lower center) and D (lower right); A lies at the left. The great circles AD, AE meet at A; the perpendicular arcs CB, ED are drawn to AD and produced to meet at F, so that BF, DF are quadrants.

- F (top): meeting point of the produced perpendicular arcs CB, ED
- C (center-left): assumed point on circle AE, intersection of AE and FB
- E (right of C): assumed point on circle AE
- A (left): mutual intersection of circles AD, AE
- B (lower center): foot of perpendicular arc CB on AD
- D (lower right): foot of perpendicular arc ED on AD ...of the quadrant BF, to the sine of arc BC — because the whole sine [sinus totus] is likewise a mean proportional between the secant of arc CF, which is the complement of arc BC, and the sine proper [sinus rectus] of arc BC. Therefore the ratio of the sine of arc AE to the sine of arc AC will also be compounded of the ratio of the secant of arc CF to the whole sine, and of the ratio of the whole sine to the secant of arc EF. And since the ratio of the secant of arc CF to the secant of arc EF is likewise compounded of the ratio of the secant of arc CF to the whole sine and of the ratio of the whole sine to the secant of arc EF — the whole sine being a mean between these two secants — it follows that as the sine of arc AE is to the sine of arc AC, so is the secant of arc CF to the secant of arc EF; and, by alternation, as the sine of arc AE is to the secant of arc CF, so is the sine of arc AC to the secant of arc EF. Which is what was proposed.

ALITER [Another way]. [Margin: e — Prop. 40 of this treatise.] Since the sine of arc AE is to the sine of arc ED as the sine of arc AC is to the sine of arc CB — that is, by alternation, as the sine of arc AE is to the sine of arc AC, so is the sine of arc ED to the sine of arc CB — [Margin: f — Prop. 22 of the treatise on Sines.] and since the secant of arc CF is to the secant of arc EF as the sine of arc ED (which is the complement of the latter arc EF) is to the sine of arc CB (which is the complement of the former arc CF), it follows too that as the sine of arc AE is to the sine of arc AC, so is the secant of arc CF to the secant of arc EF. And, by alternation, as the sine of arc AE is to the secant of arc CF, so is the sine of arc AC to the secant of arc EF. Which is what was proposed.

EADEM [The same]. This same demonstration holds even when the two points are taken on opposite sides of the point of intersection. For let the two great circles EF and BA again cut one another at D; and from the points F and E of arc EF let the perpendicular arcs FA and EB be drawn to BA. I say that the sine of arc ED is to the secant of the complement of arc FA as the sine of arc DF is to the secant of the complement of arc EB. [Margin: g — Prop. 40 of this treatise.] For since the sine of arc ED is to the sine of arc EB as the sine of arc DF is to the sine of arc FA — and, by alternation, as the sine of arc ED is to the sine of arc DF, so is the sine of arc EB to the sine of arc FA — [Margin: h — Prop. 22 of the treatise on

Sines.] and since the sine of arc EB is to the sine of arc FA as the secant of the complement of arc FA is to the secant of the complement of arc EB, it follows too that as the sine of arc ED is to the sine of arc DF, so is the secant of the complement of arc FA to the secant of the complement of arc EB; and, by alternation, as the sine of arc ED is to the secant of the complement of arc FA, so is the sine of arc DF to the secant of the complement of arc EB. Which is what was proposed.

Here we have reused the fourth figure of Proposition 35, so that — even though no mention is made of the arcs BC and CF — we should not be compelled to construct a new figure.

Diagram. The sector-figure (Menelaus configuration) reused from Proposition 35 for the *ALITER* and *EADEM* demonstrations. A curved-sided figure in which two great-circle arcs cross.

- A (apex, top): vertex from which the arc descends
- F (upper right, just below A): point on the arc toward C
- D (mid-left, below A): point where the two arcs intersect
- E (lower left): endpoint on the base
- B (lower center): point on the base
- C (lower right): base vertex

THEOR. 39. PROPOS. 41.

In every spherical triangle, the sine of any arc has to the sine of the angle it subtends the same ratio that the sine of each of the remaining arcs has to the sine of the angle which it subtends.

Let ABC be any spherical triangle whatever. I say that the sine of arc AB is to the sine of angle C (which it subtends) as the sine of arc AC is to the sine of angle B (which it subtends), and as the sine of arc BC is to the sine of angle A (which it subtends).

First, let all three angles be right angles. [Margin: a — Corollary of Prop. 25 of this treatise.] Then all the arcs will consequently be quadrants. It is therefore obvious that the whole sine of quadrant AB is to the whole sine of the right angle C as the whole sine of quadrant AC is to the whole sine of the right angle B, and as the whole sine of quadrant BC is to the whole sine of the right angle A.

Next, let only two angles, A and B, be right. [Margin: b — Prop. 25 of this treatise.] Then arcs AC and BC will accordingly be quadrants, [Margin: c — Scholium of

Prop. 26 of this treatise.] and C will be the pole of arc AB. So again it is clear that the sine of arc AB is to the sine of angle C — that is, to the sine of arc AB (for AB is the arc of angle C, since C is the pole of arc AB, as has been shown) — as the whole sine of quadrant AC is to the whole sine of the right angle B, and as the whole sine of quadrant BC is to the whole sine of the right angle A; since the ratio is always one of equality.

Thirdly, let C alone be a right angle, while of the remaining angles A and B either both are less than a right angle, or both greater, or one greater and one less than a right angle. If, then, both are less than a right angle, [Margin: d — Prop. 28 of this treatise.] all the arcs will be less than a quadrant. Let them all be produced, and let the quadrants BD, AE, BF, AG be made; [Margin: e — Theodosius, *Sphaerica* I.20.] and through the points D, F let the great-circle arc DF be drawn, and through the points E, G the great-circle arc EG. [Margin: f — Prop. 25 of this treatise.] Then the angles D, F, E, G will be right, [Margin: g — Scholium of Prop. 26 of this treatise.] and B will be the pole of arc DF, and A the pole of arc EG; and hence arcs DF and EG will be the arcs of angles B and A. And both the quadrant BD and AE is the arc of the right angle C, as is clear from Definition 6. Now since the two great circles BD and BF cut one another on the sphere at the point B, and since on arc BD two points A, D have been taken, from which the perpendicular arcs AC, DF have been dropped to arc BF, [Margin: h — Prop. 40 of this treatise.] it follows that the sine of arc AB is to the sine of arc AC as the sine of arc BD is to the sine of arc DF; and, by alternation, the sine of arc AB of triangle ABC is to the sine of quadrant BD — that is, to the whole sine of the right angle C in the same triangle ABC — as the sine of arc AC of the same triangle ABC is to the sine of arc DF, that is, to the sine of angle B in the same triangle ABC. In the same way, the sine of arc AB in triangle ABC is to the whole sine of the right angle C of the same triangle ABC as the sine of arc BC is to the sine of arc EG, that is, to the sine of angle A in the same triangle ABC. The proposition, therefore, is evident.

Diagram. The general spherical triangle ABC of Proposition 41, with curved (great-circle) sides.

- A (apex, top): vertex opposite side BC
- B (lower left): vertex opposite side AC
- C (lower right): vertex opposite side AB

Diagram. The construction for the "thirdly" case (angles A and B both less than a right angle): two great-circle arcs crossing, with the arcs produced to quadrants.

- E (far left): endpoint of a produced arc

- B (top, left of center): triangle vertex
- A (top, right of center): triangle vertex
- D (right): endpoint of a produced arc
- G (lower left): foot of a perpendicular / arc endpoint
- C (lower center): point of intersection of the two arcs (the right-angle vertex)
- F (lower right): foot of a perpendicular / arc endpoint

If, on the other hand, both angles A and B are greater than a right angle, [Margin: i — Prop. 37 of this treatise.] then arc AB will be less than a quadrant, [Margin: k — Prop. 34 of this treatise.] and both arc AC and arc BC will be greater than a quadrant. Arc AB is therefore produced in both directions until the quadrants AE, BD are formed, and the quadrants AG, BF are cut off; [Margin: l — Theodosius, *Sphaerica* I.20.] then through the points D, F let the great-circle arc DF be drawn, and through E, G the great-circle arc EG. [Margin: m — Prop. 26 of this treatise.] Then again B will be the pole of arc DF, and A the pole of arc EG. Therefore DF and EG will be the arcs of angles B and A; and, moreover, both the quadrant BD and AE is the arc of the right angle C, by Definition 6. Likewise, because of the quadrants BD and BF, [Margin: n — Prop. 25 of this treatise.] each of the angles D and F [is right]; and because of the qua-

Diagram. The construction for the case where both A and B are greater than a right angle (this figure is reprinted at the top of the following page, p. 836, and is described here only once).

- E (upper left): endpoint of the produced arc AB
- B (upper left, right of E): triangle vertex
- A (upper right): triangle vertex
- D (upper right, far right): endpoint of the produced arc AB
- F (lower middle, left): foot of perpendicular
- G (lower middle, right): foot of perpendicular
- C (bottom point): the right-angle vertex

[Margin: o — Prop. 40 of this treatise.] ...the quadrants AE, AG, and each of the angles E, G will be right. Now since the two great circles BD and BC cut one another on the sphere at B, and on arc BD two points A, D have been taken, from which the two perpendicular arcs AC, DF have been dropped to BC, it follows that the sine of arc AB is to the sine of arc AC as the sine of arc BD is to the sine of arc DF; and, by alternation, the sine of arc AB of triangle ABC is to the sine of quadrant BD — that is, to the whole sine of the right angle C in the same triangle

ABC — as the sine of arc AC of the same triangle ABC is to the sine of arc DF, that is, to the sine of angle B in the same triangle ABC. And by the same reasoning, the sine of arc AB of triangle ABC is to the sine of quadrant AE — that is, to the whole sine of the right angle C in the same triangle ABC — as the sine of arc BC is to the sine of arc EG, that is, to the sine of angle A in the same triangle ABC. Which is what was proposed.

Finally, let one of the angles A, B be greater than a right angle and the other less; let B be the greater and A the less. [Margin: p — Prop. 37 of this treatise.] Then arc AB will be greater than a quadrant. [Margin: q — Prop. 34 of this treatise.] Likewise arc AC will also be greater than a quadrant, but arc BC less than a quadrant. Therefore let the quadrants BD, AE, and AG be cut off, and, arc BC being produced, let the quadrant BF be made; [Margin: r — Theodosius, *Sphaerica* I.20.] and through the points D, F let the great-circle arc DF be drawn, and likewise through E, G the great-circle arc EG. [Margin: s — Prop. 26 of this treatise.] Then again B will be the pole of arc DF, and A the pole of arc EG. Therefore DF and EG will be the arcs of angles B and A; and, moreover, both the quadrant BD and AE is the arc of the right angle C, by Definition 6. Likewise, because of the quadrants AE, AG, [Margin: t — Prop. 25 of this treatise.] each of the angles E, G will be right. Now since the two great circles BA and BF cut one another on the sphere at B, and on BA two points A, D have been taken, from which the two perpendicular arcs AC, DF have been dropped to BF, [Margin: u — Prop. 40 of this treatise.] it follows that the sine of arc AB is to the sine of arc AC as the sine of arc BD is to the sine of arc DF; and, by alternation, the sine of arc AB of triangle ABC is to the sine of quadrant BD — that is, to the whole sine of the right angle C in the same triangle ABC — as the sine of arc AC of the same triangle ABC is to the sine of arc DF, that is, to the sine of angle B in the same triangle ABC. And in the same way, the sine of arc AB of triangle ABC is to the sine of quadrant AE — that is, to the whole sine of the right angle C in the same triangle ABC — as the sine of arc BC of the same triangle ABC is to the sine of arc EG, that is, to the sine of angle A in the same triangle ABC. Which is what was proposed.

Diagram. The construction for the case where one of A, B is greater and the other less than a right angle : a curved figure with two great-circle arcs crossing.

- B (upper left): triangle vertex
- E (upper left, right of B): endpoint of a produced arc
- D (upper right): endpoint of a produced arc
- A (upper right, far right): triangle vertex
- C (lower left): the right-angle vertex / intersection

- G (lower center): foot of a perpendicular
- F (bottom point): foot of a perpendicular

Fourthly and lastly, let none of the angles A, B, C be a right angle. [Margin: x — Theodosius, *Sphaerica* I.20.] Through the point A and the pole of circle BC let the great-circle arc AD be drawn, and let it fall first upon the side BC, within the triangle; [Margin: y — Theodosius, *Sphaerica* I.15.] then the angles at D will be right. Now since in triangle ABD the angle D is a right angle, it will be — as has already been demonstrated — that the sine of arc AB is to the sine of angle ADB as the sine of arc AD is to the sine of angle B; and, by alternation, as the sine of arc AB is to the sine of arc AD, so is the sine of angle ADB to the sine of angle B. But in the same way, since in triangle ADC the angle D is a right angle, the sine of arc AD is to the sine of angle ACD as the sine of arc CD is to the sine of angle ADC, that is, to the sine of angle ADB; and, by alternation, as the sine of arc AD is to the sine of arc AC, so is the sine of angle ACD to the sine of angle ADB, since the angles at D are right. Therefore, by *ex aequali* in perturbed proportion, the sine of arc AB is to the sine of arc AC as the sine of angle ACD is to the sine of angle B, as appears in the accompanying scheme. Hence also, by alternation, the sine of arc AB in triangle ABC is to the sine of angle ACB in the same triangle ABC as the sine of arc AC of the same triangle ABC is to the sine of angle B in the same triangle ABC.

Diagram. The construction for the "fourthly" case (no angle right): the perpendicular arc AD is dropped from A to side BC.

- A (apex, top): vertex from which the perpendicular is drawn
- B (lower left): base vertex
- D (lower middle): foot of the perpendicular from A on BC
- C (lower middle-right): base vertex
- E (lower right): point where BC produced meets the perpendicular through the pole

arcus (arc)	anguli (angle)
AB.	ACD.
AD.	ADB.
AC.	B.

[Margin: z — Theodosius, *Sphaerica* I.15.] Next, let the arc drawn through A and the pole of circle BC fall upon arc BC produced to E; then angle E will be right. Now since in triangle ABE the angle E is a right angle, it will be — as has been

demonstrated — that the sine of arc AB is to the sine of angle E as the sine of arc AE is to the sine of angle B; and, by alternation, as the sine of arc AB is to the sine of arc AE, so is the sine of angle E to the sine of angle B. But by the same reasoning, since in triangle ACE the angle E is a right angle, the sine of arc AE is to the sine of angle ACE as the sine of arc AC is to the sine of angle E; and, by alternation, as the sine of arc AE is to the sine of arc AC, so is the sine of angle ACE to the sine of angle E. Therefore, by *ex aequali* in perturbed proportion, the sine of arc AB is to the sine of arc AC as the sine of angle ACE — that is, of angle ACB (since the sine of the two angles at C is the same, because their arcs make up a semicircle, as is established from the corollary of Proposition 5 of this treatise; and it is clear from what we said in the treatment of the sines that two arcs making up a semicircle have the same sine) — is to the sine of angle B, as appears in the accompanying scheme. Therefore also, by alternation, the sine of arc AB in triangle ABC is to the sine of angle ACB of the same triangle ABC as the sine of arc AC in the same triangle ABC is to the sine of angle B of the same triangle ABC. And if from B a second perpendicular arc be drawn to arc AC — which will fall either within the triangle or upon the arc produced — we shall show in the same way that the sine of arc AB is to the sine of angle ACB as the sine of arc BC is to the sine of angle BAC. And so, in every spherical triangle, the sine of any arc, and so on. Which was to be demonstrated.

arcus (arc)	anguli (angle)
AB.	ACE.
AE.	E.
AC.	B.

COROLLARIUM.

From this it is evident that, in every right-angled spherical triangle, as the sine of the arc subtending the right angle is to the whole sine — namely, to the sine of the right angle it subtends — so is the sine of any of the remaining

arcs to the sine of the angle it subtends. I have said this because most writers demonstrate this corollary as a proposition distinct from this our Proposition 41; but we have preferred to render this proposition more universal, in that it embraces both the right-angled and the non-right-angled spherical triangle.

SCHOLIUM.

In this and the following propositions we shall bring forward problems by which the calculation of right-angled spherical triangles is carried out, and which are drawn from these very propositions. Although sometimes several things are set forth for investigation in a given problem, still the primary and most important one is always that which is sought and which is inferred first and of itself from the problem. From this proposition, then, the following three problems are collected.

I.

In a right-angled spherical triangle, given the arc which is opposite the right angle and either one of the arcs enclosing the right angle, to find the angle opposite this arc.

In triangle ABC, whose angle C is right, let the arcs AB and AC be given. I say that the angle B, opposite arc AC, is also given. [Margin: a — Prop. 41 of this treatise.] For since the sine of arc AB is to the whole sine of the right angle C as the sine of arc AC is to the sine of angle B:

[Margin: Praxis.] If it be made that as the sine of the given arc opposite the right angle is to the whole sine, so is the sine of the arc given about the right angle to a fourth term, then the sine of the sought angle will be found.

But here careful attention must be paid to whether the sought angle B is acute or obtuse. For if it is acute, the arc corresponding to the sine found will give angle B; but if it is obtuse, the same arc taken from a semicircle will leave angle B. Now the given arc AC about the right angle C will neatly show whether angle B is acute or obtuse: [Margin: b — Prop. 34 of this treatise.] for if AC is less than a quadrant, angle B will be acute; but if greater than a quadrant, obtuse. Here we take a spherical triangle in which only one angle is right, and therefore no arc is a quadrant — which is also to be understood in what follows.

Diagram. The right-angled spherical triangle used for Problems I, II, and III, with curved sides and the right angle at C.

- A (apex, top): vertex opposite the hypotenuse-side BC
- C (lower left): the right-angle vertex
- B (lower right): vertex opposite arc AC

II.

In a right-angled spherical triangle, given the arc which is opposite the right angle and either one of the non-right angles, to find the arc opposite this angle.

In the same triangle let the arc AB, opposite the right angle C, be given, and in addition the angle B. I say that the arc AC, opposite angle B, is also given. [Margin: a — Prop. 41 of this treatise.] For since the sine of arc AB is to the whole sine of the right angle C as the sine of arc AC is to the sine of angle B, it will be, by conversion, that as the whole sine is to the sine of arc AB, so is the sine of angle B to the sine of arc AC.

[Margin: Praxis.] If, then, it be made that as the whole sine is to the sine of the arc opposite the right angle, so is the sine of the given angle to a fourth term, the sine of the sought arc will be found.

[Margin: b — Prop. 34 of this treatise.] This arc will be less than a quadrant if the given angle is acute, but greater than a quadrant if it is obtuse.

III.

In a right-angled spherical triangle, given either one of the arcs about the right angle and the angle opposite it, to find the arc opposite the right angle. It must, however, be established whether the third angle is acute or obtuse, or whether the third arc is less or greater than a quadrant.

In the same triangle let the arc AC, about the right angle C, be given, and also the angle B opposite it. I say that the arc AB, opposite the right angle, is likewise given. [Margin: a — Prop. 41 of this treatise.] For since the sine of arc AC is to the sine of angle B as the sine of arc AB is to the whole sine of the right angle C, it will be, by conversion, that as the sine of the given angle B is to the sine of the given arc AC, so is the whole sine to the sine of arc AB opposite the right angle, which is sought.

[Margin: Praxis.] If, then, it be made that as the sine of the given angle is to the sine of the given arc, so is the whole sine to a fourth term, the sine of the sought arc — the one opposite the right angle — will be found.

It must, however, be established whether the third angle A is acute or obtuse, or whether the third arc CB is less or greater than a quadrant. For from this we shall learn when the sought arc AB is less than a quadrant and when greater, if it is not otherwise established. For if angle A is acute, provided B too is given as acute —

or if A is obtuse, provided B too is given as obtuse — [Margin: b — Prop. 37 of this treatise.] then arc AB, opposite the right angle, will be less than a quadrant. But if angle A is acute while B is given as obtuse — or if A is obtuse while B is given as acute — arc AB will be greater than a quadrant. So too, if arc CB is less than a quadrant, provided AC too is given as less than a quadrant — or if CB is greater than a quadrant, provided AC too is given as greater than a quadrant — [Margin: c — Prop. 35 of this treatise.] then arc AB, opposite the right angle, will be less than a quadrant. But if arc CB is less than a quadrant while AC is given as greater than a quadrant — or if CB is greater than a quadrant while AC is given as less than a quadrant — arc AB will be greater than a quadrant. Therefore it is not enough to have one arc about the right angle together with the opposite angle given, as Copernicus would have it in Proposition 4 on spherical triangles — a point of which we gave warning above in the scholium to Proposition 21 — but the species of the third angle or of the third arc must also be given. In this matter Johannes Regiomontanus [Regiomontanus] too went astray (Regiomontanus, *De triangulis* IV.27).

THEOR. 40. PROPOS. 42.

In every right-angled spherical triangle, none of whose arcs is a quadrant, the sine of either of the remaining angles has to the whole sine the same ratio that the sine of the complement of the other angle has to the sine of the complement of the arc that subtends it.

[Continuation of THEOR. 40 / PROPOS. 42, whose enunciation was given on the previous page. This page begins Clavius's demonstration.]

In the spherical triangle ABC let angle B be right, and let none of the arcs be a quadrant. I say that the sine of angle C is to the whole sine [sinum totum, the radius] as the sine of the complement of the remaining angle A is to the sine of the complement of arc BC, which subtends angle A. For since none of the arcs is assumed to be a quadrant, none of the remaining angles will be right [Margin: a — Schol. 25 of this treatise]; otherwise triangle ABC, having two right angles, would have two quadrant arcs, which is not assumed.

So let angle A first be acute, and let arc AB — which is adjacent both to it and to the right angle B — be less than a quadrant. On this assumption, angle C too will be acute [Margin: b — Prop. 33 of this treatise], and hence [Margin: c — Prop. 28 of this treatise] all the arcs of triangle ABC will be less than a quadrant. Let arcs AB and AC be produced, let AD and AE be made quadrants [Margin: d — Theodosius, *Sphaerica* I.20], and through the points D and E let the arc DE of a

great circle be drawn, meeting arc BC (produced) at F. Then both angles D and E will be right [Margin: e — Prop. 25 of this treatise], because AD and AE are quadrants; and further, since angle B is also right, both arcs BF and DF will be quadrants [Margin: f — Prop. 25 of this treatise], on account of the right angles B and D. DE will also be the arc measuring angle A [Margin: g — Prop. 26 of this treatise], because A is the pole of arc DE, since AD and AE are quadrants. Likewise arc EF will be the complement of arc DE, and arc CF the complement of arc BC, because DF and BF are quadrants.

Now since in triangle CEF angle E is right, [Margin: h — Corollary to Prop. 41 of this treatise] it follows that as the sine of arc CF is to the whole sine, so the sine of arc EF is to the sine of angle ECF; and, converting, as the sine of angle ECF — that is, of angle ACB, [Margin: i — Prop. 6 of this treatise] which is equal to it at the vertex — is to the sine of arc EF, so the whole sine is to the sine of arc CF; and, by permutation, as the sine of angle ACB is to the whole sine, so the sine of arc EF — that is, the sine of the complement of angle A — is to the sine of arc CF, that is, to the sine of the complement of arc CB. Which is what was proposed.

Diagram. The figure for the first case: a right spherical triangle ABC with the arcs AB, AC produced and the quadrant construction added.

- F (top): apex where arc DE (produced) meets arc BC produced
- E (upper middle, right): point on arc AC produced, endpoint of quadrant AE
- C (upper middle, left of E): vertex of the triangle
- A (left): vertex (acute angle), pole of arc DE
- B (bottom, center): vertex of the right angle
- D (bottom, right of B): point on arc AB produced, endpoint of quadrant AD

Second case.

Next let angle A be obtuse, arc AB still less than a quadrant. Let angle BAD be made right, and let it cut arc AD off from arc BC at D. Arc AB being likewise produced, let AE be made a quadrant, [Margin: k — Theodosius, *Sphaerica* I.20] and through the points E, D let the arc ED of a great circle be drawn, cutting arc AC at F. And since the two angles DAB, DBA are right, [Margin: l — Schol. 25 of this treatise] arcs AD, BD will be quadrants; and since AE too is a quadrant and angle DAE is right, [Margin: m — Prop. 26 of this treatise] DE will also be a quadrant, and A the pole of arc DE. Therefore arc AF will also be a quadrant, [Margin: n — Corollary 16 to Theodosius, *Sphaerica* I] since arc EF always lies a quadrant away from its pole. [Margin: o — Theodosius, *Sphaerica* I.15] Likewise each angle at F, since arc AF passes through A, the pole of arc EF, will be right.

Moreover EF will be the arc measuring angle BAC, on account of the quadrants AE, AF. Arc DF will also be the complement of arc EF, that is, of angle BAC; and arc CD the complement of arc BC, on account of the quadrants DE, BD.

Since, then, in triangle CDF angle F is right, [Margin: p — Corollary to Prop. 41 of this treatise] it will follow that as the sine of arc CD is to the whole sine, so the sine of arc DF is to the sine of angle C; and, converting, as the sine of angle C is to the sine of arc DF, so the whole sine is to the sine of arc CD; and, by permutation, as the sine of angle C is to the whole sine, so the sine of arc DF — that is, the sine of the complement of angle BAC — is to the sine of arc CD, that is, to the sine of the complement of arc BC. Which is what was proposed.

Diagram. The figure for the second case (angle A obtuse, arc AB less than a quadrant).

- C (top): vertex
- F (upper left, below C): point where arc ED cuts arc AC
- D (center): point where arc AD cuts arc BC
- A (left): vertex of the obtuse angle, pole of arc DE
- B (bottom, center): vertex of the right angle
- E (bottom, right): endpoint of quadrant AE on arc AB produced

Third case.

Now let angle A be acute, and arc AB greater than a quadrant. On this assumption, the remaining angle C will be obtuse; [Margin: q — Prop. 33 of this treatise] and therefore arc AC, which subtends the right angle B, will likewise be greater than a quadrant. [Margin: r — Prop. 37 of this treatise] Let the quadrants AD, AE be cut off, [Margin: s — Theodosius, *Sphaerica* I.20] and through the points D, E let the arc DE of a great circle be drawn, meeting arc BC (extended) at F; [Margin: t — Prop. 25 of this treatise] then each of the angles D, E will be right, on account of the quadrants AD, AE; and consequently, since angle B too is right, [Margin: u — Prop. 25 of this treatise] the arcs BF, DF will be quadrants; and therefore BD will be the arc measuring angle F. Likewise arc CF will be the complement of arc BC, and arcs DB, EC the complements of arcs AB, AC, on account of the quadrants BF, AD, AE. [Margin: x — Prop. 26 of this treatise] Now it is clear that in triangle CEF, as the sine of arc EC — that is, the sine of the complement of arc AC — is to the sine of angle F, that is, to the sine of arc DB, that is, to the sine of the complement of arc AB, so the sine of arc CF, namely the sine of the complement of arc BC, is to the sine of the right angle E, that is, to the whole sine.

(For the two angles at C have the same sine, since their arcs make up a semicircle, by the corollary to Prop. 5.) — and by permutation, as the sine of angle ACB is to the whole sine, so the sine of arc EF, or of the complement of angle A, is to the sine of arc CF, or of the complement of arc BC. Which is what was proposed.

Diagram. The figure for the third case (angle A acute, arc AB greater than a quadrant).

- F (top): apex where arc DE meets arc BC extended
- A (right): vertex of the acute angle
- E (center): endpoint of quadrant AE
- C (center, left of E): vertex
- D (bottom, center): endpoint of quadrant AD
- B (bottom left): vertex of the right angle

Fourth and last case.

Lastly let angle A be obtuse, and arc AB still greater than a quadrant. Let the right angle BAD be made, and let it cut arc AD off from arc BC at D. Let a quadrant AE also be cut off from AB, [Margin: z — Theodosius, *Sphaerica* I.20] and through the points E, D let the arc ED of a great circle be drawn, cutting arc AC (produced) at F. And since angle B is set right, and angle BAD is also right by construction, [Margin: a — Prop. 25 of this treatise] arcs AD, BD will be quadrants. Again, since arcs AD, AE are quadrants and contain the right angle DAE, [Margin: b — Prop. 26 of this treatise] arc DE will also be a quadrant, and A the pole of arc DE; and consequently, since arc AF passes through A, the pole of arc EF, [Margin: c — Theodosius, *Sphaerica* I.15] angle F will be right. EF will likewise be the arc measuring angle BAC. Moreover arc DF will be the complement of arc EF, that is, of angle BAC, and arc CD the complement of arc BC, on account of the quadrants DE, BD.

Since, then, in triangle CDF angle F is right, [Margin: d — Corollary to Prop. 41 of this treatise] it will follow that as the sine of arc CD is to the whole sine, so the sine of arc DF is to the sine of angle DCF; and, converting, as the sine of angle DCF — that is, of angle ACB (for the arcs of angles DCF, ACB have the same sine, [Margin: e — Corollary to Prop. 5 of this treatise] since they make up a semicircle) — is to the sine of arc DF, that is, to the sine of the complement of angle BAC, so the whole sine is to the sine of arc CD, that is, to the sine of the complement of arc BC; and, by permutation, as the sine of angle ACB is to the whole sine, so the sine of arc DF, or of the complement of angle BAC, is to the sine of arc CD, or of the

complement of arc BC. Which is what was proposed. Therefore, in every right-angled spherical triangle, and so on. Which was to be demonstrated.

Diagram. The figure for the fourth case (angle A obtuse, arc AB greater than a quadrant).

- F (top): apex where arc ED cuts arc AC produced
- C (upper left, below F): vertex
- D (center): point where arc AD cuts arc BC
- A (left): vertex of the obtuse angle, pole of arc DE
- E (bottom, center): endpoint of quadrant AE
- B (bottom right): vertex of the right angle

SCHOLIVM.

From this proposition we shall gather these two problems.

I.

In a right-angled spherical triangle, when two non-right angles are given, to find the arc opposite either of them, together with the arc that is opposite the right angle.

In the triangle ABC, whose angle C is right, let the two angles A, B be given. I say that either of the arcs AC, BC is thereby also given, together with arc AB. [Margin: a — Prop. 42 of this treatise] For it holds that as the sine of angle A is to the whole sine, so the sine of the complement of angle B is to the sine of the complement of arc AC. Likewise, as the sine of angle B is to the whole sine, so the sine of the complement of angle A is to the sine of the complement of arc BC.

Diagram. A right-angled spherical triangle drawn with slightly curved sides.

- A (top): vertex
- B (bottom left): vertex
- C (bottom right): vertex of the right angle

[Margin: — *Praxis* (the working)]

If it be arranged that, as the sine of the given angle which is adjacent to the sought side is to the whole sine, so the sine of the complement of the remaining given angle is to a fourth term, then the sine of the complement of the arc opposite this latter angle — which is sought — will be produced. And once both arcs about the right angle have been found, the arc opposite the right angle can

also be found, from either of them and from the angle that is set opposite the given arc, as we showed in Problem 3 of Prop. 41.

But whether arcs AC, BC are less or greater than a quadrant we shall learn thus. If angle B is acute, [Margin: b — Prop. 34 of this treatise] the arc AC opposite it will be less than a quadrant; if obtuse, greater than a quadrant. By the same reasoning, if angle A is acute, the arc BC opposite it will be less than a quadrant; if obtuse, greater than a quadrant.

II.

In a right-angled spherical triangle, when one or the other of the non-right angles is given, together with one or the other of the arcs about the right angle, to find the other non-right angle and the remaining two arcs.

In the same triangle let there first be given arc AC, together with angle A, adjacent to it. I say that angle B is thereby also given, together with arcs BC, AB. [Margin: c — Prop. 42 of this treatise] For since it holds that, as the sine of angle A is to the whole sine, so the sine of the complement of angle B is to the sine of the complement of arc AC, it will follow, by conversion, that as the whole sine is to the sine of the given angle A, so the sine of the complement of the given arc AC is to the sine of the complement of angle B, which is sought.

[Margin: — *Praxis*, when an arc is given together with an adjacent angle]

Therefore, whenever an arc is given together with an angle adjacent to it, if it be arranged that, as the whole sine is to the sine of the given angle, so the sine of the complement of the given arc is to a fourth term, the sine of the complement of the other angle, which is sought, will be found. From this, the two non-right angles now being known, the remaining two arcs will be found, as was demonstrated in the immediately preceding problem. The third [arc] is given by hypothesis.

But whether the sought angle B is acute or obtuse will be taught by the given arc AC. [Margin: d — Prop. 34 of this treatise] For if it is less than a quadrant, angle B will be acute; if greater than a quadrant, obtuse.

Next let there be given arc AC together with angle B, opposite it, and let it be established, concerning the remaining angle A, whether it is acute or obtuse; or, concerning the other arc BC about the right angle, of what sort it is. I say that in turn the remaining angle A is given, together with the remaining arcs BC, AB. For [Margin: e — Prop. 42 of this treatise] since it holds that, as the sine of angle A is to the whole sine, so the sine of the complement of angle B is to the sine of the complement of arc AC, it will follow, by conversion, that as the sine of the

complement of the given arc AC is to the sine of the complement of the given angle B, so the whole sine is to the sine of the sought angle A.

[Margin: — *Praxis*, when an arc is given together with the opposite angle]

Therefore, whenever an arc is given together with the angle opposite it, if it be arranged that, as the sine of the complement of the given arc is to the sine of the complement of the given angle, so the whole sine is to a fourth term, the sine of the remaining angle, which is sought, will be produced. From the two non-right angles now being known, then, the remaining two arcs will be found, as we showed in the preceding problem. The third is given by hypothesis.

But it must be settled whether the remaining angle A is acute or obtuse, so that one may know what kind of angle — acute or obtuse — is to be taken as corresponding to the sine found. Now if it were established of what sort arc BC is, the kind of angle A would at once be known as well. For if arc BC is less than a quadrant, [Margin: f — Prop. 34 of this treatise] angle A will be acute; if greater than a quadrant, obtuse. By the same reasoning, if it were known of what sort arc AB is — the one opposite the right angle — we should immediately know the kind of angle A. For if arc AB is less than a quadrant, and the given angle B is indeed acute, [Margin: g — Prop. 38 of this treatise] angle A too will be acute; but if the given angle B is obtuse, A too will be obtuse. On the other hand, if arc AB is greater than a quadrant, and the given angle B is acute, angle A will be obtuse; but if the given angle B is obtuse, angle A will be acute.

And so it is not enough to be given a non-right angle together with the arc opposite it — as Copernicus would have it in Prop. 4 On Spherical Triangles [Margin: — *An error of Copernicus*] — a point on which we have also given warning above, in the scholium to Prop. 21. There must in addition be given the kind of the third angle, or the kind of the other arc about the right angle, or at all events the kind of the arc opposite the right angle. On this point Nicolaus Copernicus [Copernicus] went astray, wishing, in Prop. 4 On Spherical Triangles, that it should be enough for an arc about the right angle to be given together with one or the other of the non-right angles. For this is false in the case of a given angle with the arc opposite it, unless something else besides is established, as we have said here and warned in the scholium to Prop. 21.

THEOR. 41. PROPOS. 43.

In every right-angled spherical triangle none of whose arcs is a quadrant, the sine of the complement of the arc subtending the right angle has the

same ratio to the sine of the complement of either of the remaining arcs as the sine of the complement of the remaining arc has to the whole sine.

In the right-angled spherical triangle ABC let angle B be right, and let none of the arcs be a quadrant. I say that the sine of the complement of arc AC is to the sine of the complement of, say, arc AB as the sine of the complement of the remaining arc BC is to the whole sine. For since none of the arcs is assumed to be a quadrant, none of the remaining angles will be right. [Margin: a — Schol. 25 of this treatise] Otherwise triangle ABC, having two right angles, would have two quadrant arcs, which is not assumed. So let the first angle [continue below]

[Continuation on the following page:]

be acute, and arc AB — which is adjacent both to it and to the right angle B — less than a quadrant. On this assumption, angle C too will be acute; [Margin: b — Prop. 33 of this treatise] and hence [Margin: c — Prop. 28 of this treatise] all the arcs of triangle ABC will be less than a quadrant. Let arcs AB, AC be produced and the quadrants AD, AE be made; [Margin: d — Theodosius, *Sphaerica* I.20] and through the points D, E let the arc DE of a great circle be drawn, meeting arc BC (produced) at F. [Margin: e — Prop. 25 of this treatise] Then both angles D, E will be right, on account of the quadrants AD, AE; and further, since angle B too is set right, both arcs BF, DF will be quadrants, on account of the right angles B, D. Moreover BD will be the arc measuring angle F, [Margin: f — Prop. 26 of this treatise] because F is the pole of arc BD, on account of the quadrants BF, DF. Likewise CF will be the complement of arc BC; and BD, CE the complements of arcs AB, AC, on account of the quadrants [BF, AD, AE]. [Margin: g — Prop. 41 of this treatise] Now it is clear that in triangle CEF, as the sine of arc CE — that is, the sine of the complement of arc AC — is to the sine of angle F, that is, to the sine of arc BD, or of the complement of arc AB, so the sine of arc CF, that is, the sine of the complement of arc BC, is to the sine of the right angle E, that is, to the whole sine. Which is what was proposed.

Diagram. The figure for the first case of THEOR. 41 (mirror image of the first case above).

- F (top): apex where arc DE meets arc BC produced
- E (left of center): endpoint of quadrant AE
- C (center): vertex
- A (right): vertex of the acute angle
- D (bottom left): endpoint of quadrant AD
- B (bottom, center): vertex of the right angle

Second case.

Next let angle A be obtuse, arc AB still less than a quadrant. Let angle BAD be made right, and let it cut arc AD off from arc BC at D. Arc AB being likewise produced, let AE be made a quadrant, [Margin: h — Theodosius, *Sphaerica* I.20] and through the points E, D let the arc ED of a great circle be drawn, cutting arc AC at F. And since the two angles DAB, DBA are right, [Margin: i — Schol. 25 of this treatise] arcs AD, BD will be quadrants; and further, since AE too is a quadrant and angle DAE is right, [Margin: k — Prop. 26 of this treatise] arc DE will also be a quadrant; and consequently BE, on account of the quadrants BD, ED, will be the arc measuring angle BDE — that is, angle CDF, [Margin: l — Prop. 6 of this treatise] which is equal to it at the vertex. [Margin: m — Prop. 26 of this treatise] Now since A is the pole of arc ED, arc AF too will be a quadrant, [Margin: n — Corollary 16 to Theodosius, *Sphaerica* I] since arc EF always lies a quadrant away from its pole; [Margin: o — Theodosius, *Sphaerica* I.15] and moreover both angle AFE and angle CFD will be right. Furthermore arc CF will be the complement of arc AC; arc BE the complement of arc AB; and arc CD the complement of arc BC, on account of the quadrants AF, AE, BD. [Margin: p — Prop. 41 of this treatise] Now it is evident that in triangle CDF, as the sine of arc CF — that is, the sine of the complement of arc AC — is to the sine of angle CDF, that is, to the sine of arc BE, or of the complement of arc AB, so the sine of arc CD, namely the sine of the complement of arc BC, is to the sine of the right angle F, that is, to the whole sine. Which is what was proposed.

Diagram. The figure for the second case of THEOR. 41.

- C (top): vertex
- D (center left): point where arc AD cuts arc BC
- F (right of D): point where arc ED cuts arc AC
- E (bottom left): endpoint of quadrant AE
- B (bottom, center): vertex of the right angle
- A (right): vertex of the obtuse angle, pole of arc ED

Third case.

Now let angle A be acute, and arc AB greater than a quadrant. On this assumption, the remaining angle C will be obtuse; [Margin: q — Prop. 33 of this treatise] and therefore arc AC, which subtends the right angle B, will likewise be greater than a quadrant. [Margin: r — Prop. 37 of this treatise] Let the quadrants AD, AE be cut off, [Margin: s — Theodosius, *Sphaerica* I.20] and through the points D, E let the arc DE of a great circle be drawn, meeting arc BC (produced) at F;

[Margin: t — Prop. 25 of this treatise] then each of the angles D, E will be right, on account of the quadrants AD, AE; and consequently, since angle B too is right, [Margin: u — Prop. 25 of this treatise] arcs BF, DF will be quadrants; and therefore BD will be the arc measuring angle F. Likewise arc CF will be the complement of arc BC, and arcs DB, EC the complements of arcs AB, AC, on account of the quadrants BF, AD, AE. [Margin: x — Prop. 41 of this treatise] Now it is evident that in triangle CEF, as the sine of arc EC — that is, the sine of the complement of arc AC — is to the sine of angle F, that is, to the sine of arc DB, that is, to the sine of the complement of arc AB, so the sine of arc CF, namely the sine of the complement of arc BC, is to the sine of the right angle E, that is, to the whole sine. Which is what was proposed.

Diagram. The figure for the third case of THEOR. 41.

- F (top): apex where arc DE meets arc BC produced
- C (left): vertex
- E (center): endpoint of quadrant AE
- A (right): vertex of the acute angle
- B (bottom left): vertex of the right angle
- D (bottom, center): endpoint of quadrant AD

Fourth and last case.

Lastly let angle A be obtuse, and arc AB still greater than a quadrant. Let the right angle BAD be made, and let it cut arc AD off from arc BC at D. Let a quadrant AE also be cut off from AB, [Margin: y — Theodosius, *Sphaerica* I.20] and through the points E, D let the arc ED of a great circle be described, cutting arc AC (produced) at F. And since angle B is set right, and angle BAD has been made right, [Margin: z — Prop. 25 of this treatise] arcs AD, BD will be quadrants. Again, since arcs AD, AE are quadrants and contain the right angle DAE, [Margin: a — Prop. 26 of this treatise] arc DE too will be a quadrant, and A the pole of arc ED; [Margin: b — Theodosius, *Sphaerica* I.15] and consequently angle F will be right. Moreover, since DB, DE have been shown to be quadrants, E, B will be the arc measuring angle BDE, that is, angle CDF, which is equal to it at the vertex. [Margin: c — Prop. 6 of this treatise] Likewise, since A is the pole of arc EF, arc AF will be a quadrant, [Margin: d — Corollary 16 to Theodosius, *Sphaerica* I] because arc EF always lies a quadrant away from its pole. Arc CF will likewise be the complement of arc AC; arc EB the complement of arc AB; and arc CD the complement of arc BC, on account of the quadrants AF, AE, BD. [Margin: e — Prop. 41 of this treatise] Now it is evident that in triangle CDF, as the sine of arc CF — that is, the sine of the

complement of arc AC — is to the sine of angle CDF, that is, to the sine of arc BE, or of the complement of arc AB, so the sine of arc CD, namely the sine of the complement of arc BC, is to the sine of the right angle F, that is, to the whole sine. Which is what was proposed. Therefore in every right-angled spherical triangle, and so on. Which was to be demonstrated.

Diagram. The figure for the fourth case of THEOR. 41.

- F (top): apex where arc ED cuts arc AC produced
- C (upper right, below F): vertex
- D (center): point where arc AD cuts arc BC
- B (bottom left): vertex of the right angle
- E (bottom, center): endpoint of quadrant AE
- A (right): vertex of the obtuse angle

SCHOLIVM. I.

The following problem we shall gather from this proposition in this way.

In a right-angled spherical triangle, when any two arcs are given, to find the third arc and the remaining two non-right angles.

Clavius, *Opera Mathematica*, Tomus I — Doctrine of Spherical Triangles

Note on marginalia: throughout this treatise the abbreviation *huius* ("of this [treatise]") refers to a numbered proposition of Clavius's own doctrine of triangles; *The.* = Theodosius, *Sphaerica*; *Sinuum* = the treatise on Sines. The lettered superscripts ([a], [b], ...) are Clavius's own reference marks keyed to the printed side-notes.

[Continuation of SCHOLIVM I to THEOR. 41 / PROPOS. 43]

(Page 841 opens within the scholium begun on the previous page; a problem on the right-angled spherical triangle is being worked through its cases.)

In triangle ABC, whose angle C is right, let there first be given the two arcs AC and CB about the right angle C. I say that the third arc AB is thereby also given, together with the two angles A and B. [a] For since the sine of the complement of arc AB is to the sine of the complement of arc AC as the sine of the complement of arc CB is to the total sine, it will be, by conversion [*convertendo*], that the total

sine is to the sine of the complement of arc CB as the sine of the complement of arc AC is to the sine of the complement of arc AB.

[Margin (a): 43. *huius* — prop. 43 of this treatise.]

Diagram. A small spherical triangle with A at the apex, B at the lower left, C at the lower right; all three sides drawn as arcs. Uncaptioned.

- A (apex): vertex
- B (lower left): vertex
- C (lower right): vertex (the right angle in the worked triangle)

Therefore, given the two arcs enclosing the right angle: if one makes the total sine to the sine of the complement of either of the given arcs as the sine of the complement of the other given arc is to a fourth term, that fourth term will be the sine of the complement of the arc opposite the right angle, which is sought. And from the arc opposite the right angle, together with either of the arcs about the right angle, the angle opposite it will be found, as we set forth in problem 1 of proposition 41.

[Margin: *Praxis* — when the two arcs about the right angle are given.]

But whether the sought arc AB is less or greater than a quadrant, the two given arcs will show. For if both are less, or both greater, than a quadrant, [b] arc AB will be less than a quadrant; but if one is less than a quadrant and the other greater, arc AB will be greater than a quadrant.

[Margin (b): 35. *huius* — prop. 35 of this treatise.]

Next, let arc AB, opposite the right angle, be given together with one of the arcs about the right angle, say with AC. I say that the remaining arc CB is again given, together with the two angles A and B. [c] For since the sine of the complement of arc AB is to the sine of the complement of arc AC as the sine of the complement of arc CB is to the total sine, it will be, by conversion, that the sine of the complement of arc AC is to the sine of the complement of arc AB as the total sine is to the sine of the complement of arc CB.

[Margin (c): 43. *huius* — prop. 43 of this treatise.]

Accordingly, given the arc opposite the right angle together with one of the arcs about the right angle: if one makes the sine of the complement of the given arc about the right angle to the sine of the complement of the arc opposite the right angle as the total sine is to a fourth term, the sine of the complement of the other

arc about the right angle — which is sought — will be found. And from any given arc about the right angle, together with the arc opposite the right angle, the angle opposite that arc will be found, as was demonstrated in problem 1 of proposition 41.

[Margin: *Praxis* — when the arc opposite the right angle is given, together with one of the arcs about the right angle.]

But whether the sought third arc CB is less or greater than a quadrant, we shall understand from the two given arcs. For if arc AB, opposite the right angle, is less than a quadrant: then, if the other given arc AC is also less than a quadrant, [d] arc CB too will be less than a quadrant; but if AC is greater than a quadrant, CB too will be greater than a quadrant. If, however, AB is greater than a quadrant: then, if AC is also greater than a quadrant, CB will be less than a quadrant; but if AC is less than a quadrant, CB will be greater than a quadrant.

[Margin (d): 36. *huius* — prop. 36 of this treatise.]

SCHOLIVM II.

[Margin: Whatever is proved concerning a right-angled spherical triangle all of whose arcs are less than a quadrant holds also in every right-angled spherical triangle.]

Although we have made both this proposition 43 and the preceding one, 42, four-membered [*quadrimembrem*], so that each might be demonstrated in all cases, it would nevertheless have been enough had each been confirmed by a demonstration in the first case only — namely with all the arcs being less than a quadrant. For once that case is demonstrated, we shall easily accommodate the demonstration to all the other cases. Let ACD be any right-angled spherical triangle whatever, having the right angle C. Then either the two arcs AC and CD about the right angle are less than a quadrant — [e] and consequently the third arc AD is also less than a quadrant — or one is greater than a quadrant and the other less; or, finally, both are greater than a quadrant. For we are dealing only with that right-angled spherical triangle in which no arc is a quadrant. First let the two arcs AC and CD about the right angle be less than a quadrant. This being posited, [f] each of the angles D and A will be acute, and therefore the demonstration of both propositions will suit triangle ACD, as regards the first case.

[Margin (e): 35. *huius*. — Margin (f): 34. *huius*.]

Diagram. A lens- (vesica-) shaped figure: A at the top, B at the left, C at the bottom, D at the right. Two great-circle arcs run from B to D — the upper passing through A, the lower through C — while a further arc joins A to C down the middle. The figure illustrates the two semicircles DAB and DCB, and the arc AC shared by triangles ACB and ACD. Uncaptioned.

- A (top): vertex; upper arc B–A–D
- B (left): left meeting-point of the two arcs
- C (bottom): vertex; lower arc B–C–D (right angle vertex)
- D (right): right meeting-point of the two arcs
- (A–C): the arc common to both triangles

Next let arc DC be greater than a quadrant, and CA less. When the arcs DC and DA are produced until they meet at B, [g] DAB and DCB will be semicircles, and hence CB will be less than a quadrant. There are therefore in triangle ABC two arcs, AC and CB, about the right angle C, that are less than a quadrant. Hence, as we have just shown, the demonstration of both propositions will suit it, as regards the first case. Since, then, the sines — both the proper sines and those of the complements — of the arcs and angles of triangle ACB are the same as those of the arcs and angles of triangle ACD (for, as we said in the discussion of sines, arcs CD and CB have the same sine, both proper and of the complement, and so too do arcs AD and AB; likewise the right angles at C have the same sine — namely the total sine — as do the oblique angles at A, [h] since these are equal to two right angles; and finally the angles D and B have the same sine, [i] since they are equal to one another; while arc AC is common to both triangles) — it plainly follows that whatever is shown concerning the sines of the arcs and angles of triangle ACB holds also in the sines of the arcs and angles of triangle ACD.

[Margin (g): *11.1.The.* — Theodosius, *Sphaerica* I.11. — Margin (h): *5. huius.* — Margin (i): *13. huius.*]

Finally, let the two arcs DC and CA be greater than a quadrant. This being posited, arc CB will be less than a quadrant. Triangle ACB therefore has arc AC about the right angle C greater than a quadrant, and CB less. Hence, as was just demonstrated, both propositions will suit it. Since, then, the sines — both proper and of the complements — of the arcs and angles of triangle ACB are the same as those of the arcs and angles of triangle ACD, as we said a little before, it is clear that the same propositions suit triangle ACD as well. It is therefore evident that whatever is demonstrated concerning the sines of the arcs and angles of a right-

angled spherical triangle whose two arcs about the right angle are less than a quadrant holds also in any other right-angled spherical triangle whatever.

The very same is to be said of the third case of proposition 41. For it would have been enough to have demonstrated it in the right-angled triangle all of whose arcs are less than a quadrant — such as the triangle spoken of in the second figure of proposition 41 — since the demonstration of that triangle suits all the others, as is manifest from what has been demonstrated in this scholium.

From what we have demonstrated in the last three propositions, the calculation of right-angled spherical triangles by sines is now complete; and so the calculation of non-right-angled triangles ought now to follow. But since, for the most part, the calculation of right-angled triangles is dispatched more briefly through tangent and secant lines than through sines, we shall append the following propositions, which also concern right-angled spherical triangles, before we set out the calculation of non-right-angled spherical triangles. And so that the demonstrations may be clearer and less confused, we shall always propose a right-angled spherical triangle whose two arcs about the right angle — and hence all three — are less than a quadrant. For the same demonstrations will suit

all the others, as we have demonstrated in this scholium; for both two arcs completing a semicircle, and two angles equal to two right angles, have the same tangent and secant — just as they have the same sine — as we noted in the treatment of tangents and secants.

THEOR. 42. PROP. 44.

In every right-angled spherical triangle all of whose arcs are less than a quadrant: the total sine has to the sine of either of the arcs about the right angle the same ratio that the tangent of the non-right angle adjacent to the said arc has to the tangent of the remaining arc about the right angle, which is opposite this angle.

In the spherical triangle ABC, all of whose arcs are less than a quadrant, let angle C be right. I say that the total sine is to the sine of arc BC as the tangent of angle B is to the tangent of arc AC. For when the arcs BC and BA are produced until the quadrants BF and BD are formed, and through the points F and D an arc FD of a great circle is described, [a] each of the angles F and D will be right, because of the quadrants BF and BD; and DF will be the arc [measuring] angle B, [b] since B is the pole of arc DF. Since, therefore, the two great circles BF and BD on the sphere cut one another at B, and from A and D perpendicular arcs AC and DF

have been drawn to BF, [c] it will be that as the sine of the quadrant BF — that is, the total sine — is to the tangent of arc FD — that is, to the tangent of angle B — so the sine of arc BC is to the tangent of arc AC. And, by alternation [*permutando*], as the total sine is to the sine of arc BC, so the tangent of angle B is to the tangent of arc AC. In no other way shall we demonstrate that the total sine is to the sine of arc AC as the tangent of angle A is to the tangent of arc BC — as is clear if arcs AC and AB are produced until the quadrants AG and AE are formed, and through G and E an arc GE of a great circle is described. [d] For again it will be that as the sine of the quadrant AG — that is, the total sine — is to the tangent of arc EG, or of angle A, so the sine of arc AC is to the tangent of arc BC; and, by alternation, as the total sine is to the sine of arc AC, so the tangent of angle A is to the tangent of arc BC. Therefore, in every right-angled spherical triangle, etc. Which was to be demonstrated.

[Margin (a): 25. *huius*. — Margin (b): 26. *huius*. — Margin (c): Theorem 6, scholium to prop. 40 of this treatise. — Margin (d): Theorem 6, scholium to prop. 40 of this treatise.]

Diagram. The construction for Theorem 42. A right-angled spherical triangle ABC (right angle at C) with its sides produced to quadrants. Across the top, from left to right: E, B, A, D; C stands at the centre; G and F at the bottom (G lower left, F lower right). The great-circle arcs FD (through the produced quadrants BF, BD) and GE (through AG, AE) are drawn, and the arcs cross to form the figure.

- E (top left): end of the quadrant AE (arc AB produced)
- B (top, left of centre): vertex of the triangle
- A (top centre-right): vertex of the triangle
- D (top right): end of the quadrant BD (arc BA produced)
- C (centre): right-angle vertex of the triangle
- G (bottom left): end of the quadrant AG (arc AC produced)
- F (bottom right): end of the quadrant BF (arc BC produced)

SCHOLIVM.

From this we shall gather the following two problems.

I.

In a right-angled spherical triangle, given either of the arcs about the right angle together with either of the non-right angles, to find the other arc about the right angle and the remaining non-right angle, together with the arc that is opposite the right angle: provided that, when the

given angle is opposite the given arc, it be established whether the remaining arc about the right angle is less or greater than a quadrant, or whether the remaining non-right angle is acute or obtuse.

Diagram. A right-angled spherical triangle: A at the apex, C at the lower left, B at the lower right; the sides drawn as arcs. Illustrates Problem I, the case of an arc given with its adjacent angle. Uncaptioned.

- A (apex): vertex (given angle A)
- C (lower left): right-angle vertex
- B (lower right): vertex

In triangle ABC, whose angle C is right, let there first be given arc AC together with the angle A adjacent to it. I say that arc BC is thereby also given, together with the angle B and arc AB. [e] For since the total sine is to the sine of arc AC as the tangent of angle A is to the tangent of arc BC:

[Margin: *Praxis* — when an arc is given together with the adjacent angle. Margin (e): 44. *huius*.]

If (when an arc is given with its adjacent angle) one makes the total sine to the sine of the given arc as the tangent of the given angle is to a fourth term, the tangent of the sought arc will be produced. And from the same given arc and given angle, the other non-right angle, and the arc opposite the right angle, will be found, as we demonstrated in problem 2 of proposition 42.

But whether the sought arc BC is less or greater than a quadrant, the given angle A will indicate. For if it is acute, [f] arc BC will be less than a quadrant; but if obtuse, greater than a quadrant.

[Margin (f): 34. *huius*.]

Next let arc AC be given together with the angle B opposite to it, and let it be established besides, concerning the other arc BC, whether it is less or greater than a quadrant, or whether the other angle A is acute or obtuse. I say that again arc BC is given, together with the angle A [?] and arc AB. [g] For since the tangent of angle B is to the tangent of arc AC as the total sine is to the sine of arc BC:

[Margin (g): 44. *huius*.]

If (when an arc is given with its opposite angle) one makes the tangent of the given angle to the tangent of the given arc as the total sine is to a

fourth term, the sine of the sought arc will be found. And from the given arc and given angle, the other non-right angle, and the arc opposite the right angle, will also be given, as we stated in problem 2 of proposition 42.

[Margin: *Praxis* — when an arc is given together with its opposite angle.]

But it must be established whether arc BC is less or greater than a quadrant, so that we may know what kind of arc, corresponding to the sine found, is to be taken — namely, whether less than a quadrant or greater. For if it were established what kind of angle A is, we should immediately know what kind arc BC is. For when angle A is acute, [h] arc BC will be less than a quadrant; but when it is obtuse, greater than a quadrant. So too, if it were known what kind arc AB — opposite the right angle — is, we should also know the species of arc BC.

Diagram. A right-angled spherical triangle: A at the apex, C at the lower left, B at the lower right; sides drawn as arcs. Illustrates Problem I, the case of an arc given with its opposite angle. (The same triangle is reprinted at the head of page 843.) Uncaptioned.

- A (apex): vertex
- C (lower left): right-angle vertex
- B (lower right): vertex

(Page 843. The right triangle ABC of the opposite-angle case — see fig-p842-3 above — is reprinted at the head of the page; described once, not re-transcribed.)

Diagram. The same right-angled spherical triangle ABC as fig-p842-3 (A apex, C lower left, B lower right), reprinted at the top of the page to accompany the continuation of the text.

For if AB is less than a quadrant, [i] then each of AC, BC is either less than a quadrant or greater: so, of whatever kind the given arc AC is, arc BC will also be of that kind. But if AB is greater than a quadrant, and the given arc AC is indeed less than a quadrant, then BC will be greater than a quadrant; whereas if the given arc AC is greater than a quadrant, BC will be less than a quadrant. And so it is not enough to be given an arc together with its opposite angle — as Copernicus would have it (proposition 4 on spherical triangles) — [l] as we noted above in the scholium to proposition 21.

[Margin (i): 36. *huius*.]

II.

In a right-angled spherical triangle, given the two arcs about the right angle, to determine either of the non-right angles, together with the remaining arc, which is opposite the right angle.

In the same triangle let the two arcs AC and BC be given. I say that either of the angles A and B is thereby also given, and arc AB. [k] For since the total sine is to the sine of arc AC as the tangent of angle A is to the tangent of arc BC; and, conversely, as the sine of arc AC is to the total sine, so the tangent of arc BC is to the tangent of angle A; and, by the same reasoning, as the sine of arc BC is to the total sine, so the tangent of arc AC is to the tangent of angle B:

[Margin (k): 44. *huius*.]

If one makes the sine of either of the arcs about the right angle to the total sine as the tangent of the other arc is to a fourth term, the tangent of the angle opposite this latter arc will be found. And from the two given arcs about the right angle, the third arc, opposite the right angle, will also be known, as was set forth in the problem of proposition 43. Or, at any rate, from one given arc and either of the angles once found, as was shown in problem 2 of proposition 42.

[Margin: *Praxis*.]

But whether the sought angle is acute or obtuse, the arc opposite it will show. For if this is less than a quadrant, [l] the angle opposite it will be acute; but if greater, obtuse.

[Margin (l): 34. *huius*.]

But since, in the scholium to the preceding proposition, we said that some things are dispatched more briefly through tangent and secant lines than through sines, this is to be understood of those things sought in the first place in the problems, and not of those investigated in the second place. To make this plainer, we shall set out how each problem here proposed is to be solved by sines. Thus, in order that from a given arc about the right angle, together with either of the acute angles, the other arc about the right angle may be found — which is proposed for investigation in the first place in the first problem — one must proceed as follows. If an arc about the right angle is given with its opposite angle, one must first seek the arc opposite the right angle, from problem 3 of proposition 41. Then, from this arc once found and the given arc, the other arc about the right angle — which is sought — must be elicited, through the problem of proposition 43. But if

the arc about the right angle is given with its adjacent angle, one must first seek, through problem 2 of proposition 42, the other acute angle. Then, through problem 1 of the same proposition 42, from this angle once found and the given angle, the arc opposite the given angle must be elicited. And in order that from two given arcs about the right angle either of the acute angles may be drawn out — which is sought in the first place in the second problem — one must first find the arc opposite the right angle, through the problem of proposition 43, from the two given arcs. Then, through problem 1 of proposition 41, from this arc once found and either of the given arcs about the right angle, the angle opposite this given arc must be found. You see, therefore, that what is sought in the first place in each problem is investigated by sines with a double operation, whereas by tangents we find it with a single one. The same reasoning holds in the following problems, so that it is enough to have noted this once here.

THEOR. 43. PROPOS. 45.

In every right-angled spherical triangle all of whose arcs are less than a quadrant: the total sine has to the sine of the complement of either of the acute angles the same ratio that the tangent of the arc opposite the right angle has to the tangent of the arc adjacent to the said acute angle.

In the spherical triangle ABC, all of whose arcs are less than a quadrant, let angle B be right. I say that the total sine is to the sine of the complement of angle A as the tangent of arc AC is to the tangent of arc AB. For when the arcs AB and AC, which contain the said angle, are produced until the quadrants AD and AE are formed, and through D and E an arc DE of a great circle is described and produced until it meets arc BC (likewise produced) at F: [a] each of the angles D and E will be right, because of the quadrants AD and AE; and DE will be the arc [measuring] angle A, [b] since A is the pole of arc DE. Likewise arc DF [?]; and hence arc EF is the complement of angle A. Since, therefore, the two great circles BF and DF on the sphere intersect one another at F, and from the points B and C perpendicular arcs BD and CE have been drawn to arc DF, [c] it will be that as the sine of the whole quadrant DF is to the tangent of arc BD, so the sine of arc EF — that is, the sine of the complement of angle A — is to the tangent of arc CE. And, by alternation, as the total sine is to the sine of the complement of angle A, so the tangent of arc BD is to the tangent of arc CE. [d] But (since AC and AB are the complements of the arcs CE and BD) as the tangent of arc BD is to the tangent of arc CE, so the tangent of arc AC is to the tangent of arc AB. Therefore it will also be that as the total sine is to the sine of the complement of angle A, so the tangent of arc AC — opposite the right angle — is to the tangent of arc AB, adjacent to the

acute angle A. In the same way we shall show that the total sine is to the sine of the complement of angle C as the tangent of arc AC — opposite the right angle — is to the tangent of arc BC, adjacent to the acute angle C: provided, of course, that the arcs CA and CB containing the angle C are produced, etc. Therefore, in every right-angled spherical triangle, etc. Which was to be shown.

[Margin (a): 25. *huius*. — Margin (b): 26. *huius*. — Margin (c): Theorem 6, scholium to prop. 40 of this treatise. — Margin (d): prop. 21 of the [treatise on] Sines.]

Diagram. The construction for Theorem 43. A right-angled spherical triangle ABC (right angle at B): A at the left, B at the bottom (lower left), C at the centre-left; the sides AB, AC produced to the quadrants AD and AE, with D at the lower right and E at the centre-right; the great-circle arc DE produced upward to meet arc BC (produced) at F, which stands at the top. Perpendicular arcs BD and CE are drawn to DF.

- F (top): meeting-point of arc DF (i.e. DE produced) with arc BC produced
- A (left): vertex; pole of the great circle DEF
- C (centre-left): vertex
- E (centre-right): end of quadrant AE (arc AC produced)
- B (bottom, lower left): right-angle vertex
- D (lower right): end of quadrant AD (arc AB produced)

SCHOLIVM.

From this theorem we shall solve the following three problems.

(The scholium to Theorem 43 / Proposition 45, begun on the preceding page, continues here with its enumerated sub-problems.)

I.

In a right-angled spherical triangle, given either of the arcs about the right angle together with the non-right angle adjacent to it, to find the arc opposite the right angle, and the remaining arc about the right angle together with the remaining non-right angle.

[Margin: a — Prop. 45 of this treatise ("45. *huius*"; *huius* = of this trigonometrical treatise).]

Let ABC be a triangle whose angle C is right, and let the arc AC and the angle A be given. I say that the arc AB is also given, together with the arc BC and the angle B. For since the whole sine [sinus totus] is to the sine of the complement of angle A

as the tangent of arc AB is to the tangent of arc AC, then, conversely, the sine of the complement of angle A is to the whole sine as the tangent of arc AC is to the tangent of arc AB.

[Margin: Praxis (Procedure).]

If it is arranged that, as the sine of the complement of the given angle is to the whole sine, so the tangent of the given arc is to another line, the tangent of the arc opposite the right angle — the one sought — will be found. From the arc AB and the angle A, the arc BC will be found by Problem 2 of Proposition 41; and from the arcs AB and AC, the angle B, opposite arc AC, by Problem 1 of the same Proposition 41.

[Margin: b — Prop. 34 of this treatise. c — Prop. 35 of this treatise. d — Prop. 34 of this treatise. e — Prop. 35 of this treatise.]

We shall know whether the sought arc AB is greater or less than a quadrant as follows. If the given angle A is acute, the arc BC will be less than a quadrant. Therefore if the given arc AC is also less than a quadrant, the arc AB too will be less than a quadrant; but if AC is greater than a quadrant, AB too will be greater. If, however, the given angle A is obtuse, the arc BC will be greater than a quadrant; so if the given arc AC is likewise greater, the arc AB will be less than a quadrant, while if AC is less than a quadrant, AB will be greater.

Diagram. A curvilinear (spherical) triangle drawn as a rounded three-sided figure. Labelled vertices:

- A (apex, top): the vertex at angle A.
- C (lower left): the right angle.
- B (lower right): the vertex at angle B.

II.

In a right-angled spherical triangle, given either of the arcs about the right angle together with the arc that is opposite the right angle, to investigate the angle contained by the said arcs — that is, the angle adjacent to the arc about the right angle that was given — together with the remaining arc and angle.

[Margin: f — Prop. 45 of this treatise.]

In the same triangle let the arcs AC and AB be given. I say that the angle A is also given, together with the arc BC and the angle B. For since the whole sine is to the

sine of the complement of angle A as the tangent of arc AB is to the tangent of arc AC — that is, as the tangent of arc AB is to the tangent of arc AC, so the whole sine is to the sine of the complement of angle A —

[Margin: Praxis (Procedure).]

If it is arranged that, as the tangent of the arc opposite the right angle is to the tangent of the given arc about the right angle, so the whole sine is to another line, the sine of the complement of the sought angle will be produced. Hence the rest will be found, as in the preceding problem.

[Margin: g — Prop. 36 of this treatise. h — Prop. 34 of this treatise. i — Prop. 36 of this treatise. k — Prop. 34 of this treatise.]

Whether the sought angle A is acute or obtuse we shall learn thus. If the arc AB opposite the right angle is less than a quadrant, then both arcs AC and BC will be either less than a quadrant or greater. So if the given arc AC is less, BC too will be less, and hence angle A is acute; but if AC is greater than a quadrant, BC too will be greater, and therefore angle A is obtuse. But if the arc AB is greater than a quadrant, then one of the remaining arcs will be greater and the other less. So if the given arc AC is greater, BC will be less, and on that account angle A is acute; but if AC is less than a quadrant, BC will be greater, and angle A obtuse.

III.

In a right-angled spherical triangle, given the arc that is opposite the right angle together with either of the non-right angles, to find the arc adjacent to this angle, together with the remaining arc and angle.

[Margin: l — Prop. 45 of this treatise.]

In the same triangle let the arc AB be given, together with the angle A. I say that the arc AC is also given, and so on. For since the whole sine is to the sine of the complement of angle A as the tangent of arc AB is to the tangent of arc AC —

[Margin: Praxis (Procedure).]

If it is arranged that, as the whole sine is to the sine of the complement of the given angle, so the tangent of the arc opposite the right angle is to another line, the tangent of the sought arc will be produced. The rest will be found as in the first problem of this proposition.

[Margin: m — Prop. 38 of this treatise. n — Prop. 34 of this treatise. o — Prop. 38 of this treatise. p — Prop. 34 of this treatise.]

Whether the sought arc AC is less or greater than a quadrant we shall learn thus. If the arc AB opposite the right angle is less than a quadrant, then both angles A and B will be either acute or obtuse. So if the given angle A is acute, B too will be acute, and hence the arc AC less than a quadrant; but if A is obtuse, B too will be obtuse, and therefore the arc AC greater than a quadrant. But if the arc AB is greater than a quadrant, then one of the remaining angles will be acute and the other obtuse. So if A is given acute, B will be obtuse, and therefore the arc AC greater than a quadrant; but if A is obtuse, B will be acute, and the arc AC less than a quadrant.

THEOR. 44. PROPOS. 46.

In every right-angled spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the sine of the complement of either of the acute angles the same ratio that the tangent of the complement of the arc about the right angle adjacent to the said angle has to the tangent of the complement of the arc opposite the right angle.

Let ABC be a triangle all of whose arcs are less than a quadrant, with angle B right. I say that the whole sine is to the sine of the complement of angle A as the tangent of the complement of arc AB is to the tangent of the complement of arc AC. For, the construction being made as in the preceding proposition: since the two great circles [circuli maximi] BF and DF in the sphere cut one another at F, and from the points B and C of arc BF the perpendicular arcs BD and CE have been produced to arc DF,

[Margin: q — Theorem 6 of scholium 40 of this treatise.]

it will be, as the whole sine of the quadrant DF is to the tangent of arc BD, so the sine of arc EF is to the tangent of arc CE. And by alternation, as the whole sine is to the sine of arc EF — that is, to the sine of the complement of angle A — so the tangent of arc BD, that is, the tangent of the complemen-

-t of arc AB, is to the tangent of arc CE, that is, to the tangent of the complement of arc AC. In no other way shall we demonstrate that the whole sine is to the sine of the complement of angle C as the tangent of the complement of arc BC is to the tangent of the complement of arc AC — namely, if the arcs CB and CA that contain angle C are produced, and so on. Therefore in every right-angled spherical triangle, and so on. Which was to be demonstrated.

SCHOLIVM.

From this we shall infer the following problem, which — although it was also demonstrated in the first problem of the preceding proposition — is nevertheless more easily solved here, since in the rule of three [aurea regula] the whole sine obtains the first place.

In a right-angled spherical triangle, given either of the arcs about the right angle together with the non-right angle adjacent to it, to find the arc opposite the right angle, together with the remaining arc about the right angle and the remaining non-right angle.

[Margin: b — Prop. 46 of this treatise.]

Let ABC be a triangle whose angle C is right, and let the arc AC be given together with the angle A adjacent to it. I say that the arc AB is also given, together with the arc BC and the angle B. For, since the whole sine is to the sine of the complement of angle A as the tangent of the complement of arc AC is to the tangent of the complement of arc AB —

[Margin: Praxis (Procedure).]

If it is arranged that, as the whole sine is to the sine of the complement of the given angle, so the tangent of the complement of the given arc is to another line, the tangent of the complement of the arc opposite the right angle — the one sought — will be produced. The rest will be found as was said in Problem 1 of the preceding proposition.

Moreover, we shall recognize whether the sought arc AB is less or greater than a quadrant, as we showed in the said Problem 1 of the previous proposition.

Diagram. A curvilinear (spherical) triangle. Labelled vertices:

- A (apex, top): the vertex at angle A.
- C (lower left): the right angle.
- B (lower right): the vertex at angle B.

[Margin: Praxis (Procedure).]

THEOR. 45. PROPOS. 47.

In every right-angled spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the sine of the complement of the arc opposite the right angle the same ratio that the tangent of either of the

non-right angles has to the tangent of the complement of the remaining angle.

Let ABC be a triangle all of whose arcs are less than a quadrant, with angle B right. I say that the whole sine is to the sine of the complement of arc AC as the tangent of angle C is to the tangent of the complement of angle A. Having made the construction as in Proposition 45, and having produced the arc CE to G so that CG is a quadrant, let there be described, from pole C at the distance of the quadrant CG, the arc of a great circle GH, cutting the arcs CF and EF (produced) at I and H.

[Margin: a — Corollary 16 of Book 1 of Theodosius. b — Prop. 25 of this treatise. c — Prop. 15 of Book 1 of Theodosius.]

Then CI too will be a quadrant, since the circle GH is distant a quadrant from the pole C. Likewise the arcs GH and EH will be quadrants, on account of the right angles G and E. For angle E is right, as was shown in Proposition 45; and G is right because the circle CG is perpendicular to the circle GH. Again, IG is the arc of angle C; CE is the complement of arc AC, the arc opposite the right angle; and FE is the complement of arc DE, that is, of angle A. Therefore, since the two great circles CG and CI intersect one another in the sphere at C, and from the points F and I of arc CI the perpendicular arcs FE and IG have been drawn to arc CG,

[Margin: d — Theorem 6 of scholium 40 of this treatise.]

it will be, as the whole sine of the quadrant CG is to the tangent of arc IG — that is, of angle C — so the sine of arc CE — that is, of the complement of arc AC — is to the tangent of arc FE, that is, of the complement of angle A. And by alternation it will be, as the whole sine is to the sine of the complement of arc AC (opposite the right angle), so the tangent of angle C is to the tangent of the complement of angle A. In like manner, with the figure constructed differently, we shall demonstrate that the whole sine is to the sine of the complement of arc AC as the tangent of angle A is to the tangent of the complement of angle C. Therefore in every right-angled spherical triangle, and so on. Which was to be shown.

Diagram. A spherical construction with two intersecting great-circle arcs and their perpendiculars, forming the quadrant figure of the theorem. Labelled points:

- I (upper left): intersection of the produced arc with circle GH.
- H (upper right): intersection point on circle GH.
- F (center, upper): point on the produced arcs.

- G (left): endpoint of the quadrant CG on circle GH.
- E (center, lower): foot of the perpendicular.
- C (center right): the vertex / pole of the described circle.
- A (right): the vertex at angle A.
- D (bottom left).
- B (bottom center): the right angle.

SCHOLIVM.

From this theorem the following problem is gathered.

In a right-angled spherical triangle, given the arc that is opposite the right angle together with either of the non-right angles, to find the other non-right angle and the two arcs about the right angle.

[Margin: c — Prop. 47 of this treatise.]

Let ABC be a triangle whose angle C is right, and let the arc AB be given together with the angle B. I say that the remaining angle A is also given, and the two arcs AC and CB. For, since the whole sine is to the sine of the complement of arc AB as the tangent of angle B is to the tangent of the complement of angle A —

[Margin: Praxis (Procedure).]

If it is arranged that, as the whole sine is to the sine of the complement of the given arc opposite the right angle, so the tangent of the given angle is to another line, the tangent of the complement of the sought angle will be found. Hence, from the arc AB and both angles B and A, each of the arcs AC and CB will be found, as we showed in Problem 2 of Proposition 41.

[Margin: f — Prop. 38 of this treatise.]

Whether the sought angle A is acute or obtuse we shall learn from the given arc AB and the given angle B. For if AB is less than a quadrant and angle B is acute, then A too will be acute; but if B is obtuse, A too will be obtuse. If, however, AB is greater than a quadrant and B is acute, then A will be obtuse; but if B is obtuse, A will be acute.

Diagram. A curvilinear (spherical) triangle. Labelled vertices:

- A (apex, top).
- B (lower left).
- C (lower right).

[Margin: c — Prop. 47 of this treatise.]

[Margin: Praxis (Procedure).]

THEOR. 46. PROPOS. 48.

In every right-angled spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the sine of either of the arcs about the right angle the same ratio that the tangent of the complement of the other arc about the right angle has to the tangent of the complement of the opposite angle.

Let ABC be a spherical triangle all of whose arcs are less than a quadrant, with the right angle B. I say that the whole sine is to the sine of arc AB as the tangent of the complement of arc BC is to the tangent of the complement of angle A. For, the construction being made as in Proposition 45: angle D will be right, and CF the complement of arc BC, and EF the complement of angle A, and AD a quadrant, as was there shown. Therefore, since the two great circles AD and AE in the sphere cut one another at A, and from the points C and E the perpendicular arcs CB and ED have been drawn to arc AD,

[Margin: b — Theorem 6 of scholium 40 of this treatise.]

it will be, as the whole sine of the quadrant AD is to the tangent of arc DE, so the sine of arc AB is to the tangent of arc BC. And by alternation, as the whole sine is to the sine of arc AB, so the tangent of arc DE is to the tangent of arc BC.

[Margin: c — Prop. 21 of the doctrine of Sines ("21. Sinuum").]

Moreover — since CF and EF are the complements of the arcs BC and DE — as the tangent of arc DE is to the tangent of arc BC, so the tangent of arc CF is to the tangent of arc EF. Therefore it will also be, as the whole sine is to the sine of arc AB, so the tangent of arc CF (the complement of arc BC) is to the tangent of arc EF, that is, of the complement of angle A, which is opposite arc BC. We shall demonstrate in no other way, if the figure is constructed differently, that the whole sine is to the sine of arc BC as the tangent of the complement of arc AB is to the tangent of the complement of angle C. Therefore in every right-angled spherical triangle, and so on. Which was to be demonstrated.

Diagram. A spherical construction (the quadrant figure of the theorem), with a tall arc rising to F and perpendiculars descending to the base. Labelled points:

- F (top): apex of the construction.

- E (left, middle).
- C (center): foot of a perpendicular / the vertex at angle C.
- A (right): the vertex at angle A.
- D (bottom left).
- B (bottom center): the right angle.

SCHOLIUM.

From this theorem the following problem is inferred: although it was also demonstrated in Problem 2 of Proposition 44, it is nevertheless more easily solved here, since in the rule of three the whole sine holds the first place.

In every right-angled spherical triangle, given the two arcs about the right angle, to trace out either of the non-right angles, together with the remaining arc that is opposite the right angle.

[Margin: d — Prop. 4[?] of this treatise (second digit uncertain; context favors Prop. 48).]

Let ABC be a triangle whose angle C is right, and let the two arcs AC and CB be given. I say that either of the angles A and B, and the arc AB, are likewise given. For, since the whole sine is to the sine of arc AC as the tangent of the complement of arc CB is to the tangent of the complement of angle A; and likewise, as the whole sine is to the sine of arc CB, so the tangent of the complement of arc AC is to the tangent of the complement of angle B —

If it is arranged that, as the whole sine is to the sine of either of the arcs about the right angle, so the tangent of the complement of the other arc about the right angle is to another line, the tangent of the complement of the angle opposite this latter arc will be found.

From the two given arcs about the right angle, the third arc — the one opposite the right angle — will also be known, as we showed in the problem of Proposition 43. Or indeed from either arc, once the angle opposite it has been found, as was taught in Problem 3 of Proposition 41.

[Margin: e — Prop. 34 of this treatise.]

Whether the sought angle is acute or obtuse will be shown by the arc opposite it. For if this arc is less than a quadrant, the angle opposite it will be acute; but if greater, obtuse.

Diagram. A curvilinear (spherical) triangle. Labelled vertices:

- A (apex, top).
- B (lower left).
- C (lower right).

[Margin: d — Prop. 4[?] of this treatise.]

[Margin: Praxis (Procedure).]

THEOR. 47. PROPOS. 49.

In every right-angled spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the tangent of either of the arcs about the right angle the same ratio that the tangent of the complement of the opposite angle has to the sine of the other arc about the right angle.

Let ADE be a spherical triangle all of whose arcs are less than a quadrant, with angle D right. I say that the whole sine is to the tangent of arc DE as the tangent of the complement of angle A is to the sine of arc AD. For, the construction of the figure of Proposition 45 being repeated, AB and AC will be quadrants, and CF the complement of arc BC — that is, of angle A — as was there shown. Therefore, since AB and AC are quadrants, and arc ED and AB are perpendicular,

[Margin: a — Theorem 7 of scholium 40 of this treatise.]

it will be, as the whole sine is to the tangent of arc ED, so the tangent of the complement of arc CB — that is, of angle A — is to the sine of arc AD. In the same way it will be shown that the whole sine is to the tangent of arc AD as the tangent of the complement of angle E is to the sine of arc DE — provided, of course, that the figure is constructed differently. Therefore in every right-angled spherical triangle, and so on. Which was to be demonstrated.

Diagram. A spherical construction with a tall arc rising to F and perpendiculars to the base. Labelled points:

- F (top): apex of the construction.
- A (left): the vertex at angle A.
- E (center): foot of a perpendicular / the vertex at angle E.
- C (upper right).
- D (bottom left): the right angle.
- B (bottom center).

SCHOLIVM.

From this the following problem is gathered, which can also be solved another way by Problem 1 of Proposition 44.

In a right-angled spherical triangle, given either of the arcs about the right angle together with the angle opposite it, to seek the remaining arc about the right angle and the arc opposite the right angle, together with the remaining non-right angle — provided only it be established whether the sought arc is greater or less than a quadrant, or whether the remaining non-right angle is acute or obtuse.

Let ABC be a triangle in which angle C is right, and let arc AC be given together with the opposite angle B. I say that arc BC is also given, and so on. [Margin: b — Prop. 49 of this treatise.] For since the whole sine is to the tangent of arc AC as the tangent of the complement of angle B is to the sine of arc BC:

Praxis. If it is arranged that the whole sine is to the tangent of the given arc as the tangent of the complement of the given angle is to another quantity, the sine of the sought arc will be produced. Then, from the two arcs about the right angle once known, we shall arrive at the knowledge of the remaining arc and of the remaining non-right angle, as we demonstrated in the problem of Proposition 43; or else from either of the arcs about the right angle together with the given angle, as we taught in the second problem of Proposition 42.

But here we must first establish whether the sought arc BC is greater or less than a quadrant, and whether the remaining angle A is acute or obtuse — just as was set out in the latter part of the first problem of Proposition 44, where we also exposed an error of Copernicus.

Diagram. A small spherical triangle with gently bowed sides.

- A (apex, top): vertex
- B (lower left): vertex
- C (lower right): vertex

THEOR. 48. PROPOS. 50.

In every right spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the tangent of the complement of either of the non-right angles the same ratio that the tangent of the complement of the remaining angle has to the sine of the complement of the arc opposite the right angle.

Let ABC be a triangle all of whose arcs are less than a quadrant, with B the right angle. I say that the whole sine is to the tangent of the complement of angle A as the tangent of the complement of angle C is to the sine of the complement of arc AC. Take again the figure of Proposition 47: since CG and CI are quadrants intersecting one another at C, and the arcs IG and FE are perpendicular to CG — as is evident from the construction made there — [Margin: a — Theor. 7 of scholium 40 of this treatise] it will follow that the whole sine is to the tangent of arc EF (which is the complement of arc DE, that is, of angle A) as the tangent of the complement of arc IG (that is, of angle C) is to the sine of arc CE (that is, of the complement of arc AC, the one opposite the right angle). By similar reasoning we shall show, if the construction of the figure is set up differently, that the whole sine is to the tangent of the complement of angle C as the tangent of the complement of angle A is to the sine of the complement of arc AC. Therefore in every right spherical triangle, and so on. Which was to be demonstrated.

Diagram. The figure of Proposition 47 repeated: a construction of intersecting great-circle arcs.

SCHOLIVM.

We infer from this proposition the following problem.

In a right spherical triangle, given the two non-right angles, to find the arc opposite the right angle, and the remaining two arcs about the right angle.

Let ABC be a triangle in which angle C is right, and let the two non-right angles A and B be given. I say that arc AB is also given, together with the arcs AC and BC. [Margin: b — Prop. 50 of this treatise.] For since the whole sine is to the tangent of the complement of angle A as the tangent of the complement of angle B is to the sine of the complement of arc AB:

Praxis. If it is arranged that the whole sine is to the tangent of the complement of either of the given angles as the tangent of the complement of the other given angle is to another quantity, the sine of the complement of the arc opposite the

right angle will be produced. Then, from the arc opposite the right angle together with either of the non-right angles, the arc opposite it will be found, as we showed in the second problem of Proposition 41.

Diagram. A small spherical triangle.

- A (apex, top): vertex
- C (lower left): vertex
- B (lower right): vertex

Furthermore, we shall learn whether the sought arc is greater or less than a quadrant in this way: if both angles A and B are obtuse, or both acute, [Margin: c — Prop. 37 of this treatise.] arc AB will be less than a quadrant; but if one of them is acute and the other obtuse, that same arc will be greater than a quadrant.

THEOR. 49. PROPOS. 51.

In every right spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the tangent of the complement of the arc opposite the right angle the same ratio that the tangent of either of the arcs about the right angle has to the sine of the complement of the adjacent non-right angle.

Let ABC be a spherical triangle all of whose arcs are less than a quadrant, with B the right angle. I say that the whole sine is to the tangent of the complement of arc AC as the tangent of arc AB is to the sine of the complement of angle A. Take again the construction of the figure of Proposition 45: AD and AE will be quadrants, angles D and E right, and likewise BF and DF quadrants, as was shown there. Since, then, in the sphere arc DB is drawn through the extremities of the quadrants BF and DF, which intersect at F, and CE is perpendicular to DF, [Margin: a — Theor. 7 of scholium 40 of this treatise] it will follow that the whole sine is to the tangent of arc CE (which is the complement of arc AC, the one opposite the right angle) as the tangent of the complement of arc DB — that is, the tangent of arc AB — is to the sine of arc EF (which is the complement of arc DE, or of angle A). It will be demonstrated no differently that the whole sine is to the tangent of the complement of arc AC as the tangent of arc BC is to the sine of the complement of angle C, if the construction of the figure is set up differently. Wherefore in every right spherical triangle, and so on. Which was to be shown.

SCHOLIUM.

From this theorem there arises a problem of this kind, which was also set out in the second problem of Proposition 45.

[The scholium-problem begun at the foot of the preceding page continues:]

In a right spherical triangle, given the arc opposite the right angle together with either of the arcs about that same right angle, to find the non-right angle adjacent to this arc — that is, the angle contained by the given arcs — together with the remaining arc and the non-right angle.

Let ABC be a triangle in which angle C is right, and let arc AB be given together with arc AC. I say that angle A is also given, together with arc BC and angle B. [Margin: b — Prop. 51 of this treatise.] For since the whole sine is to the tangent of the complement of arc AB as the tangent of arc AC is to the sine of the complement of angle A:

Praxis. If it is arranged that the whole sine is to the tangent of the complement of the arc opposite the right angle as the tangent of the given arc about the right angle is to another quantity, the sine of the complement of the adjacent angle sought will be found. From this the remaining parts will be found, as was set out in the first problem of Proposition 45.

Diagram. A small spherical triangle.

- A (apex, top): vertex
- B (lower left): vertex
- C (lower right): vertex

Whether the sought angle is acute or not, we shall further learn as we taught in the second problem of Proposition 45.

THEOR. 50. PROPOS. 52.

In every right spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the sine of either of the non-right angles the same ratio that the secant of the other non-right angle has to the secant of the arc opposite this angle.

Let ABC be a spherical triangle all of whose arcs are less than a quadrant, with B the right angle. I say that the whole sine is to the sine of angle A as the secant of angle C is to the secant of arc AB. With the construction made as in Proposition 47, GH, HE, AE, AD, and DF will be quadrants, GI the arc of angle C, and DE the arc of angle A, as was shown partly in Proposition 45 and partly in Proposition 47. Likewise angle I will be right, [Margin: a — 15.1.The. (a cited proposition — Theodosius, *Sphaerica* I.15 [?])] because arc CI, passing through C, the pole of arc GH, is perpendicular to GH. And so, since the two great circles BI and DH intersect one another in the sphere at F, and from the points D and H perpendicular arcs DB and HI have been drawn from arc DH to arc BI, [Margin: b — Theor. 8 of scholium 40 of this treatise] it will follow that the whole sine of the quadrant D[F] is to the secant GI (which is the complement of arc HI) as the sine of arc FH is to the secant of arc AB (which is the complement of arc DB). And by alternation: the whole sine is to the sine of arc FH — or of arc DE, for the arcs FH and DE are equal, since the whole quadrants EH and DF are also equal — that is, to the sine of angle A, as the secant of arc GI, that is, of angle C, is to the secant of arc AB, opposite angle C. By the same reasoning, if the figure is constructed differently, we shall demonstrate that the whole sine is to the sine of angle C as the secant of angle A is to the secant of arc BC. Therefore in every right spherical triangle, and so on. Which was to be shown.

Diagram. The construction of Proposition 47 repeated: intersecting great-circle arcs.

- G (far left): vertex
- I (top, left of H), H (top right): upper points

SCHOLIVM.

From this is elicited the following problem, which was also solved in another way in the first problem of the scholium of Proposition 42.

In a right spherical triangle, given the two non-right angles, to elicit the arc opposite either of them, together with the arc opposite the right angle.

Let ABC be a triangle in which angle C is right, and let the two angles A and B be given. I say that either of the arcs BC and AC is also given, together with arc AB. [Margin: c — Prop. 52 of this treatise.] For since the whole sine is to the sine of angle A as the secant of angle B is to the secant of arc AC; and likewise the whole sine is to the sine of angle B as the secant of angle A is to the secant of arc BC:

Praxis. If it is arranged that the whole sine is to the sine of the non-right angle adjacent to the sought side as the secant of the other non-right angle is to another quantity, the secant of the arc opposite this latter angle — the one sought — will be found. Once both arcs about the right angle have been found, the third arc, opposite the right angle, will be found from them, as we showed in the problem of Proposition 43; or else, from either arc once found together with the given angle opposite it, as we stated in the third problem of Proposition 41.

Diagram. A small spherical triangle.

- A (apex, top): vertex
- B (lower left): vertex
- C (lower right): vertex

Whether the two sought arcs about the right angle are less than a quadrant, or greater, we shall know as we taught in the second problem of Proposition 42.

THEOR. 51. PROPOS. 53.

In every right spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the sine of the complement of either of the arcs about the right angle the same ratio that the secant of the arc opposite the right angle has to the secant of the remaining arc.

Let ABC be a spherical triangle all of whose arcs are less than a quadrant, with B the right angle. I say that the whole sine is to the sine of the complement of arc BC as the secant of arc AC is to the secant of arc AB. With the construction of the figure made as in Proposition 45, BF will be a quadrant, and CE, BD will be perpendicular to DF, as was demonstrated there. Since, then, the two great circles BF and DF intersect one another in the sphere at F, and from the points B and C perpendicular arcs BD and CE have been drawn to DF, [Margin: a — Theor. 8 of scholium 40 of this treatise] it will follow that the whole sine of the quadrant BF is to the secant of the complement of arc CE — that is, to the secant of arc AC — as the sine of arc FC (which is the complement of arc BC) is to the secant of the complement of arc BD, that is, to the secant of arc AB. And by alternation: the whole sine is to the sine of the complement of arc BC as the secant of arc AC is to

the secant of arc AB. In like manner we shall show that the whole sine is to the sine of the complement of arc AB as the secant of arc AC is to the secant of arc BC, if only the figure is constructed a little differently. Therefore in every right spherical triangle, and so on. Which was to be demonstrated.

Diagram. A crescent- or lune-shaped construction of great-circle arcs.

- F (top): upper point
- E (middle left), C (center): points on the arcs
- A (right): vertex
- D (lower left), B (lower center): base points; arcs BD, CE, DF, BF drawn

SCHOLIVM.

The following problem is gathered from this theorem.

In a right spherical triangle, given the arc opposite the right angle together with either of the arcs about the right angle, to investigate the third arc, together with the two non-right angles.

Let ABC be a triangle in which angle C is right, and let arc AB be given together with arc AC. I say that arc BC is also given, together with the angles A and B. [Margin: a — Prop. 53 of this treatise.] For since the whole sine is to the sine of the complement of arc AC as the secant of arc AB is to the secant of arc BC:

Praxis. If it is arranged that the whole sine is to the sine of the complement of the given arc about the right angle as the secant of the arc opposite the right angle is to another quantity, the secant of the third arc sought will be produced. From this, the two arcs about the right angle being known, either of the non-right angles will be known, as we taught in the fifth problem of the scholium of Proposition 44, or in the problem of the scholium of Proposition 48.

Diagram. A small spherical triangle.

- A (apex, top): vertex
- B (lower left): vertex
- C (lower right): vertex

Whether the sought arc BC is greater or less than a quadrant, we shall learn from the two given arcs, as was set out at the end of the first problem of the scholium of Proposition 43.

THEOR. 52. PROPOS. 54.

In every right spherical triangle all of whose arcs are less than a quadrant, the whole sine has to the sine of either of the non-right angles the same ratio that the secant of the complement of the arc opposite that angle has to the secant of the complement of the arc opposite the right angle.

Let ABC be a triangle all of whose arcs are less than a quadrant, with B the right angle. I say that the whole sine is to the sine of angle A as the secant of the complement of arc BC is to the secant of the complement of arc AC. For with the construction of the figure of Proposition 47 repeated, angle I will be right, as was shown in Proposition 52, and likewise angle G. Also GH, EH, DF, BF, AE will be quadrants, as is established from what was demonstrated in Propositions 45 and 47. Since, then, in the sphere the two great circles EH and GH intersect one another at H, and from the points E and F perpendicular arcs EG and FI have been drawn from arc EH to arc GH, [Margin: a — Theor. 8 of scholium 40 of this treatise] it will follow that the whole sine of the quadrant EH is to the secant of the complement of arc FI — that is, to the secant of arc CF, which is also the complement of arc BC — as the sine of arc FH, that is, of arc DE (for arc FH is equal to arc DE, since the quadrants EH and DF are equal), which arc belongs to angle A, is to the secant of the complement of arc EG, that is, to the secant of arc EC, which is also the complement of arc AC. And by alternation: the whole sine is to the sine of arc DE, that is, of angle A, as the secant of the complement of arc BC is to the secant of the complement of arc AC. We shall show no differently, if the figure is constructed otherwise, that the whole sine is to the sine of angle C as the secant of the complement of arc AB is to the secant of the complement of arc AC. Therefore in every right spherical triangle, and so on. Which was to be demonstrated.

Diagram. The construction of Proposition 47 repeated: intersecting great-circle arcs.

- G (far left): vertex
- I (top, left of H), H (top right): upper points

SCHOLIVM.

From this theorem there follows a problem which we have also completed in another way in the third problem of Proposition 41.

In a right spherical triangle, given either of the non-right angles together with its opposite arc, to investigate the arc opposite the right angle, together with the third arc and the remaining non-right angle — provided it is established whether the arc opposite the right angle is greater or less than a quadrant, or whether the other non-right angle is acute or obtuse.

Let ABC be a triangle having angle C right, and let angle B be given together with arc AC. I say that arc AB is also given, together with arc BC and angle A. [Margin: b — Prop. 54 of this treatise.] For since the whole sine is to the sine of the given angle B as the secant of the complement of the given arc AC is to the secant of the complement of arc AB:

Praxis. If it is arranged that the whole sine is to the sine of the given angle as the secant of the complement of the given arc is to another quantity, the secant of the complement of the arc opposite the right angle — the one sought — will be produced. From the arcs AB and AC once known, the third arc BC becomes known, by the problem of Proposition 43; and likewise from the arcs AB and BC once known, angle A becomes known, by the first problem of Proposition 41.

Diagram. A small spherical triangle.

- A (apex, top): vertex
- C (lower left): vertex
- B (lower right): vertex

(Continuing the scholium from the previous page, resumed at the catchword OPORTET.)**

But here it must be established whether the sought arc AB is greater or less than a quadrant, and whether the remaining non-right angle A is acute or obtuse; otherwise we would not know what sort of arc to assume for AB, since it may be either greater than a quadrant or less, as is evident. This is what we pointed out at problem 3 of proposition 41 [Probl. 3, propos. 41] — where we also exposed the error of Copernicus [Nicolaus Copernicus] and of Johann Regiomontanus [Regiomontanus].

THEOR. 53. PROPOS. 55.

In every right spherical triangle all of whose arcs are less than a quadrant, the whole sine [sinus totus] has to the sine of the arc opposite the right angle the same ratio that the secant of the complement of either of the arcs about the right angle has to the secant of the complement of the angle opposite that arc.

Let ABC be a spherical triangle all of whose arcs are less than a quadrant, with B the right angle. I say that the whole sine is to the sine of arc AC as the secant of the complement of arc BC is to the secant of the complement of angle A, which is opposite arc BC. For, repeating the construction of the figure of proposition 45 [propos. 45], AE will be a quadrant; DE the arc of angle A, and EF its complement; and CF the complement of arc BC, as was demonstrated there.

Diagram. A right spherical triangle with its auxiliary construction.

- A (left vertex): endpoint of the base arc
- B (foot, at the right angle): the vertex of the right angle
- C (on the hypotenuse, upper-middle): intersection point
- D (foot, right of B): endpoint of the produced base arc
- E (right, above D): point on the produced arc
- F (top): apex of the construction, from which the arcs descend

Since, then, in the sphere the two great circles AE and AD intersect one another at A, and from the points C and E the arcs CB and ED have been drawn perpendicular from arc AE to arc AD, it follows [a] that as the whole sine of the quadrant AE is to the secant of the complement of arc CB — that is, to the secant of arc CF — so the sine of arc AC is to the secant of the complement of arc DE, that is, of angle A — that is, to the secant of arc EF. And, permuting, as the whole sine is to the sine of arc AC, so the secant of the complement of arc BC is to the secant of the complement of angle A. By the same reasoning, if the figure is constructed otherwise, it will follow that as the whole sine is to the sine of arc AC, so the secant of the complement of arc AB is to the secant of the complement of angle C. Therefore in every right spherical triangle, and so on. Which was to be shown.

[Margin: a — Theorem 8 of scholium 40 of this treatise [Theor. 8, scholij 40 huius].]

SCHOLIUM.

From this we will resolve the following problem, which was also solved in another way at problem 1 of proposition 41 [problemate 1, propos. 41].

In a right spherical triangle, given the arc that is opposite the right angle together with either of the arcs about the right angle, to find the angle opposite this arc, along with the remaining arc and angle.

In triangle ABC (in the figure of the scholium of proposition 54 [scholij propos. 54]), whose right angle is C, let both arc AB and arc AC be given. I say that angle B is thereby also given, together with arc BC and angle A. [b] For since the whole sine is to the sine of arc AB as the secant of the complement of arc AC is to the secant of the complement of angle B —

[Margin: b — proposition 55 of this treatise [55 huius].]

[Margin: Praxis.]

If it be arranged that, as the whole sine is to the sine of the arc opposite the right angle, so the secant of the complement of the given arc about the right angle is to a fourth term, then the secant of the complement of the sought angle — which is opposite the said arc — is produced. Now from the two given arcs we will find the third, as we set out in the problem of proposition 43 [problemate propos. 43], or in the problem of proposition 53 [problemate propos. 53]. Likewise, from the arc opposite the right angle and from this newly found arc, we will discover the remaining angle opposite the found arc, as was said in this problem, or, at any rate, as we showed in problem 1 of proposition 41 [problemate 1, propos. 41].

But whether the sought angle B is acute or obtuse, the arc AC — the given arc about the right angle — will show, as we prescribed in problem 1 of proposition 41 [problemate 1, propos. 41].

THEOR. 54. PROPOS. 56.

In every right spherical triangle whose arcs are all less than a quadrant, the whole sine has to the sine of the complement of either of the arcs about the right angle the same ratio that the secant of the angle opposite this arc has to the secant of the complement of the remaining non-right angle.

Let ABC be a spherical triangle having B a right angle, all of whose arcs are less than a quadrant. I say that the whole sine is to the sine of the complement of arc

BC as the secant of the non-right angle A is to the secant of the complement of angle C. For, repeating the construction of the figure of proposition 47 [propos. 47], the angles G and E will be right, and the arcs BF, DF, CI, EH, GH will be quadrants; DE will be the arc of angle A, and GI the arc of angle C, as is clear from what was demonstrated in propositions 45 and 47 [propos. 45 & 47].

Diagram. A right spherical triangle with an extended construction of intersecting great-circle arcs.

- A (right): a vertex of the base
- B (lower middle): vertex at the right angle
- C (interior, right of center): intersection point
- D (lower left): foot of a perpendicular
- E (interior, left of C): intersection point
- F (interior, above E): intersection point
- G (left): apex on the left
- H (upper right): apex point
- I (upper left): apex point

Therefore, since the two great circles CG and CI of the sphere intersect one another at C, and from the points F and I the perpendicular arcs FE and IG have been drawn from arc CI to arc CG, it follows [a] that as the whole sine of the quadrant CI is to the secant of the complement of arc FE — that is, to the secant of arc DE, of angle A — so the sine of arc CF, which is the complement of arc BC, is to the secant of the complement of arc GI, of angle C. And, permuting, as the whole sine is to the sine of the complement of arc BC, so the secant of angle A is to the secant of the complement of angle C. In just the same way we will show, if the figure is constructed otherwise, that the whole sine is to the sine of the complement of arc AB as the secant of angle C is to the secant of the complement of angle A. Therefore in every right spherical triangle, and so on. Which was to be demonstrated.

[Margin: a — Theorem 8 of scholium 40 of this treatise [Theor. 8, scholij 40 huius].]

SCHOLIVM.

From this a problem of the following kind is inferred.

In a right spherical triangle, given either of the arcs about the right angle together with the non-right angle opposite it, to find the remaining non-right angle and, in

addition, the remaining two arcs — provided it be established whether the sought angle is acute or obtuse, or at least whether the other arc about the right angle is less than a quadrant or greater.

In triangle ABC, having C a right angle, let arc AC be given together with angle B. I say that angle A is thereby also given, along with arcs BC and AB. [a] For since the whole sine is to the sine of the complement of the given arc AC as the secant of the given angle B is to the secant of the complement of angle A —

[Margin: a — proposition 56 of this treatise [56 huius].]

[Margin: Praxis.]

Diagram. An oblique (obtuse-looking) spherical triangle.

- A (top): apex vertex
- C (lower left): base vertex
- B (lower right): base vertex

If it be arranged that, as the whole sine is to the sine of the complement of the given arc, so the secant of the complement of the given angle is to a fourth term, then the secant of the complement of the other non-right angle will be found. From this — with the two non-right angles now known — the arc opposite the right angle will be investigated, as we showed in the problem of proposition 50 [problemate propos. 50], and consequently also the remaining arc, from the arc that is opposite the right angle and from the known angle opposite the remaining arc, as we stated in problem 2 of proposition 41 [problemate 2, propos. 41].

But it must be established whether the remaining non-right angle that is sought is acute or obtuse, or whether the remaining arc about the right angle is less or greater than a quadrant, as we advised at the close of problem 2 of proposition 42 [problematis 2, propos. 42], where we also uncovered the error of Nicolaus Copernicus [Nicolaus Copernicus].

Now, since the reckoning of right spherical triangles is at last complete, it is fitting at this point to gather into a single table all the problems so far expounded, so that anyone may more easily find what he most desires to know. And so — since in every right spherical triangle the thing sought in the first place is either the arc opposite the right angle, or either of the arcs about the right angle, or, finally, one of the two non-right angles (although, once the thing chiefly sought has been found, the rest are found as well, as we noted for the practical procedures of the individual problems) — we have made a three-part table according to the number of the things

sought, and have appended the problems of the propositions in which the discovery of the sought quantities has been demonstrated.

There follow the problems of the foregoing propositions, arranged into a three-part table.

Finding the arc opposite the right angle. (*Inuentio arcus recto angulo oppositi.*)

When there is given (Quando datur):

[Margin: What to do in a right triangle in which there are quadrants (*Quid agendum in triangulo rectangulo, in quo quadrantes sunt*).]

But since so far we have treated only that right triangle none of whose arcs is a quadrant, let us briefly teach — a matter quite easy for anyone, from what has been demonstrated — how we should proceed in one that has at least two quadrant arcs and two right angles. [a] For no triangle can be right-angled having only a single arc that is a quadrant; rather, either none will be a quadrant, or all three will be quadrants, or two will be, and so on. Let ABC then be a spherical triangle in which angle B is set right, and arc AB, about the right angle, a quadrant. This being posited, [b] arc AC, opposite the right angle, will also be a

quadrant. Therefore, since the two arcs AB and AC are quadrants, [c] the two angles B and C will be right; [d] and consequently A will be the pole of arc BC, and BC will be the arc of angle A, by definition 6 [definitione 6]. So if the third angle A is given, the third arc BC will also be given; and conversely, if the third arc BC is given, the third angle A will likewise be given.

Diagram. An equilateral-looking spherical triangle (a quadrantal triangle).

- A (top): apex vertex
- B (lower left): base vertex
- C (lower right): base vertex

In the same way, if instead the other arc BC, about the right angle, is set as a quadrant, we will show that arc AC, opposite the right angle, is also a quadrant, and that angle A is right. So if the third angle C is given, the third arc AB will also be given, and conversely, as before. But if the magnitude of the third angle, or of the arc, is not given, nothing certain can be gathered, even though the other two angles be right and the two arcs opposite them quadrants — as is evident.

[Margin: a — Corollary of proposition 38 of this treatise [Coro. 38 huius].]

[Margin: b — proposition 35 of this treatise [35 huius].] [Margin: c — proposition 25 of this treatise [25 huius].] [Margin: d — Corollary of proposition 26 of this treatise [Coro. 26 huius].]

Now let arc AC, opposite the right angle B, be posited as a quadrant. This being posited, [e] at least one of the arcs AB, BC about the right angle will also be a quadrant. Hence the rest will follow, as was just demonstrated.

But if at any time the two arcs AB, BC about the right angle are set as quadrants, [f] the third arc AC, opposite the right angle, will likewise be a quadrant. And so, since all the arcs are quadrants, [g] all the angles will be right.

From these considerations anyone will readily understand what he ought to do whenever some arc in a right triangle is set as a quadrant — especially if propositions 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38 [propos. 25.26.27.28.29.30.31.32.33.34.35.36.37.38] are attentively considered.

It now follows that we should at last set out the reckoning of non-right (oblique) triangles; but first several theorems very useful for this matter must be demonstrated.

[Margin: e — proposition 36 of this treatise [36 huius].] [Margin: f — proposition 26 or 35 of this treatise [26 vel 35 huius].] [Margin: g — Corollary of proposition 25 of this treatise [Corol. 25 huius].]

THEOR. 55. PROPOS. 57.

If in a spherical triangle two acute angles, or two obtuse angles, stand upon one arc, the perpendicular arc dropped from the third angle onto that arc falls inside the triangle. But if, of the two angles standing upon one arc, one is acute and the other obtuse, the perpendicular arc dropped from the third angle onto that arc falls outside the triangle.

In the spherical triangle ABC, let the two angles B and C, standing upon arc BC, be acute (or obtuse). I say that the perpendicular arc dropped from A onto arc BC falls inside the triangle — such as is arc AD. For if it be said to fall outside, let the perpendicular arc AE fall (if it can be done) from A onto BC produced, outside the triangle; and let the two angles B and C first be set acute, so that consequently angle ACE is obtuse. Since, then, in triangle ACE — which has E a right angle — the angle ACE is obtuse, [a] arc AE will be greater than a quadrant. Again, in triangle ABE — which has the right angle E — the angle B is acute, so [b] arc AE will be less than a quadrant; but it was also shown [above] to be greater than a quadrant — which is absurd.

Diagram. A spherical triangle with a perpendicular arc dropped from the apex to the base and produced beyond it.

- A (top): apex, from which the perpendicular arc is dropped
- B (lower left): base vertex
- C (base, right of center): base vertex
- E (base, far right): foot of the perpendicular AE on BC produced, outside the triangle

[Margin: a — proposition 34 of this treatise [34 huius].] [Margin: b — proposition 34 of this treatise [34 huius].]

Suppose next that the angles B and C are obtuse, so that the angle ACE is acute. Then, since in the triangle ACE, which has the right angle at E, the angle ACE is acute, the arc AE will be less than a quadrant. [Margin: c — Prop. 34 of this treatise.] Again, since in the triangle ABE, which has the right angle at E, the angle B is obtuse, the arc AE will be greater than a quadrant. [Margin: d — Prop. 34 of this treatise.] But it was shown to be also less than a quadrant, which is absurd. Therefore the perpendicular arc does not fall outside the triangle; nor does it

coincide with either of the arcs AB, AC, since neither of the angles B, C is assumed to be right. It therefore falls inside the triangle.

Now let it be assumed, in the same triangle ABC, that the angle B is acute and C obtuse. I say that the perpendicular arc dropped from A to the arc BC falls outside the triangle — such as the arc AE is. For if it be said to fall inside, let the arc AD, perpendicular to BC, fall inside the triangle, if that be possible. Then, since in the triangle ACD, which has the right angle at D, the angle C is obtuse, the arc AD will be greater than a quadrant. [Margin: e — Prop. 34 of this treatise.] Again, since in the triangle ABD, which has the right angle at D, the angle B is acute, the arc AD will be less than a quadrant. [Margin: f — Prop. 34 of this treatise.] But it was shown to be also greater than a quadrant, which is absurd. The perpendicular arc therefore does not fall inside the triangle; nor does it coincide with either of the arcs AB, AC, since neither of the angles B, C is assumed to be right. It therefore falls outside the triangle. And so, if in a spherical triangle over one arc there are two acute angles, and so on. Which was to be demonstrated.

THEOR. 56. PROPOS. 58.

In every spherical triangle whose two sides are unequal, the square of the whole sine [*sinus totus* — the radius, the total sine] has to the rectangle contained by the right sines [*sinus rectus* — the ordinary sine] of the two unequal sides the same ratio that the versed sine [*sinus versus* — the versed sine, i.e. $1 - \cosine$] of the angle contained by those sides has to the difference of two versed sines — of which one belongs to the difference of those same arcs, while the other answers to the third arc, the one opposite the aforesaid angle.

In the spherical triangle ABC let there be two unequal sides AB, AC, the former smaller and the latter larger. I say that the square of the whole sine has to the rectangle contained by the right sines of the arcs AB, AC the same ratio that the versed sine of the angle A has to the difference between the versed sine of the arc by which AB and AC differ from each other and the versed sine of the arc BC. To make the demonstration of this clearer and more general, we shall divide it into fifteen cases.

1. [Margin: Case 1.] Let all three arcs be less than a quadrant. Let the circle ABDGH be completed on the smaller arc AB; and, the arcs AC, BC being produced so that the quadrants AL, BM are formed, let the great circles DLEF, GMEH be described about the poles A, B at the distances of the quadrants AL, BM. About the same poles, but at the distances AC, BC, let the lesser circles kCN, OCP be drawn,

which will be parallel to those great circles; [Margin: a — Theodosius II.2.] and both these and those will be at right angles to the circle ABDGH, since that circle, passing through their poles, is at right angles to them. [Margin: b — Theodosius I.15.] After this, to avoid confusion, in the circle ABDGH drawn separately let there be marked the common sections of it and of the circles described about the poles A, B — namely DF, GH — the common sections of it and of the great circles DL, EF, GMEH, which are their diameters, intersecting one another at X, the centre of the sphere; while kN, OP are the common sections of the same circle and of the circles kCN, OCP, intersecting each other at S. These will be parallel to DF, GH, and are the diameters of the circles kCN, OCP, [Margin: c — Euclid XI.16.] since the great circle ABDGH, passing through their poles, bisects them, that is, cuts them through their diameters. [Margin: d — Theodosius I.15.] Let the semidiameters AX also be drawn, cutting kN at Y, and BX, cutting KN, OP at I and R. Then the semidiameters AX, BX will be perpendicular to the circles drawn through DF, kN, GH, OP, since they are drawn from the poles A, B of those circles through X, the centre of the sphere; and hence the angles at Y and R will be right, by the definition [Euclid] Book XI, def. 3. [Margin: e — Scholium on Theodosius I.10.] Finally let AV, kQ, kT be drawn perpendicular to BX, OP. Then, by what we wrote in the treatment of sines, AV will be the right sine of the arc AB; and kY the right sine of the arc Ak, that is, of the arc AC (since the arcs Ak, AC are equal by the definition of a pole), as appears in the first circle. BR will be the versed sine of the arc BO, that is, of the arc BC (since BO, BC are equal by the definition of a pole). BQ will be the versed sine of the arc Bk, which is the difference of the unequal arcs AB, AC — because, by the definition of a pole, the arc Ak, exceeding the arc AB by the arc Bk, is equal to the arc AC; and hence QR, or kT, will be the difference between BR, the versed sine of the third arc BC, and BQ, the versed sine of the difference of the unequal arcs AB, AC, that is, the versed sine of the arc Bk. Lastly, kS will be the right sine of the arc kC in the lesser circle kCN, since the straight line drawn from C into the common sections of the circles kCN, OCP with the circle ABDGH — that is, falling upon the point S — [Margin: f — Euclid XI.19.] (which is indeed at right angles to the circle ABDGH, being the common section of the circles kCN, OCP, which are at right angles to that same circle ABDGH) is the right sine of the same arc kC. Let DZ also be taken, the versed sine of the arc DL, that is, of the angle A, [Margin: g — Theodosius I.10.] which arc is indeed similar to the arc kC. It is therefore to be demonstrated that the square of the whole sine — that is, the rectangle contained by DX, XA — has to the rectangle contained by the right sines AV, kY of the arcs AB, AC the same ratio that the versed sine DZ of the angle A has to kT, the difference between BR, the versed sine of the arc BC,

and BQ, the versed sine of the difference of the unequal arcs AB, AC. This will come about as follows.

[Margin: h — Euclid I.15.] Since the angle XIY is equal to the angle RIS, and the right angle Y to the right angle R, [Margin: i — Euclid I.32.] the remaining angle IXY of the triangle IXY will be equal to the remaining angle ISR of the triangle ISR — that is, to the vertical angle kST. Since, then, the right angle V is also equal to the right angle T, the remaining angle XAV of the triangle XAV will also be equal to the remaining angle SkT of the triangle SkT. [Margin: k — Euclid VI.4.] For this reason, as XA is to AV, so will Sk be to kT. Again, since DZ, kS are the versed sines of the similar arcs DL, kC, it will follow that, as DX is to kY (the whole sine to the whole sine), so is DZ to kS, by the lemma of Proposition 1 of our *Gnomonics*. [Margin: l — Euclid VI.23.] And since the ratio of the rectangle contained by DX, XA to the rectan-

gle contained by KY, AV is compounded of the ratio of DX to KY (that is, of DZ to KS) and of the ratio of XA to AV; and since the ratio of DZ to KT is compounded of the same ratios — namely (KS being set as the mean term) of the ratio of DZ to KS and of the ratio of KS to KT, that is, of the ratio of XA to AV — it will follow that, as the rectangle contained by DX, XA (that is, the square of the whole sine) is to the rectangle contained by KY, AV (the right sines of the unequal arcs AC, AB), so is DZ, the versed sine of the angle A, to KT, the difference between BR, the versed sine of the arc BC opposite the angle A, and BQ, the versed sine of the difference of the unequal arcs AC, AB. Which was the thing proposed.

Diagram. A pair of circles illustrating Case 1 (all three arcs less than a quadrant). The left member is the full spherical construction (the great circles about poles A, B, the lesser circles kCN, OCP, and the dropped perpendicular); the right member is the rectilinear cross-section drawn separately, showing the common sections, diameters, and the right and versed sines derived in the text.

- Left sphere — outer/readable labels: A, B (top), K (upper right), C, O (interior right of centre), D (right rim), P (left rim), H, N (lower left rim), L (interior), E (lower centre), M (lower centre), G (lower right rim), F (bottom).
- Right sphere — outer/readable labels: A, B (top), Q, V (upper interior), K (upper right), O, D (right upper rim), P (left rim), R, S (central), Y (interior left of centre), I (centre), Z (interior below centre), T (interior right), H, N (lower left rim), X (bottom centre), G (right rim), F (bottom). : dense interior labelling; several small interior letters are at the resolution floor.

2. [Margin: Case 2.] Let there be two unequal arcs AB, AC less than a quadrant, but BC a quadrant. Let the circle ABDGH be completed on the smaller arc AB; and, the arc AC being produced so that the quadrant AL is formed, let the great circles DELF, GECH be described about the poles A, B at the distances of the quadrants AL, BC. Likewise, from the pole A, at the distance A C, let the lesser circle KCN be drawn, [Margin: o — Theodosius II.2.] which will be parallel to DELF; [Margin: p — Theodosius I.15.] and the circle ABDGH will cut the circles DELF, GECH, KCN at right angles and bisect them; and hence their common sections with it, DF, GH, will be their diameters, and DF, GH will intersect one another at X, the centre of the sphere, [Margin: q — Euclid XI.16.] and DF, KN will be parallel. Let the rest be done as in the preceding case, except that here the point R is the same as X — because the circle OCP does not differ from the circle GEH, and so the straight line ORP does not differ from the straight line GH. As before, AV will be the right sine of the arc AB; and KY the right sine of the arc AK, that is, of the arc AC, which is equal to AK by the definition of a pole. Likewise BR will be the versed sine of the arc BG, that is, of the arc BC, which is equal to BG. But BQ will be the versed sine of the arc BK, the difference of the arcs AB, AC; and so QR, or KT, will be the difference between the versed sines BR, BQ of the arcs BC, BK. Finally KS will be the right sine of the arc DL, that is, of the angle A. It is to be demonstrated that the square of the whole sine — that is, the rectangle contained by DX, XA — has to the rectangle contained by AV, KY (the right sines of the arcs AB, AC) the same ratio that the versed sine DZ of the angle A has to KT, the difference of the versed sines BR, BQ of the arcs BC, BK. This will be demonstrated as in the preceding case, except that here the triangle XAV will be shown to be equiangular with the triangle SKT from the fact that the angle IXY is equal to the angle YSX, [Margin: r — Euclid VI.18.] because the triangles IXY, YSX are similar to one another. For hence it follows that the right-angled triangles XAV, SKT are altogether equiangular with each other.

Diagram. Pair of circles for Case 2 (AB, AC less than a quadrant, BC a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A, B, K (top), D (upper right), H, P (left rim), C (centre), L, E (lower centre), O, G (right rim), N, F (bottom).
- Right sphere — readable labels: A, B (top), Q (upper interior), K (upper right), D (right rim), V, I, Y (interior), S, X, R, T, Z (central/lower interior), H, P, N (left/lower rim), O, G (right rim), F (bottom). : dense interior labelling near the resolution floor.

3. [Margin: Case 3.] Let AB, AC again be less than a quadrant, but BC greater. Let the circle be completed on the smaller arc AB; and let the quadrant BM be cut off from CB, and let AC be produced so that the quadrant AL is formed. Let the rest be constructed as in the first case. The sines here will be as they were there. It is therefore to be demonstrated that the square of the whole sine — namely the rectangle contained by DX, XA — has to the rectangle contained by AV, KY (of the arcs AB, AC) the same ratio that the versed sine DZ of the angle A has to KT, the difference of the versed sines BR, BQ of the arcs BC, BK. This will be shown as in the first case, except that here we shall show the triangle XAV to be equiangular with the triangle SKT [Margin: s — Euclid I.29.] from the fact that the angle XiY is equal to the angle SkT, the external to the internal. For hence it comes about that in the right-angled triangles XIY, SKT the remaining angles IXY, KST are equal; and therefore the right-angled triangles XAV, SKT are equiangular.

Diagram. Pair of circles for Case 3 (AB, AC less than a quadrant, BC greater). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A, B, K (top), D (upper right), H, P (left rim), M (interior), C, E (lower centre), L (lower interior), O, G (right rim), N, F (bottom).
- Right sphere — readable labels: A, B, K (top), D (right rim), Q, V (upper interior), I, Y (interior), X (centre), S, Z, R, T (lower interior), O, G (right rim), N, F (bottom). : interior labelling near the resolution floor.

4. [Margin: Case 4.] Let the arc AC be a quadrant, so that AB is less than a quadrant; let BC also be set less than a quadrant. The circle ABDGH being completed on the smaller arc AB, and the arc BC being produced so that the quadrant BM is formed, let the great circles DCEF, GMEH be described about the poles A, B at the distances of the quadrants AC, EM. Likewise, from the pole B, at the distance of the arc BC, let the lesser circle OCP be drawn. Let the rest be constructed as in the first case, except that here the two parallel circles DEF, KCN do not differ from each other, on account of the quadrant AC. From which it comes about that the straight lines DF, kN also do not differ from each other; and the same is to be said of the versed sines kS, DZ. The other sines are as before. That the square of the whole sine — or the rectangle contained by DX, XA — has to the rectangle contained by AV, KY (the right sines of the arcs AB, AC) the same ratio that the versed sine DZ of the angle A (or of the arc KC) has to KT, the difference of the versed sines BR, BQ of the arcs BC, BK, we shall show as in the first case, except that here we shall demonstrate the triangle XAV to be equiangular with the triangle SKT from the fact that the angle AXV is equal to the

angle YSR, [Margin: t — Euclid VI.18.] (because the triangles IXR, RSY are similar) and so to the angle KST. For hence it comes about that the right-angled triangles XAV, SKT are equiangular.

Diagram. Pair of circles for Case 4 (AC a quadrant, AB and BC less than a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A, B, D, K (top), P, H (left rim), C (centre), E, M (bottom), O, G (right rim), N, F (bottom).
- Right sphere — readable labels: A, B, K, D (top), Q, V (upper interior), R, S, T (central), Y, X (centre), O, G (right rim), P, H (left rim), N, F (bottom). : interior labelling near the resolution floor.

5. [Margin: Case 5.] Let AC again be a quadrant, and therefore AB less than a quadrant, but let BC also be set as a quadrant. The circle ABDGH being completed on the smaller arc AB, let the great circles DCF, GCH be described about the poles A, B at the distances of the quadrants AC, BC, and let the rest be done as before, except that here the lesser circles KN, OP do not differ from the great circles DF, GH, and so on. It is therefore to be demonstrated that the square of the whole sine — that is, the rectangle contained by DX, XA — has to the rectan-

gle contained by AV, kY (the right sines of the arcs AB, AC) the same ratio that DZ, the versed sine of the angle A (or of the arc kC), has to kT, the difference of the versed sines BY [?: possibly BR] and BQ — of which the former belongs to the arc BC, the latter to the arc Bk. This we shall show as in the first case. Only the triangle XAV will be demonstrated equiangular with the triangle SKT thus: Since the angles DSA, BSH are right (because AS, BS are the axes of the circles DF, GH), then, the common angle ASB being taken away, the remaining angles DSB, ASH will be equal; [Margin: a — Euclid I.29.] but the former is equal to the alternate angle SKT, and the latter to the alternate angle XAV. Therefore the angles SkT, XAV will also be equal; and hence the right-angled triangles XAV, SkT will be equiangular.

Diagram. Pair of circles for Case 5 (AC and BC quadrants, AB less than a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: B, K, D (top), A, H, P (left rim), C (centre), O, G (right rim), N, F (bottom).
- Right sphere — readable labels: B, K, D (top), A (left), Q, V (upper interior), S, Z, X, Y, T (central), H (left rim), O, G (right rim), N, F (bottom). : interior labelling near the resolution floor.

6. [Margin: Case 6.] Let AC still be a quadrant, so that AB is less than a quadrant, but let BC be set greater than a quadrant. The circle ABDGH being completed on the smaller arc AB, and the quadrant BM being cut off from BC, let the great circles DEF, GEH be described about the poles A, B at the distances of the quadrants AC, BM. Likewise, from the pole B, at the distance BC, let the lesser circle OCP be drawn, [Margin: b — Theodosius II.2.] which will be parallel to GEH. Let the rest be done as before, except that here the circles DF, KN do not differ from each other, and so on. We shall now demonstrate, as in the first case, that the square of the whole sine — that is, the rectangle contained by DX, XA — has to the rectangle contained by AV, KY (the right sines of the arcs AB, AC) the same ratio that DZ, the versed sine of the angle A (or of the arc DC), has to KT, the difference of the versed sines BR, BQ of the arcs BC, BK. But that the triangle XAV is equiangular with the triangle SKT we shall show thus: Since the right angles are AXK, BXG, the remaining angles AXV, KXG will be equal; [Margin: c — Euclid I.29.] but this latter is equal to its opposite, and to the internal angle TSK. Therefore the angle AXB will also be equal to the angle TSK; and hence the right-angled triangles XAV, SKT will be equiangular.

Diagram. Pair of circles for Case 6 (AC a quadrant, AB less than a quadrant, BC greater than a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A, B (top), K, D (upper right), H, P (left rim), M, E (interior), C (lower centre), O, G (right rim), N, F (bottom).
- Right sphere — readable labels: A, B (top), V, K (upper), Q, D (interior/right rim), H, P (left rim), S, X, Z (central), R, T (lower interior), O, G (right rim), N, F (bottom). : interior labelling near the resolution floor.

7. [Margin: Case 7.] Let the arc AC be greater than a quadrant, and AB, BC less than a quadrant. The circle ABDGH being completed, and the quadrant AL being cut off from AC, and the arc BC being produced so that the quadrant FM is formed, let all the rest be done as in the first case. For we shall demonstrate, as there, that the square of the whole sine — or the rectangle contained by DX, XA — has to the rectangle contained by AV, KY (the right sines of the arcs AB, AC) the same ratio that DZ, the versed sine of the angle A (or of the arc DL), has to KT, the difference of the versed sines BR, BQ of the arcs BC, BK. But that the triangle AXV is equiangular with the triangle SKT will be proved thus: [Margin: d — Euclid I.15.] The angle KST is equal to the angle ISR. Therefore, in the right-angled triangles SKT, ISR, the remaining angles SKT, SIR will be equal; and hence also, in the right-angled triangles SKT, XIY, the remaining angles KST, IXY will be equal.

[Margin: e — Euclid I.15.] Since, then, the angle IXY is equal to the angle AXV , KST will also be equal to the same AXV ; and therefore, in the right-angled triangles SKT , XAV , the remaining angles SKT , XAV will be equal.

Diagram. Pair of circles for Case 7 (AC greater than a quadrant, AB and BC less than a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A , B (top), D , K (upper right), H (left rim), L , C (interior), E , M (bottom), O , G (right rim), F , N (bottom).
- Right sphere — readable labels: A , B (top), D , K (upper right), Q , V (upper interior), R , S , T (central), X , Y , I (centre/lower interior), H (left rim), O , G (right rim), F , N (bottom). : interior labelling near the resolution floor.

8. [Margin: Case 8.] Let AC again be greater than a quadrant, and AB less than a quadrant. The circle $ABDGH$ being completed, and the quadrant AL being cut off from AC , let the great circles DEF , GEH be described about the poles A , B at the distances of the quadrants AL , BC . Likewise, from the pole A , at the distance $A C$, let the lesser circle KCN be drawn, and let the rest be done as in the first case. It will be demonstrated, as there, that the square of the whole sine — namely the rectangle contained by DX , XA — has to the rectangle contained by AV , KY (the right sines of the arcs AB , AC) the same ratio that DZ , the versed sine of the arc DL (or of the angle A), has to KT , the difference of the versed sines BR , BQ of the arcs BC , BK — provided we show the triangles XAV , SKT to be equiangular, as in the seventh case.

Diagram. Pair of circles for Case 8 (AC greater than a quadrant, AB less than a quadrant, BC a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A , B (top), D , K (right rim), H (left rim), E , L , C (interior), G (right rim), F , N (bottom).
- Right sphere — readable labels: A , B (top), V , D , K (upper right), Q (interior), R , Z , S , T (central), K , I , Y (interior), G (right rim), H (left rim), F , N (bottom). : interior labelling near the resolution floor.

9. [Margin: Case 9.] Let AC again be greater than a quadrant, and AB less than a quadrant, but BC also greater than a quadrant. The circle $ABDGH$ being completed, and the quadrants AL , BM being cut off from AC , BC , let the rest be constructed as in the first case. For, as there, so here it will be demonstrated that the square of the whole sine — namely the rectangle contained by DX , XA — has to the rectangle contained by AV , KY (the right sines of the arcs AB , AC) the same

ratio that DZ, the versed sine of the arc DL (or of the angle A), has to KT, the difference of the versed sines BR, BQ of the arcs BC, BK. But that the triangles X A V, S K T are equiangular will be confirmed thus: [Margin: f — Euclid I.15.] The angle KST is equal to the angle ISR. Therefore, in the right-angled triangles SKT, SIR, the remaining angles SKT, SIR will be equal; and hence, in the right-angled triangles SKT, IXY, the remaining angles KST, IXY (that is, AXV, [Margin: g — Euclid I.15.] since this is equal to that same IXY) will be equal to one another. Wherefore the remaining angles SKT, XAV, in the right-angled triangles SKT, XAV, will be equal.

Diagram. Pair of circles for Case 9 (AC and BC greater than a quadrant, AB less than a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A, B (top), D (upper right), K (right rim), H, P (left rim), E, L, M (interior), C (bottom), O, G (right rim), F, N (bottom).
- Right sphere — readable labels: A, B (top), V, D (upper), Q, K (right rim), R, S, T, Z, I, Y (central), J, O (interior right), G (right rim), P, H (left rim), F, N (bottom). : interior labelling near the resolution floor.

10. [Margin: Case 10.] Let the arc AC be greater than a quadrant, and AB a quadrant, but BC less than a quadrant. The circle ABGF being completed, and the quadrant AL being cut off from AC, and BC being produced so that the quadrant BM is formed, let the great circles BLEF, AEMG be described about the poles A, B at the distances of the quadrants AL, BM; and the one will pass through the point B and the other through the point A, on account of the quadrant AB, [Margin: h — Corollary of Theodosius I.16.] because a great circle is distant from a pole by a quadrant of a great circle. Likewise, about the same poles A, B, at the distances AC, BC, let the lesser circles KCN, OCP be drawn, [Margin: i — Theodosius II.2.] which will be parallel to the former. Then, when in another circle the common sections of these circles with the circle A B G F have been drawn, [Margin: k — Euclid XI.16.] which will be parallel to one another and will cut each other at right angles [Margin: l — Scholium on Theodosius I.10.] (for AX, drawn from A, the pole of the circle B F, into X, the centre of the sphere, is at right angles to that circle; and therefore, by the definition [Euclid] Book XI, def. 3, the angles at X will be right; from which it follows [Margin: m — Euclid I.29.] that the angles at R, S, Y are also right, on account of the parallel lines BF, KN and AG, OP): then AV will be the right sine of the quadrant AB; KY the right sine of the arc AC (or of the arc AK, equal to it by the definition of a pole); BR the versed sine of the arc BC (or of the arc BO, equal to it by the definition of a pole); BQ (the perpendicular K-Q having

been drawn to BF) the versed sine of the arc BK, by which the arcs AB, AC differ from each other. Finally KS, the versed sine

Diagram. Pair of circles for Case 10 (AC greater than a quadrant, AB a quadrant, BC less than a quadrant). Left: the spherical construction; right: the rectilinear cross-section.

- Left sphere — readable labels: A, B (top), D, K (right rim), H, P (left rim), E, L, M (interior), C (bottom), O, G (right rim), F, N (bottom).
- Right sphere — readable labels: A, B (top), V, D (upper), Q, K (right rim), R, S, Z, I, Y (central), J, O (interior right), G (right rim), P, H (left rim), F, N, T (bottom). : interior labelling near the resolution floor.

(Continuation of the demonstration of THEOR. 56 / PROPOS. 58 — the fifteen cases of the versed-sine / included-angle proportion. This page carries the end of the tenth case and cases 11–15.)

THEOR. 56. PROPOS. 58 (continued — the fifteen cases)

[10th case — conclusion.] ...the versed sine of arc KC. And so, if DZ is taken — the versed sine of angle A, or arc BL, which is similar to arc KC — we shall show, as in the first case, that the square of the whole sine (namely the rectangle under DX, XA) is to the rectangle under AV, KY, the right sines of arcs AB, AC, as DZ, the versed sine of angle A (or arc BL), is to KT, or to QR, the difference of the versed sines BR, BQ of arcs BC, BK; except that here no equiangular triangles are found, but AV does not differ from XA, just as KS does not differ from KT.

Diagram. The figure for the tenth case, a pair of circular diagrams. LEFT: a sphere (great-circle outline) carrying the spherical triangle and auxiliary arcs; RIGHT: a circle divided into quadrants by two perpendicular diameters, showing the "unrolled" sine/versed-sine construction. Legible perimeter labels — LEFT: B (top), K (top right), P (left), O (right), A (lower left), G (right), N (lower right), F (bottom); interior reads approximately c, L, E, M [interior lettering at the resolution floor]. RIGHT: B, D (top), K (top right), O (right), A (left), G (right), N (lower right), F (bottom); interior reads approximately Q, Z, X, R, T, S, V, Y [interior lettering at the resolution floor].

- Interior point-letters not securely resolvable at this resolution

11. [Margin: 11. casus.] Again, let AC be greater than a quadrant, but both AB and BC quadrants. With circle ABGF completed and the quadrant AE cut off from AC, let there be described from pole A, at the intervals AE, AC, the circles BEF, kCN,

and from pole B, at the interval BC, the circle AEG; and let the rest be constructed as in the preceding case. We shall therefore show, as in the first case, that the square of the whole sine — that is, the rectangle under DX, XA — is to the rectangle under AV, kY, the right sines of arcs AB, AC, as DZ, the versed sine of angle A (or arc BE), is to kT, or QR, the difference of the versed sines BR, BQ of arcs BC, Bk; except that here no equiangular triangles are present, just as in the preceding case, and AV does not differ from XA, nor DZ from BR, nor kS from kT.

Diagram. The figure for the eleventh case, again a sphere (LEFT) paired with the quadrant-divided circle (RIGHT). Legible perimeter labels — LEFT: B (top), K (top right), A (left), G (right), N (lower right), F (bottom); interior reads approximately E, C. RIGHT: B, D (top), K (top right), G (right), N (lower right), F (bottom); interior reads approximately Q, X, z, V, R, T, S, Y [interior lettering at the resolution floor].

- Interior point-letters not securely resolvable

12. [Margin: 12. casus.] Let arc AC be greater than a quadrant, and AB a quadrant, but BC also greater than a quadrant. With circle ABGF completed and the quadrants AL, BM taken away from arcs AC, BC, let circles be described from poles A, B at the intervals of the quadrants AL, BM and of the arcs AC, BC, and let everything else be done as before. Then again, as was demonstrated in the first case, the square of the whole sine — that is, the rectangle under DX, XA — will be to the rectangle under AV, kY, the right sines of arcs AB, AC, as DZ, the versed sine of angle A (or arc EL), is to KT, the difference of the versed sines BR, BQ of arcs BC, BK; although here no equiangular triangles appear, but XA and AV do not differ from each other, just as neither do kS, kT.

Diagram. The figure for the twelfth case: sphere (LEFT) with the quadrant-divided circle (RIGHT). Legible perimeter labels — LEFT: B (top), K (top right), A (left), G (right), P (lower left), O (right), N (lower right), F (bottom); interior reads approximately E, M, L, c. RIGHT: B, D (top), K (top right), G (right), P (lower left), O (right), A (left), N (lower right), F (bottom); interior reads approximately Q, X, V, R, S, Y, z, T [interior lettering at the resolution floor].

- Interior point-letters not securely resolvable

13. [Margin: 13. casus.] Let the arcs AC, AB be greater than a quadrant, but BC less than a quadrant. With circle ABGF completed and the quadrant AL cut off from AC, and arc BC likewise produced so that BM becomes a quadrant, let the rest be done as above. We shall now show, as in the first case, that the square of the whole sine — namely the rectangle under DX, XA — is to the rectangle under AV, kY, the right sines of arcs AB, AC, as DZ, the versed sine of angle A (or arc DL), is

to kT , the difference of the versed sines BR , BQ of arcs BC , Bk ; except that the triangle XAV must be shown to be equiangular with triangle SkT in this way. [Margin: a — 29. primi (Euclid, *Elements* I.29)] Since angle kST is equal to the opposite interior angle YIX , then in the right triangles SkT , IXY the remaining angle SkT will also be equal to the remaining angle IXY — that is, to the opposite interior angle VAX (since AV , GH are parallel). Therefore in the right triangles SkT , XAV the remaining angles kST , AXV will also be equal, and hence the triangles SkT , XAV will be equiangular.

Diagram. The figure for the thirteenth case: sphere (LEFT) with the quadrant-divided circle (RIGHT). Legible perimeter labels — LEFT: D , B (top), K (top right), P (upper left), H (left), A (lower left), G (center), O , p (right), N (lower right), F (bottom); interior reads approximately L , C , E . RIGHT: D , B (top), K (top right), O (right), A (left), G (right), H (left), N (lower right), F (bottom); interior reads approximately Q , z , R , T , X , V , I , Y , S [interior lettering at the resolution floor].

- Interior point-letters not securely resolvable

14. [Margin: 14. casus.] Again, let AC , AB be greater than a quadrant, but BC a quadrant. With circle $ABGF$ completed and the quadrant AL cut off from AC , and with the circles DEF , kCN described from pole A at the intervals AL , AC , let there also be described from pole B , at the interval of the quadrant BC , the great circle GEH ; and let the other things be done as above. It must therefore be shown that the square of the whole sine — that is, the rectangle under DX , XA — is to the rectangle under AV , kY , the sines of arcs AB , AC , as DZ , the versed sine of angle A (or arc DL), is to kT , the difference between the versed sines BR , BQ of arcs BC , Bk . This indeed we shall show as in the first case. Only the triangles SkT , XAV will be proved to be equiangular, in this way. Angle S is common to both right triangles SkT , SRY . Therefore the remaining angle SkT will be equal to the remaining angle SRY — [Margin: b — 29. primi (Euclid, *Elements* I.29)] that is, to the opposite interior angle VAX (since AV , GH are parallel). Hence the right triangles SkT , XAV will be equiangular.

Diagram. The figure for the fourteenth case: sphere (LEFT) with the quadrant-divided circle (RIGHT). Legible perimeter labels — LEFT: D , B (top), K (top right), H (left), A (lower left), G (center right), N (lower right), F (bottom); interior reads approximately E , L , C , H . RIGHT: D , B (top), K (top right), G (right), A (left), N (lower right), F (bottom); interior reads approximately Q , x , R , Y , T , S , V , z [interior lettering at the resolution floor].

- Interior point-letters not securely resolvable

15. [Margin: 15. casus.] Finally, let all three arcs of triangle ABC be greater than a quadrant. With circle ABGF completed and the quadrants AL, BM cut off from arcs AC, BC, let everything else be done as before. We shall show, just as in the first case, that the square of the whole sine — namely the rectangle under DX, XA — is to the rectangle under AV, kY, the right sines of arcs AB, AC, as DZ, the versed sine of angle A (or arc DL), is to kT, the difference between the versed sines BR, BQ of arcs BC, Bk; provided only that we conclude the triangles SkT, XAV to be equiangular, by this argument. [Margin: c — 29. primi (Euclid, *Elements* I.29)] Angle YIX is equal to the interior and opposite angle kST. Therefore in the right triangles SkT, IXY the remaining angle SkT will be equal to the remaining angle IXY — [continues on p. 217] that is, to the interior and opposite angle XAV (since AV, GH are parallel); and hence the right triangles SkT, XAV will be equiangular.

Diagram. The figure for the fifteenth case: sphere (LEFT) with the quadrant-divided circle (RIGHT). Legible perimeter labels — LEFT: D, B (top), K (top right), H (left), A (lower left), G (center right), o (center), P (lower left), N (lower right), F (bottom); interior reads approximately E, M, L, c. RIGHT: D, B (top), K (top right), G (right), o (center), A (left), P (lower left), N (lower right), F (bottom); interior reads approximately Q, x, Y, V, R, S, z, T [interior lettering at the resolution floor].

- Interior point-letters not securely resolvable

that is, to the interior and opposite angle XAV (since AV, GH are parallel); and hence the right triangles SKT, XAV will be equiangular. Therefore, in every spherical triangle whose two arcs are unequal, etc. Which was to be demonstrated.

SCHOLIVM I.

From all fifteen cases of this demonstration it is clear that arc BC — which is opposite angle A and is subtended by the unequal arcs — is always greater than arc BK, that is, greater than the difference of the unequal arcs. For in all the figures arc BC is, by the definition of a pole, equal to arc BO (or to arc BG, when BC is a quadrant, as in cases 2, 5, 8, 11, and 14). But it is established that arc BO (or arc BH, in the said five cases) is greater than arc BK — and that this is so, the following theorem too will easily demonstrate.

In every spherical triangle whose two arcs are unequal, the remaining arc is greater than the arc by which the unequal arcs differ from each other.

For in triangle ABC, let arc AB be greater than arc AC, and from pole A, at the interval AC, let the arc of a circle CD be described. Then arc AD will be equal to arc AC by the definition of a pole, and so arc BD is the difference of the unequal arcs AB, AC. I say that arc BC is greater than arc BD. [Margin: a — 3. huius (Proposition 3 of this treatise)] For since the two arcs AC, CB together are greater than arc AB, when the equal arcs AC, AD are removed, the remainder CB will also be greater than the remainder BD. Which is what was proposed.

Diagram. A spherical triangle with vertices A (top), B (lower left), and C (lower right); point D lies on side AB (nearer B), and the arc DC is drawn across the interior. This illustrates arc BD as the difference of the unequal sides AB, AC.

And so, in every spherical triangle whose two arcs are unequal, the versed sine of the remaining arc is always greater than the versed sine of the difference of the unequal arcs. For since that remaining arc has been shown to be greater than that difference, and a greater arc always has a greater versed sine (as is established from the treatment of sines), it is evident that the versed sine of the remaining arc is greater than the versed sine of the difference of the unequal arcs.

[Margin: In a spherical triangle of two unequal arcs, the versed sine of the third arc is greater than the versed sine of the difference of the unequal arcs.]

I have said this so that you may see the reason why, in practice — at Proposition 64 — the difference between the two versed sines (of which one belongs to the remaining third arc, the other to the difference of the unequal arcs) is directed to be *added* to the versed sine of the difference of the unequal arcs, in order to compose the versed sine of the remaining third arc; but it is never to be *subtracted* from the versed sine of that difference so as to leave the versed sine of the remaining arc.

SCHOLIVM II.

Moreover, from this Proposition 58 we shall gather the following theorem, very useful for the calculation of non-right spherical triangles, namely:

In every spherical triangle whose two arcs are unequal: the whole sine has to the quantity which is the fourth proportional to the whole sine and the two sines of the unequal arcs the same ratio as the versed sine of the angle contained by the said arcs has to the difference between the versed sine of the remaining third arc and the versed sine of the arc by which the two unequal arcs differ from each other.

In the spherical triangle ABC — as in the immediately preceding proposition — let arc AB be greater than arc AC, and from pole A, at the interval AC, let the arc of a circle CD be described, so that arcs AC, AD are equal by the definition of a pole, and thus arc BD is the excess, or difference, of the arcs AB, AC. Now let it be arranged that, as the whole sine is to the sine of arc AB, so the sine of arc AC is to another quantity — which is to be called the fourth proportional — as you see here:

Diagram. The same spherical-triangle construction reprinted for this scholium: A (top), B (lower left), C (lower right); D on side AB (nearer B), with arc DC drawn across the interior.

Whole sine.	Sine of arc AB.	Sine of arc AC.	Fourth proportional quantity.

I say that the whole sine is to the fourth-proportional quantity (proportional to the whole sine and the two sines of the unequal arcs) as the versed sine of angle A is to the difference between the versed sine of arc BC and the versed sine of arc BD, by which the arcs AB, AC differ from each other. For the ratio of the whole sine to the fourth-proportional quantity is compounded (taking the sine of arc AB as the mean) of the ratio of the whole sine to the sine of arc AB and the ratio of the sine of arc AB to the fourth-proportional quantity. And the ratio of the square of the whole sine to the rectangle under the right sines of arcs AB, AC [Margin: b — 23. sexti (Euclid, *Elements* VI.23)] is compounded of the same ratios — namely, of the ratio of the whole sine to the sine of arc AB, and of the ratio of the whole sine to the sine of arc AC, which is the same as the ratio of the sine of arc AB to the fourth-proportional quantity. (For since, as the whole sine is to the sine of arc AB, so the sine of arc AC is to the fourth-proportional quantity, then by alternation, as the whole sine is to the sine of arc AC, so the sine of arc AB is to the fourth-proportional quantity.) Therefore, as the whole sine is to the fourth-proportional quantity, so is the square of the whole sine to the rectangle contained by the sines of arcs AB, AC. [Margin: c — 58. huius [?]] (Proposition 58 of this treatise; the reference-word after the numeral is only partly legible)] Since, then, as the square of the whole sine is to the rectangle under the sines of arcs AB, AC, so the versed sine of angle A is to the difference of the versed sines of arcs BC, BD, it will follow also that, as the whole sine is to the fourth-proportional quantity, so the versed sine of angle A is to the difference between the versed sines of arcs BC, BD. Which is what was proposed.

THEOR. 57. PROPOS. 59.

If two spherical triangles have two angles equal to two angles, each to each: then the sines of the arcs about the remaining angle of the one will be proportional to the sines of the arcs about the remaining angle of the other, and the sines of the arcs subtending the equal angles will be corresponding [homologous]. And if one angle of the one is equal to one angle of the other, and the sines of the arcs about another angle of the one are proportional to the sines of the arcs about another angle of the other — in such a way that the sines of the arcs subtending the equal angles are corresponding — then the angles opposite the arcs of the remaining corresponding sines will also be equal to each other, or equal to two right angles.

In the two spherical triangles ABC, DEF let the two angles B, E be equal to each other, as well as the two angles C, F. I say that the sine of arc AB is to the sine of arc AC as the sine of arc DE is to the sine of arc DF. [Margin: a — 41. huius (Proposition 41 of this treatise)] For since the sine of arc AB is to the sine of angle C as the sine of arc AC is to the sine of angle B, then by alternation the sine of arc AB will be to the sine of arc AC as the sine of angle C is to the sine of angle B — that is, as the sine of angle F is to the sine of angle E, since these angles are assumed equal to those. [Margin: b — 41. huius (Proposition 41 of this treatise)] Likewise, since the sine of arc DE is to the sine of angle F as the sine of arc DF is to the sine of angle E, then by alternation the sine of arc DE will be to the sine of arc DF as the sine of angle F is to the sine of angle E. But it has been shown that the sine of arc AB is to the sine of arc AC also as the sine of angle F is to the sine of angle E. Therefore the sine of arc AB will be to the sine of arc AC as the sine of arc DE is to the sine of arc DF. Which is what was proposed.

Diagram. Two right triangles side by side. The first has vertices A (top), B (lower left), C (lower right), with a right-angle mark and a small arc marking the angle at the base. The second, congruent in form, has vertices D (top), E (lower left), F (lower right), similarly marked. The two figures illustrate the correspondence of the equal angles at B and E.

But now let the angles B, E be equal, and let the sine of arc AB be to the sine of arc AC as the sine of arc DE is to the sine of arc DF. I say that the angles C, F are also equal, or at least equal to two right angles. [Margin: c — 41. huius (Proposition 41 of this treatise); *Et permutando* — and by alternation] For we shall show, as before, that the sine of arc AB is to the sine of arc AC as the sine of angle C is to the sine of angle B; likewise that the sine of arc DE is to the sine of arc DF as the

sine of angle F is to the sine of angle E. Therefore, since it is assumed that the sine of arc AB is to the sine of arc AC as the sine of arc DE is to the sine of arc DF, it will follow that the sine of angle C is to the sine of angle B as the sine of angle F is to the sine of angle E; and by inversion, the sine of angle B is to the sine of angle C as the sine of angle E is to the sine of angle F. Since, then, the sines of the equal angles B, E are equal, [Margin: d — 14. quinti (Euclid, *Elements* V.14)] the sines of the angles C, F will also be equal; and hence the angles C, F will either be equal to each other, or equal to two right angles. Which is what was proposed. And so, if two spherical triangles have two angles [equal to two angles], etc. Which was to be demonstrated.

SCHOLIVM

But if the angles B, E, or C, F, were not equal, but only equal to two right angles, the truth of the theorem would still be preserved: because the angles B, E always have equal right sines, whether they are equal to each other or equal to two right angles. The same must be said of the angles C, F. This can be clearly established from what we have set out in the treatment of sines.

THEOR. 58. PROPOS. 60.

If from an angle of a spherical triangle an arc of a great circle is dropped to the base, dividing the angle into two equal parts: then the sines of the segments of the base will have the same ratio as the sines of the remaining two arcs [sides]. And if the sines of the segments of the base have the same ratio as the sines of the remaining two arcs, then the dropped arc will divide the angle into two equal parts.

In the spherical triangle ABC, let arc AD bisect angle A. I say that the sine of arc AB is to the sine of arc AC as the sine of arc BD is to the sine of arc DC. [Margin: a — 19. huius, & eius scholium (Proposition 19 of this treatise, and its scholium)] For since the triangles ABD, ACD have their angles at A equal, and their angles at D equal to two right angles, it will follow that the sine of arc AB is to the sine of arc BD as the sine of arc AC is to the sine of arc CD; and by alternation, the sine of arc AB is to the sine of arc AC as the sine of arc BD is to the sine of arc DC. Which is what was proposed.

Diagram. A spherical triangle with vertices A (top), B (lower left), C (lower right), and D on the base BC between B and C. The arc AD is drawn from the apex A down to D, dividing angle A; it illustrates the bisector dropped to the base.

But now let the sine of arc AB be to the sine of arc AC as the sine of arc BD is to the sine of arc DC. I say that angle A is bisected. For by alternation it will also follow that the sine of arc AB is to the sine of arc BD as the sine of arc AC is to the sine of arc CD. The triangles ABD, ACD therefore have their angles at D equal to two right angles, and the sines of the arcs about the angles B, C proportional, and the sines of the arcs opposite the angles at D are corresponding. [Margin: b — 59. huius, & eius scholium (Proposition 59 of this treatise, and its scholium)] Therefore the angles at A will either be equal to each other, or equal to two right angles. But they cannot be equal to two right angles, since angle A is less than two right angles. Therefore they will be equal to each other. Which is what was proposed. If, then, from an angle of a spherical triangle to the base [an arc is dropped], etc. Which was to be shown.

THEOR. 59. PROPOS. 61.

If from an angle of a spherical triangle a perpendicular arc is dropped to the base — or even to the base produced — then the sines of the angles that the perpendicular arc makes with the two arcs enclosing the said angle will stand in the same ratio as the sines of the complements of the remaining two angles of the triangle.

In triangle ABC let a perpendicular arc AD be drawn from angle A to the base BC, falling either inside the triangle or outside it; and let neither of the angles B, C, nor either of the angles BAD, DAC formed at A, be a right angle. (For whenever one of these is a right angle, the proposition will be demonstrated in the scholium; and likewise, whenever both B and C, or one of them, is a right angle, the same scholium will state what follows.) I claim that the sine of angle BAD is to the sine of angle DAC as the sine of the complement of angle B is to the sine of the complement of angle C.

For in triangle ABD, whose angle D is right, [Margin: a. Prop. 42 of this treatise (42. huius).] the sine of angle BAD will be to the whole sine [radius] as the sine of the complement of angle B is to the sine of the complement of arc AD. Likewise in triangle CAD, which has angle D right, the sine of angle DAC will be to the whole sine as the sine of the complement of angle C (for the two angles at C in the second triangle have the same sine) is to the sine of the complement of arc AD. Then, by inversion, the whole sine is to the sine of angle DAC as the sine of the complement of arc AD is to the sine of the complement of angle C. Therefore, by equal proportion (*ex aequalitate*) — as you see in the accompanying formula — the sine of angle BAD is to the sine of angle DAC as the sine of the complement of angle B is to the sine of the complement of angle C.

[Proportion formula, as printed:]

(Left terms)	(Right terms)
Sin. ang. BAD. (sine of angle BAD)	Sin. compl. ang. B. (sine of the complement of angle B)
Sinus totus. (whole sine / radius)	Sin. compl. arcus AD. (sine of the complement of arc AD)
Sin. ang. DAC. (sine of angle DAC)	Sin. compl. ang. C. (sine of the complement of angle C)

So then, "if from an angle of a spherical triangle to the base...", etc. — which was to be demonstrated.

Diagram. Two triangles set side by side, each drawn with an apex A from which a perpendicular AD descends to the base. In the left figure the perpendicular AD falls inside the triangle; in the right figure it falls outside. Read on the leaf:

- A (apex, left figure): vertex from which AD is dropped
- B (base, far left of left figure): left base vertex
- D (base, center of left figure): foot of the perpendicular, lying between B and C (perpendicular falls inside)
- C (base, right of left figure): right base vertex
- A (apex, right figure): vertex from which AD is dropped
- B (base, far left of right figure): left base vertex
- C (base, center of right figure): right base vertex of the triangle
- D (base, far right of right figure): foot of the perpendicular, lying beyond C on the base produced (perpendicular falls outside)

SCHOLIVM.

If both angles B and C are right, the proposition will not be true unless the perpendicular arc AD bisects the base BC. [Margin: b. Prop. 7 of this treatise (7. *huius*).] For then the angles at A will also be equal, and so their sines will be in a ratio of equality — the very ratio that the sines of the complements of the right angles B, C also have, since these complements are Nothing [zero].

But if only one of the angles B, C is right, the proposition will in no way be true. For since the complement of a right angle is Nothing, the sines of the complements of B and C cannot have the same ratio as the sines of the angles

formed at A: that former ratio would be Nothing to something, or something to Nothing, whereas this latter is something to something.

Now if it should happen that one of the angles formed at A is right, the proposition must be demonstrated in the following way. First let angle BAD be right. [Margin: c. Prop. 25 of this treatise (25. *huius*).] Then AB and DB are quadrants, and therefore AD is the arc measuring angle B. Hence the sine of the right angle BAD will be to the whole sine as the sine of the complement of angle B is to the sine of the complement of arc AD, since in both cases the ratio is one of equality — for the complement of angle B and the complement of arc AD are the same, seeing that AD is the arc measuring angle B. Again, since the sine of angle DAC (which is always less than the right angle BAD, because the whole angle BAC is less than two right angles, as in the earlier figure; while in the later figure DAC is itself part of the right angle BAD) is to the whole sine as the sine of the complement of angle C is to the sine of the complement of arc AD, [Margin: d. Prop. 42 of this treatise (42. *huius*).] by inversion the whole sine will be to the sine of angle DAC as the sine of the complement of arc AD is to the sine of the complement of angle C. Therefore, as before, it will follow by equal proportion that the sine of the right angle BAD is to the sine of angle DAC as the sine of the complement of angle B is to the sine of the complement of angle C — which was proposed.

Next let angle DAC be right. [Margin: e. Prop. 25 of this treatise (25. *huius*).] Then AC and DC are quadrants, and therefore AD is the arc measuring angle C. And since the sine of angle BAD (which in the first figure is less than a right angle, but in the second is greater) is to the whole sine as the sine of the complement of angle B is to the sine of the complement of arc AD; and likewise the whole sine is to the sine of the right angle DAC as the sine of the complement of arc AD is to the sine of the complement of angle C — the ratio being one of equality in both cases, for the complement of arc AD and of angle C are the same, since AD is the arc measuring angle C — [Margin: f. Prop. 42 of this treatise (42. *huius*).] it will follow by equal proportion, as before, that the sine of angle BAD is to the sine of the right angle DAC as the sine of the complement of angle B is to the sine of the complement of angle C. Which was proposed.

Further, it must be understood here that when neither of the angles B, C, and likewise neither of the angles BAD, DAC formed at A, is right — as is assumed in the demonstration of the proposition — no arc in the triangles ABD, ACD is a quadrant. For if one were a quadrant, then since angle D is right, there would be at least two quadrants, by the Corollary of Prop. 38 of this treatise; [Margin: g.

Prop. 25 of this treatise (25. *huius*.)] and consequently at least two angles would be right, which is not assumed. By the same reasoning, when one of the angles at A is right, no arc in the triangle whose angle A is less than a right angle is a quadrant, as is taken in the demonstration of the scholium. For then neither of the angles B, C can be right, because — the angles at A being unequal — the proposition would have no place, as has been shown in this scholium.

PROBL. 3. PROP. 62.

Given all the angles of a non-right spherical triangle, to make all three arcs [sides] known.

In the non-right spherical triangle ABC let all the angles A, B, C be given; and first let all three angles be unequal. [Margin: When all three given angles are unequal.] From these we must determine its three arcs. Since no angle is assumed right, at least two of them are either acute or obtuse: let B and C be either both acute or both obtuse, whatever the case with the remaining angle A, from which to the arc BC

let the perpendicular arc AD be drawn, [Margin: a. Prop. 57 of this treatise (57. *huius*.)] which will necessarily fall inside the triangle. [Margin: b. Prop. 61 of this treatise (61. *huius*.)] And since the sine of angle BAD is to the sine of angle DAC as the sine of the complement of angle B is to the sine of the complement of angle C, and this latter ratio is given in the sines of the complements of the given angles B, C, the ratio of the sine of angle BAD to the sine of angle DAC will likewise be given, namely in the sines of the complements of angles B, C. But the sum of the same two angles BAD, DAC is also given, and is less than a semicircle — namely the whole angle BAC, which is less than two right angles. [Margin: c. Prop. 6 of the [treatise on] rectilinear triangles (6. *triang. rectilinei*.)] Therefore each of the angles BAD, DAC will be known separately. Since, then, in triangle ABD, whose angle D is right, two non-right angles B and BAD are given, [Margin: d. Scholium of Prop. 50 of this treatise (*Schol. 50. huius*.)] the arc AB opposite the right angle will also be given. And from this — since in the same triangle ABD, which has the right angle D, the arc AB opposite the right angle is known, together with the non-right angle BAD:

Or else, since two non-right angles B and BAD are given,

the arc BD about the right angle, opposite angle BAD, will also become known, from the scholia cited in the margin. [Margin: e. Scholium of Prop. 41 of this treatise (*Schol. 41. huius*); Scholium of Prop. 42 or of Prop. 52 (*Schol. 42 vel 52. hu.*.)] By the same reasoning, since in triangle ACD, whose angle D is right, two

non-right angles C and CAD are given, [Margin: f. Scholium of Prop. 50 of this treatise (*Schol. 50. huius*).] the arc AC opposite the right angle will also be given. And from this — since in the same triangle ACD, which has the right angle D, the arc AC opposite the right angle is now known, together with the non-right angle CAD:

Or else, since two non-right angles C and CAD are given,

the arc CD about the right angle, opposite angle CAD, will likewise be known, from the same scholia adduced in the margin. [Margin: g. Scholium of Prop. 41 of this treatise (*Schol. 41. huius*); Scholium of Prop. 42 or of Prop. 52 (*Schol. 42 vel 52. hu.*).] And so now the two arcs AB, AC are known; while the sum of the two arcs BD, CD found in this way will also make the third arc BC known.

But if it should happen that one of the angles at A, namely BAD, is found to be right, then since D is also right, [Margin: h. Prop. 25 of this treatise (*25. hui.*).] both arcs AB, BD will be quadrants, and so the said arcs will be found without any trouble. By the same reasoning, if angle CAD is found to be right — but not BAD (for it cannot happen that both angles at A are right, since angle BAD is less than two right angles) — the arcs AC, CD will be quadrants, and hence known, without further labor.

Diagram. A single spherical triangle with curved sides. Read on the leaf:

- A (apex): vertex from which the perpendicular is dropped
- B (base, left): left base vertex
- D (base, center): foot of the perpendicular arc AD on the base
- C (base, right): right base vertex

The practical procedure (*praxis*) for this problem need not be explained here at greater length, since it is to be sought from Prop. 6 of the [treatise on] rectilinear triangles and from the scholia written in the margin. [Margin: Praxis, when all three given angles are unequal.] For if two sines of the complements of the acute or obtuse angles B, C are set down as the terms of the ratio of the sine of angle BAD to the sine of angle CAD, we shall find each of the angles BAD, CAD by the first or second procedure of Prop. 6 of the rectilinear triangles, because these are more expeditious than the third. [Margin: Prop. 6 of the [treatise on] rectilinear triangles is also to be understood of spherical angles.] For although that Prop. 6 is stated only of rectilinear arcs and angles, it is nevertheless to be understood of spherical angles as well, since their sines do not differ from the sines of the arcs of those same angles. Once each angle BAD, CAD has been found, the procedure of the problem of the scholium of Prop. 50 of this treatise must be applied, in

order that both the arc AB (opposite the right angle D in triangle ABD) and the arc AC (opposite the right angle D in triangle ACD) may be found. Finally, the procedure of Problem 2 of the scholium of Prop. 41, or of Problem 1 of the scholium of Prop. 42, or indeed the procedure of the scholium of Prop. 52, must be brought in, to elicit both the arc BD (opposite the non-right angle BAD in triangle ABD) and the arc CD (opposite the non-right angle CAD in triangle ACD).

[Margin: Praxis by sines alone, when all three given angles are unequal.] But if in unraveling this problem one wishes to use sines alone, each of the angles BAD, CAD must be found by the third procedure of Prop. 6 of the rectilinear triangles, and not by the first or second. Then, from the procedure of Problem 1 of the scholium of Prop. 42 of this treatise, both the arc BD (opposite the non-right angle BAD in triangle ABD) and the arc CD (opposite the non-right angle CAD in triangle ACD) are to be elicited. Lastly, by the procedure of Problem 3 of the scholium of Prop. 41, both the arc AB and the arc AC (each opposite the right angle D in its own triangle) are to be investigated. For besides the arc BD already found and its opposite angle BAD, and besides the arc CD already found and its opposite angle CAD, the kind [species — acute or obtuse] of each of the angles B and C is also established, since each of them is given.

This problem becomes far easier when all three given angles, or at least two, are equal. [Margin: When all three given angles, or at least two, are equal. i. Prop. 9 of this treatise (9. *huius*). k. Prop. 57 (57. *huius*). l. Prop. 21 (21. *huius*).] For if, say, two angles B, C are equal — whatever the case with the remaining angle A — the arcs AB, AC will also be equal. And since the triangle ABC is assumed non-right, each of the equal angles B, C will be either acute or obtuse; hence the perpendicular arc AD, dropped from the third angle A to the arc BC, will fall inside the triangle. Now since the triangles ABD, ACD have their angles at D right and their non-right angles B, C equal, and also their arcs AB, AC (opposite the right angles) equal, as we have shown, the arcs BD, CD and the angles BAD, CAD will be equal too; and consequently each angle BAD, CAD, being half of the given angle BAC, will be known. After this, since in triangle ABD, which has the right angle D, both non-right angles B and BAD are given, [Margin: m. Scholium of Prop. 50 of this treatise (*Schol. 50 huius*).] the arc AB opposite the right angle will also be given, and therefore AC, equal to it, will be known. And so now the two arcs AB, AC have been made known. Again, since in the same triangle ABD two non-right angles B and BAD are given:

Diagram. A single (isosceles) spherical triangle with curved sides, illustrating the case of two equal angles. Read on the leaf:

- A (apex): vertex from which the perpendicular is dropped
- B (base, left): left base vertex
- D (base, center): foot of the perpendicular arc AD, at the midpoint of the base
- C (base, right): right base vertex

Or, since the arc AB opposite the right angle is given, together with the non-right angle B:

Or finally, since the arc AB is given, opposite the right angle, together with the non-right angle BAD;

the arc BD about the right angle will also be known; [Margin: n. Scholium of Prop. 42 or of Prop. 52 (*Schol. 42 vel 52. hui.*); Scholium of Prop. 45 of this treatise (*Schol. 45 huius*); Scholium of Prop. 41 of this treatise (*Schol. 41. huius*).] and when this is doubled, it will exhibit the whole third arc BC as known. Therefore all three arcs sought have been made known.

The practical procedure for this matter is not obscure, for it depends on the scholia cited in the margin. [Margin: Praxis by sines alone, when all three given angles, or at least two, are equal.] But if one wishes to use sines alone, then in triangle ABD — in which angle B is given, and angle BAD, namely half of the given angle BAC — the arc BD must be sought by Problem 1 of the scholium of Prop. 42 of this treatise; and this arc BD, doubled, will give the whole arc BC. Then, by Problem 3 of the scholium of Prop. 41, in the same triangle, in which the arc BD and its opposite angle BAD have been found, and in which the kind of the other non-right angle B is established as given, the arc AB opposite the right angle must be elicited; and once this is found, its equal AC will also be found.

Therefore, given all the angles of a non-right spherical triangle, we have made all three arcs known. Which was to be done.

SCHOLIVM.

A non-right spherical triangle therefore differs, as you see, from a non-right rectilinear one: in the spherical case all the arcs are found from the given angles alone, as has been shown in this problem; but in the rectilinear case the sides cannot be known from the given angles alone, unless at least one side is also given. The reason for this is that two rectilinear triangles, though similar, may have the sides of one very unequal to the sides of the other, side for side, and yet have their angles equal, angle for angle — so that two rectilinear triangles may be given which are indeed equiangular with each other, but not equilateral.

[Margin: o. Prop. 19 of this treatise (19. *huius*.)] But two spherical triangles cannot be equiangular with each other without also being equilateral. From this it comes about that in a spherical triangle the arcs are also given from the given angles, since determinate arcs correspond to the angles; whereas in a rectilinear triangle the sides cannot be given from the given angles, since determinate sides do not correspond to the angles, but sides greater or smaller may be subtended under the same angles.

PROBL. 4. PROP. 63.

Given all the arcs [sides] of a non-right spherical triangle, to find all three of its angles.

In the non-right spherical triangle ABC let all three arcs be given. From these we must find all three angles. Let angle A be sought in the first place — for we do not always need all the angles; rather, very often one or another is to be sought from the given arcs. Now the two arcs AB, AC enclosing angle A (which is being sought) are either unequal or equal. If unequal, then either both are less than a quadrant, or both greater, or one greater and the other less, or one a quadrant and the other less than a quadrant, or finally one a quadrant and the other greater than a quadrant. For both cannot be quadrants, [Margin: a. Prop. 25 of this treatise (25. *huius*.)] When the two arcs enclosing the angle to be found in the first place are unequal.] since then the two angles opposite them would be right — which would be absurd, the triangle being assumed non-right.

First let the two arcs AB, AC be unequal and less than a quadrant, whatever the case with arc BC. With the arcs AB, AC produced so as to become the quadrants AD, AE, let the arc of a great circle DE be described through D, E, meeting the arc BC — produced in either direction — at F. (I would urge, however, that it be produced toward the greater arc, which here is AC.) The angles D, E will be right, because AD, AE are quadrants. Since, then, the two great circles BF, DF intersect at F, and from the points B, C perpendicular arcs BD, CE have been dropped from arc BF to arc DF, [Margin: b. Prop. 40 of this treatise (40. *huius*.)] the sine of arc BF will be to the sine of arc BD as the sine of arc CF is to the sine of arc CE; and by alternation, the sine of arc BF will be to the sine of arc CF as the sine of arc BD is to the sine of arc CE. But the ratio of the sine of arc BD to the sine of arc CE is given, since the arcs BD, CE are given, being the complements of the given arcs AB, AC. Therefore the ratio of the sine of arc BF to the sine of arc CF will also be given, namely in the sines of the complements of the given arcs AB, AC. But the difference of these same arcs BF, CF — each of which is less than a semicircle — is also given, [Margin: c. Prop. 2 of this treatise (2. *huius*.)] namely the arc BC.

[Margin: d. [treatise on] rectilinear triangles (*triang. rectilinea*).] Therefore each arc BF, CF will be made known. And so, since in triangle BFD, which has angle D right, the arc BF opposite the right angle is given, together with the arc BD (namely the complement of the given arc AB), [Margin: e. Scholium of Prop. 53 or of Prop. 43 of this treatise (*Schol. 53 vel 43. hu.*).] the third arc DF will also be known. By the same reasoning, since in triangle CFE, which has angle E right, the arc CF opposite the right angle is given, together with the arc CE (namely the complement of the given arc AC), [Margin: f. Scholium of Prop. 53 or of Prop. 43 of this treatise (*Schol. 53 vel 43. hu.*).] the third arc EF will also be known; and this, subtracted from the arc DF already found, will make known the remaining arc DE, which measures angle A. And so angle A will be known. Again, in the earlier triangle BFD, whose angle D is right, since the arc BF opposite the right angle is given, together with the arc BD (namely the complement of the given arc AB):

Or, since the two arcs BD, DF about the right angle are given:

Or finally, since the arc BF opposite the right angle is given, together with the arc DF;

Diagram. The construction for Problem 4: a spherical triangle ABC whose sides AB, AC are produced to the quadrant endpoints D, E, with the great-circle arc DE meeting BC produced at F. Read on the leaf:

- A (top): apex of the triangle
- B (left): base vertex; arc AB is produced through B down to D
- C (center): base vertex; the base arc runs from B through C on to F
- F (right): point where arc DE (produced) meets arc BC produced
- D (lower left): quadrant endpoint on arc AB produced; foot of perpendicular BD (angle D right)
- E (lower center): quadrant endpoint on arc AC produced; foot of perpendicular CE (angle E right)

Continuation of the case-by-case solution of oblique spherical triangles (given the sides, to find the angles), from the commentary on the problem begun in the preceding pages (PROBL. 4 / PROPOS. 63). The oblique triangle is split by a dropped perpendicular (or by quadrant-extension) into two right-angled sub-triangles, each solved by the rules for right spherical triangles; the alternatives keyed by "OR" / "OR finally" (VEL / AVT) enumerate the several given-and-unknown combinations. The superscript letters key the marginal citations to Clavius's own propositions and scholia ("of this treatise") and to Theodosius.

[the angle DBF] will also be found, from the scholia cited in the margin; and hence the remaining angle ABC of the two right triangles will be known. By the same reasoning, since in the latter triangle CFE, which has the right angle E, the arc CF (the one opposite the right angle) is given together with arc CE — namely the complement of the given arc AC:

[Margin: f: Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 55, or prop. 41, of this treatise.]

OR, when the two arcs CE, EF about the right angle are given:

OR finally, when arc CF (opposite the right angle) is given, together with arc EF as well;

the angle ECF will also become known, from the scholia set in the margin; and therefore the angle ACB — which is equal to it as a vertical angle — will be known. So all three angles of triangle ABC have now been found.

[Margin: g: Scholium of prop. 41, or prop. 45, of this treatise; Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 55, or prop. 41, of this treatise.]

[Margin: h: prop. 6 of this treatise.]

Next, let the two unequal arcs AB, AC be greater than a quadrant. Let them be produced until they meet at D. In triangle DBC the two arcs DB, DC will be less than a quadrant, and hence known, since they are the remainders left out of the arcs ABD, ACD — which are semicircles. Therefore, as we demonstrated just above, all three of its angles will become known; and consequently the remaining angles of the two right triangles, ABC and ACB, as well as angle A, since it is equal to angle D.

[Margin: i: Theodosius, *Sphaerica* I.11.] [Margin: k: prop. 13 of this treatise.]

Diagram. A pointed-oval (vesica) figure formed by two great-circle arcs. The two arcs spring from the apex and bow apart, then meet again at the lower vertex; a chord/arc crosses between the two side-points. It illustrates the case in which the two unequal arcs AB, AC (each greater than a quadrant) are produced until they meet at D.

- A (top vertex): common starting point of the two arcs AB, AC
- B (left): endpoint on the left arc
- C (right): endpoint on the right arc
- D (bottom vertex): point where the produced arcs meet
- (chord BC crosses between B and C, the base of triangle ABC)

Thirdly, let arc AB be less than a quadrant, but AC greater. Let arc AB be produced so as to make the quadrant AD; and, cutting off the quadrant AE from AC — as in the first of these figures — let the great-circle arc DE be drawn through D and E, cutting arc BC at F. The angles D and E will be right, because AD, AE are quadrants. Now since the two great circles BC, DE cut each other at F, and from the points B, C the perpendicular arcs BD, CE have been drawn to arc DE, it will be that as the sine of arc BF is to the sine of arc BD, so the sine of arc CF is to the sine of arc CE. And, alternately, as the sine of arc BF is to the sine of arc CF, so the sine of arc BD is to the sine of arc CE. But the ratio of the sine of arc BD to the sine of arc CE is known, because arcs BD, CE are given, being the complements of the given arcs AB, AC. Therefore the ratio of the sine of arc BF to the sine of arc CF will also be known — inasmuch as these are the sines of the complements of the given arcs AB, AC. Moreover the sum of these same arcs BF, CF is given (namely the whole arc BC), and is less than a semicircle — because any side of a spherical triangle is less than a semicircle. Therefore each of the arcs BF, CF will be known. Since, then, in triangle BFD, whose angle D is right, arc BF (opposite the right angle) is given, together with arc

[Margin: l: prop. 25 of this treatise.] [Margin: m: prop. 40 of this treatise.] [Margin: n: prop. 2 of this treatise.]

Diagram. The first of a pair of spherical-triangle figures (the left-hand one). A spherical triangle with apex A; the left side runs down to B and is produced to D at the lower left, the right side runs down to C; the great-circle arc DE (running along the base) cuts arc BC at F, with the perpendicular arcs BD and CE dropped from B and C. Illustrates the third case (AB less than, AC greater than a quadrant).

- A (apex): vertex of the triangle
- B (upper-left, on side AB): foot from which perpendicular BD is drawn
- D (lower left): end of the produced quadrant AD
- F (bottom, between D and C): intersection of arc BC with arc DE
- E (center-right): foot of perpendicular CE / end of quadrant AE
- C (bottom-right): vertex of the triangle

Diagram. The latter of the pair (the right-hand figure). A spherical triangle with apex A; a perpendicular/quadrant construction is drawn to the base, with points B, C at the base and D, E from the quadrant-extension. Serves the fourth and fifth cases (AB or AC a quadrant).

- A (apex): vertex of the triangle
- E (center-left): point of the quadrant/perpendicular construction [?]

- C (right): vertex of the triangle
- B (bottom-center): vertex of the triangle
- D (bottom-right): end of the produced quadrant

arc BD, which is the complement of the given arc AB, the third arc DF will also become known. In like manner, since in triangle CFE, which has the right angle E, arc CF (opposite the right angle) is given together with arc CE — namely the complement of arc AC — the third arc EF will likewise be found. Added to the arc DF already found, it will make known the whole arc DE, which is the measure of angle A; and therefore angle A will be known. Again, in the former triangle BFD, whose angle D is right, since arc BF (opposite the right angle) is given, together with arc BD — the complement, namely, of the given arc AB:

[Margin: o: prop. 6 of the [book on] rectilinear triangles.] [Margin: p: Scholium of prop. 53, or prop. 43, of this treatise.]

OR because the two arcs BD, DF about the right angle are given:

OR indeed, because arc BF (opposite the right angle) is given together with arc DF; the angle DBF will also be made known, from the scholia adduced in the margin; and hence the remaining angle ABC of the two right triangles will be known. By like reasoning, since in the latter triangle CFE, whose angle E is right, arc CF (opposite the right angle) is given together with arc CE — the complement, that is, of the given arc AC;

[Margin: q: Scholium of prop. 53, or prop. 43, of this treatise.]

OR when the two arcs CE, EF about the right angle are given:

OR indeed, when arc CF (opposite the right angle) is given together with arc EF; the angle C will likewise be given, by the scholia described in the margin. And thus all three angles A, B, C have been found.

[Margin: r: Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 55, or prop. 41, of this treatise.]

Fourthly, let arc AB be a quadrant, and AC less than a quadrant, as in the latter of the figures nearby. Let arc AC be produced so as to make the quadrant AD, and let the great-circle arc BD be drawn through B and D. The angles ABD and D will be right, because AB, AD are quadrants. And since in triangle BCD, whose angle D is right, arc BC (opposite the right angle) is given, together with arc CD — inasmuch as it is the complement of the given arc AC — the third arc BD, the measure of

angle A, will also be given, and therefore angle A will be known. Then, since in the same triangle BCD, having the right angle D, arc BC (opposite the right angle) is given together with arc CD — the complement, that is, of the given arc AC:

[Margin: s: Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 55, or prop. 41, of this treatise.]

[Margin: t: prop. 25 of this treatise.] [Margin: u: Scholium of prop. 53, or prop. 43, of this treatise.]

OR, because the two arcs BD, CD about the right angle are given:

OR indeed, since arc BC (opposite the right angle) is given together with arc BD;

the angle BCD will also be found from the scholia noted in the margin; and hence the remaining angle ACB of the two right triangles will be known. Lastly, since in the same adjoining triangle BCD, which has the right angle D, arc BC (opposite the right angle) is given, and besides arc CD — the complement, that is, of the given arc AC:

[Margin: x: Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 55, or prop. 41, of this treatise.]

OR when the two arcs BD, CD about the right angle are given:

OR when arc BC (opposite the right angle) is given together with arc BD;

OR when the angle BCD is given, together with arc CD or BD; for when arc BD is given, it is settled concerning the other arc CD about the right angle — given as it is — whether it is greater than a quadrant or less:

OR finally, because arc BC (opposite the right angle) is given together with angle BCD;

the angle CBD will also become known, from the scholia cited in the margin; and hence its complement too — namely the angle ABC — will be recognized. So all three angles of triangle ABC are known.

[Margin: d: Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 47 of this treatise; Scholium of prop. 47 of this treatise.] [Margin: e: prop. 25 of this treatise.]

Fifthly and lastly, let arc AC be a quadrant, and AB greater, as in the same latter of the figures nearby. Cutting off the quadrant AE from AB, let the great-circle arc CE be drawn through C and E. The angles ACE and E will be right, because AC, AE are quadrants. Since, then, in triangle BCE, which has the right angle E, arc BC

(opposite the right angle) is given, and besides arc BE — namely the complement of the given arc AB — the third arc CE, the measure of angle A, will also be given; and consequently angle A will become known. Again, since in the same triangle BCE, whose angle E is right, arc BC (opposite the right angle) is given together with arc BE — the complement, namely, of the given arc AB:

[Margin: f: Scholium of prop. 53, or prop. 43, of this treatise.]

OR when the two arcs BE, CE about the right angle are given.

OR finally, when arc BC (opposite the right angle) is given together with arc CE;

the angle CBE will likewise be given, from the scholia adduced in the margin.

Finally, since in the same triangle BCE, which has the right angle E, arc BC (opposite the right angle) is given, and arc BE too — being the complement of the given arc AB:

[Margin: g: Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 55, or prop. 41, of this treatise.]

OR, because the two arcs BE, CE about the right angle are given:

OR, since arc BC (opposite the right angle) is known, together with arc CE:

OR, because the angle CBE is given, together with arc BE or CE; for when arc CE is given, it is also settled whether the other arc BE — given as it is about the right angle — is greater than a quadrant or less:

OR finally, because arc BC (opposite the right angle) is known together with angle CBE;

the angle BCE will also become known, from the scholia cited in the margin; and therefore, adding the right angle ACE, the whole angle ACB will be given. So once again all three angles of triangle ABC have been found.

[Margin: h: Scholium of prop. 55, or prop. 41, of this treatise; Scholium of prop. 44, or prop. 48, of this treatise; Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 42 of this treatise; Scholium of prop. 47 of this treatise.]

PRAXIS. The practical working of this problem is to be sought from the scholia cited in the margin. Only, in order that the arcs BF, CF may be found — in the first and third cases — the sines of the complements of the given arcs AB, AC must be set down as the terms of the proportion of the sine of arc BF to the sine of arc CF; and in the first case one should apply either the first working of proposition 7 of rectilinear triangles, or some other of the workings of the same proposition, as

the matter requires; while in the third case the first or second working of proposition 6 of rectilinear triangles must be brought in, and so forth.

[Margin: Working, when the two arcs containing the sought angle are unequal.]

But if one wishes to use sines alone, the arcs BF, CF must be investigated, in the first case, by the second working of proposition 7 of rectilinear triangles; but in the third case by the third working of proposition 6. Then, in triangle BFD, the arc DF is to be extracted by the working of the first scholium of proposition 43; and in the same way, in triangle CFE, the arc EF — so that the remaining arc DE (in the first case), or the whole arc DE (in the third case), may be obtained, which is indeed the arc measuring angle A. After this, by the working of problem 1 of the scholium of proposition 41, the angle DBF must be found in triangle BFD; from which the remaining angle ABC of the two right triangles will become known. And in the same manner the angle ECF must be elicited in triangle CFE, from which — in the first case — the angle ACB too, its vertical angle, will be known.

[Margin: Working, by sines alone, when the two arcs flanking the sought angle are unequal.]

But in the fourth case, by the working of the first scholium of proposition 43, the arc BD — the measure of angle A — must be found in triangle BCD; and in the same way, in the fifth case, the arc CE, the measure of the same angle A, in triangle BCE. Then, in the fourth case, by the working of problem 1 of the scholium of proposition 41, the angle BCD must be traced out in triangle BCD; from which the remaining angle ACB of the two right triangles will become known. And by the same reasoning, in the fifth case, the angle ECB must be found in triangle BCE. Finally, in the fourth case, by the working of problem 2 of proposition 42, the angle CBD must be sought out in triangle BCD; from which also ABC, the remaining part of the right angle ABD, will be known. And likewise, in the fifth case, the angle BCE must be elicited; which, added to the right angle ACE, will present the whole angle ACB as known.

ANOTHER WAY, and much briefer. Again let the three arcs of triangle ABC be given, with the arcs AB, AC — which contain the angle A that is being sought — unequal. Since, then, as the whole sine [radius] is to the fourth-proportional quantity to the whole sine and the two sines of the unequal arcs AB, AC, so the versed sine of angle A is to the difference between the versed sine of arc BC (opposite angle A) and the versed sine of the arc by which the unequal arcs AB, AC exceed one another: and, conversely, as the said fourth-proportional quantity is to the whole sine, so the difference between the versed sine of arc BC and the

versed sine of the arc by which the unequal arcs AB, AC differ from each other is to the versed sine of the sought angle A.

[Margin: Another demonstration, briefer, and by sines alone.] [Margin: i: Scholium 2 of prop. 58 of this treatise.]

Diagram. A single spherical triangle with curved (great-circle) sides. Apex A at the top, with the base running between C (lower left) and B (lower right).

- A (top): apex vertex
- C (lower left): base vertex
- B (lower right): base vertex

If it be arranged that, as the whole sine is to the sine of either of the unequal arcs containing the sought angle, so the sine of the other arc about the same angle is to a fourth term, there will be found the number that is fourth proportional to the whole sine and the two sines of the said two arcs. If, then, it be again arranged that, as the fourth-proportional number just found is to the whole sine, so the difference between the versed sine of the arc opposite the sought angle and the versed sine of the arc by which the two arcs flanking the sought angle differ from each other is to a fourth term, the versed sine of the angle that is sought will be produced; from which you will elicit the arc of the sought angle, and hence the angle itself, as we taught in the explanation and use of the Table of Sines.

[Margin: Working, briefer, and by sines alone, when the two given arcs containing the sought angle are unequal.]

Moreover, the difference between the versed sine of the arc opposite the sought angle and the versed sine of the difference of the arcs containing that same angle will easily be found thus. When the arc opposite the sought angle is less than a quadrant, the sine of its complement must be subtracted from the sine of the complement of the difference of the arcs flanking the sought angle; for the remainder will be the difference that is sought. This is clearly established from the figures of cases 1, 4, 7, 10, and 13 of proposition 58. But when the arc opposite the sought angle is a quadrant, the sine of the complement of the difference of the arcs comprehending the sought angle will give the sought difference between the said versed sines; as is manifest from the figures of cases 2, 5, 8, 11, and 14 of the same proposition 58. Finally, when the arc opposite the sought angle is greater than a quadrant, the sine of its complement must be added to the sine of the complement of the difference of the arcs containing the sought angle; for the resulting number will be the sought difference — as can easily be seen from the figures of cases 3, 6, 9, 12, and 15 of the same proposition 58.

[Margin: Finding the difference between the versed sine of the arc opposite the sought angle and the versed sine of the difference of the arcs flanking that same angle.]

In the same way we shall investigate the angles B, C, if the arcs containing them are unequal.

Furthermore, once one angle has been found, the remaining two could be found with almost no trouble, if it were settled what each of them is — whether acute or obtuse. For, once (say) angle A has been found, if angle B were to be found, we would take for its sine the number that is fourth proportional to the sine of arc BC (opposite the found angle A), the sine of the found angle A, and the sine of arc AC (opposite the sought angle B). But if angle C were to be sought, we would take for its sine the number that is fourth proportional to the sine of arc BC (opposite the found angle A), the sine of the found angle A, and the sine of arc AB (opposite the sought angle C): because it is the case that, as the sine of arc BC is to the sine of angle A, so both the sine of arc AC is to the sine of angle B, and the sine of arc AB is to the sine of angle C. Therefore, if it were settled what both angle B and angle C are, we would at once find the sought angle in the table of sines from that fourth-proportional sine.

[Margin: a: prop. 41 of this treatise. When all three arcs, or only the two containing the angle to be investigated first, are equal.]

Now indeed, if all three arcs are given, or only the two AB, AC embracing angle A are equal — whatever be the case with the remaining arc BC — we shall investigate angle A and the other two B, C far more easily. Since the two arcs AB, AC are equal, the two angles B, C will also be equal to each other, because in isosceles spherical triangles the angles at the base are equal to one another. Since, then, triangle ABC is assumed to be non-right-angled, neither of the angles B, C will be right, and consequently neither of the arcs AB, AC is a quadrant — because otherwise the two angles B, C would be right. Therefore each of the angles B, C will be either acute or obtuse. So the perpendicular arc AD, dropped from A to arc BC, will fall inside the triangle. The two triangles ABD, ACD therefore have right angles at D, and the non-right angles B, C equal, and also the arcs AB, AC (opposite the right angles) equal. Hence the arcs BD, CD, and the angles at A, will also be equal to one another. And so, since in triangle ABD, whose angle D is right, arc AB (opposite the right angle) is given, and besides arc BD — inasmuch as it is half of the given arc BC —

[Margin: b: prop. 8 of this treatise.] [Margin: c: prop. 25 of this treatise.] [Margin: d: prop. 57 of this treatise.] [Margin: e: prop. 21 of this treatise.]

Diagram. An isosceles spherical triangle with a dropped perpendicular. Apex A at the top; the base runs from B (lower left) through D (the foot of the perpendicular AD, at the middle of the base) to C (lower right). The perpendicular arc AD divides the triangle into the two right-angled triangles ABD, ACD.

- D (base, center): foot of the perpendicular arc AD
- C (lower right): base vertex

the angle BAD — which is opposite the arc BD given about the right angle — will also be given; and this angle, doubled, will make the whole sought angle BAC known, since the angles at A have been shown to be equal. Again, since in the same triangle ABD, which has the right angle D, arc AB (opposite the right angle) is given, together with arc BD — namely with half of the given arc BC;

[Margin: f: Scholium of prop. 55, or prop. 41, of this treatise.]

OR, because the non-right angle BAD is given, together with its opposite arc BD about the right angle; and moreover the character of the remaining non-right angle B is settled. For if AB is less than a quadrant, angle B will be acute, just as BAD is acute; but if AB is greater than a quadrant, that same angle B will be obtuse, while BAD is acute:

OR indeed, since arc AB (opposite the right angle) is given, together with the non-right angle BAD;

[Margin: g: Scholium of prop. 51, or prop. 45, of this treatise; Scholium of prop. 52, or prop. 56, of this treatise; prop. 38 of this treatise.]

the angle B will also be given; and hence the remaining angle C, being equal to B, will be known. And thus all three angles in triangle ABC have been found.

[Margin: h: Scholium of prop. 47 of this treatise.]

When, therefore, two arcs are equal, the working of the scholium of proposition 55, or of problem 1 of proposition 41, must be applied, so that from one of the equal arcs and from half of the third arc an angle may be elicited which, doubled, presents the angle opposite the third arc. Then the working of the scholium of proposition 51 (or 45) must be applied, so that from the same arcs one of the

equal angles standing on the third arc may be found; or the working of problem 2 of the scholium of proposition 42, or of proposition 56, must be called upon; or at any rate the working of the scholium of proposition 47.

[Margin: Working, when the two arcs flanking the sought angle are equal.]

By sines alone we shall carry out the matter thus. From the working of problem 1 of proposition 41 we shall find the angle BAD, which, doubled, will give the whole angle BAC. Then, by the working of problem 2 of the scholium of proposition 42, we shall find the angle B, which is equal to C.

[Margin: Working, by sines alone, when the two arcs containing the sought angle are equal.]

SCHOLIUM.

Johannes Regiomontanus and Nicolaus Copernicus, in yet another way too — when all the arcs of a spherical triangle are given — [teach how] all three angles...

In the marginal references below, "of this treatise" (Latin *huius*) means a proposition or scholium of this treatise on spherical triangles; the numbers refer to its propositions and their scholia.

they seek the angles, investigating of course a certain rectilinear angle at the center of the sphere, whose arc exhibits the sought spherical angle as known. But I have deliberately omitted that method here — although it is acute and subtle — because it is more obscure and longer, and especially because anyone can read it in Regiomontanus [Regiomontanus], Book IV of the *Triangles*, Prop. 34, and in Copernicus [Copernicus], Book I of the *Revolutions* [*De Revolutionibus*], Prop. 13, on spherical triangles.

In the second demonstration of this problem I preferred to employ the theorem of scholium 2 of Prop. 58, rather than, with Johannes Regiomontanus, the theorem of the same Prop. 58, in order to escape the difficulty of the labor.

[Margin: (a) Prop. 58 of this treatise, and by permutation.] For it holds that, as the rectangle contained under the sines of the unequal arcs enclosing the sought angle is to the square of the whole sine [sinus totus], so the difference between the versed sine [sinus versus] of the arc opposite that same angle and the versed sine of the difference of those unequal arcs is to the versed sine of the sought angle. If we wished to use this theorem of Prop. 58, that rectangle would occupy the first place in the rule of three [regula aurea]. Consequently the division would become laborious, as is evident. But the division is easier by the theorem of

scholium 2 of the same Prop. 58, since the first place of the rule of three is occupied by the fourth-proportional quantity, which is much smaller than that rectangle, and is easily found merely by striking off from that rectangle as many figures on the right as there are ciphers (zeros) contained in the whole sine — because the said rectangle must be divided by the whole sine in order that the fourth-proportional quantity may be produced.

PROBL. 5. PROPOS. 64.

Given two sides of a non-right spherical triangle together with the angle they contain, to find the remaining side together with the remaining angles.

In the spherical triangle ABC, not right-angled, let two arcs AB and BC be given together with the angle B. From these we must find both the remaining arc AC and the remaining angles BAC and ACB. [Margin: When the two given arcs are unequal and neither is a quadrant.]

First let the given arcs be unequal, and from the end of one of them — namely from the endpoint A of arc AB — let a perpendicular arc AD be dropped to the other arc BC. Whether it falls inside the triangle or outside, the calculation and the operation will show. For since, in triangle ABD (whose angle D is right), the arc AB is given, opposite the right angle, together with the angle B, [Margin: (b) Schol. 41 of this treatise.] there will also be given the perpendicular arc AD, which is opposite the given angle B. Again, since in the same triangle the arc AB is given, opposite the right angle, together with the angle B:

EITHER — since the arc AD is known and moreover the angle B is given — the character of the other arc BD, about the right angle, is also settled. For when the arc AB is less than a quadrant: if the found arc AD is also less than a quadrant, [Margin: (c) Prop. 36 of this treatise.] then BD too will be less; if however AD is greater than a quadrant, then BD too will be greater. But if AB is greater than a quadrant: if the found AD is also greater, BD will be less; if however AD is less, BD will be greater.

OR, finally — since the arc AB is given, opposite the right angle, and the arc AD, about the right angle:

the arc BD will also be found, [Margin: (d) Schol. 45 of this treatise; Schol. 49 or 44 of this; Schol. 53 or 43 of this.] from the scholia cited in the margin. If, then, this arc BD, once found, is less than the given arc BC, it is a sign that the perpendicular arc AD has fallen inside the triangle; but outside, if it is greater.

And since a perpendicular arc to BC can be drawn on either side of arc AB, whenever it falls outside the triangle we choose, in this and the following propositions, the one that subtends the angle ABC. Now, by subtracting the found arc BD (if it is less than the given arc BC) from arc BC, or — if it is greater — by subtracting the given arc BC from the found arc BD, the remaining arc CD will become known. Therefore, since in triangle ADC the arcs AD and CD about the right angle are known, the arc AC opposite the right angle — which was sought in triangle ABC — will also be given.

Diagram. Two spherical triangles, stacked, illustrating the perpendicular arc AD dropped from A onto BC — the upper showing the perpendicular falling inside the base, the lower showing it falling outside.

- A (upper triangle, apex): vertex A
- B (upper triangle, lower-left): vertex B
- D (upper triangle, base, between B and C): foot of the perpendicular AD (falls inside)
- C [?] (upper triangle, lower-right): right-hand base vertex; the printed mark is unclear (resembles a small circle) and cannot be read with confidence
- A (lower triangle, upper-right apex): vertex A
- B (lower triangle, lower-left): vertex B
- C (lower triangle, base, middle): vertex C
- D (lower triangle, lower-right, beyond C): foot of the perpendicular AD (falls outside)

An internal arc from A to D (the perpendicular) is drawn in each triangle.

After this: since in triangle ABD, which has the right angle D, the arc AB is given, opposite the right angle, together with the angle B:

EITHER — since the arc AD, about the right angle, is known together with the angle B (which is not right), and it is moreover settled, concerning the remaining arc BD about the right angle once found, whether it is greater than a quadrant or less:

OR — since the arc AB is given, opposite the right angle, and in addition the arc AD, about the right angle:

OR, finally — since the arc AB is given, opposite the right angle, and moreover the arc BD, about the right angle —

the angle BAD will also be known, [Margin: (e) Schol. 1, 43 of this treatise; Schol. 47 of this; Schol. 56 or 42 of this; Schol. 51 or 45 of this; Schol. 55 or 41 of this.] through the scholia noted in the margin. In the same way too: since in triangle ACD, which has the right angle D, the arc AC is given, opposite the right angle, together with the arc AD about the right angle —

OR at least — since the arc AC is given, opposite the right angle, and moreover the arc CD, about the right angle —

the angle CAD will likewise be made known, [Margin: (f) Schol. 51 or 45 of this treatise; Schol. 55 or 41 of this.] through the scholia placed in the margin. Now the angle CAD just found, added to the angle BAD lately found as well — when the arc AD falls inside the triangle — or, when it falls outside, the angle CAD subtracted from the angle BAD, will make known the angle BAC, which was sought in triangle ABC.

Finally: since in triangle ACD, which has the right angle D, the arc AC is given, opposite the right angle, and the angle CAD is now found —

OR — since the arc CD about the right angle is known, and moreover the angle CAD; and it is settled, concerning the remaining arc AD about the right angle now made known, whether it is less than a quadrant or greater —

OR — since the arc AC is given, opposite the right angle, together with the arc CD about the right angle —

OR, finally — since the arc AC is known, opposite the right angle, together with the arc AD about the right angle —

the angle ACD will also become known, [Margin: (g) Schol. 56 or 42 of this treatise; Schol. 51 or 45 of this; Schol. 55 or 41 of this.] through the scholia cited in the margin; which, indeed, in the former triangle — where the arc AD falls inside the triangle — was the thing sought; but in the latter, where the arc AD falls outside the triangle, the same angle ACD, subtracted from two right angles, leaves known the sought angle ACB. And thus both the remaining arc AC and the remaining angles BAC and ACB have been found.

Moreover, in no way can either of the arcs AD, BD be a quadrant; [Margin: (h) Prop. 35 of this treatise.] because otherwise the arc AB too, opposite the right angle, would be a quadrant — which is contrary to the hypothesis.

But if the arc CD should ever be found to be a quadrant, [Margin: (i) Prop. 35 of this treatise.] then the arc AC too — the one sought, and opposite the right angle

— will be a quadrant, and the angle CAD will be right. And thus, without any labor, both the arc AC that is sought and [Margin: (k) Prop. 34 of this treatise.] the angle CAD will be found. The rest will be found as before.

The practical procedure for solving this problem is to be sought from the scholia cited in the margin.

But by sines alone one must proceed thus. By the practice of problem 2 of the scholium to Prop. 41, the arc AD is to be sought. [Margin: The procedure by sines alone, when the two given arcs are unequal and neither is a quadrant.]

Then, by the practice of scholium 1 of Prop. 43, the arc BD; from which the arc CD will be made known — by subtracting the found arc BD from the given arc BC, or the given arc BC from the found arc BD itself, according as it is found to be less than the given arc BC or greater.

In addition, in triangle BAD the angle BAD is to be sought, by the practice of problem 1 of Prop. 41, or by the practice of problem 2 of the scholium to Prop. 42. Similarly, in triangle ACD the angle CAD is to be elicited, by the practice of problem 1 of the scholium to Prop. 41. And from the two angles BAD, CAD once found, the angle BAC of the proposed triangle will become known — namely by adding one to the other, as in the former triangle, or by subtracting the angle CAD from the angle BAD, as in the latter triangle.

Finally, by the practice of problem 1 of the scholium to Prop. 41, or of problem 2 of the scholium to Prop. 42, in triangle ACD the same angle ACD is to be investigated. For in the former triangle proposed it is the thing sought, while in the latter it is the supplement of two right angles that is sought.

OTHERWISE — and indeed more expeditiously. [Margin: Another, shorter demonstration. (l) Schol. 58 of this treatise.] Again, in triangle ABC let two unequal arcs AB, AC be given, together with the angle A. Since, then, it holds that, as the whole sine is to the fourth proportional to the whole sine and the two sines of the unequal arcs AB, AC, so the versed sine of the angle A is to the difference between the versed sine of the arc BC (opposite the angle A) and the versed sine of the difference of the arcs AB, AC:

Diagram. A single spherical triangle with apex A above and a curved base, illustrating the case of two equal enclosing sides.

- A (apex, top): vertex A
- C (lower-left): vertex C
- B (lower-right): vertex B

If it be arranged that, as the whole sine is to the sine of either one of the given unequal arcs, so the sine of the other given arc is to a fourth term, there will be produced a fourth number proportional to the whole sine and the two sines of the said two arcs. [Margin: The shorter procedure, by sines alone, when the two given arcs are unequal and neither is a quadrant. (m) Schol. 1, 58 of this treatise.] If then it be again arranged that, as the whole sine is to the fourth proportional number just found, so the versed sine of the given angle A is to a fourth term, there will be found the difference between the versed sine of the third arc (which is sought) and the versed sine of the difference of the given unequal arcs. And since we showed above that the versed sine of the third arc is always greater than the versed sine of the difference of the two unequal arcs, if the difference just found is added to the versed sine of the difference of the given unequal arcs, there will be composed the versed sine of the third arc (opposite the given angle), which is sought; from which we shall elicit the arc itself, as was said in the exposition and use of the table of sines.

The angle C, moreover, we shall find from the known arcs AC, CB; and the angle B from the known arcs AB, BC — as we prescribed in the practice of the second demonstration of the preceding proposition — provided that the two arcs containing whatever angle is sought are unequal. For if they should ever be equal, the practice of the last demonstration of the same preceding proposition must be applied. But if we knew whether the angles B, C are acute or obtuse, we could easily find them, once the arc BC has been found, as we advised at the end of the second demonstration of the preceding proposition.

But if one of the given unequal arcs is a quadrant — namely AB — we shall draw from its endpoint A, to the other arc BC, a perpendicular arc AD. [Margin: When one of the given unequal arcs is a quadrant.] And at least one of the arcs AD, BD will also be a quadrant. [Margin: (n) Prop. 36 of this treatise.] But AD cannot be a quadrant; because otherwise — since AB too is posited as a quadrant — [Margin: (o) Prop. 25 of this treatise.] the angles B, D would be right, and so the triangle ABC would be right-angled, which is not posited. Therefore BD will be a quadrant, [Margin: (p) Prop. 34 of this treatise.] and hence the opposite angle BAD is right. [Margin: (q) Prop. 26 of this treatise.] B will also be the pole of the arc AD, on account of the quadrants AB, BD; and therefore the arc AD will be known from the angle B itself, which is given. And thus the two arcs AD, BD, together with the angle BAD, will be made known without any trouble of multiplication. The rest will be found as before.

But now let the given arcs AB, AC, which contain the given angle A, be equal. [Margin: When the two given arcs are equal.] Then the two angles B, C will be equal — namely either both acute or both obtuse — and neither of the arcs AB, AC a quadrant; and the perpendicular arc AD, dropped from A onto BC, will fall inside the triangle. The arcs BD, CD as well, and the angles at A, will be equal, as we showed in the last

figure of the preceding proposition; and consequently each angle at A will be given, since it is half of the given angle BAC. Since, then, in triangle ABD, which has the right angle D, the arc AB is given, opposite the right angle, together with the angle BAD — that is, with half of the given angle BAC — [Margin: (a) Schol. 41 of this treatise.] the arc BD, opposite the given angle BAD, will be known; and this, doubled, will render the whole arc BC (the thing sought) known. Again, since in the same triangle ABD, which has the right angle D, the arc AB is given, opposite the right angle, together with the arc BD about the right angle —

Diagram. A single spherical triangle with apex A above and a curved base B–D–C, with the perpendicular AD drawn inside from A to the base at D (the equal-arcs case).

- A (apex, top): vertex A
- B (lower-left): vertex B
- D (base, middle): foot of the perpendicular AD
- C (lower-right): vertex C

OR — since the arc AB is given, opposite the right angle, and moreover the non-right angle BAD —

OR, finally — since the arc BD is given, about the right angle, together with the non-right angle BAD (which is opposite the given arc BD); and moreover the character of the remaining non-right angle B is settled. For if AB is less than a quadrant, [Margin: (b) Schol. 51 or 45 of this treatise; Schol. 47 of this; Schol. 58 or 42 of this.] the angle B will be acute, just as BAD is acute; but if AB turns out greater than a quadrant, the angle B will be obtuse, since BAD is acute —

the angle B will also be known, [Margin: (c) Prop. 38 of this treatise.] from the scholia cited in the margin; and hence also the angle C, which is equal to it.

The practical procedure is to be sought from the scholia cited in the margin.

[Margin: The procedure. The procedure by sines alone, when the two given arcs are equal.]

By sines alone we shall proceed thus. By the practice of problem 2 of the scholium to Prop. 41, we shall seek the arc BD; which, doubled, will give the whole arc BC that is sought. Then, by the practice of problem 2 of the scholium to Prop. 42, we shall find the angle B; to which the other angle C is equal.

Given, therefore, two arcs of a non-right spherical triangle together with the angle contained by them, we have found the remaining arc together with the remaining angles. Which was to be done.

SCHOLIVM.

Here too, in the second demonstration of this problem, we chose rather to use the theorem of scholium 2 of Prop. 58 than the theorem of the same Prop. 58, so that the practice might become less laborious. [Margin: (d) Prop. 58 of this treatise.] For since it holds that, as the square of the whole sine is to the rectangle contained under the sines of the given unequal arcs, so the versed sine of the given angle (contained by the said arcs) is to the difference between the versed sine of the arc opposite the given angle and the versed sine of the difference of the two given unequal arcs: if we wished to use this theorem of Prop. 58, the multiplication in the rule of three would become troublesome, since the versed sine of the given angle would have to be multiplied by the said rectangle. But in our practice the multiplication is much shorter, as is evident, even though we apply the rule of three twice.

PROBL. 6. PROPOS. 65.

Given two angles of a non-right spherical triangle, together with the side adjacent to them, to investigate the remaining sides together with the remaining angle.

In the spherical triangle ABC, not right-angled, let two angles B and BAC be given, together with the adjacent arc AB. From these we must investigate the remaining arcs AC, BC, together with the remaining angle C. First let the given arc AB be not a quadrant, but either greater or less than a quadrant; and let the given angles B, BAC be unequal, from one of which — namely from BAC — let a perpendicular arc AD be dropped to the opposite arc BC. [Margin: When the two given angles are unequal, and the given adjacent arc is greater or less than a quadrant.] Whether it falls inside the triangle or outside, the calculation and the operation will indicate. For since in triangle ABD, which has the right angle D, the arc AB is given, opposite the right angle, and the angle B, [Margin: (a) Prop. 47 of this treatise.] the angle BAD will also be given; and if it is found less than the given

angle BAC, the arc AD will fall inside the triangle, but outside, if it is greater. Now, by subtracting the found angle BAD (if it is less than the given angle BAC) from the angle BAC, or — if it is greater — by subtracting the given angle BAC from the found angle BAD, the remaining angle CAD will become known.

Diagram. Two spherical triangles side by side, each with apex A above and a curved base, illustrating the perpendicular AD from A falling inside (left) and outside (right) the base.

- A (left triangle, apex): vertex A
- B (left triangle, lower-left): vertex B
- D (left triangle, base, middle): foot of the perpendicular (inside)
- C (left triangle, lower-right): vertex C
- A (right triangle, apex): vertex A
- B (right triangle, lower-left): vertex B
- C (right triangle, base, middle): vertex C
- D (right triangle, lower-right, beyond C): foot of the perpendicular (outside)

But the found angle BAD can never be right; [Margin: (b) Prop. 25 of this treatise.] because then the two arcs AB, BD would be quadrants, on account of the right angles BAD, ADB, whereas AB is posited to be not a quadrant. But CAD may sometimes be right.

Again, since in the same triangle ABD, which has the right angle D, the arc AB is given, opposite the right angle, and the non-right angle B:

EITHER — since both non-right angles B and BAD are known —

OR, finally — since the arc AB is given, opposite the right angle, together with the non-right angle BAD —

the arc AD will also be known, [Margin: (c) Schol. 41 of this treatise; Schol. 52 or 42 of this; Schol. 45 of this.] through the scholia cited in the margin. And in the same way: since in the same triangle BAD, whose angle D is right, the arc AB is given, opposite the right angle, together with the angle BAD:

EITHER — since both non-right angles B and BAD are known —

OR — since the arc AB is known, opposite the right angle, together with the non-right angle B —

OR — since the arc AB is given, opposite the right angle, and moreover the arc AD, about the right angle —

OR — since the arc AD is known, about the right angle, together with the non-right angle B opposite it; and it is moreover settled whether the other arc BD, about the right angle, is greater or less than a quadrant. For

(Continuing the treatment of Problem 6 / Proposition 65 begun in the previous pages: given two angles of a spherical triangle together with the side adjacent to them, to find the remaining sides and the remaining angle. The perpendicular AD has been dropped from A onto BC, dividing the oblique triangle ABC into the two right triangles ABD and ACD.)

if the angle BAD that has been found is acute, arc BD will be less than a quadrant; but if it is obtuse, greater.

Or, finally: since arc AD about the right angle is known, together with the non-right angle BAD adjacent to it, [d] arc BD will likewise become known from the scholia cited in the margin. Moreover, since in triangle ACD, which has the right angle D, arc AD about the right angle is known, together with the non-right angle CAD adjacent to it, [e] arc AC, which lies opposite the right angle, will also be found. And so now one of the remaining arcs, AC, has been found.

[Margin (d): scholium of prop. 41 of this treatise; scholium of prop. 52, or 42, of this; scholium of prop. 45 of this; scholium of prop. 53, or 43, of this; scholium of prop. 49, or 44, of this; scholium of prop. 44 of this.] [Margin (e): scholium of prop. 46, or 45, of this treatise.]

After this, since in the same triangle ACD — whose angle D is right — arc AC is given, opposite the right angle, together with the non-right angle CAD:

- Or because arc AC is given, opposite the right angle, and in addition arc AD, about the same right angle:
- Or, finally, because arc AD is given, about the right angle, together with the non-right angle CAD adjacent to it:

[f] arc CD will likewise become known, from the scholia described in the margin. This arc CD, added to the arc BD already found — when the perpendicular arc AD falls within the triangle — or, when it falls outside, subtracted from the found arc BD, will yield the known arc BC, which is the other of the remaining arcs that are sought.

[Margin (f): scholium of prop. 41 of this treatise; scholium of prop. 43, or 53, of this. † scholium of prop. 44 of this.]

Lastly, in the same triangle ACD: since arc AC is given, opposite the right angle, together with arc AD about the right angle:

- Or because arc AD is given, about the right angle, and the non-right angle CAD adjacent to it:
- Or because arc AD is given, about the right angle, and the non-right angle ACD opposite it — it being moreover established whether the remaining arc CD, found about the right angle, comes out greater than a quadrant or less:
- Or because both arcs AD and CD about the right angle are given:
- Or because arc AC is given, opposite the right angle, and in addition arc CD about the right angle:
- Or, finally, since arc AC is given, opposite the right angle, together with the non-right angle CAD:

[g] the angle ACD will also become known, from the scholia named in the margin. In the former triangle this angle ACD is the one sought; but in the latter, subtracted from two right angles, it leaves the sought angle ACB. And thus we have now found everything that was proposed.

[Margin (g): scholium of prop. 41, or 55, of this treatise; scholium of prop. 42 of this; scholium of prop. 56, or 42, of this; scholium of prop. 48, or 44, of this; scholium of prop. 45, or 51, of this; scholium of prop. 47 of this.]

[Margin: Practical procedure by sines alone, when the two given angles are unequal and the given arc adjacent to them is not a quadrant.]

Concerning the practical procedure we prescribe nothing new; instead, one must turn to the practical procedures of the scholia cited in the margin.

By sines alone, however, we will carry out the proposal as follows. By the practical procedure of problem 2 of the scholium to proposition 41, in the right-angled triangle ABD we will determine arc AD; and by the practical procedure of the problem of scholium 1 to proposition 43, arc BD. Then by the practical procedure of problem 1 of the scholium to proposition 41, we determine angle BAD: if it is smaller than the given angle BAC, we subtract it from the given angle BAC; or if it is larger, we subtract the given angle BAC from it — so that angle CAD becomes known.

From this, by the practical procedure of problem 2 of the scholium to proposition 42, we will elicit angle ACD in the right-angled triangle ACD. This will be the sought angle ACB in triangle ABC, if the angle BAD that was found is smaller than the given

angle BAC; but if it is larger, this same angle ACD, subtracted from two right angles, will give the remaining sought angle ACB.

Now, by the practical procedure of problem 3 of the scholium to proposition 41, we will find, in the same triangle ACD, arc AC, which lies opposite the right angle. For arc AD about the right angle is given, and the non-right angle ACD, and it is moreover established what the other non-right angle CAD is — found earlier. And this arc AC is one of the remaining arcs sought in triangle ABC.

Finally, by the practical procedure of problem 2 of the scholium to proposition 41, arc CD will be found; or by the practical procedure of problem 1 of the scholium to proposition 42, or indeed by the practical procedure of problem 1 of the scholium to proposition 43, we will determine the same arc CD. Added to the found arc BD — when the found angle BAD is smaller than the given angle BAC — or, when it is larger, subtracted from the same arc BD, it will yield the known arc BC, which is the other of those in triangle ABC that must be investigated.

[Margin: When the two angles are unequal, and the given adjacent arc is a quadrant.]

But if the found angle CAD happens to be right — since ADC is also right — [h] then AC and CD will be quadrants, and AD will be the arc of angle C; and so angle C will be known from the found arc AD. The remaining arc BC will be known from the quadrant CD and the found arc BD, as before.

[Margin (h): prop. 25 of this treatise.]

Now, if the given arc AB is a quadrant — the angles B and BAC still being unequal — angle BAD will be right, and arc BD too a quadrant. For since in the right-angled triangle ABD arc AB, opposite the right angle, is set as a quadrant, [i] at least one of the remaining arcs will be a quadrant. But AD cannot be a quadrant, [k] because the two angles B and D would be right, on account of the quadrants AB and AD, whereas triangle ABC is set as non-right-angled. Therefore BD will be a quadrant, [l] and consequently the opposite angle BAD is right. [m] B will also be the pole of arc AD, on account of the quadrants BA and BD; and so AD will be the arc of the given angle B, and therefore given. And once arcs AD and BD and the right angle BAD have been found — with no labor at all, since in investigating them we need none of the preceding problems — we will find the rest, as before.

[Margin (i): prop. 36 of this treatise.] [Margin (k): prop. 25 of this treatise.]

[Margin (l): prop. 34 of this treatise.] [Margin (m): prop. 26 of this treatise.]

Next, let two equal angles B and C be given in triangle ABC, together with the arc BC adjacent to them — whether that arc be a quadrant, or greater than a quadrant, or less. [f] Arcs AB and AC will be equal; and so the perpendicular arc AD, dropped from the opposite angle A onto the given arc BC, will fall within the triangle and will bisect both the given arc BC and the opposite angle BAC, as we demonstrated in the latter case of proposition 62. Since, therefore, in triangle ABD — which has the right angle D — arc BD about the right angle is given (being half of the given arc BC), together with the angle B adjacent to it, [g] arc AB opposite the right angle will also be given, and so AC, equal to it, will be given. And thus the two remaining arcs are now made known. Again, since in the same triangle arc AB, opposite the right angle, is given (by what was found), together with arc BD about the right angle:

[Margin: When the two given angles are equal. — f: prop. 9 of this treatise.]

- Or because arc BD is given, about the right angle, together with the non-right angle B adjacent to it:
- Or indeed because arc AB is given, opposite the right angle, together with the non-right angle B:

[h] angle BAD will also be found, through the scholia adduced in the margin; and this angle, doubled, will make the whole sought angle BAC known.

[Margin (g): scholium of prop. 45, or 46, of this treatise; scholium of prop. 41, or 55, of this; scholium of prop. 42 of this; scholium of prop. 47 of this.]

Diagram. An isosceles spherical triangle with apex A at the top and base drawn horizontally below it. The perpendicular arc AD is drawn from A straight down to the base, meeting it at D. Labels read off the scan under magnification:

- A (apex): the vertex from which the perpendicular is dropped.
- B (base, left end): base vertex.
- D (base, between B and C): foot of the perpendicular arc AD on the base BC.
- C (base, right end): base vertex. *(The rightmost base letter is printed with a rounded, tailed form that could be misread as "Q"; context — triangle ABC with foot D on BC — fixes it as C.)*

[Margin: Practical procedure, by sines alone, when the two given angles are equal.]

But by sines alone the procedure runs as follows. By the practical procedure of problem 2 of the scholium to proposition 42 — from arc BD given about the right

angle, and from angle B, given, adjacent to it — we will find angle BAD, which, doubled, will give the whole sought angle BAC. Then by the practical procedure of problem 3 of the scholium to proposition 41 — from arc BD about the right angle, and from angle BAD opposite it, now found — we will extract arc AB, opposite the right angle, and so also arc AC, equal to it. For besides the data, the species of the remaining angle B, given as non-right, is also established.

Therefore, given two angles of a non-right-angled spherical triangle together with the arc adjacent to them, we have investigated the remaining arcs along with the remaining angle. Which was to be done.

SCHOLIVM

In rectilinear non-right-angled triangles no problem similar to this was proposed. The reason is that, once two angles are given, [i] the third is given as well — namely, what remains when those two are taken from two right angles. Hence, since one side is also given, the two remaining sides will be made known by proposition 10 of the [treatise on] rectilinear triangles.

[Margin (i): prop. 32 of this treatise.]

PROBL. 7. PROPOS 66.

Given two angles of a non-right-angled spherical triangle, together with the arc opposite one of them, to find the remaining arcs along with the remaining angle. It must, however, be established whether the arc opposite the other given angle is greater than a quadrant, or less, or indeed exactly a quadrant.

In the non-right-angled triangle ABC let two angles B and C be given, together with arc AB, which is opposite angle C; and let it be established whether arc AC is greater than a quadrant, or less, or a quadrant. From these one must find the remaining arcs AC and BC, and the remaining angle BAC. First, let the two given angles B and C be unequal, and the given arc AB not a quadrant. From angle A, let the perpendicular arc AD be drawn to arc BC, which is adjacent to the given angles. [a] This perpendicular will fall within the triangle if both of the given angles B and C are acute, or both obtuse; but outside, if one is acute and the other obtuse. Since, therefore, in triangle ABD — which has the right angle D — arc AB is given, opposite the right angle, together with the non-right angle B, [b] arc AD about the right angle, opposite the given angle B, will become known. Hence, in

the same triangle ABD, since arc AB is given, opposite the right angle, together with arc AD about the right angle:

[Margin: When the two given angles are unequal and the given arc opposite one of them is not a quadrant. — a: prop. 57 of this treatise.] [Margin (b): scholium of prop. 41 of this treatise.]

Diagram. Two spherical triangles drawn side by side, each with apex A at the top, illustrating the two cases in which the perpendicular AD falls inside or outside the base.

- Left triangle: apex A; base vertices B (left) and C (right); D lies on the base between B and C (foot of the perpendicular arc AD falling *within* the triangle). Base labels, left to right: B, D, C.
- Right triangle: apex A; base vertices B (left) and C; D lies beyond C, to the right (foot of the perpendicular arc AD falling *outside* the triangle). Base labels, left to right: B, C, D.
- Or because arc AB is given, opposite the right angle, and in addition the non-right angle B:
- Or, finally, since arc AD is given, about the right angle, together with the non-right angle B opposite it — it being moreover established what the species of arc BD is. For if the given arc AB is less than a quadrant, then, if the found arc AD is likewise less, [c] BD too will be less; but if AD is greater, BD greater. If, on the other hand, the given arc AB is greater than a quadrant, then, if the found arc AD is greater, BD will be less; but if AD is less, BD will be greater.

[d] the other arc, BD, about the right angle, will also be found, from the scholia cited in the margin. Hence again, in the same triangle ABD, since arc AB is given, opposite the right angle, and in addition arc BD about the right angle:

[Margin (c): scholium of prop. 43, or 53, of this treatise; scholium of prop. 45 of this; scholium of prop. 49, or 44, of this.] [Margin (d): prop. 36 of this treatise.]

- Or because both arcs AD and BD are given, about the right angle:
- Or because arc AB is given, opposite the right angle, together with arc AD about the right angle:
- Or because arc AD is given, about the right angle, and in addition the non-right angle B opposite it — the species of angle BAD being moreover

established. For if the found arc BD is greater than a quadrant, [f] angle BAD will be obtuse; but if less, acute.

[Margin (f): prop. 34 of this treatise.]

- Or, finally, because arc AB is given, opposite the right angle, together with the non-right angle B;

[e] the non-right angle BAD will also become known, from the scholia set out in the margin.

[Margin (e): scholium of prop. 41, or 55, of this treatise; scholium of prop. 44, or 48, of this; scholium of prop. 45, or 51, of this; scholium of prop. 56, or 42, of this; scholium of prop. 47 of this. (g): scholium of prop. 41, or 54, of this.]

Next, in triangle ACD — which has the right angle D — since arc AD is given, about the right angle, together with the angle C opposite it (for when the perpendicular arc AD falls outside the triangle, angle ACD will be given, if the given angle ACB is subtracted from two right angles), and since it is moreover assumed to be established what the species of arc AC is — the arc which in the proposed triangle ABC is opposite the other given angle B, but in this triangle ACD is opposite the right angle D — [g] arc AC will likewise come out known. This is one of the remaining arcs proposed for investigation in triangle ABC. Hence, since in the same triangle ACD arc AC is given, opposite the right angle, together with arc AD about the right angle:

- Or because arc AC is given, opposite the right angle, together with the non-right angle C:
- Or, finally, since arc AD is given, about the right angle, together with the angle C opposite it — the species of arc CD being moreover established. For if arc AC, opposite the right angle, is found to be less than a quadrant, [h] both arcs AD and CD will be either less as well, or greater; and thus from the known arc AD we shall know whether CD is less or greater than a quadrant. But if the found arc AC is greater than a quadrant, and AD less, CD will be greater; whereas if AD is greater, CD will be less.

[Margin (h): prop. 36 of this treatise.]

[i] arc CD will also become known, through the scholia set in the margin. Added to the arc BD found earlier — if the perpendicular arc AD falls within the triangle — or, if outside, subtracted from the found arc BD, it will yield the known sought arc BC. And thus the remaining two arcs, AC and BC, will now have been found.

[Margin (i): scholium of prop. 43, or 53, of this treatise; scholium of prop. 45 of this; scholium of prop. 49, or 44, of this.]

Lastly, since in the same, adjacent triangle ACD arc AC is given, opposite the right angle, together with arc CD about the right angle:

- Or since arc CD is given, about the right angle, and in addition the non-right angle C:
- Or because arc AD is given, about the right angle, together with the non-right angle C opposite it — the species of the other angle CAD being moreover established. For if the found arc CD is less than a quadrant, [l] angle CAD will be acute; but obtuse, if CD is greater than a quadrant:
- Or because both arcs AD and CD are given, about the right angle:
- Or since arc AC is given, opposite the right angle, together with arc AD about the right angle:
- Or, finally, because arc AC is given, opposite the right angle, together with the non-right angle C;

[Margin (l): prop. 36 of this treatise.]

[k] the angle CAD will likewise become known, from the scholia adduced in the margin. And this angle CAD, added to the angle BAD found earlier — if the perpendicular arc AD falls within the triangle — or, if outside, subtracted from the found angle BAD, will yield the known sought angle BAC.

[Margin (k): scholium of prop. 41, or 55, of this treatise; scholium of prop. 42 of this; scholium of prop. 42, or 56, of this; scholium of prop. 44, or 48, of this; scholium of prop. 45, or 51, of this; scholium of prop. 47 of this.]

For the rest, in no way can either of the arcs AD, BD be a quadrant in this case: because if either of them were a quadrant, [m] arc AB, opposite the right angle, would also be a quadrant — which is contrary to the hypothesis.

[Margin (m): prop. 35 of this treatise.]

[Margin: Practical procedure, by sines alone, when the given angles are unequal and the given arc opposite one of them is not a quadrant.]

The practical procedure of this problem depends on the scholia noted in the margin.

By sines alone we will accomplish the matter thus. By the practical procedure of problem 2 of the scholium to proposition 41, we will find arc AD; and by the

practical procedure of the problem of scholium 1 to proposition 43, arc BD; and by the practical procedure of problem 1 of the scholium to proposition 41, angle BAD.

Then, by the practical procedure of problem 3 of the scholium to proposition 41, we will determine arc AC, since its species is established from the hypothesis. Hence, by the practical procedure of problem 1 of the scholium to proposition 43, arc CD will become known; and from it — if it is added to the found arc BD, or subtracted from it, according as the perpendicular arc AD has fallen within or outside the triangle — arc BC will become known.

Finally, by the practical procedure of problem 1 of the scholium to proposition 41, we will extract angle CAD; which, added to the found angle BAD, or subtracted from it, according as the perpendicular arc AD has fallen within the triangle or outside, will make the sought angle BAC known.

[Margin: When the two given angles are unequal and the given arc opposite one of them is a quadrant.]

But if the arc AC, opposite the other given angle B, happens to be a quadrant — which can occur when AB is not a quadrant — [n] then at least one of the other remaining arcs, AD or CD, in triangle ACD will be a quadrant. Since, then, AD cannot be a quadrant, CD will be a quadrant; [o] and consequently the angle CAD opposite it will be right. So in that case both arc CD and angle CAD will be found without any other labor; and from them both arc BC and angle BAC will be determined, as has been said.

[Margin (n): prop. 36 of this treatise.] [Margin (o): prop. 34 of this treatise.]

Now let the given arc AB be a quadrant, the two given angles B and C still being unequal. Arc BD will also be a quadrant, and angle BAD right. For since in triangle ABD arc AB, opposite the right angle, is set as a quadrant, [p] at least one of the other arcs, AD or BD, will also be a quadrant. But AD cannot be a quadrant, [q] because the two angles B and D would then be right — on account of the quadrants AB and AD — and so triangle ABC would be right-angled, which is not assumed. Therefore BD will be a quadrant, [r] and consequently the opposite angle BAD right. [s] B will also be the pole of arc AD, on account of the quadrants AB and BD; and therefore the given angle B will make arc AD known. And once arcs AD and BD have been found, with the right angle BAD, the rest will be found without any troublesome multiplication, as before. In this case, however, arc AC will in no way be a quadrant — lest AB and AC be two quadrants in triangle ABC, and consequently the two angles B and C right. That would be contrary to the hypothesis, since the triangle is set as non-right-angled.

[Margin (p): prop. 36 of this treatise.] [Margin (q): prop. 5 of this treatise.] [Margin (r): prop. 54 of this treatise.] [Margin (s): prop. 26 of this treatise.] [Margin (t): prop. 25 of this treatise.]

(Continuation of PROBL. 7 / PROPOS. 66 — the case of two given equal angles, begun on the previous page at the catchword "VERVM".)

But now suppose that in triangle ABC the two given angles B and C are equal. Then the two arcs AB and AC will also be equal — and consequently neither of them is a quadrant, so that the two angles B and C cannot both be right angles. [Margin: *Quando duo dati anguli æquales sunt* — When the two given angles are equal.] Therefore, when the perpendicular arc AD is dropped from the third angle A, it falls inside the triangle, and it bisects both the arc BC and the angle BAC, exactly as we showed above in the second case of Proposition 62. Now since in triangle ABD, which has its right angle at D, the arc AB is given (opposite the right angle) together with angle B, [Margin: *h Schol. 45. huius* — Scholium to Prop. 45 of this treatise.] the arc BD too will become known; and doubled, it makes the whole arc BC known. And AC is likewise known, since it equals the given arc AB. Then, since in the same triangle ABD the arc AB is given (opposite the right angle) together with arc BD (about the right angle just found);

Or because arc BD is given, about the right angle, together with the non-right angle B adjacent to it;

Or finally because arc AB is given, opposite the right angle, together with the non-right angle B —

[Margin: *i Schol. 41. vel 55. hui.; i Scho. 42. huius; i Scho. 47. huius* — Scholia to Props. 41 or 55, 42, and 47 of this treatise.] the angle BAD will also be obtained by means of the scholia cited in the margin; and doubled, it will yield the sought whole angle BAC.

This is how we shall proceed in this case using sines alone. [Margin: *Praxis per solos sinus quando dati duo anguli æquales sunt* — Procedure by sines alone, when the two given angles are equal.] *By the procedure of problem 2 of the scholium to Proposition 41 we find arc AD; and from this, by the procedure of problem 1 of the scholium to Proposition 43, arc BD, which doubled gives arc BC known. Then by the procedure of problem 1 of the scholium to Proposition 41, or by the procedure of problem 2 of the scholium to Proposition 42, we find angle BAD, and hence its double BAC, which is sought. The third arc AC is equal to the given arc AB, and so is known.*

Therefore, given two angles of a non-right spherical triangle together with one arc that is opposite one of them, [we have found the rest], and so on. Which was to be done.

Diagram. A spherical triangle with the apex at the top and the base curving below; a perpendicular is dropped from the apex to the midpoint of the base.

- A (apex): vertex A
- B (base, left): vertex B
- D (base, center): foot of the perpendicular AD
- C (base, right): vertex C

SCHOLIVM

To this problem too we have supplied no corresponding proposition among the rectilinear (plane) triangles, for the reason given in the scholium to the preceding proposition.

Now in the first case of this problem it is also necessary that the species of arc AC — the arc opposite the given angle B — be given as well. Otherwise, in triangle ACD, from the given arc AD and the opposite angle C (since we as yet have nothing certain established about arc CD or angle CAD, whatever these may be) the arc AC [glyph reads *AD*; contextually the hypotenuse AC, opposite the right angle D — see QA] opposite the right angle would not be found, since it could be either greater or less than a quadrant, and it is not yet established from the givens, nor demonstrated, what it will turn out to be.

Moreover, that it is not enough for two angles to be given together with an arc opposite one of them, in order to elicit the remaining arcs and the remaining angle, we pointed out some time ago in the scholium to Propositions 22 and 23. There too we indicated that Copernicus went astray on this point, in Book 1 of the *Revolutions*, Proposition 12 on spherical triangles [Copernicus, *De Revolutionibus* I.12]. This we shall now briefly demonstrate again as follows. Let there be two unequal arcs AB, AC containing angle BAC, and together equal to a semicircle — so that one of them is greater than a quadrant and the other less. Now through B and C let an arc of a great circle BC be drawn, and let another arc AD be drawn from A meeting its extension, running neither through the poles of arc BC — so that the angles at D and at CAD are not right angles. But neither is angle ACD a right angle. [Margin: *Error Copernici. Non satis esse, dari duos angulos cum arcu vni eorum opposito, ad reliqua inuenienda in triangulo non rectangulo* — Copernicus's error: that it is not enough to be given two angles together with an

arc opposite one of them, to find the rest in a non-right triangle.] For if it were right, then, because of the right angles B and C, the two arcs AB, AC would be equal, and so both would be quadrants — which is contrary to the hypothesis. Triangle ACD, therefore, is not right-angled; and in it, although the two angles ACD and D may be given together with arc AD (which is opposite angle ACD), we shall nevertheless not thereby infer that arc AC, opposite the other given angle D, is [determinate]. For since in triangle ABD the same is opposed to it — namely, arc AB is likewise unequal to AC (given that the two given angles B and D, angle B being equal to angle ACD as we showed) and the given arc AD is opposite angle B — [Margin: k 14. *huius*; l 25. *huius*. *Error Regiom.* — Prop. 14 and Prop. 25 of this treatise; Regiomontanus's error.] it is necessary that the species of the arc opposite angle D be given, so that we may know whether arc AB or AC is to be taken, since one of them is greater than a quadrant, and so on.

Johannes Regiomontanus [Regiomontanus] also slipped on this point, in Book 4 of the *Triangles*, Proposition 32 [Regiomontanus, *De triangulis* IV.32], when he wants, from two given angles together with one side opposite [one of them], to find the rest — which, however, is not sufficient, as we have here demonstrated.

Diagram. A spherical triangle with apex A at the top; the base carries three points, with the foot D of the perpendicular lying beyond the vertex C (the perpendicular AD falls outside the triangle).

- A (apex): vertex A
- B (base, left): vertex B
- C (base, center): vertex C
- D (base, right): foot of the perpendicular AD, outside the triangle

PROBL. 8. PROPOS. 67.

Given two arcs of a non-right spherical triangle, together with the angle that is opposite one of them, to find the remaining angles and the remaining arc. But it must be established whether the angle opposite the given arc is acute or obtuse.

In a non-right spherical triangle ABC let there be given two arcs AB, AC, together with angle B, which is opposite arc AC; and let it be established whether angle C is acute or obtuse. From these we must investigate the remaining angles C and BAC, and the remaining arc BC. Let the two given arcs AB, AC first be unequal, and neither of them a quadrant. From angle A, opposite the third arc, let the perpendicular arc AD be drawn to that third arc BC; [Margin: a 37. *huius* — Prop.

37 of this treatise.] it will fall inside the triangle if both angles B, C are acute, or both obtuse; but outside if one is acute and the other obtuse. Now it is established from the givens whether both angles are acute, or both obtuse, or one acute and the other obtuse — since angle B is given together with the species of angle C. [Margin: *Quando neuter datorum arcuum inæqualium est quadrans* — When neither of the two given unequal arcs is a quadrant.] And so, since in triangle ABD, which has its right angle at D,

Diagram. Two spherical triangles side by side, each with apex A and a perpendicular AD from the apex. In the left figure the foot D falls between B and C (perpendicular inside the triangle); in the right figure the foot D falls beyond C (perpendicular outside).

- Left figure — A (apex); B (base, left); D (base, center); C (base, right)
- Right figure — A (apex); B (base, left); C (base, center); D (base, right)

the arc AB is given, opposite the right angle, together with angle B; [Margin: b *Schol. 41. huius* — Scholium to Prop. 41 of this treatise.] the arc AD too, about the right angle, will be given — opposite the given angle B. Hence, in the same triangle ABD, since arc AB is given, opposite the right angle, and in addition arc AD, about the same right angle:

Or because arc AB is given, opposite the right angle, and moreover the non-right angle B:

Or finally, because arc AD is given, about the right angle, together with the opposite angle B; and there is besides established the species of arc BD. For if AB is given less than a quadrant, then, provided AD too is found less [than a quadrant], [Margin: c *Schol. 43. vel 53. hui.*; c *Schol. 45. huius*; c *Scho. 49. vel 44. hu.*; d 36. *huius* — Scholia to Props. 43 or 53, 45, 49 or 44, and Prop. 36 of this treatise.] BD too will be less; but if [AD is] greater, [BD will be] greater. On the other hand, if AB is given greater than a quadrant, then, provided AD too is found greater, BD will be less; but if AD is found less, BD will be greater —

then, [Margin: d 36. *huius* — Prop. 36 of this treatise.] by the scholia cited in the margin, the other arc BD, about the right angle, will also become known. Hence again, in the same triangle ABD, since arc AB is given, opposite the right angle, together with arc BD, about the same right angle:

Or because both arcs AD, BD are given, about the right angle:

Or because arc AB is given, opposite the right angle, together with arc AD, about the same right angle:

Or because arc AD is given, about the right angle, together with the opposite angle B, and there is besides established the species of angle BAD. For if the arc BD is found to be less than a quadrant, [Margin: e *Schol.* 41. vel 55. *hui.*; e *Schol.* 44. vel 48. *hu.*; e *Schol.* 45. vel 51. *hui.*; e *Schol.* 56. vel 42. *hu.*; e 34. *huius*; f *Schol.* 47. *huius*; g *Schol.* 51. vel 45. *hui.* — Scholia to Props. 41/55, 44/48, 45/51, 56/42, and Prop. 34, Scholium to Prop. 47, Scholium to Prop. 51/45.] angle BAD will be acute; but obtuse if it is greater:

Or finally, because arc AB is given, opposite the right angle, and in addition the non-right angle B —

f angle BAD, the non-right angle, will also be rendered known from the scholia set in the margin.

Next, since in triangle ACD, which has its right angle at D, arc AC is given (opposite the right angle) and arc AD has been found (about the right angle), g angle CAD, contained by the said arcs, will likewise become known; and this, added to the angle BAD already found, or subtracted from it — according as the perpendicular arc AD falls inside the triangle or outside (which indeed we shall know, as we said at the outset, from the given angle B and the given species of angle C) — will give the sought angle BAC.

Again, since in the same triangle ACD arc AC is given, opposite the right angle, and arc AD has been found, about the right angle:

Or because arc AD is given, about the right angle, together with the non-right angle CAD:

Or finally, because arc AC is given, opposite the right angle, and moreover the non-right angle CAD:

[Margin: h *Schol.* 55. vel 41. *hui.*; h *Scho.* 42. *huius*; h *Scho.* 47. *huius*; i 41. *huius* — Scholia to Props. 55/41, 42, 47, and Prop. 41 of this treatise.] h angle ACD will also become known. If then the perpendicular arc AD falls inside the triangle, the angle found will be ACB, which is sought; but if it falls outside, the angle ACD found, subtracted from two right angles, will leave known the sought angle ACB. And this angle ACB may indeed likewise be found even if arc AD were not available. For since, as the sine of arc AC is to the sine of angle B, so the sine of arc AB is to the sine of angle ACB: if it be made that, as the sine of the given arc opposite the given angle is to the sine of the given angle, so the sine of the other given arc is to a fourth term, the sine of the angle opposite this arc will be

produced; and hence the angle ACB itself will be known, since its species is established. And so the remaining two angles BAC, ACB are now found.

Finally, since in the same triangle ACD arc AC is given, opposite the right angle, together with angle CAD, just found:

Or because both non-right angles ACD, CAD are given:

Or because arc AC is given, opposite the right angle, together with arc AD, about the right angle:

Or because arc AD is given, about the right angle, together with the non-right angle CAD:

Or because arc AD is given, about the right angle, together with the opposite angle ACD, and there is besides established the species of the other arc CD, about the right angle. For, the found angle CAD being acute, [Margin: k Schol. 41. huius; k Scho. 42. vel 52. hui.; k Schol. 43. vel 53. hui.; k Scho. 44. huius; k Scho. 49. vel 44. hu.; k 34. huius; l Schol. 45. huius; m 35. huius. *Praxis per solos sinus quando neuter datorum arcuum inæqualium est quadrans* — Scholia to Props. 41, 42/52, 43/53, 44, 49/44, and Prop. 34, Scholium to Prop. 45, Prop. 35. Procedure by sines alone, when neither of the two given unequal arcs is a quadrant.] k arc CD will be less than a quadrant; but greater if it is obtuse:

Or finally, because arc AC is given, opposite the right angle, together with the non-right angle ACD;

l arc CD, about the right angle, will also be found by means of the scholia cited in the margin; and this, either added to the arc BD already found, or subtracted from it (according, of course, as the perpendicular arc AD has fallen inside the triangle or outside), will give the arc BC sought in the proposed triangle ABC.

Furthermore, in no way can either of the arcs AD, BD, in this case, be a quadrant: m because otherwise arc AB too, opposite the right angle D, would be a quadrant — which is contrary to the hypothesis. By the same reasoning, neither will CD be a quadrant, lest arc AC too, opposite the right angle, be a quadrant, which would likewise be contrary to the hypothesis.

Let the procedure of this problem be sought from the scholia set in the margin.

But by sines alone the problem will be solved thus. By the procedure of problem 2 of the scholium to Proposition 41 arc AD will be found, in triangle ABD; and from this, by the procedure of the problem of the scholium to Proposition 43, arc BD. Then by

the procedure of problem 2 of the scholium to Proposition 42 angle BAD will be found.

(The italic procedure continues from the previous page. The catchword "POST" does not match the opening word "ACD" here — see QA.)

...angle] ACD, which is one of the things sought, if it be established that angle C is of the same species as the given angle B; but if of a different species, the sought angle ACB will be the remainder of two right angles — [Margin: m 57. hui. — Prop. 57 of this treatise.] because in the one case the perpendicular arc falls inside the triangle, in the other outside. Again, by the procedure of the problem of the scholium to Proposition 43, arc CD will be rendered known; and this, in the former triangle added to the arc BD found, but in the latter subtracted from it, will exhibit the remaining arc BC, known, in the proposed triangle. Finally, by the procedure of problem 1 of the scholium to Proposition 41, angle CAD will be found; and this, added to or subtracted from the found angle BAD, will render known the third angle BAC, which is sought.

Now if one of the two given unequal arcs AB, AC be a quadrant: if indeed AB is a quadrant, then BD too will be a quadrant, and angle BAD a right angle, and moreover B will be the pole of arc AD; and so the given angle B will exhibit that same arc AD as known, just as we showed in the preceding proposition, when arc AB was supposed to be a quadrant. [Margin: *Quando alter duorum arcuum inæqualium datorum est quadrans* — When one of the two given unequal arcs is a quadrant.] The arcs AD, BD and angle BAD being thus found, we shall find the rest without any trouble, as before. But if arc AC be a quadrant, then by the same reasoning CD will be a quadrant, and angle CAD a right angle, and moreover C will be the pole of arc AD; and so the found arc AD will make angle ACD known — which will be one of the things sought, when arc AD falls inside the triangle; but if it falls outside, the remainder of two right angles will give the sought angle ACB. And in that case there will then be found, without any multiplication at all, both arc CD and angle CAD, and likewise angle ACD; from which the rest will be found, as before.

Now let the two given arcs AB, AC be equal. Then the two angles B, C will be equal; and the perpendicular arc AD, dropped from A onto BC, will fall inside the triangle; and moreover the arcs BD, CD, and the angles at A, will be equal, as we showed in the last case of Proposition 63. Since therefore angle B is given, C too, being equal to it, will be given. Then, since in triangle ABD, which has its right angle at D, arc AB is given, opposite the right angle, together with angle B; [Margin: *Quando dati duo arcus æquales sunt* — When the two given arcs are

equal. n *Scho. 47. huius* — Scholium to Prop. 47 of this treatise.] n angle BAD too will be given, and this, doubled, will offer known the whole angle BAC, which is sought. Hence, since in the same triangle ABD arc AB is given, opposite the right angle, together with angle BAD, found:

Or because both non-right angles B and BAD are given:

Or finally, because arc AB is given, opposite the right angle, together with angle B, which is not right;

[Margin: o *Schol. 41. huius*; o *Scho. 42. vel 52. hui.*; o *Schol. 45. huius* — Scholia to Props. 41, 42/52, and 45 of this treatise.] o arc BD, about the right angle, will also become known, by the scholia cited in the margin; and hence its double BC, which is set as the thing to be inquired.

The procedure can easily be gathered from the scholia set in the margin. [Margin: *Praxis, per solos sinus, quando duo arcus dati æquales sunt* — Procedure, by sines alone, when the two given arcs are equal.]

But if you prefer to employ sines alone, arc AD is first to be found, by the procedure of problem 2 of the scholium to Proposition 41. And from this, by the procedure of the problem of the scholium to Proposition 43, arc BD, which doubled will give the sought whole BC. Then by the procedure of problem 1 of the scholium to Proposition 41, or by the procedure of problem 2 of the scholium to Proposition 42, angle BAD is to be found; from which its double BAC, which we seek, will be known. The third angle C is already given, since it is equal to the given angle B.

Given, therefore, two arcs of a non-right spherical triangle, together with one angle that is opposite one of them, etc. Which was to be done.

Diagram. A spherical triangle with apex A and a perpendicular AD dropped from A onto the base, the foot D falling between B and C.

- A (apex): vertex A
- B (base, left): vertex B
- D (base, center): foot of the perpendicular AD
- C (base, right): vertex C

[Margin: *Quando alter duorum arcuum inæqualium datorum est quadrans* — When one of the two given unequal arcs is a quadrant.]

SCHOLIUM I.

But it is necessary, in this problem, to establish whether angle C, opposite the other given arc, is acute or obtuse, so that it may be known whether the perpendicular arc AD falls inside the triangle or not. For if this be ignored, we should not know whether angle CAD is to be added to angle BAD, or subtracted from it, in order to find the sought angle BAC; likewise, whether arc CD is to be added to arc BD, or subtracted from it, so that the sought arc BC may be found. Or finally, whether the found angle ACD is the one that is sought, or rather the remainder of two right angles — as is evident. That it is not, moreover, enough for two arcs to be given, [together with the angle opposite one of them, in order to find the] remaining angles together with the remaining arc, we have already taught above, some time ago, in the scholium to Proposition 24. And on this point we noted there that Nicolaus Copernicus [Copernicus] erred, in Book 1 of the *Revolutions*, Proposition 11 on spherical triangles [Copernicus, *De Revolutionibus* I.11]. This, however, we shall now briefly show again as follows. Let there be two equal arcs AD, AC, embracing angle DAC, and each less than a quadrant, or greater. Now through C, D let an arc of a great circle CD be drawn, and from A let another arc AB be drawn meeting its extension, running neither through the poles of arc CD nor through the poles of arc AD, so that the angles at B and at DAB are not right angles. But neither is angle ADB a right angle. For if each of the arcs AD, AC is less than a quadrant, the two angles C and ADC will be acute; but if each of the arcs AD, AC is greater than a quadrant, the two angles C and ADC will be obtuse. From this it follows that angle ADB is either obtuse — namely, when ADC is acute — or acute, namely, when ADC is obtuse: [Margin: *Error Copernici. Non satis esse, dari duos arcus cum angulo vni eorum opposito, in triangulo non rectangulo, vt reliqua inueniantur* — Copernicus's error: that it is not enough to be given two arcs together with the angle opposite one of them, in a non-right triangle, in order that the rest be found. 25. *huius* — Prop. 25 of this treatise. p 5. *huius* — Prop. 5 of this treatise.] p since the two angles at D are equal to two right angles. Triangle ABD, therefore, is not right-angled; and in it, although the two arcs AB, AD may be given together with angle B, which is opposite arc AD, we shall nevertheless not thereby be able to gather that the remaining angle opposite the other given arc AB is ADB. For to that same arc AB there is opposed, in triangle ABC as well, angle C, which is unequal to ADC: because in triangle ABC the same hypothesis holds — namely, the two given arcs AB, AC (for arc AC is set equal to arc AD) and the given angle B, opposite arc AC. It is necessary, therefore, to establish whether the angle opposite the other arc AB is acute or obtuse — that

is, whether angle ADB is to be taken, or rather C, since one is obtuse and the other acute, and so on.

Diagram. A spherical triangle with apex A and a perpendicular from A to the base, the foot D between B and C.

- B (base, left): vertex B
- D (base, center): foot of the perpendicular AD
- C (base, right): vertex C

Triangula — Praxes Problematum (rectilinear triangles)

SCHOLIVM II.

So far I have demonstrated what is required for the calculation of triangles, and through a good many propositions — and perhaps longer ones than anyone might wish for in a calculation, which ought to be easy and short. I therefore think it worth my while to set down here separately, by way of an epilogue, the practical procedures for all the problems that have been demonstrated in rectilinear and spherical triangles, gathered as it were into a single place. In this way we shall always have them ready and, so to speak, at hand whenever they are to be used, and shall not waste time fruitlessly picking them out from so large a multitude of propositions. In the margin, moreover, I shall cite the propositions and problems in which their demonstrations are contained, so that anyone can easily find them whenever the matter requires. So then, as far as the calculation of triangles is concerned, it will be enough if these few things that follow are read through attentively when there is need; for in them is comprised the sum of everything I have demonstrated about triangles. Now although in non-right spherical triangles I have usually investigated by several methods the arcs and

angles of the triangles into which we resolve the non-right ones, nevertheless in the practical procedures that follow — so as to avoid all confusion — I have chosen, for finding any given arc or angle, only one method, namely the one I judged to be the more convenient.

SEQVVNTVR PRAXES PROBLEMATVM

[There follow the practical procedures of the problems]

There follow the practical procedures of the problems of all triangles, excerpted from the demonstrations above, in which consists the whole fruit of our treatment of triangles, both rectilinear and spherical.

TRIANGVLORVM RECTILINEORVM RECTANGVLORVM PROBLEMATA, ET PRAXES.

[Problems and practical procedures of right-angled rectilinear triangles]

1. Given all the angles of any triangle whatever, to find the proportions of all the sides.

[Margin: What is sought — the proportions of the sides.]

To each side let there be assigned the right sine of the opposite angle. For the sides have among themselves the same proportions as are found among those sines of the angles assigned to the opposite sides. But if only two angles are given, the third angle must first be found — by subtracting the two given angles from two right angles — and only then are the proportions of the sides to be traced out in the same way.

[Margin: a — Scholium on Proposition 1 of rectilinear triangles.]

Aliter. (*Another way.*)

Let the right sine of any acute angle be doubled, and the side opposite that angle will be obtained, in the units of the whole sine [i.e. the radius], which the semidiameter of the circle circumscribed about the triangle represents. But for the side that is opposite the right angle, if the triangle happens to be right-angled, take the whole sine doubled. And finally, for the side that is opposite the obtuse angle, if the triangle happens to be obtuse-angled, take double the right sine that belongs to half of the sum formed from the doubles of the two acute angles.

[Margin: b — Scholium on Proposition 1 of rectilinear triangles.]

2. Given, in a right triangle, the side that is opposite the right angle, together with one of the acute angles — and consequently also with the other acute angle, since the two together are equal to one right angle — to find the side about the right angle that is opposite either of the acute angles.

[Margin: What is sought — the side, about the right angle, opposite either of the acute angles.]

Let it be done thus: as the whole sine is to the given side opposite the right angle, so is the sine of either given acute angle to a fourth; and there will be produced the side opposite that given acute angle, in the units of measure by which the side opposite the right angle was given.

[Margin: c — Proposition 2 of rectilinear triangles.]

3. Given one side of a right triangle about the right angle, together with one of the acute angles — and indeed also with the other acute angle, since the two together are equal to one right angle — to find the other two sides.

[Margin: What is sought — the side opposite the right angle, and either of the two sides about the same right angle.]

Let it be done thus: as the whole sine is to the given side about the right angle, so is the tangent of the acute angle adjacent to the given side to a fourth; and the other side about the right angle will be found. Likewise let it be done: as the whole sine is to that same given side about the right angle, so is the secant of the same acute angle adjacent to the given side to a fourth; and there will be produced the side opposite the right angle, in the units of measure by which the side about the right angle was given.

[Margin: d — Proposition 2 of rectilinear triangles.]

Aliter per solos sinus. (*Another way, by sines alone.*)

Let it be done thus: as the sine of the acute angle opposite the given side is to the given side about the right angle, so is the sine of the other acute angle to a fourth; and there will be found the side, about the right angle, opposite this other acute angle. Likewise let it be done: as the sine of the acute angle opposite the given side is to the given side about the right angle, so is the whole sine to a fourth; and

there will be produced the side opposite the right angle, in the units of measure by which the side about the right angle was given.

[Margin: e — Proposition 2 of rectilinear triangles.]

4. Given, in a right triangle, the side opposite the right angle, together with either of the two remaining sides about the right angle, to find the two acute angles and the other side about the right angle.

[Margin: What is sought — the two acute angles, and one side about the right angle.]

Let it be done thus: as the given side opposite the right angle is to the whole sine, so is the given side about the right angle to a fourth; and there will be produced the sine of the acute angle opposite this latter given side. From this angle, once found, the other acute angle also becomes known, since the two together are equal to one right angle. Again let it be done: as the whole sine is to the given side opposite the right angle, so is the sine of the acute angle that has been found — the one opposite the third side sought — to a fourth; and this other side about the right angle will be found, in the units of measure by which the two other sides were given.

[Margin: f — Proposition 3 of rectilinear triangles.]

5. Given the two sides about the right angle, to find the two acute angles and the side opposite the right angle.

[Margin: What is sought — the two acute angles, and the side opposite the right angle.]

Let it be done thus: as either of the given sides is to the whole sine, so is the other given side to a fourth; and there will come out the tangent of the acute angle opposite this latter side. From this angle, once found, the other acute angle becomes known, since the two acute angles together are equal to one right angle. Again let it be done: as the whole sine is to either of the given sides about the right angle, so is the secant of the acute angle taken [i.e. found], adjacent to this side, to a fourth; and there will be found the side opposite the right angle, in the units in which the two sides about the right angle were given.

[Margin: g — Proposition 3 of rectilinear triangles.]

Aliter per solos sinus. (*Another way, by sines alone.*)

Let the squares of the two given sides about the right angle be added together; for the root of this sum will be the side opposite the right angle. Then let it be done: as the side opposite the right angle, which has now been found, is to the whole sine, so is either of the given sides about the right angle to a fourth; and there will come out the sine of the acute angle opposite the side about the right angle that was taken. From this angle, once found, the other also becomes known, since the two acute angles together are equal to one right angle.

[Margin: h — Proposition 3 of rectilinear triangles.]

TRIANGVLORVM RECTILINEORVM NON RECTANGVLORVM PROBLEMATA, ET PRAXES.

[Problems and practical procedures of non-right-angled rectilinear triangles]

6. Given the sum of two arcs or angles — which is less than 180 degrees — together with the proportion that their sines have, to exhibit each of them as known.

[Margin: What is sought — the two arcs or angles, from their sum.]

Let it be done thus: as half the sum of the terms of the given proportion which the sines of the arcs or angles have is to the tangent of half the given sum of the arcs or angles — finding the tangent by the proportional part corresponding to 30 seconds, in case the sum of the arcs or angles cannot be divided in two without seconds — so is the difference between half the sum of the terms of the given proportion and either of the terms, to a fourth. For there will be found the tangent of the arc or angle by which each arc or angle sought differs from half of the given sum of those same arcs or angles. And thus the arc or angle of this tangent, once found, added to half of the given sum of the arcs or angles, will give the greater arc or angle sought; but subtracted from that same half, it will leave the lesser arc or angle.

[Margin: a — Proposition 6 of rectilinear triangles.]

Aliter. (*Another way.*)

Let it be done thus: as half the difference between the two terms of the given proportion is to the tangent of half the difference between the given sum of the arcs or angles and a semicircle, so is the sum of [i] half the difference between the two terms of the given proportion and [ii] the consequent term of the same

proportion, to a fourth. For there will be produced the tangent of an arc or angle; and if from this arc there be subtracted half the difference between the given sum of the arcs or angles and the semicircle, the remainder will become the lesser arc or angle sought. And this one, in turn, subtracted from the given sum, will leave the greater arc or angle sought.

[Margin: b — Proposition 6 of rectilinear triangles.]

Aliter per solos sinus. (*Another way, by sines alone.*)

Let it be done thus: as half the sum of the terms of the given proportion is to the sine of half the sum of the arcs or angles, so is the difference between half the sum of the terms of the given proportion and either of the terms, to a fourth; and a certain fourth number will be found. If the square of this number be added to the square of the sine of the complement of half the sum of the arcs or angles, and again it be done — as the square root of the sum of the two said squares is to the whole sine, so is that fourth number found to a fourth — there will be produced the sine of the arc or angle by which each arc or angle differs from half of their given sum. Therefore this arc or angle, added to half of the given sum, will yield the greater arc or angle; but taken away from that same half, it will leave the lesser arc or angle.

[Margin: c — Proposition 6 of rectilinear triangles.]

But if the given proportion of the sines should happen to be one of equality, then half of the given sum of the arcs or angles will give each arc or angle.

7. Given the sum of two arcs, each of which is less than a semicircle, or of two angles — a sum which is greater than 180 degrees — together with the proportion that their sines have, to render each of them known.

[Margin: What is sought — the two arcs or angles, from their sum.]

Subtracting the given sum from 360 degrees, let each arc or angle of the remaining sum be found by Problem 6 — this remaining sum being always less than 180 degrees, while the same proportion of the sines remains. For if the two thus found are each subtracted separately from a semicircle, the remainders will be the arcs or angles sought.

[Margin: d — Proposition 6 of rectilinear triangles.]

When the given proportion is one of equality, half of the given sum will likewise give each arc or angle sought.

But if the given sum should happen to contain precisely 180 degrees, the problem cannot be solved.

8. Given the difference of two arcs, each of which is less than a semicircle, or of two angles, together with the proportion that their sines have, to make each of them known.

[Margin: What is sought — the two arcs or angles, from their difference.]

If the ratio of the sine of the greater arc (or angle) to the sine of the lesser is a ratio of greater inequality, then arrange that as the half of the difference of the terms of the given ratio is to the tangent of the half of the given difference of the arcs (or of the angles), so the sum of the half of the difference of the terms of the ratio together with the consequent term of that same ratio is to a fourth. [Margin: e — Proposition 7, plane triangles.] This will produce the tangent of an arc (or angle) which, added to the half of the given difference of the arcs (or angles), makes up the greater arc (or angle); but if it is subtracted from that same half, the remainder will be the lesser arc or angle.

If, on the other hand, the ratio of the sine of the greater arc (or angle) to the sine of the lesser is a ratio of lesser inequality, then invert its terms so that a ratio of greater inequality results. From this ratio, together with the given difference of the arcs (or angles), find the two arcs (or angles), as was said. For the greater of them, taken away from the semicircle, will give the lesser arc (or angle) sought; while the lesser, subtracted from the semicircle, will yield the greater.

Another way.

When the sine of the greater arc (or angle) has to the sine of the lesser a ratio of greater inequality, then from that given ratio of greater inequality, and from the arc (or angle) which is left after the given difference has been subtracted from the semicircle — treating this as the sum of two arcs (or angles) — seek the two arcs (or angles) of this sum, as we prescribed in Problem 6. [Margin: f — Proposition 7, plane triangles.] For the greater arc (or angle) found, if it is taken away from the semicircle, will give the greater arc or angle sought; while the lesser one found will be the lesser sought.

But when the given ratio is one of lesser inequality, invert its terms so that a ratio of greater inequality results. From this ratio, together with the given difference of the arcs (or angles), investigate the two arcs (or angles), as has already been said. For the greater of them, subtracted from the semicircle, will give the lesser arc (or angle) sought; while the lesser will give the greater.

Another way, by the sines alone.

If the given ratio of the sine of the greater arc (or angle) to the sine of the lesser is a ratio of greater inequality, then arrange that as the half of the difference of the terms of the given ratio is to the sine of the half of the given difference of the arcs (or angles), so the sum of the half of the difference of the terms of the ratio together with the consequent term of that same ratio is to a fourth. [Margin: g — Proposition 7, plane triangles.] A certain fourth number will be found; and let the square of this number be added to the square of the sine of the complement of the half of the given difference of the arcs (or angles). Then again arrange that as the square root of the sum of the said squares is to the whole sine, so that fourth number found is to a fourth: the sine of the arc (or angle) will be found, to which if the half of the given difference of the arcs (or angles) is added, the greater arc (or angle) becomes known; but if from it that same half is taken away, the remainder will be the lesser.

But if the given ratio is one of lesser inequality, one must proceed as we said above.

Now if by chance the given ratio is one of equality, let the given difference of the arcs (or angles) be subtracted from the semicircle. For the half of the remainder will be the lesser arc (or angle) sought; and that same half, added to the given difference, will give the greater.

9. If from any one angle of any triangle whose sides are given a perpendicular is dropped to the opposite side, to find how great is the straight line lying between the perpendicular and either of the remaining angles.

[Margin: The fall of the perpendicular line is sought.]

Let the difference between the squares of the two sides enclosing the angle from which the perpendicular has been dropped be divided by the third side, and a number is produced. If this number is less than the third side, [Margin: h — Proposition 9, plane triangles.] it will indicate that the perpendicular has fallen inside the triangle; and the same number, subtracted from that same third side, will leave a number whose half gives the lesser segment of the base, while this lesser segment, subtracted from the whole third side, gives the greater segment. But if the same number produced by the division is greater than the third side, it will be an argument that the perpendicular has fallen outside the triangle. Therefore, if the third side is taken away from it, the remainder will be a number whose half gives the straight line outside the triangle between the perpendicular

and the obtuse angle; while that same half, added to the third side, gives the other straight line between the perpendicular and the acute angle.

Another way, and easier.

Arrange that as the third side, onto which the perpendicular has been dropped, is to the sum of the other two sides, so the difference of those same two sides is to a fourth; and a number results, [Margin: i — Proposition 9, plane triangles.] from which we shall find the straight line between the perpendicular and either angle, as we said just now.

Another way.

When the perpendicular falls inside the triangle, let the half of the difference between the square of either of the sides enclosing the angle from which the perpendicular has been dropped and the sum of the squares described on the other two sides be divided by the side onto which the perpendicular falls.

[Margin: k — Scholium to Proposition 9, plane triangles.] This produces the segment of the base near the angle contained by the two sides whose sum of squares was taken; and this segment, subtracted from the whole base, will leave the other segment.

But when the perpendicular falls outside the triangle, let the half of the difference between the square of the side opposite the obtuse angle and the sum of the squares described on the other two sides be divided by the side onto whose extension the perpendicular falls. This will produce the line outside the triangle between the perpendicular and the obtuse angle; and this line, added to the whole base, will make up the other straight line between the perpendicular and the acute angle of the base.

And if the two sides about the perpendicular are equal, [Margin: l — Corollary to Proposition 8, plane triangles.] the perpendicular will cut the base into two equal parts. Therefore half the base will give each of the straight lines sought.

10. Given all the angles of a non-right triangle, together with one side, to find the other two sides.

[Margin: Two sides are sought.]

Arrange that as the sine of the angle opposite the given side is to the sine of either of the remaining angles, so the given side is to a fourth, [Margin: m — Proposition 10, plane triangles.] and the side opposite this latter angle will be found. Arrange again that as the sine of the angle opposite the given side is to the sine of the third

angle, so the given side is to a fourth, and the third side, opposite this third angle, will be produced.

If the triangle is isosceles, the finding of only one side is needed, provided one side is given together with the angles. The same is to be said of a scalene triangle, if two of its sides are given together with the angles. But in an equilateral triangle, if one side is given, the rest will also be given, being equal to it.

11. Given all the sides of a non-right triangle, to find all its angles.

[Margin: The angles are sought.]

When a perpendicular has been drawn to the greatest side from the opposite angle (so that the perpendicular always falls inside the triangle), [Margin: n — Proposition 11, plane triangles.] let there be found, by the preceding problem, the straight lines lying between the perpendicular and the two angles at the greatest side. Then arrange that as the least side is to the whole sine, so the lesser segment of the base is to a fourth, and a sine is produced whose arc's complement gives the base angle adjacent to the least side. Again arrange that as the middle side is to the whole sine, so the greater segment of the base is to a fourth, and a sine is produced whose arc's complement gives the base angle adjacent to the middle side. The third angle, opposite the greatest side, will be composed of the two arcs of the two sines found; or else it will be left over after the subtraction of the two angles found from two right angles.

If the triangle is isosceles, [when] the perpendicular is drawn it will be perpendicular to the base, which it will bisect. [?] For if then one arranges that as one of the equal sides is to the whole sine, so half the base is to a fourth, a sine will be found whose arc's complement gives one of the equal angles above the base, and consequently the other as well. The third angle will be elicited from these two.

In an equilateral triangle the angles will be given, even if the sides are not given, since each one is a third part of two right angles, or two-thirds of one right angle.

12. Given two sides of a non-right triangle, together with the angle contained by them, to find the third side and the remaining angles.

[Margin: A side is sought, together with its two angles.]

When the given angle has been subtracted from two right angles, so that the sum of the other two is obtained, let each of them be found, [Margin: o — Proposition 12, plane triangles.] by the sixth problem of plane triangles, from this sum

together with the ratio of the given sides opposite them (which is the same as that found between their sines). Then arrange that as the sine of either of these angles found is to the sine of the angle given at the outset, so the side opposite the angle found — the one that was taken in the rule of three — is to a fourth, and the third side will be found.

But if the two given sides are equal, then, the given angle having been taken away from two right angles, the half of the remainder will give each of the equal angles. And if one arranges that as the sine of one of them is to the sine of the given angle, so one of the equal sides is to a fourth, the third side will come out.

13. Given two sides of a non-right triangle, together with the angle that is opposite one of them, to investigate the remaining angles and the third side: provided only, when the given angle is acute, that it be established whether the angle opposite the other given side is likewise acute, or rather obtuse.

[Margin: Two angles are sought, together with one side.]

Arrange that as the side opposite the given angle is to the other given side, so the sine of the given angle is to a fourth, [Margin: p — Proposition 13, plane triangles.] and the sine of the angle opposite the other given side is found. If this angle is acute (and it will always be acute if the given angle is obtuse), it will become known from the found sine itself; but if it is obtuse, the found sine will give an angle which, subtracted from two right angles, will leave the sought angle opposite the other given side. Moreover, the sum composed of the given angle and the found angle, if it is subtracted from two right angles, will indicate the third angle contained by the given sides. Then arrange that as the sine of the given angle is to the sine of this third angle found, so the side opposite the given angle is to a fourth, and the third side sought is produced.

If the given sides are equal, the angle opposite the other given side will also be given, since it is equal to the given angle. Hence the third angle and the third side will be found, as before.

TRIANGVLORVM SPHÆRICORVM RECTILINEORVM RECTANGVLORVM PROBLEMATA, AC PRAXES.

Problems and Praxes of Right-Angled Spherical Triangles.

1. Given an arc in a right-angled triangle which is opposite the right angle, together with either of the arcs about the right angle, to find the angle opposite this arc.

[Margin: A non-right angle is sought.]

Arrange that as the sine of the given arc opposite the right angle is to the whole sine, so the sine of the given arc about the right angle is to a fourth, [Margin: a — Problem 1, Proposition 41, spherical triangles.] and the sine of the angle opposite this arc, which is sought, will be found. This angle will be acute if the given arc opposite to it about the right angle is less than a quadrant; but obtuse, if greater.

Another way.

Arrange that as the whole sine is to the sine of the arc opposite the right angle, so the secant of the complement of the given arc about the right angle is to a fourth, [Margin: b — Problem, Proposition 55, spherical triangles.] and the secant of the complement of the angle sought, which is opposite this arc, is produced.

2. Given an arc in a right-angled triangle which is opposite the right angle, together with either of the non-right angles, to find the arc opposite this angle.

[Margin: An arc about the right angle is sought.]

Arrange that as the whole sine is to the sine of the arc opposite the right angle, so the sine of the given angle is to a fourth, [Margin: c — Problem 2, Proposition 41, spherical triangles.] and the sine of the arc opposite this angle, which is sought, will be found. This arc will be less than a quadrant if the given angle opposite to it is acute; but greater, if obtuse.

3. Given either of the arcs about the right angle in a right-angled triangle, together with the angle opposite it, to find the arc opposite the right angle: provided only it be established whether it is less than a quadrant or greater; or whether the other angle adjacent to the given arc is acute or obtuse; or, finally, whether the other arc about the right angle is less than a quadrant or greater.

[Margin: The arc opposite the right angle is sought.]

Arrange that as the sine of the given angle is to the sine of the given arc, so the whole sine is to a fourth, [Margin: d — Problem 3, Proposition 41, spherical triangles.] and the sine of the arc opposite the right angle is produced. This arc

cannot be known from the found sine unless it is established whether it is less than a quadrant or greater; or whether the other, non-right, angle is acute or obtuse; or whether the other arc about the right angle is less than or greater than a quadrant. For if the other angle is acute — provided the given angle too is acute; or if both that one and this are obtuse — the sought arc opposite the right angle will be less than a quadrant. But if that other angle is acute and the given one obtuse, or that one obtuse and this one acute, the same sought arc will be greater than a quadrant. Likewise, if the other arc about the right angle and the given arc are of the same kind — namely both less or both greater than a quadrant — the sought arc opposite the right angle will be less than a quadrant; but if of different kinds — namely one less than a quadrant and the other greater — the same sought arc will be greater than a quadrant.

Another way.

Arrange that as the whole sine is to the sine of the given angle, so the secant of the complement of the given arc is to a fourth, [Margin: e — Problem, Proposition 54, spherical triangles.] and the secant of the complement of the arc opposite the right angle is produced.

4. Given two non-right angles in a right-angled triangle, to find the arc opposite either of them, together with the arc subtending the right angle.

[Margin: Both arcs about the right angle are sought; then the arc opposite the right angle.]

Arrange that as the sine of the given angle adjacent to the sought arc is to the whole sine, so the sine of the complement of the other given angle is to a fourth, [Margin: f — Problem 1, Proposition 42, spherical triangles.] and the sine of the complement of the arc opposite this latter angle is produced. Either arc found will be less than a quadrant if the given angle opposite to it is acute; but greater, if obtuse.

Now, once both arcs about the right angle have been found, the arc opposite the right angle will also be found, by Problem 3, from either of them together with the angle given opposite to it.

Another way.

Arrange that as the whole sine is to the sine of the non-right angle adjacent to the sought arc, so the secant of the other non-right angle is to a fourth, [Margin: g —

Problem, Proposition 52, spherical triangles.] and the secant of the arc opposite this latter angle, which is sought, will be found.

5. Given either of the arcs about the right angle in a right-angled triangle, together with the angle adjacent to it, to investigate the other angle opposite that same arc, and the remaining two arcs.

(Continuation of the recipe for Praxis 5, broken off at the catchword "FIAT," on the previous page.)

Set it up so that as the whole sine is to the sine of the given angle, so the sine of the complement of the given arc is to a fourth term [Margin: h — Problem 2, proposition 42, of the spherical triangles]; and there will be produced the sine of the complement of the other angle, which we are seeking. This angle will be acute if the given arc is less than a quadrant, but obtuse if greater.

Then, from the two non-right angles — one given, the other now found — the remaining two arcs will be found, as was stated in the preceding problem.

[Margin: Sought: a non-right angle; then the other two arcs.]

6. Given either of the arcs about the right angle in a right-angled triangle, together with the angle opposite it, to investigate the other non-right angle adjacent to that same arc, and the two remaining arcs — provided only that it is established whether that other non-right angle sought is acute or obtuse, and whether either of the arcs sought is less than a quadrant or greater.

Set it up so that as the sine of the complement of the given arc is to the sine of the complement of the given angle, so the whole sine is to a fourth term [Margin: i — Problem 2, proposition 42, of the spherical triangles]; and there will be found the sine of the other non-right angle sought. This angle will not be drawn out from the sine so found unless it is first established whether it is acute or obtuse, and whether either of the remaining two arcs (the ones not given) is less than a quadrant or greater. For if the other arc about the right angle — the one not given and opposite the angle sought — is less than a quadrant, the angle sought will be acute; but if it is greater, obtuse. By the same reasoning, if the arc opposite the right angle, and not given, is less than a quadrant, then, provided the given angle is acute, the angle sought will likewise be acute; but if the given angle is obtuse, obtuse. But if the arc opposite the right angle is greater than a quadrant, then, provided the given angle is acute, the angle sought will be obtuse; but if it is obtuse, acute.

Then, from the two non-right angles — one given, the other now found — the remaining two arcs will be found, as was shown in problem 4.

Another way.

Set it up so that as the whole sine is to the sine of the complement of the given arc, so the secant of the given angle is to a fourth term [Margin: k — the problem of proposition 56 of the spherical triangles]; and there will be found the secant of the complement of the other non-right angle, which is sought. The rest will be found as stated above.

[Margin: Sought: the arc opposite the right angle; then the two non-right angles.]

7. Given two arcs about the right angle in a right-angled triangle, to find the third arc opposite the right angle, and the two non-right angles.

Set it up so that as the whole sine is to the sine of the complement of either of the given arcs, so the sine of the complement of the other given arc is to a fourth term [Margin: l — the problem of proposition 43 of the spherical triangles]; and there will be produced the sine of the complement of the arc opposite the right angle. This arc will be less than a quadrant if both arcs about the right angle that are given are less than a quadrant, or both greater; but greater than a quadrant if one of the given arcs is less than a quadrant and the other greater.

Then, from the arc subtending the right angle now found, together with either of the given arcs about the right angle, the angle opposite it will be found, as we stated in problem 1.

[Margin: Sought: an arc about the right angle; then the two non-right angles.]

8. Given the arc in a right-angled triangle that is opposite the right angle, together with either of the arcs about the right angle, to inquire the other arc about the right angle, and the two non-right angles.

Set it up so that as the sine of the complement of the given arc about the right angle is to the sine of the complement of the arc opposite the right angle, so the whole sine is to a fourth term [Margin: m — problem, proposition 43, of the spherical triangles]; and there will be generated the sine of the complement of the other arc about the right angle, which is sought. This arc will be less than a quadrant if each given arc is less than a quadrant, or each greater; but greater if one of the given arcs is less than a quadrant and the other greater.

Once the other arc about the right angle has been found, the angles will be found, as was stated in the preceding problem.

Another way.

[Margin: n — the problem of proposition 53 of the spherical triangles.]

Set it up so that as the whole sine is to the sine of the complement of the given arc about the right angle, so the secant of the arc opposite the right angle is to a fourth term; and there will be produced the secant of the third arc, which is sought, etc.

[Margin: Sought: an arc about the right angle; then the other non-right angle, and the arc opposite the right angle.]

9. Given either of the arcs about the right angle in a right-angled triangle, together with the non-right angle adjacent to it, to search out the other arc about the right angle, and another non-right angle, together with the arc subtending the right angle.

Set it up so that as the whole sine is to the sine of the given arc, so the tangent of the given angle is to a fourth term [Margin: o — Problem 1; p — proposition 44, of the spherical triangles]; and there will be produced the tangent of the arc sought. This arc will be less than a quadrant if the given angle opposite it is acute, but greater if it is obtuse.

Furthermore, from the same given arc about the right angle, together with the adjacent angle, the other non-right angle and the arc opposite the right angle will both be found, as we taught above in problem 5.

[Margin: Sought: an arc about the right angle; then the other non-right angle, and the arc opposite the right angle.]

10. Given either of the arcs about the right angle in a right-angled triangle, together with the angle opposite it, to trace out the other arc about the right angle, and another non-right angle, together with the arc subtending the right angle — provided only that it is established whether the remaining arc about the right angle that is sought is less than a quadrant or greater; or whether the other non-right angle is acute or obtuse; or, finally, whether the arc opposite the right angle is less than a quadrant or greater.

Set it up so that as the tangent of the given angle is to the tangent of the given arc, so the whole sine is to a fourth term [Margin: a — Problem 1, proposition 44, of the spherical triangles]; and there will be found the sine of the arc sought. This arc will not be recognized from the sine so found unless it is established whether

it is less than a quadrant or greater; or whether the other non-right angle is acute or obtuse; or, finally, whether the arc opposite the right angle is less than a quadrant or greater. For if the other angle is acute, the arc sought opposite it will be less than a quadrant; but if obtuse, greater. So too, if the arc opposite the right angle is less than a quadrant: provided the given arc is also less than a quadrant, the arc sought will likewise be less than a quadrant; but if greater than a quadrant, greater as well. But if the arc opposite the right angle is greater than a quadrant: provided the given arc is also greater, the arc sought will be less than a quadrant; but if it is less than a quadrant, greater.

Now indeed, from the same given arc about the right angle and the angle opposite, the other non-right angle and the arc opposite the right angle will be found, as was shown in problem 6. Or, alternatively, from the two arcs about the right angle — one given, the other now found — the arc opposite the right angle will be found, together with the two non-right angles, as was shown in problem 7.

Another way.

[Margin: b — problem, proposition 49, of the spherical triangles.]

[Margin: Sought: each non-right angle; then the arc opposite the right angle.]

Set it up so that as the whole sine is to the tangent of the given arc, so the tangent of the complement of the given angle is to a fourth term; and there will be found the sine of the arc sought. The rest will be found, as we prescribed just now.

11. Given two arcs about the right angle in a right-angled triangle, to find either of the non-right angles, and, besides, the arc opposite the right angle.

Set it up so that as the sine of either of the given arcs is to the whole sine, so the tangent of the other given arc is to a fourth term [Margin: a — Problem 2, proposition 44, of the spherical triangles]; and there will be brought forth the tangent of the angle opposite this latter arc. This angle will be acute if the given arc opposite it is less than a quadrant, but obtuse if greater.

From the same two given arcs the third arc opposite the right angle will be found, by problem 7; or, alternatively, by problem 3, from either of the given arcs and the angle opposite it, once found.

Another way.

[Margin: b — the problem of proposition 48 of the spherical triangles.]

[Margin: Sought: the arc opposite the right angle; then the other arc about the right angle, together with the other non-right angle.]

Set it up so that as the whole sine is to the sine of either of the given arcs, so the tangent of the complement of the other given arc is to a fourth term; and there will come forth the tangent of the complement of the angle opposite this latter arc. The rest will be found, as was said just now.

12. Given either of the arcs about the right angle in a right-angled triangle, together with the non-right angle adjacent to it, to find the arc opposite the right angle, and the remaining arc about the right angle, together with the other non-right angle.

Set it up so that as the sine of the complement of the given angle is to the whole sine, so the tangent of the given arc is to a fourth term [Margin: a — Problem 1, proposition 45, of the spherical triangles]; and there will be found the tangent of the arc opposite the right angle. This arc will be less than a quadrant if the given arc adjacent to it is less than a quadrant, or if the given angle is obtuse and the given arc greater than a quadrant. But the same arc sought will be greater than a quadrant if the given angle is acute and the given arc greater than a quadrant, or if the given angle is obtuse and the given arc less than a quadrant.

Now indeed, by problem 2, from the arc subtending the right angle now found and the given angle, the other arc about the right angle, opposite the given angle, will be found. And from the same arc subtending the right angle, together with the arc given at the start, the other non-right angle, opposite the given arc, will be found, by problem 1.

Another way.

[Margin: b — the problem of proposition 46 of the spherical triangles.]

[Margin: Sought: a non-right angle; then the other arc about the right angle, and the other non-right angle.]

Set it up so that as the whole sine is to the sine of the complement of the given angle, so the tangent of the complement of the given arc is to a fourth term; and there will be found the tangent of the complement of the arc opposite the right angle. The rest will be found, as before.

13. Given either of the arcs about the right angle in a right-angled triangle, together with the arc subtending the right angle, to find the angle contained by the said arcs — that is, the one adjacent to the given

arc about the right angle — and, in addition, the remaining arc and angle.

Set it up so that as the tangent of the arc opposite the right angle is to the tangent of the given arc about the right angle, so the whole sine is to a fourth term [Margin: a — Problem 2, proposition 45, of the spherical triangles]; and there will be produced the sine of the complement of the angle contained by the said arcs, which is sought. This angle will be acute if the given arc opposite the right angle is less than a quadrant and the given arc about the right angle is also less; or if both are greater than a quadrant. But the same angle sought will be obtuse if the given arc opposite the right angle is less than a quadrant and the given arc about the right angle is greater than a quadrant; or if the former is greater than a quadrant and the latter less.

The rest will be investigated, as was shown in the preceding problem.

Another way.

[Margin: b — the problem of proposition 51 of the spherical triangles.]

[Margin: Sought: an arc about the right angle; then the other arc about the right angle, together with the remaining non-right angle.]

Set it up so that as the whole sine is to the tangent of the complement of the arc opposite the right angle, so the tangent of the given arc about the right angle is to a fourth term; and there will be found the sine of the complement of the adjacent angle, which is desired.

14. Given the arc subtending the right angle in a right-angled triangle, together with either of the non-right angles, to find the arc about the right angle adjacent to this angle, and, besides, the other arc about the right angle, together with the other non-right angle.

Set it up so that as the whole sine is to the sine of the complement of the given angle, so the tangent of the arc opposite the right angle is to a fourth term [Margin: a — Problem 3, proposition 45, of the spherical triangles]; and there will be produced the tangent of the arc sought. This arc will be less than a quadrant if the given arc opposite the right angle is less than a quadrant and the given angle acute; or if the given arc is greater than a quadrant and the given angle obtuse. But the same arc sought will be greater than a quadrant if the given arc opposite the right angle is less than a quadrant and the given angle obtuse; or if the given arc is greater than a quadrant and the given angle acute.

The remaining matters will be explored, as we taught in problem 12.

[Margin: Sought: a non-right angle; then the two remaining arcs.]

15. Given the arc in a right-angled triangle that is opposite the right angle, together with either of the non-right angles, to inquire the other non-right angle, and the two arcs about the right angle.

Set it up so that as the whole sine is to the sine of the complement of the given arc opposite the right angle, so the tangent of the given angle is to a fourth term [Margin: a — problem, proposition 47, of the spherical triangles]; and there will be found the tangent of the complement of the angle sought. This will be acute if the arc opposite the right angle is less than a quadrant and the given angle acute; or if the given arc is greater than a quadrant and the given angle acute; or if the given arc is greater than a quadrant and the given angle obtuse. But the same angle sought will be obtuse if the arc opposite the right angle is less than a quadrant and the given angle obtuse; or if that arc is greater than a quadrant and the given angle acute.

Hence, from the given arc subtending the right angle, and the two non-right angles — one given, the other now found — each arc about the right angle will be found, by problem 2.

[Margin: Sought: the arc opposite the right angle; then the two arcs about the right angle.]

16. Given two non-right angles in a right-angled triangle, to find the arc opposite the right angle, and the remaining two arcs about the right angle.

Set it up so that as the whole sine is to the tangent of the complement of either of the given angles, so the tangent of the complement of the other given angle is to a fourth term [Margin: a — problem, proposition 50, of the spherical triangles]; and there will be brought forth the sine of the complement of the arc opposite the right angle, which we desire. This arc will be less than a quadrant if each of the given angles is acute, or each obtuse; but greater than a quadrant if one is acute and the other obtuse.

Furthermore, from the arc subtending the right angle now found, and either of the given angles, the arc opposite it will be found, as was shown in problem 2.

PROBLEMS AND PRAXES OF OBLIQUE-ANGLED SPHERICAL TRIANGLES

[Margin: Sought: all the arcs.]

17. Given all the angles of a non-right-angled triangle, to find all its arcs.

[Margin: When all the given angles are unequal.]

Diagram. A spherical triangle drawn with curved (arc) sides, apex uppermost, its base at the bottom, with a perpendicular arc dropped from the apex to a point on the base, dividing the triangle into two right-angled sub-triangles.

- A (apex, top): vertex A
- B (lower left): vertex B
- C (lower right, just above and to the right of D): vertex C
- D (on the base between B and C): foot of the perpendicular arc AD dropped from A to the base BC

Let all the angles first be given in the triangle ABC as unequal, two of which — B and C — are acute (or obtuse); and from the third angle, A, let the perpendicular arc AD be drawn to BC [Margin: a — proposition 62 of the spherical triangles], which will fall inside the triangle. Let the sines of the complements of the angles B and C be set down as the terms of the proportion of the sine of angle BAD to the sine of angle CAD. And from this proportion, together with the sum of the angles BAD and CAD — that is, from the given angle BAC — let each of the angles BAD and CAD be inquired, by problem 6 of the plane triangles. Then, by problem 16 of the spherical triangles, from the two non-right angles B and BAD let the arc AB, opposite the right angle D in the triangle ABD, be investigated; and likewise, from the two non-right angles C and CAD, the arc AC, opposite the right angle D in the triangle ACD. Lastly, by problem 2, from the arc AB subtending the right angle D and the angle BAD, both now found, let the arc BD be found; and likewise, from the arc AC subtending the right angle D and the angle CAD, both found, the arc CD. For the sum of the arcs BD and CD will make the whole arc BC known. And thus all three arcs — AB, AC, BC — will be made known.

[Margin: By the sines alone, when all the given angles are unequal.]

By the sines alone we will solve the problem thus. Let each of the angles BAD and CAD be found by praxis 3 of problem 6 of the plane triangles. Then, by praxis 1 of problem 4 of the spherical triangles, from the two angles B and BAD let the arc BD

be investigated, and from the two angles C and CAD the arc CD. For the sum of the arcs BD and CD will make the whole arc BC known. Lastly, by problem 3 of the spherical triangles, let the arc AB opposite the right angle D be found from the arc BD and the angle opposite it, BAD, both now found; and likewise the arc AC opposite the right angle D, from the arc CD and the angle CAD opposite it, both found. For, besides the data, the species of both the one angle B and the other angle C is also established, since each is given.

But if at any time one of the angles at A — namely BAD — turns out to be a right angle, the two arcs AB and BD will be found, since each is a quadrant, on account of the right angles D and DAB. By the same reasoning, if the angle CAD is discovered to be a right angle, but not BAD — for it cannot happen that both angles at A be right, since the whole angle BAC is less than two right angles — the two arcs AC and CD will be found, being quadrants, on account of the right angles D and DAC.

(Continuation of the solution begun on the previous page — Problem 17, the oblique spherical triangle solved when at least two of its angles are equal.)

Next, let at least two of the given angles, B and C, be equal, whatever the third angle A may be, and from A let the perpendicular arc AD be drawn to BC. Then the two arcs AB and AC, and the two arcs BD and CD, and the two angles at A will all be equal; and consequently each angle at A is known, being half the given angle BAC. Therefore, by Problem 16 of spherical triangles, from the two angles B and BAD find the arc AB opposite the right angle D; and AC, being equal to it, is likewise known. Next, by Problem 14 of spherical triangles, from the found arc AB (which subtends the right angle) and the given angle B, find the arc BD; and CD, being equal to it, is likewise known; and therefore the whole BC is known. And now all three arcs AB, AC, BC will have been found.

By sines alone we shall carry out the matter thus. By Praxis 1 of Problem 4 of spherical triangles, seek the arc BD from the two angles B and BAD; and therefore CD, being equal to it, is known, and consequently the whole BC is known. Then, by Problem 3 of spherical triangles, from the found arc BD and its opposite angle BAD, find the arc AB opposite the right angle — since, besides the data, the species of the other angle B is also settled, it being given — and therefore the arc AC, being equal to AB, is known.

[Margin: When the two given angles are equal.] [Margin: By sines alone, when the two given angles are equal.]

Diagram. An oblique spherical triangle with curved sides, drawn for the case of two equal base angles.

- A (apex, top): vertex of the equal angles' summit
- B (lower left): base vertex
- D (base, between B and C): foot of the perpendicular arc AD dropped from A
- C (lower right): base vertex

18. DATIS omnibus arcubus trianguli non rectanguli, investigare omnes eius angulos.

18. Given all the arcs of a non-right triangle, to find all its angles.

[Margin: All the angles are sought.]

[Margin: (note a) When the two given arcs are unequal and less than a quadrant. From Proposition 63 of spherical triangles.]

Let all the arcs in triangle ABC be given, and let the angle A be sought first; and let the two arcs AB, AC that contain it be unequal and less than a quadrant, whatever the arc BC may be. Extend the arcs AB, AC so that AD, AE become quadrants, and through D, E describe the arc of a great circle DE, meeting the arc BC — produced toward the greater arc, which is AC — at the point F. Set the sines of the complements of the given arcs AB, AC as the terms of the proportion: the sine of arc BF to the sine of arc CF. From this proportion, together with the given arc BC (which is the difference of the arcs BF, CF), find each of the arcs BF, CF by Problem 8 of plane triangles. Then, by Problem 8 of spherical triangles, find the arc DF from the found arc BF (subtending the right angle D) and the arc BD (which is the complement of the given arc AB); and likewise the arc EF from the found arc CF (subtending the right angle E) and the arc CE (which is the complement of the given arc AC). For, subtracting the found arc EF from the found arc DF, the arc DE of the angle A remains known; and therefore the angle A will be known. After this, by Problem 11 of spherical triangles, from the known arcs BD, DF about the right angle D, find the angle DBF, and hence the remaining one of the two right angles, ABC. Finally, by the same reasoning, from the arcs CE, EF known about the right angle E, obtain the angle ECF, and thus also the angle ACB, which is equal to it at the vertex. And thus now all three angles A, B, C will have been found.

By sines alone we shall proceed thus. Each arc BF, CF is found by Praxis 3 of Problem 8 of plane triangles. Then, by Praxis 1 of Problem 8 of spherical

triangles, find the arc DF from the found arc BF (subtending the right angle D) and the arc BD (the complement of the given arc AB), and likewise the arc EF from the found arc CF (subtending the right angle E) and the arc CE (the complement of the given arc AC). For, subtracting arc EF from arc DF, the arc DE of the angle A is left known; and thus the angle A will be known. After this, by Praxis 1 of Problem 1 of spherical triangles, from the found arc BF (subtending the right angle D) and the found arc DF, seek the angle DBF opposite the arc DF: from which the remaining angle of the two right angles, namely ABC, also becomes known. Finally, by the same reasoning, from the found arc CF (subtending the right angle E) and the found arc EF, find the angle ECF opposite the arc EF: from which becomes known also the angle ACB equal to it at the vertex.

[Margin: By sines alone, when the two given arcs are unequal and less than a quadrant.]

Diagram. The quadrant construction for the first case of Problem 18: the sides are produced to quadrants and a great-circle arc DE is drawn cutting the produced base at F.

- A (apex, top): common vertex of the arcs
- B (left, on the base): base vertex
- C (on the base, between B and F): base vertex
- F (right): point where the great-circle arc DE meets BC produced
- D (lower left): endpoint of the quadrant on side AB produced
- E (lower middle): endpoint of the quadrant on side AC produced

Next, let the two unequal arcs AB, AC be greater than a quadrant; extend them until they meet at D. Then in triangle DBC the two arcs DB, DC will be unequal and less than a quadrant. Hence, as we said just now, all its three angles will be found; and consequently the remaining ones of the two right angles, ABC and ACB, will be known, as well as A, which is equal to D.

[Margin: When the two given arcs are unequal and greater than a quadrant.]

Diagram. A lens-shaped (biangular) figure for the case where both sides exceed a quadrant and, produced, meet at D.

- A (top): upper meeting point of the two arcs
- B (left): base vertex
- C (right): base vertex

- D (bottom): point where the produced arcs AB, AC meet

Third, let the arc AB be less than a quadrant, and AC greater than a quadrant. Extend AB so that AD becomes a quadrant, and cut off from AC the quadrant AE, and through D, E draw the arc of a great circle DE, cutting BC at F, as in the first of these two figures. Set the sines of the complements of the given arcs AB, AC as the terms of the proportion: the sine of arc BF to the sine of arc CF; and from this proportion, together with the sum of the arcs BF, CF — that is, from the given arc BC — find each of the arcs BF, CF by Problem 6 of plane triangles. Then, by Problem 8 of spherical triangles, find the arc DF from the found arc BF (subtending the right angle D) and the arc BD (the complement of the given arc AB); and the arc EF from the found arc CF (subtending the right angle E) and the arc CE (the complement of the given arc AC). For the sum of the found arcs DF, EF will give the whole arc DE of the angle A; and therefore the angle A will be known. After this, by Problem 11 of spherical triangles, from the arcs DB, DF known about the right angle D, work out the angle DBF, and hence the remaining one of the two right angles, ABC. And finally, in the same way, from the arcs CE, EF known about the right angle E, obtain the angle C: and all three angles A, B, C will have been found.

By sines alone the work is to be done thus. Each arc BF, CF is found by Praxis 3 of Problem 6 of plane triangles. Then, by Praxis 1 of Problem 8 of spherical triangles, let both be obtained: the arc DF, from the found arc BF (subtending the right angle D) and the arc BD (the complement of the given arc AB); and the arc EF, from the found arc CF (which is opposite the right angle E) and the arc CE (the complement of the given arc AC). For the sum of the found arcs DF, EF will give the whole arc DE of the angle A. After this, by Problem 1 of spherical triangles, from the known arc BF (subtending the right angle D) and the arc DF, find the angle DBF, and hence the remaining one of the two right angles, ABC. And finally, in the same way, from the known arcs CF, EF, find the angle C.

[Margin: When the two given arcs are unequal, and one is greater than a quadrant and the other less.] [Margin: By sines alone, when the two given arcs are unequal, and one is greater than a quadrant and the other less.]

Diagram. The left of a pair of figures at the foot of the page, for the case where AB is less than a quadrant and AC greater. The figures are crowded and overlapping.

- A (apex, top): common vertex
- B (upper left): base vertex

- C (right): base vertex
- D (lower left): endpoint of the quadrant AD
- E (interior, middle): endpoint of the quadrant AE
- F (lower middle): intersection of DE with BC

Diagram. The right of the pair of figures at the foot of the page, showing an interior great-circle construction (this figure is referred to on the next page as "the latter of the two nearby figures").

- A (apex, top): common vertex
- B (lower middle): base vertex
- C (upper right): base vertex
- D (lower right): endpoint of the quadrant construction
- E (interior, middle): intersection point of the interior arcs

Fourth, let the greater arc AB be a quadrant, and AC less than a quadrant, as in the latter of the two nearby figures. Extend the arc AC so that AD becomes a quadrant, and through B, D draw the arc of a great circle BD. Then, by Problem 8 of spherical triangles, from the given arc BC (subtending the right angle D) and the arc CD (the complement of the given arc AC), find the arc BD of the angle A; from which the angle A itself will be known. After this, by Problem 11 of spherical triangles, from the two known arcs BD, CD about the right angle D, find the angle BCD; from which the remaining one of the two right angles, ACB, will also be known. Finally, by the same Problem 11, from the same arcs BD, CD, find the angle CBD; which, subtracted from the right angle ABD, leaves the angle ABC known.

By sines alone we shall proceed thus. By Praxis 1 of Problem 8 of spherical triangles, from the given arc BC (subtending the right angle D) and the arc CD (the complement of the given arc AC), find BD, the arc of the angle A: from which the angle A itself will be known. Then, from the known arcs BC, BD, by Problem 1 of spherical triangles, obtain the angle BCD: and hence the remaining one of the two right angles, ACB. Finally, by the same reasoning, from the known arcs BC, CD, seek the angle CBD, which, subtracted from the right angle ABD, leaves the angle ABC known.

[Margin: When the two given arcs are unequal, and the greater arc is a quadrant while the lesser is less than a quadrant.] [Margin: By sines alone, when the greater arc is a quadrant.]

Fifth and last, let the greater arc AB be greater than a quadrant, and the lesser arc AC be a quadrant, as in the same latter of the two nearby figures. Cut off the quadrant AE from AB, and through C, E draw the arc of a great circle CE. Then, by Problem 8 of spherical triangles, from the given arc BC (subtending the right angle E) and the arc BE (the complement of the given arc AB), find the arc CE of the angle A; from which the angle A itself will be known. After this, by Problem 11 of spherical triangles, from the two known arcs BE, EC about the right angle E, obtain the angle BCE; to which, if the right angle ACE is added, the whole angle ACB becomes known. Finally, by the same reasoning, from the same arcs BE, EC, find the angle EBC.

By sines alone we shall carry out the proposition thus. By Praxis 1 of Problem 8 of spherical triangles, from the given arc BC (subtending the right angle E) and the arc BE (the complement of the given arc AB), seek the arc CE of the angle A: and thus the angle A becomes known. Then, by Problem 1 of spherical triangles, from the known arcs BC, BE, find the angle BCE; to which, if the right angle ACE is added, the whole ACB will be known. Finally, by like reasoning, from the known arcs BC, CE, find the angle CBE.

[Margin: When the greater given arc is greater than a quadrant and the lesser is a quadrant.] [Margin: By sines alone, when the greater given arc is greater than a quadrant and the lesser is a quadrant.]

ALITER, & facilius, per solos sinus, quando duo arcus quaesitum angulum comprehendentes sunt inaequales quomodocunque.

ALTERNATIVELY, and more easily, by sines alone, when the two arcs containing the sought angle are unequal in any way whatever.

Arrange it so that, as the whole sine is to the sine of either of the unequal arcs containing the sought angle, so is the sine of the other arc about the same angle to a fourth term; and a certain fourth number will be found. Then again, arrange it so that, as that found fourth number is to the whole sine, so is the difference between the versed sine of the arc opposite the sought angle and the versed sine of the arc by which the two arcs surrounding the sought angle differ from one another, to another term; and the versed sine of the sought angle will be produced: from which the angle itself will be obtained.

In the same way the other two angles will be found, if the arcs containing them are unequal.

[Margin: An easier and more general praxis, by sines alone, when the two arcs containing the sought angle are unequal.]

Now let the two arcs AB, AC containing the sought angle A be equal. The perpendicular arc AD will bisect both the angle A and the base BC. Therefore, by Problem 1 of spherical triangles, from the given arc AB (subtending the right angle D) and the arc BD (half the given arc BC), find the angle BAD, which, doubled, gives the whole angle BAC. Then, by Problem 13 of spherical triangles, from the known arcs AB, BD, find the angle B, to which the angle C is equal (on account of the equal arcs AB, AC), and which is therefore also known.

By sines alone we shall do this. By Praxis 1 of Problem 1 of spherical triangles, from the given arc AB (subtending the right angle D) and the arc BD (half the given arc BC), find the angle BAD, which, doubled, makes the whole BAC known. Then, by Praxis 1 of Problem 6 of spherical triangles, from the arc BD (half the given arc BC) and its found opposite angle BAD — since the species of the other angle B is settled: for if the given arc AB, opposite the right angle D, is less than a quadrant, the angle B will be acute, just as BAD is acute; but if AB is greater than a quadrant, the angle B will be obtuse, since BAD is acute — find the angle B, to which the angle C is equal, on account of the equal arcs AB, AC.

[Margin: When the two given arcs are equal.] [Margin: By sines alone, when the two given arcs are equal.]

Diagram. An isosceles spherical triangle for the equal-sides case, with the perpendicular AD bisecting both the vertex angle and the base.

- A (apex, top): vertex of the equal sides
- B (lower left): base vertex
- D (base, middle): foot of the perpendicular AD
- C (lower right): base vertex

Nor indeed can the two equal arcs be quadrants. For otherwise the two angles above the base would be right, and thus the triangle would be right-angled — which is contrary to the hypothesis.

19. DATIS duobus arcibus trianguli non rectanguli cum angulo ab ipsis comprehenso, inuestigare reliquum arcum, cum reliquis duobus angulis.

19. Given two arcs of a non-right triangle together with the angle contained by them, to find the remaining arc, together with the remaining two angles.

[Margin: An arc is sought, together with the two adjacent angles.]

[Margin: (note a) When the two given arcs are unequal and neither of them a quadrant. From Proposition 64 of spherical triangles.]

Let two arcs AB, BC in triangle ABC be given, together with the angle B; and let them first be unequal, and neither of them a quadrant. From A, the endpoint of one of them, let the perpendicular arc AD be dropped to the other; whether it falls inside or outside the triangle, we shall learn from the operation itself. For, by Problem 2 of spherical triangles, from the given arc AB (subtending the right angle D) and the given angle B, find the arc AD opposite the angle B. Again, from the given arc AB (subtending the right angle D) and the found arc AD, find, by Problem 8 of spherical triangles, the third arc BD. If, then, this found arc BD is less than the given arc BC, the arc AD falls inside the triangle, but outside if it is greater. Now, subtracting the found arc BD from the given arc BC (if the former is less than the latter), or subtracting the given arc BC from the found arc BD (if the latter is greater than the former), the arc CD is left known. Finally, from the arcs AD, CD about the right angle D, find, by Problem 7 of spherical triangles, the third arc AC, which is sought.

Diagram. A pair of triangles for Problem 19, illustrating the perpendicular AD falling inside the triangle (left) and outside it (right).

- Left figure — A (apex), B (lower left), D (foot of perpendicular, on the base), C (lower right); AD falls within the triangle.
- Right figure — A (apex), B (lower left), C (base), D (lower right, beyond C); AD falls outside the triangle.

Next, by Problem 13 of spherical triangles, from the given arc AB (subtending the right angle D) and the found arc AD, find the angle BAD contained by the said arcs. And by the same reasoning, from the found arc AC (subtending the right angle D) and the found arc AD, find the

angle CAD, contained by the said arcs. For the angle CAD, added to the angle BAD (when the arc AD falls inside the triangle), or the angle CAD subtracted from the angle BAD (when the arc AD falls outside the triangle), will make up, or leave, the sought angle BAC.

Finally, by Problem 13 of spherical triangles, from the found arc AC (subtending the right angle D) and the found arc CD, obtain the angle C, which — when the arc AD falls inside the triangle — is the one sought; but when the arc AD falls outside the triangle, subtracted from two right angles it leaves the sought angle ACB.

By sines alone we shall do thus. By Problem 2 of spherical triangles, find, from the given arc AB (subtending the right angle D) and the given angle B, the opposite arc AD; and hence, by Praxis 1 of Problem 8 of spherical triangles, the arc BD. For this, subtracted from the given arc BC (if the former is less than the latter), or the given arc BC subtracted from the found arc BD (if the latter is less than the former), leaves the arc CD known. Then, by Praxis 1 of Problem 1 of spherical triangles, obtain both angles: from the given arc AB (subtending the right angle D) and the found arc AD, the opposite angle BAD; and from the found arc AC (subtending the right angle D) and the found arc CD, the opposite angle CAD. For from the two found angles BAD, CAD the sought angle BAC will be known — if one is added to the other, when the arc AD falls inside the triangle, or, when it falls outside, if CAD is subtracted from BAD. Finally, by Praxis 1 of Problem 1 of spherical triangles, seek, from the found arc AC (subtending the right angle D) and the found arc AD, the opposite angle C. For this, in the first triangle, is the one sought; but in the second, the remaining one of the two right angles, ACB, is the one sought.

But if perhaps the arc CD is found to be a quadrant (though BD will never be a quadrant, given that AB is not a quadrant), then the sought arc AC will also be a quadrant, and the angle CAD a right angle. And thus without difficulty the sought arc AC will have been found, together with the angle CAD, from which we shall find the sought angles BAC, ACB, as before.

[Margin: By sines alone, when the two given arcs are unequal and neither of them a quadrant.]

Now let one of the given unequal arcs be a quadrant, namely AB, from whose endpoint A the perpendicular arc AD is dropped to the other. Then the arc BD will also be a quadrant, and the angle BAD a right angle; and B will be the pole of the arc AD; and therefore the arc AD will become known from the given angle B. And thus in this case the two arcs BD, AD, together with the angle BAD, will have been

made known without any further labor: from which the rest will be found, as before.

[Margin: When one of the two given unequal arcs is a quadrant.]

ALITER, & facilius, per solos sinus, quando dati duo arcus inaequales sunt quomodocunque.

ALTERNATIVELY, and more easily, by sines alone, when the two given arcs are unequal in any way whatever.

Arrange it so that, as the whole sine is to the sine of either of the given unequal arcs, so is the sine of the other given arc to a fourth term; and a certain fourth number will be produced. Then again, arrange it so that, as the whole sine is to that found fourth number, so is the versed sine of the given angle to another term; and there will be found the difference between the versed sine of the third arc (which is sought) and the versed sine of the difference of the given unequal arcs. This difference, once found, if added to the versed sine of the difference of the given arcs, composes the versed sine of the sought third arc. Now, the three arcs of the proposed triangle being known, the other two angles will be found by the preceding problem — especially by that easier praxis; and if the two arcs containing either of them are equal, the last praxis of the same preceding problem is to be used.

[Margin: An easier and more general praxis, by sines alone, when the two given arcs are unequal.]

But now let the two given arcs AB, AC that contain the given angle A be equal, and hence let neither be a quadrant. The perpendicular arc AD will bisect both the given angle A and the base BC. Therefore, by Problem 2 of spherical triangles, from the given arc AB (subtending the right angle D) and from the angle BAD (half the given angle BAC), find the opposite arc BD, which, doubled, gives the whole sought arc BC. Then, by Problem 13 of spherical triangles, from the given arc AB (subtending the right angle D) and the found arc BD, seek the angle B contained by the said arcs; to which the angle C is equal, on account of the equal arcs AB, AC.

By sines alone the matter will be carried out thus. From the given arc AB (subtending the right angle D) and the angle BAD (half the given angle BAC), find, by Problem 2 of spherical triangles, the opposite arc BD, which, doubled, will give the whole sought arc BC. Then, by Praxis 1 of Problem 6 of spherical triangles, from the found arc BD and the angle BAD (half the given angle BAC) — since

besides this the species of the other angle B is settled: for if the arc AB is less than a quadrant, the angle B will be acute, just as BAD is acute; but if AB is greater than a quadrant, B will be obtuse, since BAD is acute — obtain the angle B; to which the angle C is equal.

[Margin: When the two given arcs are equal.] [Margin: By sines alone, when the two given arcs are equal.]

Diagram. An isosceles spherical triangle for the equal-sides case of Problem 19, with the perpendicular AD bisecting the vertex angle and the base.

- D (base, middle): foot of the perpendicular AD
- C (lower right): base vertex

20. DATIS duobus angulis trianguli non rectanguli, cum arcu ipsis adiacente, indagare reliquos arcus, cum angulo reliquo.

20. Given two angles of a non-right triangle, together with the arc adjacent to them, to find the remaining arcs, together with the remaining angle.

[Margin: Two arcs are sought, together with the angle contained by them. When the given angles are unequal and the adjacent arc is not a quadrant. From Proposition 65 of spherical triangles.]

Let two angles B, BAC in triangle ABC be given, together with the adjacent arc AB; and let the given angles first be unequal, and the arc AB not a quadrant. From one of the given angles, namely from A, let the perpendicular arc be dropped to the opposite arc BC; whether it falls inside or outside the triangle, the operation itself will show. For, by Problem 15 of spherical triangles, from the given arc AB (subtending the right angle D) and the given angle B, find the other non-right angle BAD: which, if it is less than the given angle BAC, means the arc AD falls inside the triangle; but outside, if greater. In the first case the found angle BAD, subtracted from the given angle BAC; in the second the given angle BAC subtracted from the found angle BAD — leaves the angle CAD known. Again, by Problem 2 of spherical triangles, from the given arc AB (subtending the right angle D) and the given angle B, find the opposite arc AD. Likewise, by Problem 12 of spherical triangles, from the found arc AD and the adjacent found angle CAD, obtain the arc AC opposite the right angle D; which indeed is one of the sought quantities.

Diagram. A pair of triangles for Problem 20, illustrating the perpendicular AD falling inside the triangle (left) and outside it (right).

- Left figure — A (apex), B (lower left), D (foot of perpendicular, on the base), C (lower right); AD falls within the triangle.
- Right figure — A (apex), B (lower left), C (base), D (lower right, beyond C); AD falls outside the triangle. Then, by Problem 8 of spherical triangles, from both the given arc AB (which subtends the right angle D) together with the found arc AD, let arc BD be traced out; and likewise, from the found arc AC (subtending the right angle D) together with the found arc AD, arc CD. When arc AD falls inside the triangle, this arc CD is added to the found arc BD; when arc AD falls outside the triangle, it is subtracted from that same arc BD. Either way it yields the sought arc BC as known.

Finally, by Problem 15 of spherical triangles, from the found arc AC (subtending the right angle D) together with the found angle CAD, investigate angle ACD. In the first triangle this is itself the angle sought; in the second, subtracted from two right angles, it leaves the remainder ACB, which is sought.

[Margin: By sines alone, when the given angles are unequal and the adjacent arc is not a quadrant.]

By sines alone the business will be settled as follows. By Problem 2 of spherical triangles, from the given arc AB (which subtends the right angle D) together with the given angle B, find the opposite arc AD. Then, by Praxis 1 of Problem 8 of spherical triangles, from the given arc AB (subtending the right angle D) together with the found arc AD, obtain the third arc BD. Likewise, by Praxis 1 of Problem 1 of spherical triangles, from the given arc AB (subtending the right angle D) together with the found arc BD, seek the opposite angle BAD. This angle, removed from the given angle BAC (if it is the smaller), or the given BAC subtracted from it (if this is the smaller of the two), leaves angle CAD known. Again, by Problem 5 of spherical triangles, from the found arc AD together with the adjacent angle CAD, derive angle ACD — which in the first triangle is the one sought, but in the second is the remainder of the two right angles, namely ACB, which is sought.

After this, by Praxis 1 of Problem 4 of spherical triangles, from both found angles CAD and ACD find arc CD. In the first triangle this arc, added to the already-found arc BD, or in the second subtracted from it, makes the sought arc BC known.

Finally, by Problem 7 of spherical triangles, from the found arcs AD and CD about the right angle D, find the third arc AC, opposite the right angle D, which is

sought. And so the two remaining arcs BC and AC will have been found, together with the remaining angle ACB.

But if it should happen that the found angle CAD is right — for BAD can never be right, given that AB is not a quadrant — then AC and CD will be quadrants, and AD the arc of angle C; and consequently angle C will become known from the found arc AD. The remaining arc BC will then be known from the found arc BD and the quadrant CD, as before.

[Margin: When the given arc is a quadrant.]

Now if the given arc AB is a quadrant, angles B and BAC still being given as unequal, then angle BAD will be right and arc BD likewise a quadrant. Also B will be the pole of arc AD; and therefore arc AD itself will be known from the given angle B. Once arcs AD and BD and the right angle BAD have been found with such ease, we shall recover the rest as before.

Diagram. A spherical triangle for the equal-angles case that follows. The apex A is at the top; the base runs B–D–C along the bottom, with D the foot of the perpendicular AD dropped from A.

- A (apex): vertex of the two equal base angles
- B (lower left): base endpoint
- D (base, middle): foot of the perpendicular from A
- C (lower right): base endpoint

[Margin: When the two given angles are equal.]

Next, suppose that in triangle ABC the two angles B and C are given as equal, together with the adjacent arc BC, whether or not it is a quadrant. Then arcs AB and AC will be equal, and the perpendicular arc AD, dropped from the third angle A onto BC, will bisect both the arc BC and the angle A. Therefore, by Problem 12 of spherical triangles, from arc BD (the half of the given arc BC) together with the given adjacent angle B, find arc AB opposite the right angle D; and since AC is equal to it, the two remaining arcs will have been found. Again, by Problem 5 of spherical triangles, from the same arc BD (the half of the given arc BC) together with the given adjacent angle B, find the other non-right angle BAD. For this, when doubled, gives the whole sought angle BAC.

[Margin: By sines alone, when the two given angles are equal.]

By sines alone we shall proceed thus. By Problem 5 of spherical triangles, from arc BD — the half of the given arc BC — together with the given adjacent angle B, find

angle BAD, which doubled gives the whole BAC, sought. Then, by Praxis 1 of Problem 3 of spherical triangles, from arc BD (the half of the given arc BC) together with the found angle BAD (its opposite), find — since besides this the species of the other angle B, which is given, is established — arc AB opposite the right angle D, to which AC is equal.

21. Given two angles of a non-right triangle, together with the arc opposite one of them, to investigate the remaining arcs together with the remaining angle: provided only it be established whether the arc opposite the other given angle is greater than a quadrant, or less, or exactly a quadrant.

[Margin: Two arcs are sought, together with one angle. When the two given angles are unequal and the given arc is not a quadrant. ^a By Proposition 66 of spherical triangles.]

^a Suppose that in triangle ABC the two angles B and C are given, together with arc AB, which is opposite angle C. Let these angles first be unequal, with AB not a quadrant, and let there be established besides the species of arc AC, opposite the other given angle B. From the third angle A drop the perpendicular arc AD to arc BC. It will fall inside the triangle if both given angles B and C are acute, or both obtuse; but outside if one is acute and the other obtuse. (It is settled whether both angles are acute or obtuse, or not, because angle B is given together with the species of angle C.)

Now, by Problem 2 of spherical triangles, from the given arc AB (which subtends the right angle D) together with the given angle B, find the opposite arc AD. Also, by Problem 14 of spherical triangles, from the same given arc AB (subtending the right angle D) together with the given angle B, obtain arc BD. Again, by Problem 15 of spherical triangles, from the same given arc AB (subtending the right angle D) together with the given angle B, find angle BAD. Furthermore, by Problem 3 of spherical triangles, from the found arc AD together with the given opposite angle C, find arc AC as well. (For, when arc AD falls outside the triangle, angle ACD, opposite arc AD, is left known after subtracting the given angle ACB from two right angles.) Arc AC, opposite the right angle D — since its species is supposed to be established — is thus found; and so arc AC, one of the sought arcs, will have been found.

Then, by Problem 14 of spherical triangles, from the found arc AC (subtending the right angle D) together with the given angle C, find arc CD. This arc, added to the arc BD found above, or subtracted from it — according as arc AD falls inside or outside the triangle — makes arc BC known, which is the other of the sought arcs.

Lastly, by Problem 15 of spherical triangles, from the same found arc AC (subtending the right angle D) together with the given angle C, find angle CAD. This, added to angle BAD if arc AD falls inside the triangle, or, if outside, subtracted from it, will make known angle BAC, sought.

Diagram. Two spherical triangles illustrating the two positions of the perpendicular in Problem 21. In the upper figure the perpendicular AD falls inside the triangle (apex A, base B–D–C). In the lower figure it falls outside, so that D lies beyond the base (apex A at the right, base at B–C–D).

- A (apex, upper figure): vertex from which the perpendicular is dropped
- B (lower left, upper figure): base endpoint
- D (base, upper figure): foot of the perpendicular (inside)
- C (right, upper figure): base endpoint
- A (upper right, lower figure): apex
- B (lower left, lower figure): base endpoint
- C (base, lower figure): base endpoint
- D (base right, lower figure): foot of the perpendicular (outside)

We shall use the sines of the same quantities thus. By Problem 2 of spherical triangles, from the given arc AB (which subtends the right angle D) together with the given angle B, seek the opposite arc AD. From this, by Praxis 1 of Problem 8 of spherical triangles, from the given arc AB (subtending the right angle D) together with the found arc AD, find the third arc BD. And again, by Praxis 1 of Problem 1 of spherical triangles, from the given arc AB (subtending the right angle D) together with the found arc BD, derive the opposite angle BAD. After this, by Praxis 1 of Problem 3 of spherical triangles, from the found arc AD together with the given opposite angle C, elicit arc AC, opposite the right angle D, since its species is established by hypothesis: this arc AC is one of the sought quantities.

[Margin: By sines alone, when the two given angles are unequal and the given arc is not a quadrant.]

Then, by Praxis 1 of Problem 8 of spherical triangles, from the found arc AC (subtending the right angle D) together with arc AD, find the third arc CD. From this — if in the first triangle it is added to the found arc BD, or in the second subtracted from it — the other sought arc BC becomes known.

Finally, by Praxis 1 of Problem 1 of spherical triangles, from arc AC (subtending the right angle D) together with the found arc CD, seek the opposite angle CAD.

For this, added in the first triangle to the found angle BAD, or in the second subtracted from it, makes angle BAC known, sought.

[Margin: When the given arc is a quadrant and the two given angles are unequal.]

But if the arc AC, opposite the other given angle B, should be a quadrant — which can happen when AB is not a quadrant (in which case AD or BD can never be a quadrant) — then CD too will be a quadrant, and angle CAD right. So one need not then labour over investigating arcs AC and CD and angle CAD; but from these arc BC and angle BAC are to be found, as we said.

[Margin: When the given arc is a quadrant and the two given angles are equal.]

But now suppose the given arc AB is a quadrant, the two angles B and C still being given as unequal. That granted, BD too will be a quadrant, and angle BAD right; also B will be the pole of arc AD; and consequently arc AD, since it is its arc, will become known from the given angle B. Once arcs BD and AD and the right angle BAD have been found with such ease, the rest will be found, as before.

[Margin: When the two given angles are equal.]

Finally, suppose the two angles B and C are given equal. Then arc AD will bisect both the base BC and angle A, and arcs AB and AC will be equal. By Problem 14 of spherical triangles, from the given arc AB (which subtends the right angle D) together with the given angle B, find arc BD, which doubled offers the whole sought BC. The other sought quantity, AC, will be given, since it is equal to the given AB. Again, by Problem 15 of spherical triangles, from the same given arc AB together with angle B, obtain angle BAD; and this doubled gives the whole BAC, which is sought.

Diagram. An isosceles spherical triangle for the equal-angles case. Apex A at the top; base B–D–C along the bottom, with the perpendicular AD dropped from A onto the midpoint D of the base.

- A (apex): vertex of the two equal angles
- B (lower left): base endpoint
- D (base, middle): foot of the bisecting perpendicular
- C (lower right): base endpoint

[Margin: By sines alone, when the two given angles are equal.]

By sines alone we shall settle the problem thus. By Problem 2 of spherical triangles, investigate arc AD from the given arc AB (which subtends the right angle D)

together with the given angle B, opposite arc AD. From this, by Praxis 1 of Problem 8 of spherical triangles, find, from the given arc AB (subtending the right angle D) together with the found arc AD, the third arc BD, which doubled gives the whole sought BC. Then, by Praxis 1 of Problem 1 of spherical triangles, from the given arc AB (subtending the right angle D) together with the found arc BD, trace out the opposite angle BAD, which doubled offers the whole BAC, sought.

In this case, moreover, the given arc AB cannot be a quadrant.

22. Given two arcs of a non-right triangle, together with the angle opposite one of them, to search out the remaining angles together with the remaining arc: provided only it be established whether the angle opposite the other given arc is acute or obtuse.

[Margin: Two angles are sought, together with one arc. When the two given arcs are unequal and neither of them is a quadrant. ^a By Proposition 67 of spherical triangles.]

^a Suppose that in triangle ABC the two arcs AB and AC are given, together with angle B, which is opposite arc AC. Let these arcs first be unequal, and neither a quadrant, and let there be established besides the species of angle C, opposite the other given arc AB. From angle A, comprehended by the given arcs, drop the perpendicular arc to arc BC. It will fall inside the triangle if both angles B and C are acute, or both obtuse; but outside if one is acute and the other obtuse. (It is settled whether both angles are acute or obtuse, or not, because angle B is given together with the species of angle C.)

Therefore, by Problem 2 of spherical triangles, from the given arc AB (which subtends the right angle D) together with the given angle B, find the opposite arc AD. From this, by Problem 8 of spherical triangles, from the same given arc AB together with the found arc AD, elicit the third arc BD. Then again, by Problem 1 of spherical triangles, from the given arc AB (subtending the right angle D) together with the found arc BD, find angle BAD, opposite arc BD. And by Problem 13 of spherical triangles, from the given arc AC (subtending the right angle D) together with the found arc AD, derive angle CAD, comprehended by the said arcs. For this angle, added to the found angle BAD, or subtracted from it — according as arc AD falls inside or outside the triangle — gives the sought angle BAC. Find besides, by Problem 15 of spherical triangles, from the given arc AC (subtending the right angle D) together with the found angle CAD, angle ACD: this will be the one we seek if arc AD falls inside the triangle; but if outside, removed

from two right angles it gives angle ACB, sought. And so the two remaining angles BAC and ACB will have been found.

Then, by Problem 8 of spherical triangles, from the given arc AC (subtending the right angle D) together with the found arc AD, seek arc CD. For this, added to the found arc BD, or subtracted from it (according as arc AD falls inside or outside the triangle), yields the sought arc BC as known.

In this case, moreover, none of the arcs AD, BD, CD can be a quadrant.

Diagram. Two spherical triangles illustrating the two positions of the perpendicular in Problem 22. In the left figure the perpendicular falls inside the triangle (apex A, base B–D–C). In the right figure it falls outside, so that D lies beyond the base (apex A, base B–C–D).

- A (apex, left figure): vertex from which the perpendicular is dropped
- B (lower left, left figure): base endpoint
- D (base, left figure): foot of the perpendicular (inside)
- C (right, left figure): base endpoint
- A (apex, right figure): apex
- B (lower left, right figure): base endpoint
- C (base, right figure): base endpoint
- D (base right, right figure): foot of the perpendicular (outside)

[Margin: By sines alone, when the two given arcs are unequal and neither of them is a quadrant.]

By sines alone the work is to be done thus. By Problem 2 of spherical triangles, from the given arc AB (which subtends the right angle D) together with the given angle B, find the opposite arc AD. From this, by Praxis 1 of Problem 8 of spherical triangles, from the given arc AB (subtending the given right angle D) together with the found arc AD, obtain the third arc BD. And from this again, by Praxis 1 of Problem 1 of spherical triangles, from arc AB (subtending the right angle D) together with the found arc BD, find the opposite angle BAD.

Also, by Praxis 1 of Problem 8 of spherical triangles, from the given arc AC (subtending the right angle D) together with the found arc AD, derive the third arc CD; which, either added to the found arc BD, or subtracted from it (according as arc AD falls inside or outside the triangle), gives the sought arc BC.

Then investigate, by Praxis 1 of Problem 1 of spherical triangles, from the given arc AC (subtending the right angle D) together with the found arc CD, the opposite

angle CAD: which, joined to angle BAD, or taken away from it (according as arc AD falls inside or outside the triangle), will exhibit the sought angle BAC. Finally, by Problem 5 of spherical triangles, from the found arc AD together with the found adjacent angle CAD, find the other angle ACD: this will be the other of the sought quantities if arc AD falls inside the triangle; but if it falls outside, it must be subtracted from two right angles, so that the remainder becomes the other sought angle ACB.

[Margin: When one of the given arcs is a quadrant.]

But if one of the given arcs is a quadrant: if indeed AB is a quadrant, then BD too will be a quadrant, and angle BAD right, and also B the pole of arc AD; consequently arc AD will be known from the given angle B. And so, arcs AD and BD and the right angle BAD being known, we shall find the rest, as before. By the same reasoning, if AC is a quadrant, then CD too will be a quadrant, and angle CAD right, and also C the pole of arc AD; and thus the found arc AD will make its own angle ACD known — which will be one of the sought quantities if arc AD falls inside the triangle; but if it falls outside, the same, subtracted from two right angles, leaves the sought angle ACB. Once angles CAD and ACD and arc CD have been found with such ease, the rest will be found, as before.

Diagram. An isosceles spherical triangle for the equal-arcs case. Apex A at the top; base B–D–C along the bottom, with the perpendicular AD dropped from A onto the midpoint D of the base.

- A (apex): vertex of the two equal angles
- B (lower left): base endpoint
- D (base, middle): foot of the bisecting perpendicular
- C (lower right): base endpoint

[Margin: When the two given arcs are equal.]

Now suppose the two arcs AB and AC are given equal. Then arc AD will bisect both the base BC and angle A, and angles B and C will be equal; and so only angle BAC, together with arc BC, is to be sought. Therefore, by Problem 15 of spherical triangles, from the given arc AB (which subtends the right angle D) together with the given angle B, find angle BAD; which doubled offers the whole sought BAC. Again, by Problem 2 of spherical triangles, from arc AB (subtending the right angle D) together with the found angle BAD, find the opposite arc BD: which doubled gives the whole sought BC.

[Margin: By sines alone, when the two given arcs are equal.]

By sines alone, thus. By Problem 2 of spherical triangles, find, from the given arc AB (which subtends the right angle D) together with the given angle B, the opposite arc AD. From this, by Praxis 1 of Problem 8 of spherical triangles, from the given arc AB (subtending the right angle D) together with the found arc AD, derive the third arc BD, which doubled will exhibit the whole sought BC. Then, by Problem 5 of spherical triangles, investigate, from the found arc BD together with the given adjacent angle B, angle BAD, opposite arc BD. For this doubled gives the whole BAC, which we desire.

Moreover, in order that we may more easily find that problem which we most wish for — especially among spherical triangles — we have here compiled an index of all the problems needed for calculation. To these we have prefixed numbers, which will indicate what place each one holds among the problems whose praxes we have just now set out; just as, above, we also wrote in the margin, alongside the problems themselves, the propositions and problems in which the praxes are demonstrated in our treatises on rectilinear and spherical triangles. And although in the index only single things to be found are set forth for the individual problems of right-angled spherical triangles, nevertheless, once these are found, most other things too are found within the same, as is clear from what precedes.

INDEX PROBLEMATVM, ET PRAXIVM TRIANGVLORVM

Index of the Problems and Exercises on Triangles

Structure of this index: each block opens with a heading naming the class of triangle, then a caption line ("Inuenitur / Inueniuntur ...") stating what is to be found; the numbered entries below give the data from which it is found. The left-hand number is the proposition (problema) number where the case is solved — not a folio reference. These proposition numbers are read individually from the page; they are non-sequential in the spherical sections (see QA note).

IN TRIANGVLIS RECTILINEIS RECTANGVLIS

In right-angled rectilinear triangles

Inuenitur. — *The following is found:*

Prop.	Given (Latin, verbatim)	Given (English)
2.	Latus circa angulum rectum vtrilibet angulorum acutorum oppositum; ex latere rectum angulum subtendente, & alterutro acutorum angulorum.	A side about the right angle, opposite either of the acute angles; from the side subtending the right angle (the hypotenuse) and one of the acute angles.
3.	Latus angulo recto oppositum, & alterutrum duorum circa eundem rectum angulum; ex altero latere circa angulum rectum, & vno acutorum angulorum.	The side opposite the right angle, and one of the two sides about the same right angle; from the other side about the right angle and one of the acute angles.
4.	Vterque angulus acutus, & alterutrum duorum laterum circa angulum rectum; ex latere angulum rectum subtendente, & altero latere circa eundem rectum angulum.	Both acute angles, and one of the two sides about the right angle; from the side subtending the right angle and the other side about the same right angle.
5.	Vterque angulus acutus, & latus recto angulo oppositum; ex duobus lateribus circa eundem angulum rectum.	Both acute angles, and the side opposite the right angle; from the two sides about the same right angle.

IN TRIANGVLIS RECTILINEIS NON RECTANGVLIS

In non-right-angled rectilinear triangles

Inueniuntur. — *The following are found:*

Prop.	Given (Latin, verbatim)	Given (English)
10.	Duo latera; ex omnibus angulis, & reliquo latere.	Two sides; from all the angles and the remaining side.
11.	Omnes anguli: ex omnibus lateribus.	All the angles; from all the sides.
12.	Vnum latus, & duo anguli illi adiacentes; ex reliquis duobus lateribus, & reliquo angulo ab ipsis comprehenso.	One side, and the two angles adjacent to it; from the remaining two sides and the remaining angle contained by them.
13.	Duo anguli, & vnum latus vni	Two angles, and one side opposite

Prop.	Given (Latin, verbatim)	Given (English)
	eorum oppositum; ex reliquis duobus lateribus, & reliquo angulo, qui vni eorum opponitur.	one of them; from the remaining two sides and the remaining angle, which is opposite one of them.

IN TRIANGVLIS SPHÆRICIS RECTANGVLIS

In right-angled spherical triangles

Inuenitur arcus angulo recto oppositus. — *The arc opposite the right angle is found:*

Prop.	Given (Latin, verbatim)	Given (English)
3.	Ex arcu circa rectum angulum, & angulo ei opposito.	From an arc about the right angle and the angle opposite to it.
12.	Ex arcu circa angulum rectum, & angulo ei adiacente.	From an arc about the right angle and the angle adjacent to it.
7.	Ex vtroque arcu circa angulum rectum.	From both arcs about the right angle.
16.	Ex vtroque angulo non recto.	From both non-right angles.

Inuenitur arcus circa angulum rectum. — *An arc about the right angle is found:*

Prop.	Given (Latin, verbatim)	Given (English)
2.	Ex arcu rectum angulum subtendente, & angulo, qui quæsito arcui opponitur.	From the arc subtending the right angle and the angle opposite to the sought arc.
14.	Ex arcu rectum angulum subtendente, & angulo, qui quæsito arcui adiacet.	From the arc subtending the right angle and the angle adjacent to the sought arc.
8.	Ex arcu angulum rectum subtendente, & altero arcu circa angulum rectum.	From the arc subtending the right angle and the other arc about the right angle.
10.	Ex altero arcu circa rectum angulum, & angulo ei opposito.	From the other arc about the right angle and the angle opposite to it.
9.	Ex altero arcu circa angulum rectum, & angulo ei adiacente.	From the other arc about the right angle and the angle adjacent to it.
4.	Ex vtroque angulo non recto.	From both non-right angles.

Inuenitur angulus non rectus. — *A non-right angle is found:*

Prop.	Given (Latin, verbatim)	Given (English)
1.	Ex arcu rectum angulum subtendente, & arcu circa angulum rectum, qui quæsito angulo opponitur.	From the arc subtending the right angle and the arc about the right angle which is opposite to the sought angle.
13.	Ex arcu angulum rectum subtendente, & arcu circa angulum rectum, qui quæsito angulo adiacet.	From the arc subtending the right angle and the arc about the right angle which is adjacent to the sought angle.
15.	Ex arcu rectum angulum subtendente, & altero angulo non recto.	From the arc subtending the right angle and the other non-right angle.
11.	Ex vtroque arcu circa angulum rectum.	From both arcs about the right angle.
5.	Ex arcu circa rectum angulum, qui angulo quæsito opponitur, & altero angulo non recto illi arcui adiacente.	From the arc about the right angle which is opposite to the sought angle, and the other non-right angle adjacent to that arc.
6.	Ex arcu circa angulum rectum, qui angulo quæsito adiacet, & altero angulo non recto illi arcui opposito.	From the arc about the right angle which is adjacent to the sought angle, and the other non-right angle opposite to that arc.

IN TRIANGVLIS SPHÆRICIS NON RECTANGVLIS

In non-right-angled spherical triangles

Inueniuntur. — *The following are found:*

Prop.	Given (Latin, verbatim)	Given (English)
17.	Omnes tres arcus; ex omnibus tribus angulis.	All three arcs; from all three angles.
18.	Omnes tres anguli; ex omnibus tribus arcubus.	All three angles; from all three arcs.
19.	Vnus arcus, & duo anguli illi adiacentes; ex aliis duobus arcubus, & reliquo angulo ab ipsis	One arc, and the two angles adjacent to it; from the other two arcs and the remaining angle

Prop.	Given (Latin, verbatim)	Given (English)
	comprehenso.	contained by them.
20.	Duo arcus, & angulus ab ipsis comprehensus; ex reliquo arcu, & aliis duobus angulis huic arcui adiacentibus.	Two arcs, and the angle contained by them; from the remaining arc and the other two angles adjacent to this arc.
21.	Duo arcus, & vnus angulus vni eorum oppositus; ex reliquo arcu & aliis duobus angulis, quorum vni hic arcus opponitur: si modo constet species arcus alteri angulo dato oppositi.	Two arcs, and one angle opposite one of them; from the remaining arc and the other two angles, to one of which this arc is opposite — provided the species [species, i.e. the quadrant-classification] of the arc opposite the other given angle is established.
22.	Duo anguli, & vnus arcus vni eorum oppositus; ex reliquo angulo, & aliis duobus arcubus, quorum vni hic angulus opponitur: si modo constet species anguli alteri arcui dato oppositi.	Two angles, and one arc opposite one of them; from the remaining angle and the other two arcs, to one of which this angle is opposite — provided the species of the angle opposite the other given arc is established.

*But we have set out this same index far more clearly in Lemma 53 of Book 1 of the Astrolabe**, where we also resolve every problem of spherical triangles by six methods.*

And with this let our treatise on triangles reach its end. In it I believe I have covered everything required for their calculation. So enjoy these in the meantime, kind reader, while — with God favoring our undertakings — we prepare to bring to light three complete books of Menelaus [Menelaus of Alexandria] on spherical triangles, together with two by Francesco Maurolico [Francesco Maurolico]. Those works contain far more than what we have explained here, and are indeed most delightful to know, set out with clearer demonstrations.

FINIS TRIANGVLORVM SPHÆRICORVM

The end of the spherical triangles

[Library stamp: "Bayerische Staatsbibliothek München" (blue oval), lower centre; a second, blurred oval stamp appears in the same region on the preceding page]

Opera Mathematica, Tomus I — end of volume (rear endleaf and back cover)

This closing opening carries **no printed text**: no colophon or imprint, no printer's device, no privilege statement, and no errata or index. It consists of the rear free endleaf (blank paper bearing only modern pencil library notations and the offset bleed-through of the binding) and the inside of the blind-tooled leather back cover.

Page 895 — rear free endleaf (blank)

The leaf is **blank** printed matter. It carries no letterpress. At the upper left are a few lines of modern pencil annotation in a librarian's/cataloguer's hand (collation or shelf notes), together with the ghosted offset of the tooled binding panel showing through from the facing board.

The pencil notations read approximately:

- 1-5 followed by tally strokes: xxxx xxxx xxxx xxx [?]
- 1 followed by xxx xxx [?]
- $\overline{\text{VIII}}$. 84 [?] (Roman numeral with overbar; possibly III . 84)
- $\overline{\text{XI}}$. 88 [?]

A faint reddish ink speck and scattered foxing are present; the grey shapes across the sheet are show-through/offset of the decorative binding, not printed content.

Page 896 — inside back cover (blind-tooled leather binding)

This is the physical end of Tomus I.
