Translator Version 2

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: "What do I need this new instrument for?" — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBris HaShalem* (1797)

A note on the work

Tomus I of Clavius's collected mathematical works gathers his geometry and trigonometry. Its core is his celebrated commentary on Euclid's *Elements* (Books I–XV, with a sixteenth added) — the standard Renaissance Euclid, dense with labelled construction diagrams and scholia. It is followed by his commentary on Theodosius's *Sphaerica* (the geometry of the sphere) and by a treatise on the doctrine of sines, tangents, and secants with the theory of plane and spherical triangles, accompanied by extensive numeric trigonometric tables. Together they form the geometric and trigonometric foundation on which the astronomical volumes build.

A note on the translation process

This translation was produced with the [translation-pipeline](#). See the linked repository for details on the process.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Acknowledgements

[The two leaves following the cover are blank flyleaves bearing only handwriting and library markings; no printed text of the work appears yet.]

[Margin: handwritten shelfmark, upper left of the front flyleaf: "2. Math. m. 10" over "71" (or "/1") — a Bayerische Staatsbibliothek pressmark.]

[Margin: handwritten author name, centre of the front flyleaf: "Clavius".]

[On the following flyleaf, a printed library barcode label:]

[Approval stamp: "<36616685880014>" (repeated on a second line) / "Bayer. Staatsbibliothek" (Bavarian State Library)]

[Margin: handwritten "33" in pencil at the lower left of the label, and a red-pencil mark to its upper right.]

Front matter — engraved title page

Front flyleaf (recto)

Blank flyleaf. At the upper left, in brown ink, the Bayerische Staatsbibliothek shelfmark handwritten: "2 Math. m. 10 – 1" [handwritten]. A few faint pencil marks and offset show-through elsewhere; no printed text.

Engraved title page

Diagram. An engraved architectural title page (frontispiece) in the form of a monumental portal, signed by the engraver Johann Leybold. A central oval cartouche carries the title lettering. The whole is framed by an ornamented architrave above and a plinth below, with allegorical figures at the sides and small narrative roundels and panels at the base. Handwritten ownership annotations in brown ink are overlaid across the middle of the title.

Transcription of the engraved and printed lettering, top to bottom:

Upper pediment / entablature. Two winged putti sit at the outer corners: the one at left holds up a radiant sun or sundial; the one at right holds a pair of crescent moons. Between them, in the broken pediment, are set two standing figures of the patron saints of Bamberg, each labelled on the ledge beneath:

- **S. HEINRIC.** [St. Henry — Emperor Henry II, patron of Bamberg] — mitred figure at left of centre.

- **S. KVNIGVND.** [St. Kunigunde — Empress Cunigunde, his consort] — mitred/crowned figure at right of centre.

Between the two saints, a central shield bears the arms of the See of Bamberg.

Side cartouches flanking the title.

- Left roundel: **IHS** [the Jesuit Christogram], with a small cross and three nails beneath.
- Right roundel: **MAR** [Maria — the monogram of the Virgin Mary].

Central title cartouche (large engraved capitals):

CHRISTOPHORI CLAVII BAMBERGENSIS. E Societate IESV OPERA
MATHE- MATICA V Tomis distributa. Ab auctore nunc denuo correcta, et
plurimis locis aucta. Ad Reverendiss. et Illustriss. Principem ac
Dominum, D. IOANNEM GODEFRIDVM EPISCOpum Bambergensem &c.
MOGVNTIAE, Sumptibus Antonij Hierat Excudebat Reinhard Eltz Cum
gratia et privilegio Sac. Cæs. Maiest. Anno M. DCXII.

Translation of the title cartouche:

The Mathematical Works of Christoph Clavius [Christophorus Clavius] of Bamberg, of the Society of Jesus, distributed in five volumes. Now once more corrected by the author, and enlarged in very many places. To the most reverend and most illustrious Prince and Lord, Lord Johann Gottfried [Johann Gottfried von Aschhausen], Bishop of Bamberg, etc. At Mainz [Moguntiae], at the expense of Antonius Hierat; printed by Reinhard Eltz. With the grace and privilege of His Sacred Imperial Majesty. In the year 1612.

Handwritten ownership annotations overlaid across the middle of the title (brown ink): to the left of the word "MATICA," a signature reading "Almerij" or "Alberti" [?]; to the right, a signature "Scheiner" [Christoph Scheiner?] with a flourish [?]; a further line of cursive beneath ("Ab auctore..." region) and two more short inscriptions ("Monac[ensis]" [?] and "Scheiner" [?]) lower down. These are later hands, not part of the printed sheet.

Engraver's signature on the socle beneath the side figures:

- Left: **Ioan. Leypolt** [Johann Leypolt, the engraver] ... | right: **sculp.** [sculpsit — "engraved (this)"].

Allegorical side figures standing on the plinth:

- Left: a woman drawing with a compass/dividers on a tablet, labelled on the pedestal band **GEOMETRIA** [Geometry].
- Right: a woman holding an armillary sphere, labelled on the pedestal band **ASTRONOMIA** [Astronomy].

Base register (three roundels and flanking panels around a central portrait):

- Central medallion: a bust-length portrait of an elderly bearded scholar — Clavius himself — seated with drawing compasses over instruments, an armillary sphere and geometrical solids about him. Faint inscriptions "IESV" (above left), "Christophorus" (above right), and beneath, partly legible, "CLAVIVS" [?] and other lettering [?].
- Small circular and rectangular scenes at the four corners depict biblical/astronomical episodes (figures observing the heavens, a battle scene at right, an ark/vessel at lower right) [subjects only partly legible].

Scroll beneath the portrait (printed motto):

Dedit mihi Deus ut sciam anni cursus et stellarum dispositiones. Sap. 7.

Translation: "God gave me to know the courses of the year and the dispositions of the stars. Wisdom 7." [Wisdom 7:19]

Title-page verso / flyleaf

Blank leaf (verso of the engraved title, showing offset of the plate through the paper). Near the centre, an inked oval library stamp:

BIBLIOTHECA / REGIA / MONACENSIS.

[Stamp: "Royal Library of Munich" — the Bayerische Staatsbibliothek's earlier institutional stamp.]

Below and to either side of the stamp, two handwritten cursive inscriptions in brown ink [illegible — later ownership hands, "...Scheiner" [?] at right] and a few faint marks. No printed text.

To the Most Reverend and Most Illustrious
Prince and Lord, Lord Johann Gottfried [Johann
Gottfried von Aschhausen, Bishop of Bamberg],
Bishop of Bamberg and Provost of the
Metropolitan Church of Würzburg
[Herbipolensis], etc., his most gracious Lord.

Christoph Clavius [Christoph Clavius] of Bamberg, of the Society of Jesus.

Since it has pleased almighty God, Most Reverend and Most Illustrious Prince, of his singular favor to grant that I should live to reach an age which we see not very many attain in these times — whether through the decay of an aging world (so that, just as the primal force and vigor of all things, so too that of Nature itself gradually grows faint), or rather, as I am more inclined to believe, by the sole will and dispensation of God — this above all has been most welcome to me: that whereas it commonly befalls other mortals that, as they sail this stormy sea, all the calamities and miseries of life flow together into its final stretch as into a kind of bilge, I, by contrast, find the very opposite to be true — that no part of my life has been heaped with greater joy and delight than this my decrepit old age. Not that I have been blessed beyond the common lot of humanity, or ever set apart and exempt from those evils that beset the rest of one's life, and above all this bloodless and worn-out age I now live through. But whatever it is that we all suffer alike, I now bear it so easily that I seem to have lost all sense of pain entirely.

For whereas I had once desired nothing more than to see the Church of Bamberg — in which I had been born and raised — as secure and flourishing as it could possibly be, I would often recall to mind its first origins and cradle-days from the auspicious founding by Saint Otto [Otto of Bamberg], and, passing through the whole memory of former ages, I traced its growth and maturity down to these present years. And although I found that it had always advanced, keeping pace with the age, toward immortal glory and the dignity of its own name — so that nothing seemed less to be feared than that it should ever fall away from the excellent institutions of its forefathers — yet the wickedness of these times brought it about that, while the neighboring peoples round about were being infected with the deadly plague of heresy, the Church of Bamberg indeed most

steadfastly maintained its religion; and yet all good men greatly feared that, just as we see that under a diseased sky diseases can scarcely be guarded against, so, if some pestilent breath of that license which the heretics devise should waft in from somewhere, then, even though the people might most firmly turn away from the [heretical] doctrine itself, they might nonetheless — innocent though they are — grow accustomed to the corruption of morals and of loosened discipline.

For these reasons it came about that I, who held my homeland dearer than my own life, when I learned that the Most Reverend and Most Illustrious Prince Johann Philipp [Johann Philipp von Gebsattel], your predecessor of blessed memory, had been called by God out of this life, thought it altogether necessary to commend to God, with all the zeal I could, the widowhood of the Church now bereft of its shepherd — praying that in these most difficult times it might obtain the best possible leader, one endowed with the greatest courage and virtue for driving off the onrushing diseases both of heresy and of every vice. While this concern was weighing on me as gravely as it deserved, behold — word of your most happy installation was brought to me, not through vague rumors at first, as usually happens, but with the common applause of the whole Christian world. At this news I suddenly began to exult with such joy that, casting off the burden of age that most oppressed me, I seemed to myself to have returned, like Aeson [Aeson], to the first bloom of youth. And so, raising my hands to heaven, I gave thanks to God, that He had not willed me to meet my final day before I had obtained so great a good — so that now, with the safety of my homeland brought to security, nearly the same thing befalls me as befell that old man of the Gospel who, having beheld the Savior of the world, joyfully awaited his last day.

I would be lying if I spoke anything otherwise than I feel; nor do I fear that anyone should ever charge me with that fault. For, besides the fact that I am now of an age at which I ought to appear unwilling to affirm anything lightly, the opinion of Your Virtue is so illustrious and so attested by every rank and age that what I might seem to have said out of private affection is shared with me by all, bad and good alike. For there is, believe me, there is a kind of virtue that towers so high above all the malice of detractors that — just as the loftiest mountains rise with their whole summit above the clouds and never feel the storms of wind and rain — so this virtue, forever serene and untroubled, rises as far as it possibly can above all the storm-clouds of slander. In this way it came about that, when news first spread that you had been raised to the episcopal dignity, to the very great good of the Christian commonwealth, no one was found [recte: inventus] either so estranged from the truth or so hostile to the public good as not to confess that

this honor had been most deservedly conferred upon you. Indeed, all were of one mind and one voice: that ever since the days of Saint Otto no happier day had dawned upon the Church of Bamberg than the one on which it obtained you as its bishop; that in you alone lay everything; that under your auspices above all the state could be happily governed; and that vows should be offered to God, praying that He might will this benefit of His to endure as long as possible [recte: diuturnum].

In this common joy and rejoicing, no one could rightly deny that some place ought to belong to me as well. For who would take it ill if I openly declare that I have, by God's supreme favor, obtained what I earnestly prayed of almighty God — namely, that He would set at the head of affairs above all the man who could best come to the aid of my struggling homeland? If what is celebrated in the talk of all peoples, I alone do not pass over in silence? If, now made certain of the most happy condition of my homeland, I cannot restrain the force of my joy? And even if I had passed my whole earlier life in silence and obscurity, known to the public by no writings at all, pardon would still have to be granted me if, stirred by that acclamation and applause of the whole world, I could not hold myself back, but sang out something — to mark the celebration and to attest my goodwill — in a swan-like voice tuned by nature rather than by art. But now that I have earned some name among the learned — a slight one, perhaps, yet one I trust will pass down to posterity — I could not fail to leave behind, by some illustrious testimony, as full a proof as I could of my love for my homeland and of my zeal to honor your name.

And to do this the more freely, both the greatness of the matter demands it, and I feel myself spurred on by the example and authority of Basil the Great [Basil of Caesarea]. When Basil had learned about Saint Ambrose [Ambrose of Milan] — that he had been elected Bishop of Milan — he began to love ardently a man he had never before seen, commended to him by the fame of his virtue alone, not so much for his own sake as for the sake of the Christian commonwealth, and to proclaim him, to the great good of that age, as one dropped, so to speak, from heaven:

"We have glorified our God," he says, "who chooses, out of every generation of mortals, those who have pleased Him. He who once raised up a leader for His people from among the shepherds of sheep, and who took Amos from the herd of goats and instructed him by His Spirit and raised him to prophetic dignity — now He has drawn to the pasturing of Christ's flock a man from the royal city, to whom the governance of the whole nation had been entrusted: a man lofty in wisdom,

distinguished in the nobility of his lineage, in the splendor of his life, in his gift of eloquence, and in worldly affairs; a man who, casting away all the wealth of this life and counting it as loss so that he might gain Christ, has taken up the helm of the great and noble ship committed to him — namely, the Church of God — in the faith of Christ. Come, then, O man of God: since it was not from men that you received or were taught the Gospel of Christ, but you yourself..."

Dedicatory Epistle (continued)

[The Basil quotation, begun on the preceding page, concludes:]

...whom the Lord, taking him from the midst of the judges of the earth, has raised to the Apostolic presidency. Fight the good fight without wavering; correct and temper the weakness of the people; and if any part of it has been touched by the taint of Arian madness, renew the ancient footsteps of the fathers, and so on.

You understand, I am sure, most Reverend and most Illustrious Prince, how perfectly all of this applies to you. Yet if, out of that modesty for which you are so highly commended, you feel otherwise than I do, I will not offend your modesty, nor will I ask for anything more beyond the testimony of those who know you more intimately.

Allow me to say somewhat more openly what St. Basil [Basil of Caesarea] urged in his closing words: he wished the ancient morals and religion to be restored, and the Arian heresy then raging to be rooted out of men's minds. Everyone promised themselves that both would come about, as soon as they had learned of your Election. Now we see it happily begun and, with incredible speed, already in great part accomplished. With the flood of vices banished, ancient piety returns as though from exile; integrity of life is restored, and the examples of the old discipline are renewed.

There is one thing more that deserves great praise — one I would gladly have mentioned in the first place, had I not held the consideration of the public good to be more important. Yet even this is of such a kind that it does not seem far separated from the common benefit. Among the deeds gloriously accomplished by St. Otto [Otto of Bamberg], this stands out as exceptional and singular: that at the very outset — when the fortunes of churches are usually too slender to meet great expenditures — he nevertheless erected very ample dwellings for religious men in many places, and endowed them with yearly revenues. Nothing mattered more to you than that this one thing should not be wanting: that there be nothing among his glorious deeds you had not imitated. And so, as soon as you were able

to overcome the difficulties that stood in the way, you willed that the Society of Jesus [Societas Iesu] — which from boyhood you had always embraced with your whole heart — should have a seat at Bamberg, and be enlarged with perpetual revenues. Although you are certain how ample the rewards are that God has appointed for this beneficence of yours — so that you desire nothing at all from us — the Society, I hope, will nonetheless see to it that you may never at any time regret this benefaction.

As for myself: certain Fathers of our Society from the College of Mainz [collegio Moguntino], out of their remarkable zeal and love for the mathematical disciplines, offered me their effort and labor. My works, which had been produced and published by me, were circulating scattered into many parts; they undertook to gather them all, to arrange each in its own order and place, and to set them in type. Judging that there should be no delay, I praised their willingness and urged them to undertake the task with great spirit. Indeed, examining myself, since I understood that I owed everything on your account, and believing that I could do everything, I set my own hand to the work, so that what I intended to dedicate to your Name might be completed as soon as possible. And although now heavily burdened by age, yet with the greatest speed that could be managed, all...

Dedicatory Epistle (conclusion) — p. 11

the books I reviewed from beginning to end, and — with the typographers' errors removed — enriched them by the addition of many things, wherever it seemed most opportune. These, then, most Reverend and most Illustrious Prince, are the fruits of my studies, bound together as in a single bundle. They are in no way equal to your great merits, but they are the richest witnesses to posterity of the devotion and love that I and the whole Society bear you; and by my last will I consecrate and dedicate them to your Name. If I learn that they have been pleasing to you, I shall reckon that I have received a great reward and recompense for my life and labors. As for what remains, most Reverend and most Illustrious Prince, I pray God that — since you were born not for yourself alone, but for the highest good of the whole Christian Commonwealth — He may will that you survive as long as possible, no more for your own sake than for hers. Rome, the Kalends of May, in the year 1611.

INDEX GENERALIS

GENERAL INDEX OF WHAT IS CONTAINED IN THE INDIVIDUAL VOLUMES

VOLUME ONE.

On Euclid } Commentaries.

On Theodosius }

- On sines, and on tangent and secant lines.
- Rectilinear (plane) triangles.
- Spherical triangles.

VOLUME TWO.

- Practical Geometry.
- Refutation of the *Cyclometria* of Joseph Scaliger [Joseph Justus Scaliger].
- Practical Arithmetic.
- Algebra.

VOLUME THREE.

- Commentary on the *Sphere* of Johannes de Sacrobosco.
- The Astrolabe.

VOLUME FOUR.

- Gnomonics, in eight books.
- The construction and use of the instrument of clocks [sundials].
- A new description of clocks [sundials].

VOLUME FIVE.

- An explanation of the Roman Calendar restored by Gregory XIII, Supreme Pontiff.
- A corrected *Elenchus* and castigation of the *Castigation of the Gregorian Calendar* by Joseph Scaliger.

- A reply to the abuse and calumnies of Joseph Scaliger against the Gregorian Calendar.
- A confutation of the *Calendar* of Georg Germann of Wartenberg, the Prussian [Georgius Germannus Wartenbergensis Borussus].

Christoph Clavius, Opera Mathematica, Tomus I

[Title page]

CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS.

THE MATHEMATICAL WORKS.

VOLUME ONE.

Comprising

Commentaries { On Euclid's Elements of Geometry, / On the Spherics of Theodosius;

The account and canons of Sines, Tangents, and Secants:

The treatment of triangles, both rectilinear and spherical.

MAINZ [MOGVNTIAE],

At the expense of Antonius Hierat [Antonius Hierat], printed by Reinhard Eltz [Reinhardus Eltz].

With the grace and privilege of His Sacred Imperial Majesty.

In the year 1611 [M.DC.XI].

[Verso]

CHRISTOPH CLAVIUS OF BAMBERG, OF THE SOCIETY OF JESUS. PROLEGOMENA TO THE MATHEMATICAL DISCIPLINES.

Why the Mathematical Disciplines Are So Called

The mathematical disciplines, all of which are concerned with quantity, took their name from the Greek word μάθημα [Greek: mathēma, "learning, that which is learned"], or μάθησις [Greek: mathēsis, "learning"], which means a discipline or body of teaching. As to why these arts that deal with quantity alone, among all the rest, obtained the name of "discipline" or "teaching," I find two chief reasons in reputable authors.

The Pythagoreans and Platonists believed that rational souls are contained within a certain fixed and determinate number, and that they migrate from body to body—though the Christian faith plainly teaches this to be false. They held that these arts obtain the name of teaching or discipline because it is chiefly through them that we acquire the recollection and remembrance of that knowledge with which our soul (so runs their error) was endowed before it gave form to the body. Plato tries to prove this readily, by a familiar example, in the dialogue titled *Meno* [Plato, *Meno*], where he brings in Socrates questioning a certain young boy about some geometrical matters concerning the measurement of a square. Although at first the boy answers like a child, yet by advancing step by step he is led to the point of answering what he would in the end have been able to say, had he thoroughly learned geometry over a very long time.

Others hold that these arts claim for themselves the name of "knowledge" and "teaching" above the rest because they alone preserve the method and rational procedure of a science. For they always proceed from certain foreknown principles to the demonstration of conclusions—which is the proper task and function of teaching or discipline, as Aristotle too testifies in the first book of the *Posterior Analytics* (*Posterior Analytics* I). Nor do mathematicians ever assume anything that has not been proved; but whenever they wish to teach something, if anything relevant belongs to what they have already taught, they take it as granted and proved, and then explain only that about which nothing had previously been written. This, we see, other arts and disciplines do not always

observe, since for the most part, in confirmation of the things they wish to show, they bring in as demonstrated things that have not yet been explained.

The Division of the Mathematical Disciplines

The Pythagoreans—whom afterwards nearly all mathematicians and not a few philosophers followed—divided the whole of the mathematical disciplines into four parts: arithmetic, music, geometry, and astronomy. For since all quantity with which they are concerned is either discrete, under which all numbers fall, or continuous, under which all magnitudes are comprehended, and since each can be considered both in itself and in comparison with the other, it seemed fitting to them to establish the four aforesaid faculties, which would carefully examine each kind of quantity under its twofold consideration. Thus arithmetic deals with discrete quantity in itself, investigating and accurately explaining all the properties and affections of numbers. Music treats the same discrete quantity—that is, number compared with another—insofar as it regards the concord and harmony of sounds. Geometry disputes about magnitude, or continuous quantity, likewise in itself, as it exists unmoved. Finally, astronomy considers the same magnitude as it is in motion, such as the heavenly bodies are, inasmuch as they are set in motion by continuous movement. To these four mathematical sciences—of which arithmetic and geometry are called pure, while music and astronomy are called mixed—the others that deal with quantity in any way, such as optics [Perspectiva], geography, and the rest of this kind, can readily be reduced, as to the heads on which they depend.

On another basis the mathematical disciplines are divided by Geminus [Geminus] the ancient geometer, and by others, as Proclus [Proclus] reports in the commentaries he published on the first book of Euclid (Proclus, *Commentary on Euclid, Book I*). Since he teaches elegantly and fully how far the mathematical disciplines extend, I have decided to append here that division, taken almost word for word from Proclus according to the translation of Francesco Barozzi [Francisci Barocij], a patrician of Venice. The aforesaid authors hold that some of the mathematical sciences are concerned only with intelligibles separated from all matter, while others are concerned with sensibles, so that they touch upon matter subject to the senses. Of the former kind they set the two by far first and foremost sciences, arithmetic and geometry; while in the latter kind they establish six: astro-

astronomy, optics, geodesy, music or canonics, computation, and mechanics.

They say that astronomy [astrologia] is the discipline that treats of the motions of the heavens, of the magnitudes, shapes, and illuminations of the celestial bodies, of their distances from the earth, and of other matters of this kind. It in turn is divided into three parts. The first is gnomonics [gnomonica], which is concerned with the measurement of the hours by means of the gnomon set up as an instrument. The second is meteoroscopy [meteoroscopica], which determines the differences of altitude and the distances of the stars, and teaches many other and various astronomical theorems besides. The third is dioptrics [dioptrica], which ascertains the distances of the planets and of the other stars by means of dioptric instruments of this sort.

They say that optics [perspectiva] is the offspring of geometry, and that it uses lines of sight as though they were geometrical lines, together with the angles formed by these visual rays. It is divided as follows. One part, which properly bears the name optics, gives the reason why things regularly present themselves to us otherwise than they actually are — on account of the differing positions and distances of the objects that fall under sight — for example, why parallel lines appear to converge, or why squares are seen as though they were circles. Another part is the whole science of mirror-images [specularia], which deals with the various and manifold kinds of reflection. And there is a further part called scenography [sciographice], that is, the art of representing shadows, which shows how it can come about that the things appearing in images do not look ungraceful or distorted on account of the distances and heights of the objects depicted. They call geodesy [geodaesia] the science that measures magnitudes as quantities — measuring heaps of material objects as though they were cones, and wells as though they were cylinders. This it does not accomplish through intelligible straight lines, as geometry does, but only through sensible ones — sometimes indeed by more reliable means, such as the rays of the Sun, but at other times by cruder means, such as cords and the plumb line. Geodesy, like geometry, is divided into the part that measures plane figures and the part that measures solid ones. They call canonics or music [canonica, sive musica] the science that considers the ratios of audible harmonies, everywhere relying upon the aid of the senses; it is such a science that, as Plato [Plato] says, it seems to have set the ears themselves before the mind. Computation [supputatrix] is among them what practical arithmetic is among us: for it considers numbers not as they exist in intelligible things, but as they are in sensible things themselves. Finally, mechanics [mechanica], which consists in the knowledge of sensible things joined to matter, is among them of several kinds. One kind produces instruments — this is called ὀργανοποιητικὴ [Greek: organopoiētikē, "instrument-making"] — namely those instruments suited to the waging of war, such as Archimedes [Archimedes]

is indeed reported to have built, which resisted the besiegers of Syracuse both by land and by sea. Another kind produces altogether marvelous effects and is called θαυματοποιητική [Greek: thaumatopoiētikē, "wonder-working"]: for it constructs some of its devices by means of air and breath with the greatest artifice — just as Ctesibius [Ctesibius] and Heron [Heron of Alexandria] also worked — and others by means of weights, whose disequilibrium is to be reckoned the cause of their motion and whose equilibrium the cause of their rest, as Timaeus [Timaeus] also determined; and still others by means of sinews and cords that imitate living coilings and motions. Another kind is entirely the science of balancing bodies and of what are called centers of gravity [centropanderantia]. And a final kind produces spheres and is called σφαιροποιία [Greek: sphairopoiia, "sphere-making"], for the imitation of the revolutions of the heavens — such a sphere as Archimedes also constructed. And, to say it in a word, mechanics is the whole art that has the power of moving matter.

These, then, are the mathematical disciplines as the ancients had them. As for the military art — I mean the one concerned with drawing up and arranging battle-lines, which the Greeks call τακτική [Greek: taktik[?]ō, "tactics"] — they do not hold that it should be counted as one of the parts of mathematics, as certain others have wished; rather, they hold that it makes use of mathematics in this way: sometimes it employs the art of computation, as in numbering the legions, and sometimes geodesy, as in laying out and measuring the spaces for an encampment in the field. In the same way they say that neither history nor the art of healing is any part of mathematics, even though historians and physicians alike very often make use of mathematical theorems. Writers of history do so in reporting the situations of climatic zones, or the sizes and diameters of cities, or their circuits and circumferences; and physicians do so in elucidating a great many matters of their art by methods of this kind. For the usefulness that has come to medicine from astronomy is shown by Hippocrates [Hippocrates] himself, and by nearly everyone who has said anything about the favorable times and places. By the same reasoning, the man who devotes his effort to drawing up battle-lines does indeed make use of mathematical theorems, yet he will not on that account be a mathematician — even though he may sometimes deliberately, when he wishes to make a numerous host appear as small as possible, form his camp and his armies into the figure of a circle, and at other times, when he wishes it to appear as large as possible, into the figure of a square, or a pentagon, or some other polygon. These, then, are more or less the things the ancient mathematicians have left us concerning the division of these sciences.

INVENTORS OF THE MATHEMATICAL DISCIPLINES

The histories clearly testify that all the mathematical disciplines took their rise and origin from various and different authors; indeed, it has also been handed down to memory that the several disciplines by no means attained their full perfection at the very outset, but advanced little by little from imperfect beginnings toward greater perfection. The first inventors of arithmetic are believed to have been the Phoenicians, on account of their frequent trading and commerce, as Proclus [Proclus] reports; and afterward Pythagoras [Pythagoras] and his successors, as well as the Egyptians, and finally the Greeks and the Arabs, wonderfully enlarged it and adorned it with various problems and theorems. Many writers hand down that music was first invented by Mercury [Mercury], who afterward entrusted and committed it to the famous musician Orpheus [Orpheus]; he in turn passed it to Thamyras and Linus [Linus], and Linus to Hercules [Hercules], and so by continuous succession, through other distinguished musicians, it has flowed down to our own times. Geometry, on the authority of Proclus, was discovered by the Egyptians and had its origin in the measurement of fields. For when the yearly inundation of the Nile so confounded and laid waste the boundaries and limits of the fields that no one could recognize his own, the Egyptians began to apply their minds to a method of measuring the fields, so that in this way each man might be given back what was his own. This method of measuring fields, although at that time it was still quite rough and unpolished, nevertheless took the name "geometry" from that very office; for γεωμετρέομαι, or γεωμετρέω [Greek: *geōmetreō*, "I measure the earth"], means the same as "I measure the land." But little by little geometry then began to be refined; and, not content with its own boundaries, it turned to measuring the heavenly bodies as well, and handed down the principles of the whole of astronomy, of cosmography, and of very many other disciplines that depend upon it as upon a root. Thales of Miletus [Thales] is said to have been the first to carry it over from Egypt into Greece; and thereafter many most distinguished and most acute philosophers and mathematicians enriched and adorned it with demon-

—strations. Among these the chief of the ancients are: Pythagoras, Anaxagoras of Clazomenae [Anaxagoras], Hippocrates of Chios [Hippocrates of Chios], Plato, Oenopides [Oenopides of Chios], Zenodorus, Brito [Bryson (?)], Antipho [Antiphon], Theodorus [Theodorus of Cyrene], Theaetetus [Theaetetus], Aristarchus [Aristarchus of Samos], Eratosthenes [Eratosthenes], Archytas of Tarentum [Archytas], Euclid [Euclid], Serenus [Serenus of Antinoöpolis], Hypsicles of Alexandria [Hypsicles], Archimedes of Syracuse, Apollonius of Perga

[Apollonius], Theodosius of Tripolis [Theodosius], Milaeus the Roman, who is also Menelaus [Menelaus of Alexandria], Theon of Alexandria [Theon], Ptolemy [Ptolemy], Eutocius of Ascalon [Eutocius], Pappus [Pappus of Alexandria], Proclus, and others almost beyond number, whom it would be tedious to recount in full. As for astronomy, not a few maintain that it was first invented by Atlas [Atlas]; and hence, on account of the extraordinary knowledge of astronomy with which he was endowed as the first among mortals, they hold that the fable arose that he supports the heavens upon his shoulders. Others think that the Chaldaeans discovered the science of the stars by long observation — which Cicero [Cicero] too affirms in his book *On Divination* [*De Divinatione*]. Others make the Egyptians the first inventors of this science; others the Assyrians; and others, finally, judge that this glory and praise should be given to the Babylonians. But this pursuit, or science, since it is most excellent, has also been made illustrious by most distinguished authors — which it is not the place here to set forth. Now, once these four chief mathematical disciplines had been invented, all the rest, which deal in any way with quantity, were easily derived and drawn from them, like streams from a spring.

THE NOBILITY AND EXCELLENCE OF THE MATHEMATICAL SCIENCES

Since the mathematical disciplines treat of things that are considered apart from all sensible matter — although in reality they are immersed in matter — it is plain that they hold a middle place between metaphysics and natural science, if we consider their subject, as is rightly proved by Proclus. For the subject of metaphysics is separated from all matter both in reality and in reasoning; the subject of physics, by contrast, is joined to sensible matter both in reality and in reasoning; and so, since the subject of the mathematical disciplines is considered apart from all matter, though in reality it is found within matter, it clearly follows that this middle stands between the other two. And if the nobility and excellence of a science is to be judged by the certainty of the demonstrations it employs, then without doubt the mathematical disciplines will hold the first place among all the rest. For they demonstrate everything they take up for discussion by the firmest reasonings, and confirm it so as truly to beget knowledge in the mind of the hearer and to remove every last doubt. This is what we can scarcely grant to the other sciences, since in them the mind often hangs in suspense and remains uncertain, amid a multitude of opinions and a variety of views, when it must judge the truth of the conclusions. The sects of the Peripatetics [Peripatetici] plainly show this to be so — to pass over the other philosophers in silence for

now — for, having sprung from Aristotle [Aristotle] like branches from some trunk, they so disagree among themselves, and sometimes even with Aristotle their very source, that one is left utterly at a loss to know what Aristotle means, and whether he is conducting his dispute about words or rather about things. Hence it comes about that some follow the Greek interpreters, some the Latin, others the Arabs, others the Nominalists, and others, finally, those they call the Realists — all of whom nevertheless boast that they are Peripatetics — as their leaders. How far this is from mathematical demonstrations, I think escapes no one. For the theorems of Euclid and of the other mathematicians retain in the schools today the same purity of truth, the same certainty of their matter, the same strength and firmness of demonstration, as they did so many years ago. To this may be added what Plato says in the *Philebus*, the dialogue entitled *On the Highest Good [Philebus]*: that the more worthy and excellent science is the one that is more devoted to sincerity and truth. Since, then, the mathematical disciplines so seek out, cherish, and cultivate truth that they admit nothing false, nothing merely probable — indeed nothing at all that they do not confirm and corroborate by the most certain demonstrations — there can be no doubt that the first place among all the other sciences must be granted to them.

THE VARIOUS USES OF THE MATHEMATICAL DISCIPLINES

The mathematical disciplines ought to be reckoned not only useful but even quite necessary — both for thoroughly learning the other arts and for rightly establishing and administering the commonwealth. For, as Proclus elegantly shows, there is no access to mathematics except through the mathematical disciplines. Indeed, if we should try to raise the powers and edge of our intellect from the sensible things that the physicist considers up to the things wholly separated and set apart from sensible matter, which the metaphysician contemplates — and this without any intermediate step — we should blind ourselves, no differently than happens to a man who is brought out from some dark prison, in which he has long lain hidden, into the most brilliant light of the Sun. For this reason, before the intellect ascends from physical things, which are bound and joined to matter subject to the senses, to metaphysical things, which are torn away from that same matter, it is necessary — lest it be dazzled by their brightness — that it first be accustomed to less abstract things, such as the mathematicians consider, so that it may more easily grasp those higher things. And so the divine Plato rightly affirms that the mathematical disciplines lift up the mind and sharpen its edge for the contemplation of divine things. As for how much benefit these disciplines confer toward rightly perceiving and interpreting the sacred Scriptures, Blessed Augustine [Augustine] most beautifully sets forth to

us in Book 2, chapter 16, of *On Christian Doctrine* [*De Doctrina Christiana*], showing that, through ignorance of numbers, many things are not understood by many people that are set down in the Scriptures figuratively and mystically. Of this he brings forward not a few examples, and he repeats the same view at much greater length, in the same book, in chapter 37. Saint Jerome [Jerome] teaches the same in Volume 1, Letter 5, asserting that there is great force in numbers for understanding many mysteries in the Scriptures; and in the same passage he declares that geometry too affords great usefulness to theologians. Again, Blessed Augustine, in the passage already cited, chapter 16, which I mentioned a little earlier, testifies that music is thoroughly necessary to the Christian teacher, adding a little later, in chapter 19, that theologians ought also to be diligently instructed in geography. Not unaware of this, the divine Gregory of Nazianzus [Gregory of Nazianzus] extols with the highest praises the divine Basil [Basil the Great], his teacher, because in astronomy, geometry, the knowledge of numbers, and the other mathe-

—matical sciences he was no ordinary master. These arts also contribute not a little toward thoroughly acquiring natural philosophy, moral philosophy, dialectic, and the other doctrines and arts of that kind, as Proclus clearly teaches. Add to this that all the volumes of the ancient philosophers — especially of Aristotle and Plato, whom we deservedly set before ourselves as the guides to be followed for sound and correct philosophizing — and indeed almost all the volumes of the Greeks and of the Latins as well, are filled with mathematical examples, chiefly for this reason: that things which otherwise seemed to be beset by many difficulties might, through examples of this kind, be made clearer and more evident. And this the man wholly ignorant of the mathematical sciences will surely be unable in any way to perceive. What of the fact that in former times no one dared to frequent the celebrated school of the divine Plato who had not first been well adorned with the mathematical disciplines? Hence he is said to have inscribed over the doors of the Academy this motto: ἀγεωμέτρητος οὐδεὶς εἰσὶτω [Greek: ageōmetrētos oudeis eisitō, "let no one ignorant of geometry enter"]. Indeed, this same Plato did not hesitate to assert, in the *Philebus*, that without mathematics the disciplines are worthless. For this reason he prescribes, in Book 7 of the *Republic* [*De Republica*], that the mathematical disciplines are to be learned first of all, on account of their various and manifold uses — as he writes at length — not only for perceiving the other arts more correctly, but also for administering the commonwealth well. Of this I could bring forward many examples, both from times past and from our own age, if it were necessary. In the same place he affirms in the clearest words that arithmeticians especially are by nature apt and suited to all branches of learning; so much so that, even if these

sciences brought us no other usefulness — though we do gain from them countless other advantages besides — he would still hold that they must be thoroughly learned with all diligence, because they render the mind and intellect keener and sharper for grasping all the other arts. And this is easily confirmed by experience herself as our teacher. For we see that those whose minds readily and effortlessly adapt themselves to these disciplines reap no small fruit from the other sciences; whereas, on the contrary, those found least suited to these pursuits are altogether unfit for the rest. For this reason Plato with the very best justification, again and again in his works, impresses upon us and commends the usefulness of these disciplines — especially in Book 7 of the *Republic*, or the *Philosopher*, and in the *Timaeus* [*Timaeus*], where he calls the mathematical disciplines the road to all noble learning — and in very many other places besides, which, mindful of brevity, I now diligently forbear to enumerate. To all these uses is added the greatest pleasantness and delight, with which anyone's mind is filled in cultivating and practicing these arts. For these are the chief of the seven liberal arts, in which not only well-born young men but also nobles, princes, kings, and emperors used to spend much time long and often — deriving from them a most honorable and most liberal delight of the mind, joined with the highest usefulness. And we see many in our own age still imitating their example. The divine Plato testifies, in Book 7 of the *Republic*, that great pleasure of the mind is gained from these arts, where he boldly says, and confidently affirms, that the eye of the soul, which is blinded and buried by other studies, is by the mathematical disciplines alone restored and roused once more to the contemplation of that which truly is. I pass over very many other testimonies of Plato and of other most weighty philosophers, by which the usefulness of these disciplines — joined with their necessity and delight — and their excellence can be abundantly proved.

COMMENDATION OF EUCLID AND OF GEOMETRY

Who Euclid was, the founder of these Elements — so that we may bring forward something about the author whom we have proposed to expound, and about geometry as a whole — and at what time he flourished, is not sufficiently agreed among the writers. For many, as the received edition of Euclid's Elements according to Campanus [Campanus of Novara] and Theon [Theon of Alexandria] testifies, together with the heading of that edition, suppose that Euclid was the philosopher born at Megara — a town lying by the Isthmus — and a pupil of Socrates [Socrates], who established the Megarian school, called after himself, which by another name was called dialectic, because his followers wrote books by questioning and answering (which is the proper office of the dialecticians).

Concerning him there is much in Diogenes Laertius [Diogenes Laertius], in his *Lives of the Philosophers*; and Cicero too writes of him in his second book, where he says: "After him, Euclid, the Megarian pupil of Socrates, from whom those same Megarians were named, who held that the only good is that which is one, and alike, and the same, and everlasting." These authors are supported in no small degree by what Valerius Maximus [Valerius Maximus] writes in his eighth book: namely, that the contractors of a sacred altar, who tried to confer with Plato — himself also a pupil of Socrates — about its manner and form, were sent by him to Euclid the geometer. But if we are to believe Proclus, that noble writer, and other ancient authors, this Euclid of ours was younger than the Megarian, and flourished in the time of Ptolemy the First [Ptolemy I], who began to rule over Egypt after the death of Alexander the Great [Alexander the Great], in the 115th Olympiad and in the year 319 before the birth of Christ, as Ioannes Lucidus [Giovanni Lucido] reports. And this I would believe to be the truer view, chiefly persuaded by this argument: that Diogenes Laertius, most carefully enumerating all the works of that Megarian Euclid, makes no mention whatever of this most celebrated volume on the elements of geometry, in which Euclid won for himself lasting and never-dying fame and glory. For it is not to be thought that Diogenes, so thoroughly practiced in the records of the philosophers, would either have wished knowingly to pass over so remarkable a work, or have been ignorant that it was composed by his own Euclid. And so our Euclid, that most acute geometer, is far different from the Megarian philosopher: for, having been engaged with the highest distinction in the teaching of the Academics, he turned his whole mind to the mathematical disciplines, in which he so excelled that, by the agreed judgment of all, he rightly claimed for himself the first place among mathematicians. He wrote, moreover, not a few other volumes, in which his extraordinary diligence and admirable learning readily shine forth — such as his *Optics*, his *Catoptrics*, his *Elementary Institutions*, and works pertaining to the study of music, his *Phenomena*, and the book of *Data* [Data], the work *On Divisions* (which some suspect to be that little book *On the Divisions of Surfaces* ascribed to Machometus of Baghdad [Muhammad al-Baghdadi], which was lately published through the labors of John Dee of London [John Dee] and Federico Commandino of Urbino [Federico Commandino]). He also composed *Elements of Conics*, according to Proclus, which, however, have not yet reached us, and other small works of that kind. But above all this volume of the *Geometrical Elements* — never-

—which, by the universal consensus, can never be praised enough, he composed with such marvelous order and such great learning that no one who has ever written comparable Elements (and there have been not a few, as Proclus

[Proclus] tells us) has equaled him, much less surpassed him. In this work he not only displayed the highest sharpness of intellect, but also declined to publish everything that pertains to geometry. He chose to make public only what seemed genuinely necessary and useful for the common good, and he resolved to establish it by the firmest arguments and reasoning.

As for how great the excellence and usefulness of these Geometrical Elements of Euclid [Euclid]—and therefore of geometry as a whole—may be, this can be seen clearly enough partly from what we have written already and partly from what we shall now say. They are called *geometrical elements* for this reason: that without them we can undertake no mathematical work at all, let alone gather any fruit from it. Indeed, all the writers on mathematical subjects—Archimedes [Archimedes], Apollonius [Apollonius], Theodosius [Theodosius], and the rest—make use of these Euclidean elements in their demonstrations, treating them as first principles long since examined and proved by everyone.

And so, just as anyone who wishes to read first learns the letters of the alphabet and, by constant repetition, uses them to spell out every word, in the same way whoever wants to make the other mathematical disciplines familiar to himself must first have a full and perfect command of these geometrical elements. For from these elements, as from a most abundant spring, flows all measurement of breadths, lengths, heights, and depths; all measuring and dividing of fields, mountains, and islands; all observation of the stars in the heavens by means of instruments; all construction of sundials [horologiorum sciotericorum]; all the power of machines and the calculation of weights; and all the variety of the various appearances such as we see in mirrors, in paintings, in water, and in air variously illuminated.

By these elements, I say, the middle and center of this whole world-machine has been discovered; its poles [cardines] have been found, about which it perpetually turns; and finally the shape and size of the entire globe have been determined. By the power of this single science it is shown and demonstrated how the whole heaven and the stars perform their endless revolution—their rising and setting, their departure and return, their ascent and descent—and how, throughout the whole year and across every region of the earth and every inclination of the sphere, the variation of day and night and of the seasons comes about. Likewise the conjunctions of the planets, their oppositions, and their various aspects are known so readily that the positions of the planets in the sky and the eclipses—the failures of the Sun and Moon—can be predicted by mathematicians with the utmost certainty, for all time to come, before they occur. In short, we behold this

vast work of God and Nature—the whole world, I mean—laid open before the eyes of our mind by the gift and service of geometry.

Consider further that geometry makes plain, and shows to be credible, many things that seem utterly incredible and beyond all belief. Such is the story told of Archimedes of Syracuse. When Hiero [Hiero], king of Syracuse, had built a ship of such enormous bulk—one he intended to send to Ptolemy [Ptolemy], king of Egypt—that the Syracusans could not all together budge it from its place, Archimedes, that most skilled geometer, relying on the resources of geometry alone, promised the king that he would arrange for the king himself, alone and without any effort, to draw it down to the sea. When he had made good on this, the astonished king is reported to have exclaimed before them all: "From this day on, whatever Archimedes says must be believed." Not unlike this, in my view, is that most beautiful feat which the same Archimedes accomplished at Syracuse by the help of geometry: when a crown had been made of gold and silver mixed together—one the king had ordered fashioned with the greatest care—he detected with the utmost subtlety, without breaking it apart, the separate weights of gold and of silver that had been fraudulently blended by the goldsmith's deceit. Nor should it be passed over in silence that this same Archimedes, relying on the strength and force of geometrical demonstrations, often boasted that if he had another earth on which to set his foot, he could move this earth of ours, on which we dwell, from its place—and by the same reasoning, given any force whatever, he could move any weight whatever.

Other feats of this kind, achieved not only by Archimedes but by other renowned and illustrious geometers as well, have been handed down to memory. In the end, this one science of geometry won Archimedes so great a name that Marcellus [Marcellus], commander of the Roman army—against whom Archimedes had long defended the city of Syracuse with certain engines devised and built through geometrical demonstrations—provided by public edict, in the sack of the captured city and the slaughter of its citizens, for the safety of Archimedes alone. When Marcellus learned that Archimedes had been killed, against his command and his will, by some common soldier, he grieved deeply, and paid to the dead man the honor he had been unable to pay the living. Cicero [Cicero] boasts, in a wonderful way, that he himself discovered Archimedes' tomb while serving as quaestor in Sicily. No one, then, should be surprised that geometry was always held in the highest honor among the Greeks, no less than among the Romans.

Yet another point adds to the excellence and usefulness of geometry: since geometrical demonstrations are supremely clear, no one without them will

adequately grasp what the force of demonstration is, and no one lacking them will be a perfect master of method. This is what Galen [Galen], the distinguished philosopher and prince of physicians, frankly admits in the book he entitled *On His Own Books*. For in matters of dialectic, most closely reasoned as they are, he testifies that although he had gone through all the schools of the Peripatetics and Stoics of his time, and had seized upon their precepts with wonderful eagerness and zeal of mind, he heard almost nothing from them that bore on the understanding of demonstration. On the contrary, he found that most of what they had handed down was left in dispute by them, and that some of it even conflicted with natural reason. So much so that he would have ended up in the hesitancy of the Pyrrhonists (those philosophers who decided nothing but doubted everything) had he not been called back by his knowledge and mastery of arithmetic, geometry, and dialectic—arts in which he had been trained by his grandfather and his father. Hence he urges that we should follow those arithmetical characters and the demonstrations of lines. Plato [Plato] too said that geometry must be learned—among other reasons, for this one especially: that knowledge of it is most useful for grasping the other arts more easily and correctly.

Finally, this is the crowning praise of geometry, to be proclaimed in every way: that it did not remain stuck in the small and lowly devices from which it took its origin, but flew up all the way to the heavens; it lifted our human minds, cast down upon the ground, back up to that heavenly seat, and laid open to our understanding the marvelous fabric of this world, together with its ordering and governance.

DIVISION OF GEOMETRY AND OF EUCLID'S ELEMENTS

Geometry is divided into the study of planes—which by a general term is called *geometry* [Geometria]—and into the doctrine of solids, which mathematicians call by the proper and special name *stereometry* [Stereometria].

For geometry, taken in general, sets itself this aim: either to construct planes or solids, or, when they have been constructed, to compare them with one another and to divide them. And no one should think it strange that, although there are three kinds of magnitude—line, surface, and solid—proper studies exist, as we have said, only for the two latter, and not for lines or even points. It should not, I say, seem strange, since (as Proclus says) geometry is concerned above all with figures, and all figures consist only of planes or solids. For points and lines constitute no figure without planes or solids; and so there was no need to establish a separate science of points and lines, whereas for surfaces (that is,

planes) and for bodies (that is, solids) it was most fitting that they should each receive their own treatment.

Wishing, then, to hand down in these elements a perfect knowledge of geometrical matters, complete in every respect, Euclid, that supreme master of the subject, treats of planes in the first six books, and of solids most acutely and fully in the following five, investigating their most notable properties.

But since geometrical matters generally—and in particular those five regular solids commonly called the Platonic bodies [corpora Platonica]—could not be perfectly treated without a knowledge of commensurable and incommensurable lines (indeed, a great many magnitudes can by no means be brought under measure without knowledge of those same lines, since their sides are very often such that no common and known given measure can measure them, as is plainly evident to those who have ever put geometrical demonstrations into practice and use), Euclid, in order to embrace in these geometrical elements all the material required for the understanding and measuring of magnitudes, placed before his stereometry the tenth book, in which he treats subtly and fully of lines of this kind.

Understanding, again, that this treatment of commensurable and incommensurable lines could not stand without a knowledge of numbers, before the tenth book he treats of the properties of numbers, and he pursued them fully and carefully in the three books that precede it.

For this reason the whole of this volume of geometrical elements, comprised in fifteen books (of which the first thirteen are without any dispute ascribed to Euclid by everyone, while the last two are believed by some to be the work of Hypsicles of Alexandria [Hypsicles]), can rightly be divided into four parts. The first part, contained in the first six books, deals with planes; the second, comprising the three following books, examines the properties of numbers; the third, which the tenth book alone constitutes, discusses commensurable and incommensurable lines; and the fourth, made up of the remaining five books, embraces the science of solids, or bodies.

The first part is itself threefold. In the first four books planes are treated absolutely, by investigating their equality and inequality; in the fifth book proportions of magnitudes in general are discussed; and in the sixth, finally, the proportions of plane figures are examined. What Euclid treats in each of the other books we shall explain in their proper places.

WHAT A PROBLEM, WHAT A THEOREM, WHAT A PROPOSITION, AND WHAT A LEMMA ARE AMONG MATHEMATICIANS

Every mathematical demonstration is divided by the ancient writers into *problem* and *theorem*. They call a *problem* a demonstration that bids and teaches us to construct something. For example, if someone should try to demonstrate that an equilateral triangle can be constructed upon a given finite straight line, such a demonstration will be called a *problem*, because it teaches by what method an equilateral triangle is to be constructed upon a finite straight line.

This kind of demonstration was called a *problem* by analogy with the dialectical problem. For just as among dialecticians a *problem* is called that question whose two sides of contradiction (as they put it) are each probable—such as this question: "Is a whole really distinct from its parts taken together?"—so too among mathematicians the inquiry by which they bid us construct something, and whose contrary can also be effected, is called a *problem*. Thus if someone proposes to demonstrate that an equilateral triangle can be constructed upon a given finite straight line, he will certainly succeed—and yet a non-equilateral triangle (an isosceles or a scalene) can also be constructed upon the same line. By the same reasoning, whoever sets out to bisect a rectilinear angle presents us with a problem, because the same angle can also be divided into unequal parts.

There is, however, no small difference between the dialectical and the mathematical problem. For in a dialectical problem, whichever side of the contradiction is taken up is confirmed only probably, so that anyone's intellect remains in doubt which of its two sides is true. But in a mathematical problem, whichever side one chooses, one will prove it by firm demonstration, so that nothing doubtful at all remains. For if a geometer resolves to draw a perpendicular line from any given point of a proposed straight line, he will accomplish this very thing by fixed and evident reasoning; and the same must be said if he wishes to draw a non-perpendicular line from the same point.

A *theorem*, on the other hand, is the name they give to a demonstration that merely examines some property or attribute of one or more quantities together. Thus if someone chooses to demonstrate that in every triangle the three angles are equal to two right angles, they will call such a demonstration a *theorem*, because it does not bid or teach us to construct a triangle or anything else, but only contemplates this property of any given triangle: that its angles are equal to two right angles. Hence, from that very contemplation, this demonstration is

called a *theorem*. In a theorem it is in no way possible for both sides of the contradiction to be true. For if someone demonstrates that the angles of any triangle are equal to two right angles, it can in no way come about that they are also unequal to two right angles. The same reasoning is to be understood in the case of other theorems.

And so, to put it in a word: that mathematical inquiry which, in teaching us to construct something, also admits of an opposite that can be effected, is called a *Problem*; but that which teaches us to construct nothing, and whose opposite side is always false, is called a *Theorem*. Hence if someone were to propose, in the manner of a problem, that he wishes to construct a right angle in a semicircle, he would deserve to be wholly laughed at and judged utterly ignorant of geometry, since all angles constructed in a semicircle are right, as will be demonstrated in Book 3, Proposition 31. For this reason it must be called a theorem, and not a problem. Both problem and theorem, however, are customarily called by mathematicians a *Proposition*, because each of them proposes something to us, as is clear from the examples adduced. I have said all this so that the diligent reader may not be surprised when he finds

in Euclid, Apollonius, and the other mathematicians that some propositions are called problems and others theorems. For the Geometrical Elements of Euclid, and the *Conics* of Apollonius (to say nothing of the volumes of others for now), consist partly of problems and partly of theorems. The demonstrations of problems always close with roughly these words: "which was to be done"; those of theorems with these: "which was to be shown," or "which was to be demonstrated"—with due regard, of course, to the aim of each. For in any given problem and theorem several demonstrations are contained, and not just one, even though the final demonstrative syllogism alone concludes what was proposed for demonstration at the outset, as we shall make clear in the first proposition of Euclid, and as will be evident in all the rest.

But since, for the demonstrations of problems and theorems, there are very often required certain other, less principal theorems or problems—ones that can easily be understood from what has been proved before—geometers sometimes insert theorems and problems of this kind among the problems and theorems that are their chief concern, so that these may be demonstrated more briefly. They call these *Lemmas*, because they are assumed solely for the sake of other demonstrations, and are not made the subject of principal discussion as the others are. And so a *Lemma* may be described as a demonstration, or a construction, of something that is assumed for the demonstration of some

principal theorem or problem, so that the demonstration may be made quicker and briefer.

WHAT THE PRINCIPLES ARE AMONG MATHEMATICIANS

Since every branch of learning and every discipline is generated from pre-existing knowledge—as Aristotle [Aristotle] is our authority—and demonstrates its conclusions from certain assumed and conceded principles, while no science (by the judgment of the same philosophers) demonstrates its own principles, the mathematical disciplines too will certainly have their own principles, from which, once laid down and granted, they may confirm their problems and theorems.

Now only three kinds of these are found among mathematicians. In the first are found all the *definitions*, which some, following Aristotle, call *suppositions* (as Proclus prefers). By these the technical terms are explained, so that in the discussion itself we may not, deceived by the ambiguity or obscurity of terms, fall into fallacious reasoning.

The second kind embraces the *Petitions*, or *Postulates*, which are so clear and evident in the science under consideration that they require no confirmation, but demand only the assent of the hearer, lest there be any hesitation or difficulty in demonstrating. To the third kind are referred the *Axioms*, or common notions of the mind, which are manifest and evident not only in the science proposed but in all others as well, so that no one who has rightly grasped the very terms could by any reasoning dissent from them. And to these principles, it seems to me, can rightly be applied what Aristotle writes about first principles in the *Metaphysics*: "Who could miss a barn door?"—so that, as Cicero splendidly puts it, they may be called *Pronouncements* or *Dicta*.

Euclid, then, in this volume of the Geometrical Elements, sets out all these principles before the demonstrations of his conclusions, so that from them—easily understood by anyone—he may deduce those admirable theorems to which no one would ever assent unless they were confirmed by sure and evident reasoning. On this account too geometry deserves to be exalted with the highest praise and proclaimed through every age: that from such slender beginnings, most familiar and perfectly easy to anyone however untrained and ignorant, it advances to theorems at first sight far removed from all human sense and understanding—and yet confirms them all, by a marvelous order and an easy method and the most certain demonstrations, so that nothing doubtful at all is left in them.

Moreover, in setting out principles of this kind, Euclid observes this order: at the very entrance to the science he proposes the principles common to all of geometry, while in the other books that follow, where the subject requires it, he sets out those principles that seem to pertain, in a proper and special way, to the particular matter treated there. Not, however, that all geometrical principles have been explained by Euclid in these elements; he has left much for the reader to investigate—things that can nonetheless be grasped and understood, without great labor and study, from what he has handed down. Yet, so that we may not seem to have failed the students of mathematics in this respect as well, we have added in various places, to the principles laid down by Euclid, several others drawn from approved authors, whose ignorance we judged would most delay the course of the demonstrations.

PREFACE TO EUCLID'S ELEMENTS

Should anyone happen to wonder why, after so many distinguished commentaries on Euclid's geometrical *Elements* — published by outstanding writers, expert above all in mathematical matters — I have myself composed yet new expositions, he will readily convince himself that I have not done so rashly, once he understands the reasoning behind my plan. For long and continued experience had shown and proved to me that these *Elements* are so useful, indeed so necessary, that no one can hope, without their support, to grasp the extremely acute and subtle demonstrations of Archimedes, Apollonius, Theodosius, Menelaus [Menelaus of Alexandria], Ptolemy, and the other illustrious mathematicians. I therefore deeply regretted that so remarkable and distinguished an author should be almost wholly neglected by most, and treated as he deserves by very few — so much so that in our own age one can scarcely find anyone who devotes diligent effort and study to mastering these *Elements*. The chief reason for this, I believe, is that people are deterred by the difficulty and obscurity of the matters treated, and have no guide in this field whom they might set before themselves to follow without risk of error.

There do exist, to be sure, the genuinely learned commentaries of Campanus [Campanus of Novara] and of Theon [Theon of Alexandria] on the several books of Euclid, which might well suffice for anyone to attain the doctrine of these *Elements* easily. But the one followed the tradition of the Arabs throughout, and they for the most part perverted Euclid's order and method and altered the wording of his propositions with more than a few substitute terms, so that the author's true and genuine sense can be understood only with great difficulty — as

is most apparent in Book 10. The other (I mean Theon) has been so corrupted by nearly countless errors and faults through the carelessness of copyists, and so encumbered by the Greek notes used in his demonstrations — obscure and badly rendered as they are — that he breeds great difficulty and perplexity even in trained minds. The result is that no one grasps Euclid himself except by the greatest labor and study.

And if others down to our own day have devoted much study and effort to the task of expounding Euclid's *Elements*, these have set out only the first six books; or if any have published commentaries on the whole of Euclid, they have very often abandoned the wholly reliable demonstrations of the ancients and fabricated other, new ones of their own — which for the most part are not so sound, nor do they settle the matter simply and completely. This is especially so in that they now wrongly strip certain words from the propositions, now ineptly add others, and now rashly change still others, so that one may with good reason come to doubt Euclid's true and proper meaning. In this matter, however, I make an exception of Federico Commandino of Urbino [Federico Commandino], no ordinary geometer, who recently restored Euclid — rendered into Latin — to his original luster, save in a few places where he strayed not a little from the truth, as I shall point out in the proper place.

Since this is so, and since a subject so distinguished and a science so worthy deserve that effort, study, and industry — and whatever else can contribute anything to it — be brought to bear on it, I decided, after devoting a long stretch of time to work in mathematics, that I should publish my labors and long night-watches, so as to bring students of these matters some help (unless I am mistaken). Now hear briefly by what method, path, and plan the whole is handled here, and what has been achieved in this exposition. The demonstrations of others — above all of Theon, which, on no slight grounds, I had come to believe, with most people, to be Euclid's own (and Proclus too attests this) — I have tried to render more concise, so far as the difficulty of the matter allowed, or at least plainer and clearer where I could not make them briefer. For I have not set them out bare, and in exactly as many words as they were written.

Indeed their brevity is sometimes such that what the most elegant poet said comes about: "I labor to be brief; I become obscure." [Horace, *Ars Poetica* 25–26] And sometimes, on the other hand, when things could be expressed more briefly and succinctly than is enough, a longer discourse brings annoyance to the reader. Avoiding both faults, I have handed them down as it were [Greek: [?]] — a term for paraphrase/restatement I cannot resolve on the page, and in roughly the

manner I observed when I taught Euclid publicly — in this too wishing, so far as lies in me, to satisfy the desire and wish of my hearers. For thus, in my judgment, Euclid will be learned more easily and successfully by students — especially by those who, as beginners, are now first taking up these mathematical studies — and with greater pleasure and profit.

Besides this, I have added in many places various problems and theorems, not unpleasant to know and not foreign to the aim of geometry, which I have partly culled from Proclus, Campanus, and other authors, and partly worked out myself by my own effort (as they say) and by constant reflection. I have moreover taken diligent care in this work that Euclid's definitions — especially the more obscure ones, and those that seemed to hold some difficulty (upon which very many, striking as it were on certain rocks, have veered from the straight course and slipped into various absurd errors wholly at odds with the design of the discipline) — should be explained clearly and plainly, so far as could be done; and students of these arts will readily judge this.

WHAT THE CHIEF THINGS ARE THAT HAVE BEEN ADDED TO THIS FIRST EDITION OF EUCLID

I.

A geometrical demonstration of Euclid's eleventh axiom [*If a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, those two straight lines, produced to infinity, meet one another on that side where the angles are less than two right angles*], far more evident than the one Proclus offers. (*To prop. 28, bk. 1.*)

II.

The division of a straight line into any number of equal parts, by the first 40 propositions of Book 1 alone, without the aid of the proportions of Book 6. (*To prop. 40, bk. 1.*)

III.

How obtuse-angled [amblygonia] and acute-angled [oxygonia] triangles are to be constructed, so that they can be exhibited in numbers — which Euclid demonstrated in props. 12 and 13 of Book 2. (*To props. 12 and 13, bk. 2.*)

III.

A reply to the *Apology* of Jacques Peletier [Jacques Peletier], on the angle of contact. (*To prop. 16, bk. 3.*)

V.

A most beautiful consideration of plane equilateral and equiangular figures inscribed within a circle and described outside a circle: namely, whether every equilateral figure is also equiangular, and every equiangular one is likewise equilateral. (*To the end of bk. 4.*)

VI.

A most abundant treatment of proportions, and of the three chief proportionalities — arithmetic, geometric, and harmonic. (*To def. 4, bk. 5.*)

VII.

A beautiful reflection on why Euclid, in defs. 6 and 8 of Book 5, defined four proportional and non-proportional magnitudes by their equimultiples. (*To def. 8, bk. 5.*)

VIII.

A most easy description of a certain curved line, by which both a figure of any number of equal sides is inscribed in a circle; the circle is squared; a rectilinear angle is divided into any number of equal parts; a straight line equal to any arc of a circle is produced, and conversely; and finally other most pleasant things are accomplished. (*To the end of bk. 6.*)

IX.

How most of the theorems of Book 7 are demonstrated also of fractional numbers, whether or not whole numbers are attached to them. (*To the propositions of bk. 7.*)

X.

Most clear demonstrations of *minutiae*, that is, of fractional numbers. (*To the end of bk. 7.*)

XI.

On the composition of proportions: namely, in what way addition, subtraction, multiplication, and division ought to be carried out — against certain more recent writers. *(To the end of bk. 9.)*

XII.

A description of the five regular solids in a given sphere, from Pappus of Alexandria [Pappus of Alexandria] — and indeed easier than the one Euclid handed down to us. *(To the end of bk. 16.)*

XIII.

A comparison of the solidities and convex surfaces of these same five regular solids with one another. *(To the end of bk. 16.)*

The other things, not few, that have been added here and there throughout these commentaries and are lacking in other editions — such as, in particular, the more accurate finding of the last points of the quadratrix by perpendicular lines, and not by oblique intersections of lines, and so on — the diligent reader will note without any trouble.

[The third leaf of this opening is blank; only offset show-through from the facing page is visible. The Definitions of Book I begin on the following page.]

Euclid's Elements, Book One

Definitions

I.

(Euclid) **A point is that of which there is no part.**

(Clavius) This entire first book is devoted to conveying to us the origin and properties of triangles — both as regards their angles and as regards their sides, which it sometimes compares with one another, and sometimes examines and considers each on its own. For sometimes it investigates the angles from the sides of a triangle, and sometimes the sides from the angles, testing them for equality and inequality; and it pursues the same inquiry in various ways when two triangles are compared with each other. It then opens up for us the properties of parallels and takes up the study of parallelograms, both among themselves and also as they are compared with triangles set between the same parallels. And so that Euclid may carry all this out more correctly and conveniently, he teaches the

bisection of a rectilinear angle and of a straight line, the construction of a perpendicular, how one angle is made equal to another, and other such things. To sum up the whole matter in a word: in the first book — following Proclus's view — are treated the foremost and principal of the rectilinear figures, namely triangles and parallelograms.

But before all else Euclid, in the manner of mathematicians, begins the proposed subject from first principles, starting with the definitions, the first of which explains the point, teaching that in continuous quantity that is called a point which has no parts. This definition will be grasped more plainly and easily if we first understand that continuous quantity has three kinds of parts: some according to length, others according to breadth, and others according to depth or height. Not every quantity, however, has all these parts. Some have only one, according to length; some have two, adding to these the parts of breadth as well; and some, finally, besides these two kinds of parts, contain a third also, that of height or depth. For every continuous quantity is either long only, or at once long and broad, or long, broad, and deep. No magnitude can have any further dimension, as Ptolemy [Ptolemy] rightly demonstrated in his little book *On the Analemma* — recently restored to its former dignity by the work of Federico Commandino of Urbino [Federico Commandino] — and also, as Simplicius [Simplicius] reports, in his little book *On Dimension*, which, so far as I know, has not yet been printed. Therefore, whatever exists in continuous quantity or magnitude and is conceived without any part, so that it is thought of as neither long nor broad nor deep — thereby excluding, of course, the rational soul, the Now or instant of time, and unity, which likewise have no parts — this is what Euclid and the geometers call a point.

[Margin: *punctum* · (a point)]

No example of it can be found among material things, unless you wish to take the tip of some very sharp needle as representing the likeness of a point. Yet even that is not wholly true, since that tip can be divided and cut without end, whereas a point must be regarded as altogether indivisible. In short, in magnitude that must be conceived to be a point which in number is the unit, and in time the instant; for these too must be conceived as indivisible.

II.

(Euclid) **A line is length without breadth.**

(Clavius) Here he defines the line, the first species of magnitude, which he says is a quantity that is long only, not broad — understand, nor deep either. For from

whatever quantity breadth is excluded, from that same quantity depth too is necessarily removed; but not conversely. We can conceive and understand this line — that is, length without breadth — not absurdly, from the boundary of some place that is partly lit and partly in shadow. For the end, or common boundary, of the lit region and the shadowed one is a certain length, extended along the length of the light and the shadow themselves and lacking all breadth, since it is the limit of both. Mathematicians too, to impress on us the true understanding of a line, imagine the point already described in the previous definition to be moved from place to place. For since a point is utterly indivisible, there will be left from that imaginary motion a certain long trace devoid of all breadth. Thus if the point A is understood to flow from A to B, the trace produced, AB, will be called a line —

Diagram. Two lines are drawn, one above the other, illustrating a straight line and a curved line with the same endpoints.

- A (upper left) — left endpoint of the upper, straight line AB.
- B (upper right) — right endpoint of the upper, straight line AB.
- A (lower left) — left endpoint of the lower line, an arc bowing upward from A to B.
- B (lower right) — right endpoint of the lower, curved line AB.

— since the interval comprehended between the two points A and B is indeed a certain length lacking all breadth, because the point A, being deprived of every dimension, could in no way have produced [breadth]. Hence it has come about that some have said a line is nothing other than the flowing of a point, while others have said it is a magnitude contained by a single interval. For a line can be cut and divided in one way only, namely according to length.

III.

(Euclid) **The extremities of a line are points.**

(Clavius) He teaches what the extremities or boundaries of any line are, saying that a line is bounded, or closed off at either end, by points — not that every line has boundaries; for how could we assign boundaries to an infinite line? and on the same reasoning, how could we detect any extremity in a circular line? Rather, that every line which has extremities receives points at its extremities. Thus the line AB above has as its extremities the points A and B. The same is to be understood of all bounded and finite lines, so that we conceive their extremities to be points only.

IV.

(Euclid) **A straight line is one which lies evenly with the points on itself.**

(Clavius) Among mathematicians a line is of three kinds in all: straight, circular (which they also call curved), and mixed, or composed of both. Of these, Euclid here describes the straight line, which he says is that which extends evenly between its points — that is, in which no intermediate point leaps up above or drops down below the extremities, or swerves this way and that by bending, and in which, in short, nothing bent is found. A fine thread stretched taut with the greatest force represents this vividly for us; for in it all the middle parts keep an equal position with the extremities, and none is higher or lower, but all run on uniformly between the two ends. Proclus, expounding this definition, says that a line then lies evenly with its points when it occupies a space equal to that which lies between its extreme points. Thus the line ACB will be called straight, because it occupies precisely as much space as is the distance of point A from point B;

Diagram. Over a horizontal base line, three arcs of increasing height are drawn between the same two endpoints; the base line and each arc share the endpoints A and B.

- A (bottom left) — left endpoint shared by the base and all three arcs.
- B (bottom right) — right endpoint shared by the base and all three arcs.
- C (bottom center) — the midpoint of the straight base line ACB.
- D (top, highest) — apex of the highest arc, ADB.
- E (below D) — apex of the middle arc, AEB.
- F (below E, just above the base) — apex of the lowest arc, AFB.

whereas the lines ADB, AEB, AFB will not be called straight, since they occupy greater spaces than the distance of the extreme points A and B. In the same way you see that all the points of the line ACB, [with] the point C, lie evenly between the extremities A and B, in accordance with Euclid's definition — which is not observed in the other lines, since the points D, E, F leap up away from the extremities A and B. Plato [Plato] defines the straight line very elegantly thus: a straight line is one whose middle points hide its extremities. Thus in the line ACB, if the point C, or any other middle point, had the power of hiding, and A, the extremity, had the power of illuminating, the interposed point C would certainly be an obstacle to the other extremity B being illuminated from A; and again, an eye placed at the extremity A would not see the other extremity B, because of the interposed point C — which does not happen in lines that are not straight, as is plain in the lines ADB, AEB, AFB. Archimedes [Archimedes], for his part, says that

the straight line is the least of those which have the same endpoints; such is ACB compared with ADB, AEB, AFB. For if ACB were not the least of those which have the same endpoints A and B, it would not lie evenly with its points; rather, that line would do so which would be said to be smaller than ACB. Campanus [Campanus of Novara], finally, describing the straight line, calls it the shortest extension from one point to another.

Now, just as mathematicians conceive a line to be described by the imaginary flowing of a point, so from the character of the point's flowing they understand the character of the line described. For if a point is conceived to flow straight through the shortest space, so as to swerve neither to this side nor to that but to keep a certain even motion and progress, that line described will be called straight. But if the flowing point is thought to waver in its motion and stagger this way and that, the line described will be called mixed. And if, finally, the flowing point does not waver in its motion but is carried round in a circle with a certain uniform motion and at a fixed distance from some point about which it is carried, that line described will be called circular. And so, if two points move with wholly similar motions, so that they always remain equally distant from each other, two similar lines will be described by them: that is, if one of them is straight, the other too will be straight; but if one is curved, the other too will be curved in exactly the same way, and so on. The lines that are not straight — all of which may be called oblique — Euclid does not define here, but he will set out the circular one in the fifteenth definition, omitting the mixed line altogether, because it has no use in these geometrical Elements. There are, however, very many kinds of mixed lines: some are uniform, some non-uniform. Of the uniform, again, some lie in a plane, some in a solid. In a plane are the hyperbola, the parabola, and the ellipse, which Apollonius [Apollonius of Perga] treats most fully in his *Elements of Conics*; the conchoid line, treated by Nicomedes [Nicomedes]; the helical line [linea helica], on which Archimedes set up a treatment in his book *On Spiral Lines*; and others of this sort. In a solid, or on a curved surface, there are helical lines of a different kind from the one described by Archimedes — such as the one that winds about some cylinder, and also the one that lies about a cone, or again the one about a sphere, of which sort are those spirals that the Sun describes from its rising to its setting, as we have taught in *the Sphere*. Of the non-uniform ones the number is infinite, and there is no need to review them here. From all this it is established that there are only two simple lines, the straight and the circular, while all the others, whatever they are, are called mixed, because they are composed of these. Hence Aristotle [Aristotle] ingeniously concludes, in his book *On the Heavens*, that corresponding to the threefold line there are only three motions: two simple, the straight and the circular, and a third mixed, or composed of those two.

But since we are accustomed to draw straight lines with a ruler [regula], let us show by what method we may test a given ruler, to see whether the line drawn by it is straight or not.

Diagram. A long, thin straight-edge (a ruler) is drawn as a narrow rectangle with hatched lower edge. Its lower corners are lettered A (left) and B (right); the upper edge used for ruling carries C (left) and D (right).

- A (lower left) — one end of the ruler AB.
- B (lower right) — the other end of the ruler AB.
- C (upper left) — one end of the ruling edge CD.
- D (upper right) — the other end of the ruling edge CD.

Let AB, then, be a ruler; along its edge CD let the straight line CD be drawn from point C to point D. Then let the ruler be turned about, so that — the same side remaining uppermost — the point C is set at D and the point D at C, and along the same edge CD of the ruler let a straight line be drawn from the same point C to point D. For if this second line agrees at every point with the first, there can be no doubt that we may rely on the ruler AB for drawing straight lines. But if it does not agree at every point, that edge CD will not be perfectly straight, and must be corrected more carefully.

V.

(Euclid) **A surface is that which has length and breadth only.**

(Clavius) After the line, which is the first species of continuous quantity and has a single dimension, he defines the surface, which constitutes the second species of magnitude and adds to the first dimension, that of length, a second, that of breadth. For in a surface is found not only length, as in a line, but also breadth, yet without any depth.

Diagram. A square, its interior filled with fine horizontal hatching, representing a plane surface. Its four corners are lettered clockwise from the top left.

- A (top left) — corner of the surface.
- B (top right) — corner of the surface.
- C (bottom right) — corner of the surface.
- D (bottom left) — corner of the surface.

Thus the quantity ABCD, comprehended between the lines AB, BC, CD, DA, and considered according to its length AB (or DC) and according to its breadth AD (or

BC), being wholly without depth, is called a surface. The outermost breadth of any body presents this to us, if all solidity is removed from it by the understanding. Not inaptly too, as Proclus says, the shadows of bodies exhibit to us as it were an expressed image of a surface; for these, since they cannot penetrate the inner part of the earth, will be only long and broad. Mathematicians, however, to set it before our eyes, bid us understand some line to be moved crosswise: the trace left by that motion will indeed be long, on account of the length of the line, and broad too, on account of the motion made crosswise; but it can in no way be deep, since the line describing it lacks all depth — and so it will be called a surface. Thus if the line AB flows toward DC, the surface ABCD will be produced. Others, in describing a surface, say that it is the boundary of a body; others, that it is a magnitude consisting of two intervals. For a surface can be divided and cut in two ways: in one according to length, in the other according to breadth.

VI.

(Euclid) **The extremities of a surface are lines.**

(Clavius) This definition is not unlike the previous one, in which the boundaries of a line were explained. For he means that the extremities of a surface are lines, just as the boundaries of a line were points. Thus of the surface ABCD above, the extremities are the lines AB, BC, CD, DA. And in the same way, in any other surface that has extremities, one must conceive lines at its extremities — but not in an infinite surface, or in a spherical one that surrounds a spherical body. A surface can also be closed and bounded by a single line only, such as is the circular surface, as we shall say in the definition of the circle.

VII.

(Euclid) **A plane surface is one which lies evenly with the lines on itself.**

(Clavius) This definition too bears a certain resemblance to the description of the straight line. For a surface that lies evenly with its lines — so that its middle parts do not depart from the extremities by leaping up or dropping down — will be called plane: such as the surface of some well-polished marble, in which all the parts are set in a level arrangement, so that it has nothing cut into it by angles, nothing broken by unevenness, nothing projecting, nothing hollowed out. For in it the intermediate parts have obtained an equal position with the extremities, and none is higher or lower, but all extend uniformly. Others define a plane surface by saying that it is one whose middle parts hide its extremities; or that it is the least, or shortest, of all those that have the same extremities; or one to all of

whose parts a straight line can be fitted, as Hero the ancient geometer [Hero of Alexandria] holds.

Diagram. A plane surface ABCD (roughly a rectangle) with a bundle of straight lines radiating from the fixed corner A, illustrating a straight line swept round about A across the surface.

- A (top left) — the fixed point about which the straight line is carried round; corner of the surface ABCD.
- B (top, to the right of A) — upper-right corner of the surface ABCD; the ray AB continues to E.
- C (right, below B) — lower-right corner of the surface ABCD.
- D (left, below A) — lower-left corner of the surface ABCD; the ray AD continues to H.
- E (far right, top) — endpoint of the swept ray AE (the extension of AB).
- F (far right, below E) — endpoint of the swept ray AF.
- G (bottom center) — endpoint of the swept ray AG.
- H (bottom left) — endpoint of the swept ray AH (the extension of AD).

Thus the surface ABCD is to be called plane only when a straight line AE, carried round about the fixed point A — so that now it is the same as AF, now the same as AG, and now the same as AH — [finds] nothing on the surface depressed or raised, but all the points of the surface are touched and in a manner grazed by the straight line. But if some least particle of the surface, lying lower, were not touched by the straight line, or if the straight line itself could not be freely carried round because of some swelling or prominence met with on the surface, it could no longer be called plane. And so, for it to be plane, it is required that a straight line can be made to measure it in every way — that is, that a straight line can be applied to it along AB and AF, and finally along all its parts. This surface, moreover, will be the only one that we can imagine and understand to be described by the motion of a straight line crosswise, carried over two other straight lines. Thus if the straight line AB is carried over the two straight lines AD, BC, a perfectly plane surface will be produced, in accordance with all the definitions; for it will not be difficult to fit the descriptions handed down to this surface. Mathematicians commonly call a plane surface simply a "plane," so that when they speak of a plane, a plane surface is always to be understood. All other surfaces, to which a straight line cannot be fitted at every point — such as the interior surface of some vault [fornix], or the exterior of some globe, or of a round column, or of a cone, and so on — are called curved and not plane.

Diagram. An engraved woodcut of a semicircular vault or arch [fornix], shown in perspective with its curved band hatched, illustrating a curved (concave/convex) surface. No lettered points.

For although a straight line can be fitted to the surface of a round column, or cylinder, along its length, yet along its breadth it cannot at all. And the same is to be said of the others. A curved surface, moreover, is of two kinds: convex — namely, the exterior surface of a sphere or cylinder — and concave, as the interior of a vault or of some arch. But since the study of all these belongs to stereometry, Euclid in this first book has explained to us the plane surface only, which he is going to discuss in the first six books.

VIII.

(Euclid) **A plane angle is the inclination to one another of two lines in a plane which touch one another and do not lie in a straight line.**

(Clavius) He declares what a plane angle is, saying: whenever two lines in some plane surface meet one another and are not set in a straight line, there is produced from such a meeting — or from the inclination of the one to the other — an angle that is called plane, because it is formed in a plane surface. For example, because the two lines AB, AC meet at A and do not lie in a straight line, they therefore form the angle A, plane, existing in the same surface in which those two lines are set.

Diagram. Three separate figures side by side, each showing two lines meeting at an apex A and descending to feet B (left) and C (right), illustrating plane angles formed by straight and by curved lines.

- A (apex of each figure) — the vertex where the two lines meet.
- B (lower left of each figure) — the foot of the left-hand line.
- C (lower right of each figure) — the foot of the right-hand line.
- In the first (left) figure the left arm AB is curved and the right arm AC is nearly straight.
- In the second (middle) figure the left arm AB is curved and the right arm AC is straight.
- In the third (right) figure both arms, AB and AC, are straight, forming a rectilinear angle.

Now, two lines are said not to lie in a straight line when one of them, extended toward the meeting-point, does not coincide with the other, but either cuts it, or at any rate immediately after the point of meeting recedes from it. This I say on

account of the angle of contact, which arises when two circles touch one another, or also when a straight line touches a circle. For a straight line drawn out beyond the point of contact, although it does not cut the circle, nevertheless immediately after that point separates from it. In the same way that circular line, extended according to its own disposition and form, recedes from the straight tangent line, although it does not cut it. Hence there truly is an angle formed...

(Continuing the commentary on Definition VIII, the plane angle — the angle of contact between a tangent and a circle.)

formed in that point of contact — a matter on which we shall write more at Proposition 16 of Book III, against Jacques Peletier [Jacques Peletier du Mans], who contends that it is not an angle.

But if two lines touch one another while lying in a straight line, so that either one, when produced, coincides with the whole of the other, no angle at all will arise from that meeting, since there is no inclination; rather, the two together will make up one single line. For example, because the straight line AB, when produced, meets the straight line BC, no angle will be produced at B. Likewise, no angle will arise at B from the curved lines AB, BC, because either one, extended along its own bending and oblique course, coincides with the other. They are therefore said to lie in a straight line. And so, for straight lines to make an angle, they must, after meeting, be produced so as to cut one another. Curved lines, however — or lines of which one is curved and the other straight — can genuinely form an angle even without cutting one another; for it is enough that they touch, in such a way that immediately after the contact the one separates from the other, just as they are seen to stand apart before that same point.

The size of any angle consists solely in the inclination, not in the length of the lines; for lines running out farther do not increase their inclination, and therefore do not increase the size of the angle either. There are also two other kinds of angles. The first comprises solid angles, which Euclid [Euclid] discusses in his stereometry and which exist in solid bodies; the second, spherical angles, which are formed on the surface of a sphere by the circumferences of the greatest circles, and which are treated at length in the *Spherics* of Menelaus [Menelaus of Alexandria]. But the explanation of all these we put off to another place, since here the discussion is to concern plane angles alone.

Diagram. Two small specimen figures illustrating lines that "lie in a straight line" (and so form no angle at their meeting-point).

- Upper figure: a horizontal straight line with endpoint **A** (left), **B** (marked at the middle), and **C** (right) — the two straight segments AB and BC continuing as one line, with no angle at B.
- Lower figure: an arc rising from **A** (lower left) to a peak at **B** (top middle) and descending to **C** (lower right) — two curved lines AB and BC joining smoothly at B, with no angle.

IX.

[Euclid, Definition IX] When the lines that contain an angle are straight, that angle is called *rectilinear*.

[Clavius's commentary] Every plane angle is formed either from two straight lines — and this one is called *rectilinear*, the only kind Euclid treats here — or from two curved lines, which may be called *curvilinear*; or from one curved and one straight line, which is not inaptly called *mixed*. Now from these lines, curvilinear angles can be varied in three ways, and mixed angles in two, according to the varying inclination or disposition of the curved lines — namely by the convex or the concave side, as is plainly and clearly seen in the angles set out here. A rectilinear angle, by contrast, cannot be varied by reason of the inclination or disposition of its lines — unless we should choose to call a greater or lesser inclination a "varied disposition," which is absurd; for in this way the rectilinear angle is only increased or diminished, which it has in common with the others, and it is not varied so as to constitute a different kind.

Diagram. A horizontal row of specimen angle-figures — several pointed and hooked forms — illustrating curvilinear angles (both containing lines curved, in convex and concave variants) and mixed angles (one line straight, one curved). The figures carry no lettered points.

X.

[Euclid, Definition X] When a straight line standing on a straight line makes the adjacent angles equal to one another, each of the equal angles is a *right angle*; and the line that stands on the other is called a *perpendicular* to the line on which it stands.

[Clavius's commentary] The right angle and the perpendicular line are found in very frequent use in geometry, as also the obtuse and the acute angle; and therefore Euclid teaches in this place which rectilinear angle is called "right" among geometers, and which line is "perpendicular." In the two following

definitions he will explain the obtuse and the acute angle — for no rectilinear angle can be given other than the right, the obtuse, and the acute.

So, if a straight line AB, standing on a straight line CD, makes at the point B two angles (which are called by mathematicians "adjacent" [deinceps], precisely because the same line CD, produced, makes them near the same point B) equal to one another — which will happen only when AB inclines no more toward C than toward D, but stands evenly upon CD — then each angle at B will be called a right angle, and AB will be called perpendicular to CD, on which it stands. By the same reasoning, CB will be named perpendicular to AB; for although CB makes only one angle with AB, yet if AB were extended in a straight and continuous line toward the point B, another angle would be produced equal to the first. By what technique a line ought to be drawn making two equal angles with another, Euclid will teach in Propositions 11 and 12 of this first book.

And so, to conclude in geometry that some angle is right, or that the line producing it is perpendicular to another, it is required and sufficient that we prove the angle adjacent to it to be equal to it. By the same reasoning, if some angle is said to be right, or the line forming it perpendicular to another, we may infer that the angle adjacent to it is equal to it as well. For whenever the adjacent angles are equal to one another, each of them is called a right angle, and the line forming them a perpendicular, according to this tenth definition; but whenever they are not equal, neither of them is called right, as will be established from the two following definitions, and therefore the line forming them is not called perpendicular either. I have said this so that you may see what may be inferred from this definition in geometrical matters, and what use the descriptions of terms have among geometers. For without much labor what we have said can be carried over to the other definitions.

Diagram. The perpendicular of Definition X.

- **A** (top): upper end of the vertical line.
- **B** (bottom middle): foot of the perpendicular, where line AB stands on CD.
- **C** (left) and **D** (right): the two ends of the horizontal line CD.
- The vertical line AB stands on CD at B, making the two equal (right) angles ABC and ABD.

XI.

[Euclid, Definition XI] An *obtuse* angle is one that is greater than a right angle.

[Clavius's commentary] When the straight line AB, standing on the straight line CD, does not make the angles at the point B equal, and for that reason neither of them is right, but one is greater than a right angle and the other less, the greater angle is called obtuse — such as is the angle B verging toward the point C, which is contained by the straight lines AB, BC.

Diagram. The obtuse and acute angles of Definitions XI–XII.

- **A** (top left): upper end of the oblique line.
- **B** (middle): the vertex, where AB meets the horizontal line CD.
- **C** (left) and **D** (right): the ends of the horizontal line.
- The oblique line AB meets CBD at B, making the obtuse angle ABC (toward C) and the acute angle ABD (toward D).

XII.

[Euclid, Definition XII] An *acute* angle, in turn, is one that is less than a right angle.

[Clavius's commentary] As in the preceding figure, the lesser angle B, verging toward the point D, contained by the straight lines AB, BD, is called acute. And so the right angle, as is gathered from what has been said, admits of no variation such that one should be greater or less than another, since the perpendicular line producing it must not incline more to one side than to the other. The obtuse and the acute, by contrast, can be increased and diminished

in infinitely many ways, since a straight line can depart in infinitely many ways from that inflexibility of the perpendicular line, as is evident.

Since two lines meet to form any plane angle, and sometimes several angles exist at one point, mathematicians are accustomed — in order to remove confusion — to express any given angle by three letters, the middle of which indicates the point at which the lines form the angle, while the outer two signify the beginnings of the lines that contain the angle. For example, in the figure above they understand the obtuse angle by the angle ABC, and the acute by the angle ABD — which must be carefully noted, so that we may easily distinguish the angles mentioned in the demonstrations.

Now, given some rectilinear angle, if we wish to test whether it is right, obtuse, or acute, we shall do it in this way. Let two straight lines AB, AC contain the angle A. Draw the straight line BC arbitrarily, so as to subtend the angle, and bisect it at D; then from D as center, with radius DA, describe the circumference of a circle. If it

passes through the points B and C, [Margin: a — Elements III.31] the angle A will be right, inasmuch as it stands in the semicircle BAC. But if the same semicircle cuts the straight line BC at E, F, the angle BAC will be obtuse; because, when the straight lines EA, FA are drawn, [Margin: b — Elements III.31] the angle EAF, standing in the semicircle EAF, is right, and it is a part of the angle BAC. And if, finally, the same semicircle cuts the straight line BC *produced* at E, F, the angle BAC will be acute; because, when the straight lines EA, FA are drawn, [Margin: a — Elements III.31] the angle EAF, standing in the semicircle EAF, is right, and it is greater than the angle BAC.

Diagram. Three triangles illustrating the first test (radius DA from the midpoint D of BC), stacked at the right of the page. In each, A is the apex (the angle under test), B the left vertex, C the right vertex, and D the midpoint of the base BC; a dotted circular arc is drawn from D.

- Right-angle case: the arc passes through B, A, C (semicircle BAC).
- Obtuse case: the arc cuts the base at E and F (between B and C); straight lines EA, FA are drawn.
- Acute case: the arc cuts the base *produced* at E and F (beyond B and C); straight lines EA, FA are drawn.

We shall obtain the same result in another way. From the point D — which bisects the straight line BC, the subtense of the given angle A — describe a semicircle with radius DB or DC. If it passes through the point A, [Margin: b — Elements III.31] the given angle will be right, since it stands in a semicircle. But if the same semicircle passes *above* the point A, the given angle will be obtuse. For when the straight line DA is drawn, cutting the circumference at E, let the straight lines EB, EC be joined; [Margin: c — Elements III.31 [?]] then the angle BEC will be right, standing in a semicircle. Since, then, the given angle BAC is [Margin: d — Elements I.21] greater than the angle BEC, the given angle A will be greater than a right angle — that is, obtuse. And if, finally, the same semicircle cuts the straight lines AB, AC, the given angle will be acute. For, taking a point E between the straight lines AB, AC on the circumference, let the straight lines EB, EC be joined; [Margin: e — Elements III.31] then the angle BEC will be right, standing in a semicircle; [Margin: f — Elements I.21] and since it is greater than the given angle A, the given angle A will be less than a right angle — that is, acute.

Let no one think it strange that for the demonstration we assume propositions that are demonstrated later by Euclid, which may seem foreign to the purity of geometrical demonstrations. Let no one, I say, think it strange; for since what we here show is not necessary for the following demonstrations, it can conveniently

be deferred until the required propositions have been demonstrated. It is enough that the practical procedure of this matter be understood here. We shall observe the same in several practical problems; for we shall propose them in their proper places, so far as may be done — as, for instance, we shall teach the division of a rectilinear angle into any number of equal parts in the place where Euclid teaches the division of that same angle into two equal parts, and so on — although the propositions demonstrated later are necessary for the demonstrations of those procedures.

Diagram. Three triangles illustrating the second (alternative) test (semicircle from midpoint D with radius $DB = DC$), stacked at the right of the page.

- Right-angle case: **A** apex, **B** left vertex, **D** midpoint of base, **C** right vertex; the dotted semicircle passes through A.
- Obtuse case: the semicircle passes above A; the line DA, produced, meets the arc at **E** (drawn above A), and EB, EC are joined (angle BEC right). Labels **B, E, A, D, C**.
- Acute case: the semicircle cuts sides AB, AC; a point **E** is taken on the arc between the sides, and EB, EC are joined. Labels **A** (apex), **E** (interior), **B, D, C**.

We shall recognize the same more easily by means of a set-square [normal] accurately made, such as the instrument ABC represents, consisting of two rulers AE, AF joined at a right angle at A. For if the side AB of this set-square is applied to the straight line AB, with the point A falling on the point A: then, if the set-square's side AC also coincides with the straight line AC, the angle A will be right; but if the set-square's side AC falls short of the straight line AC, the angle A will be obtuse; and if, finally, the set-square's side AC falls beyond the straight line AC, the angle will be acute, as is evident.

We shall test the set-square itself — whether it is accurately made or not — as follows. Describe a semicircle BAC of any size from center G, and draw the diameter BC; place the angle A at some point of the circumference, say at A, and let one side of the set-square, namely AB, pass through B, an endpoint of the diameter. Then, if the other side AC passes through the other endpoint C, the set-square ABC is rightly made; [Margin: a — Elements III.31] because then the angle BAC, standing in the semicircle BAC, is right. But if the side AC does not pass through C, the set-square must be corrected, because its angle A is then not right. By the same reasoning we shall test the inner part of the set-square, if we apply the angle D to the circumference and [test whether] its sides DE, DF [pass through] the endpoints B, C, and so on.

Diagram. The set-square (norma) and the semicircle used to test it, at the foot of the page.

- **A** (top-left apex): the outer right-angle vertex of the set-square, where the two rulers meet.
- **E** (lower left) and **F** (lower right): the far ends of the two rulers (AE and AF); the right ruler AF is drawn as a hatched straight-edge.
- **D**: the inner corner of the set-square (just below A), whose inner edges are DE and DF.
- **B** (left) and **C** (right): the endpoints of the diameter BC of the test-semicircle, through which the ruler-sides are to pass.
- **G** (center, on the diameter): the center of the described semicircle BAC.

XIII.

[Euclid, Definition XIII] A *boundary* [terminus] is that which is the extremity of something.

[Clavius's commentary] There are three boundaries according to this definition. For a point is the boundary, or extremity, of a line; a line, of a surface; and a surface, of a body. But a body can bound nothing further, since no other magnitude is found having more than three dimensions. For everything bounded exceeds its own boundary by one dimension, as is evident from the examples adduced.

XIII.

[Euclid, Definition XIV] A *figure* is that which is contained under one or several boundaries.

[Clavius's commentary] Not every magnitude possessing boundaries can be called a figure — lest we be forced to call a finite line a figure. Rather, only those magnitudes that have breadth — namely a bounded surface — and those that have also acquired depth — namely a finite solid — will be called by the name of "figure." For these are properly said to be enclosed by boundaries. For a finite line is not properly said to be enclosed by its extreme points, since points do not surround a line, but rather it is said to be *bounded* by points. And so the boundaries must *surround* the quantity that is called a figure, and not merely bound it. An infinite surface, too, or even a body, since it is enclosed by no boundaries, can in no way be called a figure. Figures enclosed by a single boundary are the circle, ellipse, sphere, spheroid, and the like; but figures

enclosed by several boundaries are the triangle, square, cube, pyramid, and so on. Bounded surfaces are called *plane* figures; but circumscribed solids, *solid* or *corporeal* figures. Moreover, since you will inspect very many forms or types of various figures in what follows — plane figures in the first ten books, solid figures in the last five — no figure seems to need to be drawn in this place.

XV.

[Euclid, Definition XV] A *circle* is a plane figure contained under one line, which is called the *periphery*, to which all the straight lines falling from one of the points placed within the figure are equal to one another.

[Clavius's commentary] Here he defines the circle, the most perfect of plane figures, teaching that that plane figure which is circumscribed by a single line — to which line all the straight lines drawn from one point that lies within the figure are equal — is called a circle. Thus, if a surface, or space, is enclosed by a single line ABC, and has this condition, that from some point taken within it — say from D — all the straight lines falling to the boundary ABC, such as DA, DB, DC, are equal to one another, such a plane figure will be called a circle, and otherwise not. By what method that middle point in the circle ought to be found, Euclid will teach in Proposition 1 of Book III. Euclid also adds that the outermost line of the circle, such as ABC, is called the *periphery*, or, as the Latins render it, the *circumference*.

A circle can also be described in this way: A circle is a plane figure described by a finite straight line carried around, one of its endpoints remaining at rest, when it has been restored again to the same place from which it began to move. This description is very like the one by which the sphere is described by Euclid in Book XI. Thus, if the straight line AD is understood to be moved about the point D, which stays at rest, until it returns to the same place from which it began to move, the straight line itself will describe the whole circular space,... and will trace out the periphery ABC. The resting point D will also be that from which all the lines falling upon the periphery are equal to one another, because the straight line AD, carried around, measures equally all the lines that can be drawn out from D to the periphery. Therefore the ellipse, although it is a plane figure circumscribed by one line, yet because in it there is no point from which all the straight lines to the bounding line itself are equal, cannot be called a circle.

Diagram. The circle of Definition XV.

- **D (center):** the interior point from which the equal radii are drawn.

- **A** (upper left), **B** (upper right), **C** (bottom): three points on the circumference.
- The three radii **DA**, **DB**, **DC** divide the circle into three parts and are equal to one another; **ABC** is the periphery (circumference).

XVI.

[Euclid, Definition XVI] This point, in turn, is called the *center* of the circle.

[Clavius's commentary] He teaches that that point within the circle, from which all the straight lines drawn to the circumference are equal, is called the center of the circle — such as is the point **D** of the preceding figure. From which it is evident that the *pole* of some circle on a sphere — from which all the straight lines falling to the periphery of the circle are equal, as Theodosius [Theodosius of Bithynia] says in the *Spherics* — ought not to be called the center of the circle, since that point which is called the pole lies on the surface of the sphere, and not on the surface of the circle; which, however, is a necessarily required condition for any point to be called a center. Moreover, for some point to be called the center of a circle, it is enough that only three lines falling from it upon the periphery be equal to one another, as Euclid demonstrates in Proposition 9 of Book III. For in this way it comes about that all the others sent out from the same point are equal to one another.

XVII.

[Euclid, Definition XVII] The *diameter* of a circle, in turn, is a certain straight line drawn through the center and terminated on both sides at the periphery of the circle, which bisects the circle.

[Clavius's commentary] If in a circle a straight line **AB** is drawn through the center **C**, so that its endpoints **A** and **B** are terminated at the periphery, it will be called the diameter of the circle. Not, therefore, will every straight line drawn in a circle be called a diameter, but only that one which extends through the center all the way to the periphery on both sides. Hence several diameters can be assigned in a circle, but only one center. As for Euclid's addition that the circle is bisected by the diameter, it can be evident from this: that the diameter is drawn through the middle of the circle, that is, through the center. For hence it comes about that, because of the straight passage of the diameter through the center, equal circumferences are cut off on both sides. This, however, Proclus [Proclus] testifies that Thales of Miletus [Thales] demonstrated in this way.

Let us conceive in our mind the portion ADB to be fitted and adapted to the remaining portion AEB, so that the diameter AB is common to both portions. If, then, the circumference ADB coincides entirely with the circumference AEB, it is manifest that those two portions made by the diameter are equal to one another, since neither exceeds the other. But if the circumference ADB is said not to fall on every side upon the circumference AEB, but either outside it, or partly outside and partly inside, then — a straight line being drawn from the center C, cutting the circumference ADB at D and the circumference AEB at E — the two straight lines CD, CE, drawn from the center to the circumference of the same circle, will be equal (by the definition of the circle), and yet one will be a part of the other, which is absurd. Therefore one circumference will not fall outside another, nor inside, nor partly outside and partly inside, but both will fit to one another, and therefore will be equal — which was what was to be demonstrated.

From this demonstration it is established that the diameter bisects not only the circumference but also the whole area of the circle. For since the semicircumferences coincide with one another, as has been shown, the surfaces themselves — enclosed between the diameter and each circumference — will also coincide, since neither exceeds the other. Therefore they will be equal to one another.

Diagram. The diameter of Definition XVII.

- **A** (left) and **B** (right): the endpoints of the diameter on the periphery.
- **C** (center): the center of the circle, through which the diameter AB passes.
- **E** (top) and **D** [?] (bottom): points on the upper and lower semicircles respectively (the arcs AEB and ADB).

Diagram. The figure for the Thales bisection argument.

- **A** (bottom left) and **B** [?] (bottom right): the shared endpoints of the two circumferences, joined by the base line AB (the common diameter).
- **C** (bottom center): the center, from which the secant line is drawn.
- **D** (on the outer arc, upper): where the secant from C cuts the circumference ADB.
- **E** (on the inner arc): where the secant from C cuts the circumference AEB.
- The figure shows the outer arc ADB and the inner arc(s) AEB not coinciding (the "absurd" case), with the radial line from C crossing them at D and E.

XVIII.

[Euclid, Definition XVIII] A *semicircle*, in turn, is a figure that is contained under the diameter and under that line which is cut off from the periphery of the circle.

[Clavius's commentary] For example, in the circle above, the figure ADB, contained under the diameter AB and the periphery ADB, is called a semicircle, because...

because, as we showed in the preceding definition, it is half the circle. By the same reasoning the figure AEB will be a semicircle. And the same point C, which bisects the diameter, is the center both in the circle and in the semicircle.

Now suppose the straight line BD does not pass through the center E. Then the circle will not be cut by it into two equal halves, but into two unequal portions, BAD and BCD. Of these, the one in which the center of the circle lies — namely the portion BAD — is greater than the other, BCD, outside which the center E lies. That these portions BAD and BCD are unequal can be proved as follows.

Suppose that through the center E a diameter AC is drawn perpendicular to the straight line BD. Now if the said portions were claimed to be equal, and the portion BCD were imagined to be revolved about the straight line BD so as to fall onto the portion BAD, then that portion would coincide with this one, and the straight line FC would coincide with the straight line FA — this because of the right angles at F, which are all equal to one another by definition 10, since they are adjacent to one another. The straight line FC, then — which is now the same as FA — would be greater than EA, a part of that same FA. But since EC is equal to EA (because both are drawn from the center to the circumference), FC would also be greater than EC: the part greater than the whole, which is absurd.

Therefore the portion BCD will not coincide with the portion BAD, but will fall within it — as does the portion BGD, so that the straight line FG, now being the same as FC, could be less than EA or EC. For if it were said instead to fall outside — as if the circle were BCDG, whose center is E, and the portion BCD fell outside BGD (as the portion BAD does) — then FA, now being the same as FC, would again be greater than EG, that is, greater than EC; and so once more the part FC would be greater than the whole EC, which is absurd. From this it is clear that the portion BAD, in which the center E lies, is greater than the remaining portion BCD, since this latter is equal to the portion BGD, which is a part of the portion BAD. For since it has been shown that the portion BCD, revolved about the

straight line BD, can neither coincide with the portion BAD nor fall outside it, it will fall entirely within it — as does BGD.

Diagram. A circle with two mutually perpendicular diameters and an inner arc, illustrating the demonstration that a chord not through the center divides the circle unequally.

- A (top of circle): upper end of the vertical diameter
- C (bottom of circle): lower end of the vertical diameter AC
- B (left of circle): left end of the horizontal chord BD
- D (right of circle): right end of the horizontal chord BD
- E (center): center of the circle, on the vertical diameter
- F (on the vertical diameter, just below E): the point where the chord BD crosses the diameter AC
- G (on the vertical diameter, between E and A): a point of the inner reflected arc BGD

Definition XIX

[Euclid] Rectilinear figures are those contained by straight lines.

[Clavius] After the definition of the circle, Euclid — about to hand down descriptions of various figures — first explains which figures are called rectilinear, since these will be the chief subject of discussion in these books. All plane figures, then, that are enclosed on every side by straight lines are termed rectilinear. From this it is plain that plane figures bounded by curved lines are called curvilinear, while those bounded partly by curves and partly by straight lines are called mixed. Euclid will now describe the various kinds of rectilinear figures.

Definition XX

[Euclid] Trilateral figures are those contained by three [straight lines].

[Clavius] By affirming that those rectilinear figures are called trilateral which are bounded by three straight lines, Euclid plainly hints at how the triangle ought to be defined. For since in rectilinear figures there are as many angles as there are sides (that is, as the straight lines of which they consist), a triangle will be defined as a figure contained by three straight lines — and all its species will be presented shortly.

Definition XXI

[Euclid] Quadrilateral figures are those contained by four [straight lines].

[Clavius] By the same reasoning, a quadrangle will be a figure contained by four straight lines, whose various species will follow shortly.

Definition XXII

[Euclid] Multilateral figures are those contained by more than four straight lines.

[Clavius] Since the species of rectilinear figures are innumerable, owing to the infinite progression of numbers — for three straight lines enclosing a figure produce the first species, under which all triangles are contained; four constitute the second, which embraces all quadrangles; five compose the third species; six the fourth; and so on to infinity — Euclid, so as not to be forced to pursue this endless multitude of figures, calls all the other rectilinear figures that are bounded by more than four straight lines by the general term *multilateral*. He is content with the names of trilateral and quadrilateral figures, perhaps for this reason: that in these earlier books the discussion is chiefly about triangles and quadrangles, and because all the remaining species could easily be defined by anyone on the analogy of these two. For who would not gather from what has been said that a figure contained by five straight lines is called five-sided, one bounded by six lines six-sided, and the rest in the same way? Such figures may likewise be called five-angled, six-angled, seven-angled, and so on.

Definition XXIII

[Euclid] Of trilateral figures, an *equilateral* triangle is one that has its three sides equal.

[Clavius] Euclid now comes down to the individual species of triangles. Since triangles can be divided either with respect to their sides or with respect to their angles, he first sets out the species of the former division, which are just three, because three sides can be related to one another in only three ways. For either all are equal; or only two, the third being either greater or less; or all are unequal. When, therefore, all three sides are equal to one another, the triangle is called *equilateral*. Furthermore, from the equality of all three sides of an equilateral triangle it is inferred that all three of its angles are likewise equal, as we shall demonstrate at the fifth proposition of this book.

Diagram. An equilateral triangle, illustrating Definition XXIII. No labels.

Definition XXIV

[Euclid] An *isosceles* triangle is one that has only two sides equal.

[Clavius] From this equality in turn of the two sides of an isosceles triangle it follows that the two angles upon the remaining side are also equal, as Euclid will demonstrate at proposition 5 of this book. We have set down two isosceles triangles: the first has its third side greater than either of the equal sides, while the second has that side smaller. Thus there are two species of the isosceles triangle: one whose third side is greater than either of the equal sides, and another whose third side is smaller than either of the equal ones.

Diagram. Two isosceles triangles, illustrating Definition XXIV: at left a broad, low triangle (third side greater than either equal side), at right a tall, narrow triangle (third side smaller than either equal side). No labels.

Definition XXV

[Euclid] A *scalene* triangle is one that has its three sides unequal.

[Clavius] Here, finally, from the inequality of all the sides of a scalene triangle the inequality of all its angles is inferred, as will be shown at proposition 18 of this first book. Moreover, it is clear from these considerations that the triangle could have been divided into three species in the same way if the criterion of the equality of the angles had been taken. For since either all three angles are equal to one another; or only two, the third being greater or less; or all three are unequal — every triangle will be either equiangular, having all three angles equal, or having only two angles equal, or having all its angles unequal. Of these, the first corresponds to the equilateral triangle, the second to the isosceles, and the third finally to the scalene. But by what technique the triangles of this classification are to be constructed upon any given finite straight line, we shall show at proposition 1 of this book.

Diagram. A scalene triangle, illustrating Definition XXV. No labels.

Definition XXVI

[Euclid] Further, of trilateral figures, a *right-angled* triangle is one that has a right angle.

[Clavius] He now sets out the species of triangles according to the latter division, taking account of the variety of the angles. Since there are only three different kinds of rectilinear angle — for every rectilinear angle is either right, or obtuse,

or acute, as we said above — it happens that three species of triangles are likewise found under this consideration. For either one angle of the triangle is right, and for that reason the others are acute (as will be established from proposition 17 of book 1); or one is obtuse, and for the same reason the others acute; or finally none is right and none obtuse, but all are acute. When, therefore, some triangle has one right angle, it is called by Euclid and other geometers a *right-angled* triangle. A triangle of this kind can be isosceles or scalene, as the figures indicate, but in no way equilateral. For on account of the equality of the sides, all its angles would also be equal (by what we shall say at proposition 5); and so, since one angle is granted to be right, all three would be right — which conflicts with propositions 17 and 32 of this book.

Diagram. Two right-angled triangles, illustrating Definition XXVI. No labels.

Definition XXVII

[Euclid] An *obtuse-angled* triangle [amblygonium] is one that has an obtuse angle.

[Clavius] An obtuse-angled triangle [amblygonium], or one with an obtuse angle, can likewise be either isosceles or scalene, as is seen in these figures, but not equilateral — for otherwise, by the same reasoning, all three of its angles would be equal (by what we shall show at proposition 5); and so, since one is posited as obtuse, all three would be obtuse, which conflicts even more strongly with propositions 17 and 32 of this book.

Diagram. Two obtuse-angled triangles, illustrating Definition XXVII. No labels.

Definition XXVIII

[Euclid] An *acute-angled* triangle [oxygonium] is one that has three acute angles.

[Clavius] Every acute-angled triangle [oxygonium] can be either equilateral, or isosceles, or scalene, as may be seen in the triangles that we displayed for examination among the species of the earlier division, so that the same figures need not be pointlessly repeated here. From what has been said, then, it is plain that any equilateral triangle is necessarily acute-angled; but that every triangle, whether isosceles or scalene, is either right-angled, obtuse-angled, or acute-angled; and that the isosceles acute-angled triangle is in turn twofold — namely, the isosceles acute-angled triangle having its third side greater than either of the equal sides, and the isosceles acute-angled triangle having its third side smaller than either of the equal sides. Thus there is a single species of the equilateral

triangle, four of the isosceles, and three of the scalene; and in all, eight kinds of triangle: the equilateral, which we said is perpetually acute-angled; the isosceles right-angled; the isosceles obtuse-angled; the isosceles acute-angled having its third side greater than either of the equal sides; the isosceles acute-angled having its third side smaller than either of the equal sides; the scalene right-angled; the scalene obtuse-angled; and the scalene acute-angled. These may also be named with the terms transposed: right-angled isosceles, right-angled scalene, obtuse-angled isosceles, obtuse-angled scalene, acute-angled equilateral, acute-angled isosceles having its third side greater than either of the equal sides, acute-angled isosceles having its third side smaller than either of the equal sides, and acute-angled scalene. Hence it is plain what connection or kinship the triangles of each division have with one another.

That there can be an isosceles acute-angled triangle in which either of the two equal sides is smaller than the third, as Franciscus Barocius [Francesco Barozzi] rightly observed in his *Cosmographia*, we shall show at proposition 15 of book 4. Furthermore, in every triangle, whichever two sides are expressly named, the remaining third side is usually called by mathematicians the *base*, whether it occupies the lowest position in the figure or the highest, and so on. I wanted to advise you of this briefly, so that you would not suppose that some mystery lies hidden in the base of a triangle, and would understand that any side whatever, with every distinction removed, can be called by the name of *base*.

Definition XXIX

[Euclid] Of quadrilateral figures, a *square* [quadratum] is one that is both equilateral and right-angled.

[Clavius] After the species of trilateral figures, Euclid now sets out the quadrilateral figures one by one, reviewing just five of their kinds — of which the first four are regular, but the last, the fifth, is irregular. The first quadrilateral figure is called the *square*, whose four sides are all equal to one another and all whose angles are right. And so a quadrangle that is equilateral but not right-angled, or on the contrary right-angled but not equilateral, will by no means be called a square. Euclid will teach at proposition 46 of this book in what way a square is to be constructed upon a given finite straight line.

Diagram. A square, illustrating Definition XXIX. No labels.

Definition XXX

[Euclid] An *oblong* [altera parte longior] is a figure that is right-angled but not equilateral.

[Clavius] The second quadrilateral figure is called the *oblong* ["longer on one side"], in which the angles are indeed right, but the sides are not all equal to one another — although the two opposite sides are equal to each other. Thus in the oblong ABCD the sides AB and DC are equal to each other, and AD and BC likewise equal to each other; and since ABCD, on account of the rightness of its angles, is a parallelogram, as we shall show at proposition 34 of this book.

Diagram. A rectangle (oblong) labelled ABCD, illustrating Definition XXX.

- A (top-left corner)
- B (top-right corner)
- D (bottom-left corner)
- C (bottom-right corner)

Definition XXXI

[Euclid] A *rhombus* is a figure that is equilateral but not right-angled.

[Clavius] This third figure among the quadrilaterals, which is called the *rhombus*, has conditions altogether opposite to and different from those of the oblong. For it has all its sides equal, but its angles not right and not equal — although the two opposite angles are equal to each other. Thus in the rhombus ABCD the angles A and C are equal to each other, and B and D likewise equal to each other; and since ABCD, on account of the equality of its sides, is a parallelogram, as will be demonstrated at the same proposition 34 of this book.

Diagram. A rhombus labelled ABCD, illustrating Definition XXXI.

- A (top-left corner)
- B (top-right corner)
- D (bottom-left corner)
- C (bottom-right corner)

Definition XXXII

[Euclid] A *rhomboid* is a figure that has its opposite sides and angles equal to one another, but is neither equilateral nor right-angled.

[Clavius] This figure, which is called the *rhomboid*, is in every respect opposite to the square. For neither are all its sides equal, nor is any of its angles right; yet the two opposite sides — such as AB, DC and AD, BC in the rhomboid ABCD — are equal to each other, and likewise the two opposite angles — such as A, C and B, D — are equal to each other. These four quadrilateral figures, then, can be called regular; but all the rest, whatever they may be, are irregular.

Diagram. A rhomboid (oblique parallelogram) labelled ABCD, illustrating Definition XXXII.

- A (top-left corner)
- B (top-right corner)
- D (bottom-left corner)
- C (bottom-right corner)

Definition XXXIII

[Euclid] Besides these, the remaining quadrilateral figures are called *trapezia*.

[Clavius] All the remaining quadrilateral figures, which differ from the four just mentioned — in that they have neither all their sides equal, nor all their angles equal (that is, right), nor the two opposite sides, nor the two opposite angles equal to one another — Euclid names with the general term *trapezia*. Since these can be varied in infinitely many ways, they are rightly called irregular. For two of their angles can be right, or one obtuse and the others acute, or two obtuse and the others acute, and so on. And the same kind of division can be made with respect to the sides: for either some are equal to one another, or none is equal to another, and so on. We shall present certain determinate species of trapezia after the definition of parallel (that is, equidistant) lines and of the parallelogram.

Diagram. An irregular quadrilateral (trapezium), illustrating Definition XXXIII. No labels.

Definition XXXIV

[Euclid] *Parallel* straight lines are those which, being in the same plane and produced to infinity in both directions, do not meet each other on either side.

[Clavius] For two or more straight lines to be called parallel, or equidistant, it is not enough that, produced in any direction even through infinite space, they never come together at a single point; it is also necessary that they lie in one plane surface. For many straight lines that do not lie in the same plane surface,

though produced to infinity, never meet in one point, and yet are not to be called parallel — such as, for example, two straight lines set crosswise in mid-air and not touching each other; for these can never come together.

Two straight lines are said to lie in the same plane surface when some plane surface, fitted to one of them so that it touches all its points, and revolved about it while it stays fixed, can be fitted to the other as well at all its points — even though in actual fact the lines are found in two different surfaces. Thus, given two straight lines AB and CD, if some plane surface is applied to the straight line AB, touching all its points, so that, revolved about it, it also touches all the points of the other straight line CD, then two such straight lines will be said to lie in the same plane surface — otherwise not. If, then, these two straight lines do not meet, even though produced to infinity both toward the parts A, C and toward B, D, they will be called parallel, or equidistant.

But you will understand more clearly and completely, in book 11, in what manner two or even more straight lines are said to lie in the same surface. Let it suffice here to have briefly noted that Euclid rightly laid down both conditions in the definition of parallel lines. For they must lie in the same plane, and, being produced in either direction, never meet in one point, however far this production is continued into infinite space. But if two straight lines, extended through some immense space, are not seen to meet, yet it is established that, drawn out further on one side, they will at length come together at a single point — even though on the other side they always grow more and more distant and separated — they are by no means to be called parallel. Whenever, therefore, two straight lines are said by anyone to be paral-

Diagram. Two parallel horizontal straight lines, illustrating Definition XXXIV.

- A (left end of the upper line) — B (right end of the upper line)
- C (left end of the lower line) — D (right end of the lower line)

Euclid, *Elements*, Book I — end of the Definitions; the Postulates and the Common Notions

(Clavius's commentary on Euclid. The numbered enunciations set in large type are the lemmata; the passages in italic beneath each are Clavius's own commentary and scholia. Definitions XXXV and XXXVI, and Axioms X and XI, are Clavius's own additions, as he notes.)

Definition XXXIV, continued (parallel lines)

[parallel], one must grant that they lie in one and the same surface and can never meet. Likewise, if someone wishes to conclude that two straight lines are parallel, he must first prove that they lie in the same plane and that, produced in neither direction, they cannot be joined. On this point not a few seem to be deceived: they try to show that certain straight lines are parallel merely on the ground that they do not converge in either direction even if produced to infinity, making no mention at all of the other condition — the one that requires these lines to lie in the same plane.

Here Euclid brings the definitions of Book I to a close. But since in this same book mention will be made of the figure called a *parallelogram*, and of the things called the *complements* of a parallelogram, we have judged it necessary to explain, by adding two definitions, what a parallelogram is and what the complements of a parallelogram are, so that the demonstrations may be grasped more easily.

XXXV.

A PARALLELOGRAM is a quadrilateral figure whose two pairs of opposite sides are parallel, or equidistant.

Take a quadrilateral figure ABCD. If side AB is equidistant from (parallel to) side DC, and side AD from side BC, it is called a *parallelogram*.

Diagram. A parallelogram, its four vertices lettered.

- A (top-left vertex)
- B (top-right vertex)
- C (bottom-right vertex)
- D (bottom-left vertex)

There are only four parallelograms: the square [*quadratum*], the figure longer on one side (the oblong) [*figura altera parte longior*], the rhombus, and the rhomboid. The first two are called rectangular, because all their angles are right; the latter two are called non-rectangular, because none of their angles is right. That these four figures are parallelograms we shall show at Proposition 34 of this book (*Elements* I.34).

And so we can — as the ancient geometers did — divide quadrilateral figures into the parallelogram and the trapezium. The parallelogram in turn divides into: the rectangular and equilateral, such as the square; the neither rectangular nor

equilateral, such as the rhomboid; the rectangular but not equilateral, such as the oblong; and the equilateral but not rectangular, such as the rhombus. Of trapezia, likewise, one kind has two opposite sides parallel and the others not, while another kind has no opposite sides parallel. Moreover, the former kind either has the two non-parallel sides equal to one another — and is then called an *isosceles trapezium* — or unequal, in which case it is called a *scalene trapezium*. From all of this, then, seven kinds of quadrilateral figure can be constituted: the square, the oblong, the rhombus, the rhomboid, the isosceles trapezium, the scalene trapezium, and that irregular trapezium in which no sides are parallel.

XXXVI.

When in a parallelogram a diameter [diagonal, *diameter*] has been drawn, and two lines parallel to the sides cut the diameter at one and the same point, so that the parallelogram is divided by these parallels into four parallelograms, then the two through which the diameter does not pass are called the COMPLEMENTS, while the two remaining, through which the diameter runs, are said to lie ABOUT THE DIAMETER.

Let there be a parallelogram ABCD, in which AC is the diameter, and EF a line cutting the diameter at G and parallel to the sides AD and BC. Likewise let HI be a line cutting the diameter at the same point G and parallel to the sides AB and DC. Since this is so, it is evident that the whole parallelogram is divided into four parallelograms. Of these, the two EBIG and GFDH, through which the diameter AC does not pass, are called by geometers the *complements*, or supplements, of the remaining two, AEGH and GICF, which are said to lie about the diameter, since the diameter passes through them — as may be seen in the present figure.

Diagram. A parallelogram ABCD with its diameter AC drawn, and two internal lines EF and HI parallel to the sides, both cutting the diameter at the interior point G, dividing the figure into four smaller parallelograms.

- A (top-left vertex; one end of the diameter)
- E (midpoint of the top side; upper end of line EF)
- B (top-right vertex)
- H (midpoint of the left side; left end of line HI)
- G (interior intersection point, where diameter AC, line EF, and line HI meet)
- I (midpoint of the right side; right end of line HI)
- D (bottom-left vertex)

- F (midpoint of the bottom side; lower end of line EF)
- C (bottom-right vertex; other end of the diameter)
- Sub-parallelograms about the diameter (diameter passes through them): AEGH and GICF.
- Complements (diameter does not pass through them): EBIG and GFDH.

THE PETITIONS, OR POSTULATES [*PETITIONES, SIVE POSTVLATA*]

I.

Let it be granted that from any point to any point a straight line may be drawn.

This first postulate is quite plain, if what we wrote a little earlier about the line is rightly considered. For since a line is a kind of imaginary flow of a point, and a straight line is a flow advancing along an altogether direct path, it follows that, if we conceive some point to be moved directly toward another, a straight line is thereby drawn from point to point. This is just what Euclid postulates in this first petition — as you see here, that a straight line has been drawn from point A to point B; another from the same point to point C; likewise another to point D; and thus innumerable others can be led out from the same point to yet other points.

Diagram. A single point A from which three straight lines fan out to three separate points.

- A (common point at left)
- B (upper endpoint)
- C (middle endpoint)
- D (lower endpoint)

II.

And to produce a finite straight line continuously in a straight line.

If we further conceive that point to be carried along by a direct motion, one free of all deflection, the finite straight line will be produced, and there will never be an end to this production, since we can understand the point to be moved to an infinite distance. Thus the straight line AB is produced, first in a straight line to point C, then to point D, and so on.

Diagram. A straight segment AB continued in a straight line to further collinear points C and D.

- A (left endpoint)
- B (next point along the line)
- C (further point along the same line)
- D (endpoint at right)

III.

Likewise, to describe a circle with any center and radius [*intervallo*].

Now if we have conceived in the mind a finite straight line of any size whatever, applied by one of its ends to any point, and then turned about that fixed point until it returns to the place from which it began to move, a circle will have been described — the very thing the third postulate requires. You have an example in these five lines AB, AC, AD, AE, AF, each of which, revolving about the center A, has described its own circle according to its length, that is, its radius.

Diagram. Five concentric circles sharing the common center A; five radii of increasing length are drawn from A into the upper-right region, their endpoints lettered (innermost to outermost) B, C, D, E, F, each endpoint lying on its own circle.

- A (common center)
- B (endpoint of the shortest radius, on the innermost circle)
- C (endpoint of the next radius)
- D (endpoint of the next radius)
- E (endpoint of the next radius)
- F (endpoint of the longest radius, on the outermost circle)

Besides these three postulates, with which Euclid was content, there are many others

Equally easy, of which I have decided to bring forward only the one that will need to be repeated more often in the course of the whole of geometry; the rest the prudent reader will easily understand by himself.

IV.

Likewise, given any magnitude, that another magnitude can be taken, either greater or lesser.

For every continuous quantity can be increased infinitely by addition, and diminished infinitely by division. Hence there will never be given a continuous quantity so great that a greater cannot be given, nor one so small that a smaller cannot be exhibited. The same holds true of numbers as regards addition: for any number can be increased infinitely by the continual addition of a unit — although in its diminution one arrives at the indivisible unit.

COMMON NOTIONS, OR AXIOMS [*COMMVNES NOTIONES SIVE Axiomata*], which are also usually called Pronouncements [*Pronunciata*], or Dignities [*Dignitates*]

I.

Things equal to the same thing are also equal to one another. And what is greater or less than one of two equals is also greater or less than the other of the equals. And if one of two equals is greater or less than some magnitude, the other of the equals too is greater or less than the same magnitude.

It can in no way happen that two unequal quantities are equal to another single quantity. For if the lesser of them proved equal to the given quantity, the greater of them would necessarily exceed that same quantity; and if the greater were equal to the given quantity, the lesser would be surpassed by it. Hence it is rightly concluded that quantities which are equal to the same quantity are also equal to one another. The remaining parts of the axiom, which we have added, are perfectly clear, since they are in frequent use.

II.

And if equals are added to equals, the wholes are equal.

For if the aggregate, or composite, quantities were unequal, then without doubt more would have been added to the greater than to the lesser — whereas beforehand they were equal. Therefore, from the addition of equal quantities to equal quantities, quantities that are likewise equal will be produced.

III.

And if equals are subtracted from equals, the remainders are equal.

For if the remaining quantities were unequal, more would have been taken from the lesser than from the greater.

IV.

And if equals are added to unequals, the wholes are unequal. And if unequals are added to unequals — greater to greater, and less to less — the wholes are unequal, the former of course greater and the latter less.

Moreover, if unequals are added to equals, the wholes will be unequal: because the greater quantity, added to one of the equals, constitutes a greater quantity than the lesser added to the other of the equals; just as, if equals are added to unequals, the quantity composed from the greater is greater than that composed from the lesser. This second part of the axiom we ourselves have added, on account of its frequent use.

V.

And if equals are subtracted from unequals, the remainders are unequal. And if unequals are subtracted from unequals — the less from the greater, and the greater from the less — the remainders are unequal, the former of course greater and the latter less.

So too, if unequals are subtracted from equals, the remainders will be unequal: because the greater quantity, once taken away, will leave a smaller remaining quantity than the lesser does; just as the remainder of the greater is greater than the remainder of the lesser, if equals are taken from unequals. For the rest, Euclid does not teach what is produced, simply and absolutely, from adding unequal quantities to unequal quantities, nor what is left after the subtraction of unequal quantities from unequal quantities; the reason being that nothing certain can be concluded from it, except when a greater is added to a greater, or a lesser is taken from a greater, as was said in the second part of the axiom, which we added on account of its notable usefulness. For the composite or remaining quantities can be either unequal or equal. Thus, if to 7 and 5 are added 4 and 3, there result 11 and 8, which are unequal. So too, if from 7 and 5 are subtracted 2 and 1, there remain 5 and 4, which are unequal. But if to 7 and 5 are added 4 and 6, there result 11 and 11, which are equal. Likewise, if 3 and 1 are subtracted from 7 and 5, there remain 4 and 4, which also turn out equal.

Furthermore, in all these pronouncements — the first excepted — by the term "equal quantities" one must understand also one and the same quantity common to many. For if the same common thing is added to equals, the wholes will

become equal; and if the same common thing is taken from equals, the remainders will be equal. And if the same common thing is added to unequals, or unequals are added to the same common thing, the wholes will become unequal; and if the same common thing is taken from unequals, or unequals are taken from the same common thing, the remainders will turn out unequal.

VI.

And things that are doubles of the same thing are equal to one another. And what is the double of one of two equals is also the double of the other of the equals.

Likewise, things that are triples, quadruples, quintuples, and so on, of the same thing are equal to one another. For if they were unequal, and the greater of them were double (or triple, etc.) of some quantity, then the lesser would fall short of the double (or triple, etc.); whereas if, on the contrary, the lesser were the double (or triple, etc.) of some quantity, the greater would surely exceed that same double (or triple, etc.). This can also be proved from the second axiom, in this way. If two quantities are equal to some third, [a] and to each of them that third is added, the aggregates will be doubles of that third, [Margin: a — 2. pron. (the 2nd Pronouncement/Axiom)] but also equal to one another, because of the same addition. And if [b],

[Margin: b — 2. pron. (the 2nd Pronouncement/Axiom)] again, to the aggregates that same third is added, the sums will be triples of that same third. Since therefore they are also equal to one another, on account of the same addition, and since the same reasoning holds for the other multiples, the axiom proposed will be evident. The second part of this axiom we have appended, because its use is not rarely required in geometrical matters.

VII.

And things that are halves of the same thing are equal to one another. And conversely, things that are equal are halves of the same thing.

By the same reasoning, things that are the thirds, or fourths, or fifths, and so on, of the same thing are equal to one another. In these two pronouncements, by "the same quantity" one must understand quantities that are also equal. For things that are doubles, or triples, etc., of equals are also equal to one another; likewise things that are halves, or thirds, or fourths, etc., of equals are necessarily equal to one another as well. The second part of this axiom too we have added, because it is used by geometers no less frequently than the first.

VIII.

And things that coincide with one another are equal to one another.

That is: two quantities, one of which laid upon the other, neither exceeds the other, but both coincide with one another, will be equal. Thus two straight lines are said to be equal when, one laid upon the other, the one that is superposed coincides wholly with the other, so as neither to exceed it nor to be exceeded by it. So too two rectilinear angles will be equal when, one laid upon the other, the one superposed neither exceeds the other nor is exceeded by it, but the lines of the one wholly coincide with the lines of the other; for then the inclinations of the lines will be equal, even though the lines themselves may sometimes be unequal to one another.

Conversely: things that are equal to one another will coincide, if the one is laid upon the other. But it must be understood that quantities coinciding with one another are equal only in respect of that in which they coincide. Now length coincides only with length, surface with surface, solid with solid, the inclination of lines with the inclination of lines, and so on.

IX.

And the whole is greater than its part.

Since a part taken from the whole leaves something still remaining — lest the whole itself be taken away — it is evident that every whole is greater than its part.

In the following pronouncements the order of Euclid is interrupted, because we judged that two other axioms, quite necessary, ought to be inserted at this place, since from them Axiom 12 (which is Euclid's tenth) can be demonstrated, as we shall say there. In the margin, however, we have added the numbers corresponding to Euclid's order.

X.

Two straight lines do not have one and the same common segment.

[Margin: o.]

This axiom is not difficult, provided the nature of a straight line is perfectly understood. For since a straight line is produced along an ever-direct path, deflecting in no direction, it can in no way happen that two straight lines have

one part — however small — in common, except the single point at which they mutually intersect. Proclus [Proclus], however, demonstrates this briefly as follows. Let there be, if it be possible, two straight lines AB, AC having a common part AD. From the center D and with the radius DA, [a] let a circle be described cutting the two given lines at the points B and C. [b] Then the two circumferences AB and AC will be equal to one another (for they are the circumferences of equal semicircles, since ADB and ADC are supposed to be diameters) — a part and a whole, which is absurd. Therefore two straight lines do not have one and the same common segment. Which was to be proved.

[Margin: a — 3. petit. (the 3rd Postulate)] [Margin: b — 17. def. (the 17th Definition)]

Diagram. A circle whose center is D; a nearly vertical line runs from A at the top down through D to B and C at the bottom, illustrating the two supposed straight lines AB and AC sharing the common part AD, with the circle (radius DA) cutting them at B and C so that ADB and ADC are diameters of equal semicircles.

- A (top; endpoint above the circle)
- D (center of the circle)
- B (lower endpoint, at the foot of the figure)
- C (lower endpoint, beside B at the foot of the figure)

Yet two straight lines can have a common segment when they constitute one and the same straight line. Thus in this figure, the straight lines AD and BC have the common segment CD, because both together constitute the single straight line AB. But when two straight lines are distinct — as AB and AC were in the earlier example — they cannot possess any common segment, as was rightly demonstrated by Proclus.

Diagram. A single straight line from A to B, with two interior points C and D marked, illustrating that the straight lines AD and BC overlap in the common segment CD while together forming the one line AB.

- A (left endpoint of the line)
- C (interior point, left of center)
- D (interior point, right of center)
- B (right endpoint of the line)

XI.

Two straight lines meeting at one point will, if both are produced, necessarily intersect one another at that point.

[Margin: o.]

This axiom too depends on the nature of the straight line. We shall demonstrate it thus. Let two straight lines AB, CB meet at B. I say that, when produced, they cut one another at B — namely, that CB, when produced, falls at E, above the straight line AB produced. For if CB produced does not fall above AB produced, it will coincide with AB produced, so as to pass through D; and thus the two straight lines ABD, CBD will have the common segment BD, which was shown in the preceding axiom to be impossible. Or else it will certainly fall below AB produced, so that CB produced falls at F, and CBF is a single straight line. Therefore, with center B, let a circle ACFD be described with any radius, cutting the straight lines AB, CB produced at D and F. Since, then, each of the straight lines ABD, CBF is drawn through the center B, both ACD and CF will be a semicircle, by Definition 18; and hence the circumferences ACD and CF will be equal — while, as we demonstrated at Definition 17, they are a whole and a part. Which is absurd.

Diagram. A circle with center B; the straight line ABD runs roughly horizontally through the center from A (left) to D (right), while the line through C (lower left) and B is produced to E (upper right) and to F (lower right). The circle, labelled ACFD, passes through A, C, F, and D and cuts the produced lines at D and F.

- A (left; on the circle, one end of line ABD)
- B (center of the circle; the meeting point of the lines)
- C (lower left; on the circle, one end of the line through B)
- D (right; on the circle, where AB produced meets it)
- E (upper right; where CB produced would fall above AB)
- F (lower right; on the circle, where CB produced falls below AB)

The two axioms just given are not posited by Euclid; but since they are nevertheless necessary for the proofs of the other axioms, we have inserted them here. The three that follow, however, are Euclid's.

Euclid's *Elements*, Book I — Clavius's Commentary (Axioms continued; Prefatory notes to the Propositions)

Axiom XII

[Margin: *x.*]

Likewise, all right angles are equal to one another.

This axiom can be perfectly evident to anyone from Definition 10, by which a right angle is defined — because the inclination of the lines that constitute a right angle can be neither increased nor diminished, but is utterly unchangeable. For a right angle is produced by a perpendicular line, one that stands upon another straight line in such a way as to make the angles on both sides equal, inclining no more to one side than to the other. From this it follows that all right angles are equal to one another, since the inclination is always the same, even though the lines forming them may sometimes be unequal.

Proclus [Proclus], however, attempts to demonstrate this from Definition 10 in the following way. Let there be two right angles ABC and DEF, which I claim are equal to one another. For if it were possible for them to be unequal, let ABC be the greater. If, then, we imagine the point E applied to point B, and the straight line DE laid along the straight line AB, the straight line EF will fall between the straight lines AB and BC — namely along BG — because the angle DEF is supposed smaller than the angle ABC.[Margin: a — 2.pet. (Postulate 2)] Let CB be produced in a straight and continuous line as far as H. Then, since the angle ABC is a right angle,[Margin: b — 10.def. (Definition 10)] the adjacent angle ABH will also be equal to it, and therefore likewise a right angle — and so greater than the angle ABC as well. But when GB is produced in a straight and continuous line as far as I, [Margin: a — 2.pet. (Postulate 2)] the produced portion BI will fall below CB when the latter is produced, as was demonstrated in the preceding axiom. Therefore, since the angle ABG is supposed a right angle,[Margin: b — 10.def. (Definition 10)] the adjacent angle ABI will be made equal to it. Consequently the angle ABH will also be greater than the angle ABI — the part greater than the whole, which is absurd. Therefore the two proposed right angles are not unequal, but equal. Which is what was to be proved; and the same reasoning holds in the other cases.

Pappus [Pappus of Alexandria] rightly points out here that this axiom cannot be converted: for not every angle equal to a right angle is itself a right angle, since a

curvilinear angle too can be equal to a right angle, as we shall demonstrate in Book 5 — and yet such an angle is not called a right angle, because it is not rectilinear. Therefore only a rectilinear angle equal to a right angle will be termed a right angle; and all right angles will be equal to one another, without any exception.

Diagram. The figure for Axiom XII, showing two right angles side by side. On the left, a right angle at B is formed by the vertical line AB (A at top) and the horizontal line through B; the horizontal is extended leftward to H, a ray BG rises from B toward the upper right to G, and a line runs down and to the left from B to I. On the right, a right angle at E is formed by the vertical line DE (D at top) and the horizontal line CEF.

- A (top left): upper end of the vertical AB
- H (left): left end of the horizontal produced through B
- B (center): vertex of the first right angle
- G (upper middle): end of the ray BG rising from B
- I (lower left): end of the line produced downward from B
- C (bottom middle): point on the horizontal, left of E
- D (top right): upper end of the vertical DE
- E (bottom, right of C): vertex of the second right angle
- F (bottom right): right end of the horizontal EF

Axiom XIII

[Margin: xj.]

And if a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, then those two straight lines, produced to infinity, will meet one another on that side on which the angles are less than two right angles.

Thus, if a straight line EF falling on two straight lines AB and CD makes two interior angles on the same side, BEF and DFE, less than two right angles, Euclid [Euclid] holds that the lines will eventually converge at some single point, toward the side on which the two angles less than two right angles lie, as the appended example shows. The reason for this is clear: when two interior angles on the same side are equal to two right angles, the two straight lines can converge on neither side, but extend forever at an equal distance apart, as will be demonstrated at Proposition 28 of this book. Therefore, if the two interior angles on the same side are made less than two right angles, the space between the said

lines must necessarily be narrowed on that side and widened more and more on the other; and so they will eventually converge at some point.

But because this axiom tends to seem rather obscure to beginners — indeed it is excluded from the number of first principles by Geminus [Geminus] the geometer, by Proclus, and by others, on the ground that it does not readily win everyone's assent, especially since certain other lines are found whose intervening space, though it grows ever narrower (just as happens with the two straight lines AB and CD, as we shall demonstrate at Proposition 28 of this book), nevertheless never meet in a single point even if produced to infinity, as is clear from the conic elements of Apollonius of Perga [Apollonius of Perga] and from the conchoid line of Nicomedes [Nicomedes] — for this reason we defer its fuller explanation to the scholium on Proposition 28 of this book, where we shall demonstrate it geometrically after the view of Proclus, so that it may be assumed, firmly and beyond all doubt as most certain, for Proposition 29 of this book (where its use first begins to appear) and for the demonstrations of the other propositions. This, however, we shall demonstrate in a different way from Proclus — and indeed more geometrically — so that no room for doubt is left.

Diagram. The figure for the parallel axiom (Axiom XIII), showing a straight line A–B cut by a transversal, together with a second line, the interior angles on one side being drawn less than two right angles so that the lines converge. The engraving appears to draw the transversal at two positions; the labels legible in the cut are A (far left), a pair of E's at the top, B (upper right) and D (lower right), C (lower left), and a pair of F's at the bottom. The text of the demonstration works with the lines AB and CD, the transversal EF, and the interior angles BEF and DFE; the right-hand termini are the upper B (line AB) and the lower D (line CD).

- A (far left): end of the upper line
- E, E (top): transversal endpoint(s), drawn at two positions
- B (upper right): endpoint of the upper line AB
- C (lower left): end of the second line
- F, F (bottom): transversal endpoint(s), drawn at two positions
- D (lower right): endpoint of the second line CD

Axiom XIV

[Margin: xij.]

Two straight lines do not enclose a space.

This principle presents no difficulty at all. For if two straight lines meet on one side to form an angle, they must necessarily, when produced, be separated more and more on the other side, as is evident in the example set out. Therefore, in order that any rectilinear surface or space be enclosed on every side, a third line must be joined to the two straight lines. For only so is a triangular space produced — the first of the rectilinear figures.

Proclus, however, demonstrates this principle in the following way. Suppose it were possible for two straight lines ABC and ADC to enclose a surface ABCD, so that those two straight lines meet at two points, A and C. Then, with C taken as center, [Margin: a — 3.pet. (Postulate 3)] let a circle be described with radius CA, [Margin: b — 2.petit. (Postulate 2)] and let the straight lines ABC and ADC be produced in a straight and continuous line to the circumference, namely to the points E and F. Then, since the straight lines ACE and ACF pass through the center C, [Margin: c — 17.def. (Definition 17)] the semicircles AE and AF will be equal to one another, and therefore the arc AE too will be equal to the arc AF — the part equal to the whole, which cannot be. Therefore two straight lines do not enclose a space. Which is what was proposed.

Diagram. Two circles drawn side by side, each illustrating the same construction: a circle with center C and radius CA, in which the two lines from A (through B and through D) pass through the center C and reach the circumference at E and F. Both circles carry the same six labels.

- A (left): starting point, on the circumference at the left
- B (upper center): point on the line ABC, near the center
- C (center): center of the circle
- D (lower center): point on the line ADC, near the center
- F (right): point where line ADC produced meets the circumference
- E (lower right): point where line ABC produced meets the circumference

Now, an opponent might perhaps object that the straight lines ABC and ADC, when produced, meet again at some point of the circumference — say at E, or at F — and that consequently it does not follow that a part is equal to the whole. We shall then demonstrate this same axiom in the following way. Let those two lines meet again, if it be possible, at E. Taking any point F on the straight line ADC whatever, AF will be less than FE, since it is less than AFC — that is, than CHE, which is equal to AFC itself — and therefore much less than FE. A circle, therefore, described from F with radius FA, will cut the straight line FE at H, and likewise CGE at G. Since, then, AFH is a diameter of the circle, AIH will be a

semicircle, as we showed at Definition 17; but the portion AIG, which the straight line ABG cuts off, and in which the center F does not lie, is less than a semicircle, as we demonstrated at Definition 18. The arc AIG is therefore less than AIH — the whole less than the part, which is absurd.

And that the portion AIG is less than a semicircle we shall show as above. For when a perpendicular is drawn from the center F to the straight line ABG, and the portion AIG is revolved about the straight line ABG, the circumference AIG will fall within the circumference AKG, lest a part be greater than the whole, as we demonstrated above.

This axiom is also established from the definition of a straight line. For since a straight line is the shortest extension from one point to another, only a single line can be drawn from one point to another. Therefore, if ABC is a straight line, ADC will not be a straight line. This is also clear from Plato's [Plato] definition. For if ABC is a straight line, its middle points will screen its own extremities from view; but the middle points of the line ADC do not screen its extremities when the sight is directed along the straight line ABC. Therefore ADC is not a straight line.

Diagram. The figure for Proclus's alternative demonstration of Axiom XIV: a large outer circle (with A at the left and K at the bottom) and a second circle passing through I at the top, forming a lens- (vesica-) shaped region across the middle, with the horizontal diameter running from A on the left to the right, and the constructed points marked within. The peripheral labels resolve at native resolution (A, I, K, B, D, F, G, H); only the right vertex (best-read B, semantically E) remains uncertain.

- A (far left): left end of the horizontal, on the outer circle
- B (upper, inside): upper vertex of the lens region
- I (top): top point of the inner circle
- H (center right): constructed intersection near the center
- D (lower left, inside): point on the lower line
- F (lower center): center of the constructing circle
- G (center, below): intersection point
- B / E (far right): right vertex of the lens (best-read B, semantically E) [?]
- K (bottom): lowest point on the outer circle

[Transition — Clavius now adds axioms beyond Euclid's.]

To these axioms laid down by Euclid we shall add certain others, culled from other geometers — no less necessary for the demonstrations to come, both of the

problems and of the theorems, of Euclid as well as of the other mathematicians, than those that Euclid himself handed down to us.

Diagram. The vesica-and-circle figure of Proclus's demonstration of Axiom XIV, repeated at the head of the page (a re-impression of fig-p37-4) so that the continuing demonstration has its figure to hand. The same construction and the same labels appear: the outer circle with A at the left and K at the bottom, the inner circle through I at the top, and the lens-shaped middle region with the interior points B, D, F, G, H (and the right vertex). The labels resolve at native resolution (A, I, K, D, H, F, G); only the right vertex E remains uncertain.

- A (far left): left end of the horizontal, on the outer circle
- I (top): top of the inner circle
- D (upper/left, inside): constructed point
- H (center right): constructed point
- F (lower center): center of the constructing circle
- G (center, below): constructed point
- E (far right): right vertex of the lens [?]
- K (bottom): lowest point on the outer circle

Axiom XV

If unequals are added to equals, the excess of the wholes will be equal to the excess of the things added.

Proclus took this axiom, and the following one, from Pappus. So, to the equal quantities AB and CD let the unequal quantities BE and DF be added, and let BE be greater than DF. From BE let BG be cut off, equal to DF, so that GE is the excess by which the added quantity BE exceeds the added quantity DF. Since, then, to the equals AB and CD equal quantities BG and DF have been added, [Margin: a — 2.pron. (Common Notion 2)] the wholes AG and CF will be equal. Hence it is clear that the whole quantity AE exceeds the whole CF by the same excess GE by which the added magnitude DF is exceeded by the added magnitude BE. Which is what was proposed.

Diagram. The figure shared by Axioms XV and XVI: two parallel line-segments. The upper segment carries the points A, B, G, E (from left to right); the lower segment carries the points C, D, F.

- Upper segment: A (left), B, G, E (right)
- Lower segment: C (left), D, F (right)

Axiom XVI

If equals are joined to unequals, the excess of the wholes will be equal to the excess of those quantities that were unequal at the outset.

In the same figure, to the unequal quantities BE and DF let the equals AB and CD be added. From the greater, BE, let BG be cut off, equal to DF, so that GE is the excess by which the quantity BE exceeds the quantity DF. Since, then, to the equals BG and DF equal quantities AB and CD have been added, [Margin: a — 2.pron. (Common Notion 2)] the wholes AG and CF will be equal. Therefore the whole quantity AE will exceed the whole CF by the same excess GE by which the greater proposed quantity BE exceeds the smaller DF. Which is what was proposed.

Axiom XVII

If unequals are taken from equals, the excess of the remainders will be equal to the excess of the things taken away.

From the equals AB and CD let the unequals BE and DF be taken away. Let EG be the excess by which the quantity BE exceeds the quantity DF, so that BG is equal to DF. Since, then, from the equals AB and CD the equals BG and DF have been taken away, [Margin: b — 3.pron. (Common Notion 3)] the remainders AG and CF will be equal. It is therefore evident that the remainder AE is exceeded by the remainder CF by the same excess EG by which the removed magnitude BE exceeds the removed magnitude DF. Which is what was proposed.

Diagram. The figure for Axiom XVII: two parallel line-segments. The upper segment has endpoints A (left) and B (right), with the interior points E and G marked; the lower segment has endpoints C (left) and D (right), with the interior point F marked.

- Upper segment: A (left), E, G, B (right)
- Lower segment: C (left), F, D (right)

Axiom XVIII

If equals are taken from unequals, the excess of the remainders will be equal to the excess of the wholes.

From the unequals AB and CD let the equals AE and CF be taken away. Let BG be the excess by which the whole quantity AB exceeds the whole quantity CD, so that AG is equal to CD. Since, then, from the equals AG and CD the equals AE and CF

have been taken away, the remainders EG and FD will be equal. Hence the remainder EB will exceed the remainder FD by the same excess BG by which the whole quantity AB exceeds the whole quantity CD. Which is what was proposed.

Diagram. The figure for Axiom XVIII: two parallel line-segments. The upper segment has endpoints A (left) and B (right), with interior points E and G marked; the lower segment has endpoints C (left) and D (right), with interior point F marked.

- Upper segment: A (left), E, G, B (right)
- Lower segment: C (left), F, D (right)

[Clavius's general remark on Axioms XV–XVIII.] In these four axioms just set down, by the term "equal quantities" one may also understand a single quantity common to many. For if unequals are added to the same common quantity, the excess of the wholes will be equal to the excess of the things added. And if the same common quantity is joined to unequals, the excess of the wholes will be equal to the excess of those quantities that were unequal at the outset. And if unequals are taken from the same common quantity, the excess of the remainders will be equal to the excess of the things removed. And if the same common quantity is taken from unequals, the excess of the remainders will be equal to the excess of the wholes.

For with numbers: if to 6 you add 5 and 3, you get 11 and 9, whose excess is 2 — the same as the excess of 5 and 3 themselves. Again, if to 5 and 3 you add 6, you get 11 and 9, whose excess is 2 — the same as that of 5 and 3. Likewise, if from 8 you take 5 and 2, there remain 3 and 6, whose excess is 3 — the same as that of 5 and 2. Finally, if from 10 and 7 you take 3, there remain 7 and 4, whose excess is 3 — the same as that of 10 and 7.

Axiom XIX

Every whole is equal to all its parts taken together at once.

Since all the parts taken together at once constitute the whole of which they are parts, the truth of this axiom is manifest.

Axiom XX

If a whole is the double of a whole, and the part removed the double of the part removed, then the remainder too will be the double of the remainder.

For example: the whole number 20 is the double of the whole number 10; and the removed 6 is the double of the removed 3; therefore the remainder of the former, 14, is likewise the double of the remainder of the latter, 7. In general, however, this will be demonstrated at Proposition 5 of Book 5 — namely: if one magnitude is the same multiple of another as the removed part is of the removed part (as tenfold, or a hundredfold, and so on), then the remainder too will be the same multiple of the remainder as the whole is of the whole.

[Clavius on the distinction between postulates, axioms, problems, and theorems.]

From what has been said, one may gather, with Proclus and Geminus, this distinction between postulates and axioms: although both are self-evident and indemonstrable, the former have the character of problems, in that they demand that something be done, whereas the latter resemble theorems, since they ask that nothing be done but only propose some most evident statement. A postulate differs from a problem in that the construction of a postulate needs no demonstration, whereas no one would grant the construction of a problem without a demonstration, since a problem sets before us something difficult to construct. The same distinction is found between an axiom and a theorem: an axiom ought not to be demonstrated, whereas a theorem must by no means be granted unless it is demonstrated. For no one will require a demonstration, or even a proof, of this proposition: *Things equal to the same thing are also equal to one another*. But of this one someone will at once desire a demonstration: *The three interior angles of every triangle are equal to two right angles*. Hold the same judgment concerning the remaining axioms and theorems, and also the postulates and problems.

It is likewise established that some of the postulates are proper to geometry — such as those three that Euclid set before us — while others are common both to geometry and to arithmetic, of which sort is this: *that a quantity can be increased infinitely*. For both number and magnitude can be increased by addition, so that no end of this increase is ever found. You will say the same of the axioms, or common notions. For the eighth, tenth, eleventh, twelfth, thirteenth, and fourteenth belong to geometry alone, whereas all the rest are applied both to geometric and to arithmetic demonstrations. For just as equal magnitudes taken away from equal magnitudes leave equal magnitudes — whether these magnitudes be lines, or surfaces, or solids — so too equal numbers subtracted from equal numbers leave equal numbers, and so on.

Let this be what we have said about this threefold kind of first principles. Let us now proceed to the demonstrations, from which the nature of all the principles

will be more fully and perfectly perceived. For there are very many principles of the mathematicians of such a kind that they are not clearly understood at all unless their use first appears in demonstrations — as experience itself will sufficiently teach you.

Before we proceed, moreover, to interpreting the propositions of Euclid, a few words must be said about the order and method we have followed in the demonstrations themselves. First, to each proposition we have attached two numbers. One, depicted in the margin, indicates the order that Campanus [Campanus of Novara], following the tradition of the Arabs, observed in Euclid's propositions; the other, written in the series of the propositions itself, reports the arrangement of the propositions from the tradition of Theon [Theon of Alexandria], which we still see observed in the Greek codices. We did this for the following reason: since the propositions of Euclid are cited by some geometers according to the order of Campanus, but by others according to the series of Theon — and since these two interpreters very often differ from each other in the series and order of the propositions, which is especially evident in Books 6, 7, and 10 — we judged it necessary to add the number of each interpreter. For thus it will come about that, whenever a proposition-number cited by some geometer does not correspond to one interpreter, it may at least agree with the other. Then, so that the course of the demonstrations should not be interrupted, we have cited the principles and propositions of Euclid by prefixing in the margin to each citation some little letter of the alphabet, or some other sign, to which a similar little letter or sign corresponds in the demonstration, so that it may be more easily recognized to what place each citation is to be referred. The citations, then, are to be understood in the following way.

Citation	Meaning
1. def.	The first definition; and so of the other numbers, as 4. def., 23. def., etc.
1. pet.	The first petition, or first Postulate.
1. pron.	The first pronouncement, or axiom; and so of the remaining numbers, as before.
1. primi.	The first proposition of the first book.
23. Undec.	The twenty-third proposition of the eleventh book.
6. tertijd.	The sixth of the thirteenth book.
9. sextid.	The ninth of the sixteenth book.
13. duod.	The thirteenth of the twelfth book.

Citation	Meaning
7. quind.	The seventh of the fifteenth book.
5. quartid.	The fifth of the fourteenth book, etc.

From these, the other citations may easily be understood by anyone. For the reasoning is the same in all.

PROPLEMA I. PROPOSITIO I.

Enunciation (Euclid). On a given finite straight line to construct an equilateral triangle.

In every problem there are two things above all to consider: the construction of what is proposed, and the demonstration by which it is shown that the construction has been rightly carried out. For example, since this first problem directs us to construct an equilateral triangle on any given finite straight line, in such a way that the given straight line is one side of the triangle — for a figure is said to be constructed *on* a straight line when that line becomes one side of the figure — we must therefore first construct some triangle out of the granted principles, and then demonstrate that the triangle so constructed is equilateral, that is, that it has all three sides equal to one another. The same may be seen in the other problems. These two elements are also found in nearly every theorem. For very often, in order to demonstrate what is proposed, something must first be constructed and carried out, as will be clear in what follows. Very few indeed are the theorems that require no construction.

Let there then be proposed a finite straight line AB, upon which we are directed to construct an equilateral triangle. With center A and radius the line AB, let a circle CBD be described [Margin: a — Post. 3]; likewise with center B and radius the same line BA, let another circle CAD be described, cutting the first at the points C and D. From either of these, say from C, let two straight lines CA, CB be drawn to the points A and B [Margin: a — Post. 1]; and there will have been constructed on the straight line AB the triangle ABC — that is, a rectilinear figure contained by three straight lines. I say that this triangle, so constructed, is necessarily equilateral. Since the straight lines AB, AC are drawn from the center A to the circumference of the circle CBD, the line AC will be equal to the line AB [Margin: b — Def. 15]; again, because the lines BC, BA are drawn from the center B to the circumference of the circle CAD, the line BC will be equal to the line BA. Both AC and BC, therefore, are equal to the line AB. And so AC and BC will be equal to one another [Margin: c — Axiom 1], and for that reason the triangle ABC

will be equilateral. Therefore on a given finite straight line, and so on. Which was to be done.

Diagram. The construction of Proposition 1. Two equal intersecting circles are drawn on the base line AB; the equilateral triangle ABC stands on that base, with a further point D marking the lower intersection of the circles.

- A (left end of base): center of circle CBD; left vertex of the triangle.
- B (right end of base): center of circle CAD; right vertex of the triangle.
- C (upper intersection of the two circles): apex of the equilateral triangle.
- D (lower intersection of the two circles).

SCHOLIUM

That you may see several demonstrations contained in a single proposition, I have chosen to resolve this first proposition into its own first principles, beginning from the last syllogism of the demonstration. If, then, anyone wishes to prove that the triangle ABC, constructed by the method described above, is equilateral, he will use this demonstrative syllogism:

Every triangle having three equal sides is equilateral [Margin: d — Def. 23]. The triangle ABC has three equal sides. Therefore the triangle ABC is equilateral.

He will confirm the minor premise by this further syllogism:

Things equal to the same thing are also equal to one another [Margin: e — Axiom 1]. The two sides AC, BC are equal to the same side AB. Therefore the two sides AC, BC are also equal to one another. And for that reason all three sides AB, BC, AC turn out to be equal.

The minor premise of this syllogism he will establish in this way:

Straight lines drawn from the center to the circumference of a circle are equal to one another [Margin: f — Def. 15]. The lines AB, AC are drawn from the center A to the circumference CBD. Therefore the lines AB, AC are equal to one another.

By the same reasoning the lines AB, BC will be equal, since they are drawn from the center B to the circumference CAD. And so the minor premise of the preceding syllogism will be wholly confirmed.

In no other way can all the remaining propositions be resolved — not only those of Euclid, but also those of the other mathematicians. Yet mathematicians neglect this resolution in their demonstrations, because they can demonstrate what is

proposed more briefly and easily without it, as may be seen clearly enough from the demonstration above.

But if anyone should wish to construct on a given straight line an isosceles or a scalene triangle as well, he will accomplish it, following Proclus, in this way. Let there be a straight line AB, about which, from the centers A and B, let two circles be described as before [Margin: a — Post. 3]. Then let AB be produced in both directions as far as the circumferences, up to the points C and D. And with center A and radius AD, let a circle EDF be described [Margin: b — Post. 3]; likewise with center B and radius BC, a circle ECF, cutting the first at the points E and F. From either of them, say from E, let two straight lines EA, EB be drawn to the points A and B [Margin: c — Post. 1]. There will have been constructed on the line AB the triangle ABE [Margin: d — Def. 20], which I say is isosceles — namely, that its two sides AE, BE are both equal to one another and greater than the side AB. For since the lines AE, AD are drawn from the center A to the circumference EDF, AE will be equal to the line AD [Margin: e — Def. 15]; likewise, since the lines BE, BC are drawn from the center B to the circumference ECF, BE will be equal to the line BC [Margin: f — Def. 15]. But the lines AD, BC are equal to one another (for each of AC and BD is equal to the line AB, since AB, AC are drawn from the same center A to the circumference, and BA, BD likewise go out from the same center B to the circumference [Margin: g — Axiom 1]. Therefore AC, BD will be equal to one another. And so, when the common line AB is added, the whole AD will be equal to the whole BC [Margin: h — Axiom 2]). Therefore AE, BE will also be equal to one another [Margin: i — Axiom 1]. That each of AE, BE is greater than AB is plain, since AD, shown to be equal to AE, is greater than AB [Margin: a — Axiom 9]; likewise BC, demonstrated to be equal to BE, is also greater than AB [Margin: b — Axiom 9]. There has therefore been constructed on the line AB the isosceles triangle ABE, having its two sides AE, BE equal to one another and greater than the side AB — which was to be done. And this is the demonstration of Proclus and the other interpreters of Euclid.

It seems to me, however, that the triangle ABE can be shown to be isosceles more briefly, in this way. Since AE is equal to the line AD, and the line AD is double the line AB — because BA, BD are equal to one another [Margin: c — Def. 15] — AE too will be double the line AB. Again, since BE is equal to the line BC [Margin: d — Def. 15], and BC is double AB — because AB, AC are equal to one another [Margin: e — Def. 15] — BE too will be double AB. Since, then, each of AE, BE is double the same line AB, AE and BE will be equal to one another [Margin: f — Axiom 6], and greater, on that account, than the line AB. Therefore the triangle ABE is isosceles.

Now if from the point A a straight line AG is drawn to the circumference EGF [Margin: g — Post. 1], one that is not the same as AE or AD, cutting the circumference EHD at the point H, and if from G a line GB is drawn to B [Margin: h — Post. 1], there will have been constructed on the line AB the triangle ABG [Margin: i — Def. 20], which I say is scalene. For AG is greater than AH [Margin: k — Axiom 9]; but AH, AE, drawn from the center A, are equal to one another [Margin: l — Def. 15]; therefore AG will be greater than AE, that is, than BE, which was shown to be equal to AE. And so AG will also be greater than BG [Margin: m — Def. 15], since BG is equal to BE. But BG is also greater than AB, because the whole BC, equal to BG, is greater than AB, its part [Margin: n — Axiom 9]. All three sides of the triangle ABG, therefore, are unequal, and so it is scalene by definition — which was to be done.

We shall also show more briefly that the triangle AGB is scalene, in this way. Since AH, AD, drawn from the center A, are equal, and BG, BC, drawn from the center B, are likewise equal [Margin: o — Def. 15]; and since AD, BC are each double AB, while BD, AC are equal; then AH, BG will also each be double AB, and therefore greater than AB. Since, then, AG is greater than AH, or than BG [Margin: p — Axiom 9], the triangle AGB will be scalene, having AG for its greatest side, BG for its middle side, and AB for its least.

Diagram. The isosceles/scalene construction of the scholium. On the horizontal diameter, the given line AB is produced both ways to C (left) and D (right); circles centered at A (radius AD) and B (radius BC) intersect at E (above) and F (below). The isosceles triangle is ABE; the scalene construction adds the line AG, cutting the inner arc at H. Dotted arcs mark the two constructing circles.

- C (left end of the produced diameter).
- A (left center on the diameter): center of circle EDF.
- B (right center on the diameter): center of circle ECF.
- D (right end of the produced diameter).
- E (upper intersection of the two circles): apex of the isosceles triangle ABE.
- F (lower intersection of the two circles).
- H (upper region, where AG cuts the inner arc EHD).
- G (upper right, endpoint of AG on the circumference EGF).

LIBER I.

(The scholium of Proposition 1 concludes; the marginal citation keys for the passage above continue here on p. 29: g — Axiom 1; h — Axiom 2; i — Axiom 1; a — Axiom 9; b — Axiom 9; c–e — Def. 15; f — Axiom 6; g — Post. 1; h — Post. 1; i — Def. 20; k — Axiom 9; l–m — Def. 15; n — Axiom 9; o — Def. 15; p — Axiom 9.)

PRAXIS

We shall try, in nearly every one of Euclid's problems, to hand down a certain easy and brief practical method by which one may accomplish what Euclid strives to construct with many words and lines. And we shall observe this especially in those cases that are in more frequent use among mathematicians, and in which the practical method seems to bring with it some shortcut.

Thus an equilateral triangle will be constructed easily on the given line AB in this way. From the centers A and B, with radius the given line AB, let two arcs of circles be described, cutting one another at the point C, whether this falls below the line or above it. After this, let two straight lines AC, BC be drawn from the point C to the points A and B; and what is proposed will have been done. The demonstration of this is the same as the one above, provided only the circles were whole and complete — for they would necessarily pass through the points A and B.

Diagram. The practical equilateral construction: two short arcs cross at C above the base AB, forming the triangle ABC.

- A (left end of base).
- B (right end of base).
- C (apex, where the two arcs cross).

An isosceles triangle will be made in this way. From the centers A and B, with a radius greater than AB (if we wish the given line to be the shorter side), or smaller (if we choose the same line to be the longer side), let two arcs be described cutting one another at C. Then let the lines AC, BC be drawn; and an isosceles triangle will have been constructed, since AC, BC will be equal because of the equal radius assumed — greater, that is, or less, than the line AB.

Diagram. Two practical isosceles constructions side by side, each with apex C above a base AB, the crossing arcs shown at the apex. In the left figure the base AB is short relative to the equal sides; in the right figure the base is longer.

- A, B (ends of the base) in each figure.
- C (apex, crossing of the arcs) in each figure.

Finally a scalene triangle will be fashioned in this way on the given line AB. From the center B, with a radius greater than BA, let some arc be described. Likewise from the center A, with a radius still greater than the one assumed before, let another arc be described cutting the former at C. Then let the lines AC, BC be drawn; and a scalene triangle will have been constructed, as is evident from the inequality of the radii that were assumed in the construction.

Diagram. The practical scalene construction: a triangle with apex C above the base AB, the right side (toward B) drawn markedly steeper, the arcs crossing at C.

- A (left end of base).
- B (right end of base).
- C (apex).

For the rest, in what manner a triangle is to be constructed having three sides equal to any three given lines whatsoever, each to each, we shall explain more fully at Proposition 22 of this book.

PROBLEMA 2. PROPOSITIO 2.

Enunciation (Euclid). At a given point to place a straight line equal to a given straight line.

Let there be a given point A, and a given straight line BC, to which another straight line, equal to it, is to be placed at the point A. Taking either end of the line BC, say C, as center, let a circle BE be described with radius the line BC [Margin: a — Post. 3]. And from A to the center C let a straight line AC be drawn [Margin: b — Post. 1] (unless the point A should lie within the line BC: for then AC itself will be taken as the drawn line, as the second figure indicates). On the line AC let an equilateral triangle ACD be constructed [Margin: c — Prop. 1 of Book I], turned upward or downward as one pleases; and let its two sides just constructed, DA and DC, be extended toward the line AC [Margin: d — Post. 2] — DC on the side opposite the given point A, as far as the circumference, at E; and DA on the side opposite the center C, as far as one pleases, at F. Then, with center D and radius the line DE (which passes through the center C), let another circle EG be described [Margin: e — Post. 3], cutting the line DF at G. I say that the line AG, which has been placed at the given point A, is equal to the given line BC. Since DE, DG are drawn from the center D to the circumference EG, they will be equal to

one another [Margin: f — Def. 15]. Therefore, when the equal sides DA, DC of the equilateral triangle ACD are taken away, AG will remain equal to the line CE [Margin: g — Axiom 3]. But the line BC is equal to that same CE [Margin: a — Def. 15] (since both lines CB, CE fall from the center C to the circumference BE). Therefore the lines AG, BC — seeing that each has been shown equal to the line CE — will be equal to one another [Margin: b — Axiom 1]. Therefore at the given point, and so on. Which was to be done.

But if the given point should be at the end of the given line, such as C, the problem will be solved easily. For if, with center C and radius CB, a circle is described [Margin: c — Post. 3], to whose circumference a straight line CE is drawn in any direction [Margin: d — Post. 1], this line, placed at the given point C, will be equal to the given line BC [Margin: e — Def. 15], since both BC and CE go out from the same center C to the circumference BE.

Diagram, first case. The point A lies outside the line BC. A circle is drawn about center C through B; the equilateral triangle ACD is raised on AC; DC is produced to E on that circle and DA to F; the second circle about D (radius DE) cuts DF at G, so that AG equals BC.

- B (left, on the first circle).
- C (center of the first circle, on the base).
- D (top, apex of the equilateral triangle ACD).
- A (given point, near the top center).
- E (lower, where DC meets the first circle's circumference).
- G (right, where the second circle cuts the produced line DF).
- F (below G, endpoint of the produced side DA).

Diagram, second case. The point A lies within the line BC, so AC itself serves as the drawn line; the same lettering is used.

- B (left, on the first circle).
- A (center, the given point within BC).
- C (right, center of the first circle).
- D (top, apex of triangle ACD).
- E (lower right, on the circumference).
- G (bottom, where the second circle cuts the produced line).
- F (bottom, endpoint of the produced side).

EVCLID. GEOM.

SCHOLIUM

This problem can have various cases, as Proclus says. For either the given point is set on the given line itself, or outside it. If on the line, it will be either one of its ends, or it will lie between the two ends. If, however, outside the line, it will be either in a straight line with the given line — so that the line, produced straight and continuous, passes through the point itself — or not in a straight line, so that a line drawn from the point makes an angle with the given line; in which case it will be constructed either above the given line or below, as is plain. But in all these cases the construction and demonstration are always the same. And if in the construction an isosceles triangle ACD is made on the line AC, we shall show in the same way that the line AG is equal to the line BC.

PROBL. 3. PROPOS. 3.

Enunciation (Euclid). From two given unequal straight lines, to cut off from the greater a straight line equal to the less.

Let there be two unequal straight lines: A, the lesser, and BC, the greater; and let it be required to cut off from the greater, BC, a line equal to the lesser, A. At either end of the greater line BC, say at the point B, let some line be placed which is BD, equal to the lesser A [Margin: a — Prop. 2 of Book I]. Then with center B and radius BD let a circle be described [Margin: b — Post. 3], cutting BC at E. I say that BE, so cut off, is equal to A. Since BE is equal to the line BD [Margin: c — Def. 15], and the line A is equal to that same BD by the construction, A and BE will be equal to one another [Margin: d — Axiom 1]. Therefore from two given straight lines, and so on. Which was to be done.

But if the two given lines are joined at one end — as are BD and BC, joined at their common end B — a circle must be described from B, with radius the lesser line BD. For this will cut off BE, equal to BD, as is evident from the definition of a circle.

Diagram. The lesser line A is drawn separately above. A circle is drawn about center B with radius BD (= A); its diameter runs from C on the left through E to B, with D on the upper circumference, so that BE is the segment cut off from BC equal to A.

- A (above the figure): the given lesser line.

- D (upper left, on the circumference).
- C (far left, end of the diameter through the circle).
- E (lower left, where the circle cuts BC).
- B (center of the circle).

SCHOLIUM

That there can also be various cases in this problem, no one is unaware — since the two given unequal lines may either stand apart from one another, so that neither touches the other; or not, but either be joined at one end, or cut one another mutually, or at least the one touch the other with its end only, and so on. On this matter, read Proclus in this place.

THEOREMA 1. PROPOS. 4.

Enunciation (Euclid). If two triangles have two sides equal to two sides respectively, each to each, and have the angle contained by the equal straight lines equal to the angle: then they will also have the base equal to the base; the triangle will be equal to the triangle; and the remaining angles will be equal to the remaining angles respectively, namely those which the equal sides subtend.

Let there be two triangles ABC, DEF, and let each side AB, AC of the one be equal to each side DE, DF of the other — that is, AB to DE, and AC to DF — and let the angle A, contained by the sides AB, AC, be equal to the angle D, contained by the sides DE, DF. I say that the base BC is also equal to the base EF; that the triangle ABC is equal to the triangle DEF; and that each angle B and C is equal to each angle E and F respectively — that is, the angles B and E, which are opposite the equal sides AC, DF, are equal to one another, and the angles C and F, which are opposite the equal sides AB, DE, are also equal to one another. For since the line AB is set equal to the line DE, it follows that, if the one is understood to be laid upon the other, with the point A placed on the point D, they will exactly fit one another [Margin: a — Axiom 8], and the point B will fall on the point E. For no one will be able to say that part of the line AB fits the line DE and part does not, since then two straight lines would have a common segment [Margin: b — Axiom 10], which is impossible. And if anyone should say that, the point A being placed on D, the point B does indeed fall on E, but the line AB falls either to the right or to the left of DE, then two straight lines would enclose a surface [Margin: c — Axiom 14], which cannot happen. Therefore the line AB will fit the line DE, as has been said. Since, then, the angle A is set equal to the angle D, the one will also fit the other [Margin: d — Axiom 8] — that is, the line AC will fit the line DF, and the

point C will fall on the point F, because of the equality of the lines AC, DF. Therefore the base BC will also fit the base EF; for otherwise, if it fell above or below, so that the line EGF or EHF were produced, two lines EF, EGF, or EF, EHF, would enclose a surface (for no one will be able to deny that both EGF and EHF are straight, since each is supposed to be the same as the straight line BC) — which is absurd. For two straight lines cannot enclose a surface. Wherefore the base BC will be equal to the base EF [Margin: f — Axiom 8], since neither exceeds the other; and the triangle ABC will be equal to the triangle DEF; and the angle B to the angle E; and the angle C to the angle F, for the same reason. Therefore, if two triangles have two sides equal to two sides, and so on. Which was to be demonstrated.

(Marginal citation keys for this demonstration: a — Axiom 8; b — Axiom 10; c — Axiom 14; d — Axiom 8; e — Axiom 14; f — Axiom 8.)

Diagram. Two triangles for Proposition 4. The left triangle ABC has apex A over base BC. The right triangle DEF has apex D over base EF; the additional points G and H mark the two impossible positions of a would-be base (EGF above, EHF below) used in the reductio.

- A (apex of the left triangle).
- B (lower left of the left triangle).
- C (lower right of the left triangle).
- D (apex of the right triangle).
- E (lower left of the right triangle).
- F (lower right of the right triangle).
- G (within the right figure, above the base EF).
- H (within the right figure, below the base EF).

SCHOLIUM

Euclid rightly laid down two conditions in the antecedent of this theorem. The first is that the two sides of the one triangle be equal to the two sides of the other, each to each; the second, that the angle of the one contained by those sides be equal to the angle of the other contained by the sides which are equal to them. For if either of these conditions is lacking, neither the bases nor the remaining angles will ever be able to be equal, as is well demonstrated in this place by Proclus. The triangles themselves, however, may indeed be equal when only the latter condition is lacking, as will be clear from the scholium to Proposition 37 of this book — though that happens only very rarely. For let the angles A and D of

the triangles ABC, DEF be equal, namely right angles, and let the sides AB, AC be equal to the sides DE, DF — not indeed each to each, but the two taken together to these two taken together. Let AB be 3 and AC be 4, so that both together make 7; while DE is 2 and DF is 5, so that both together likewise make 7. On these suppositions, the base BC will be 5, and the base EF will be the square root of the number 29, which is indeed greater than 5 but less than 6. Likewise the area of the triangle ABC will be 6, but the area of the triangle DEF will be 5. Finally the angles on the base BC will be unequal to the angles on the base EF. That all this is so we would show here, were it not that its demonstration requires many things not yet established. You see, therefore, that all these quantities are unequal, because it is not the case that each side is equal to each side in the said triangles ABC, DEF.

Diagram. Two right triangles illustrating the numerical counter-example of the scholium. The left triangle ABC has legs 3 and 4, base 5, and area 6; the right triangle DEF has legs 2 and 5, base the square root of 29, and area 5.

- A (apex of the left triangle); "3" on side AB, "4" on side AC, "6" (the area) marked within.
- B (lower left); "5" on the base BC.
- C (lower right).
- D (apex of the right triangle); "2" on side DE, "5" on side DF.
- E (lower left); " $\sqrt{29}$ " (radix quadrata of 29) marked on the base EF.
- F (lower right).

[The page opens in the middle of Clavius's scholium on Proposition 4 (continued from the previous page).]

Again, let triangles ABC and DEF have their sides AB and AC equal to the sides DE and DF, each to each, and let each of them be 5; but let the angles A and D contained by those sides be unequal, with A greater than D. On these assumptions the base BC will be greater than the base EF, as will be shown at proposition 24 of this book [Elements I.24]. Now suppose we take the base BC to be 8 and the base EF to be 4. Then the area of triangle ABC will be 12, while the area of triangle DEF will be the square root of the number 84 — which is indeed greater than 9 but less than 10, a fact perfectly familiar to geometers. Therefore, in order that two triangles may have both their bases and their angles equal, and the triangles themselves equal to one another, it is necessary that each side of the one be equal, respectively, to each side of the other, and that the angles contained by those sides likewise be equal — exactly as Euclid rightly stated.

Diagram. Two triangles drawn side by side, illustrating that equal sides with unequal included angles yield unequal bases and unequal areas.

- Left triangle ABC: **A** (apex); **B** (lower-left base vertex); **C** (lower-right base vertex). The two sides AB and AC are each marked 5 (with tick-marks); the base BC is marked 8; the area **12** is written inside.
- Right triangle DEF: **D** (apex); **E** (lower-left base vertex); **F** (lower-right base vertex). The two sides are each marked 5; the base EF is marked 4; the area is written inside as $\sqrt{84}$ (the square root of 84).

THEOR. 2. PROPOS. 5.

[Margin: v — proposition 5]

[Proposition — Euclid's enunciation] In isosceles triangles the angles at the base are equal to one another; and, if the equal straight lines are produced, the angles under the base will also be equal to one another.

[Clavius's demonstration] Let ABC be an isosceles triangle in which the sides AB and AC are equal to one another. I say that the angles ABC and ACB above the base BC are equal to one another; and likewise, if the equal sides AB and AC are produced as far as one pleases, up to the points D and E, that the angles DBC and ECB below the same base BC are also equal.

For, on the line AE produced indefinitely, let AF be cut off equal to AD [Margin: a — Elements I.3], and let the straight lines BF and CD be drawn [Margin: b — Postulate 1]. Then consider the two triangles ABF and ACD. Since the two sides AB and AF of triangle ABF are equal to the two sides AC and AD of triangle ACD, each to each — namely AB to AC by hypothesis, and AF to AD by construction — and since the angle A contained by the sides AB and AF is equal to the angle A contained by the sides AC and AD (indeed, angle A is common to both triangles), the base BF will be equal to the base CD, the angle F to the angle D, and the angle ABF to the angle ACD [Margin: c — Elements I.4]; for both the former pair and the latter pair stand opposite equal sides in those triangles, as is evident.

Now consider the two triangles BDC and CFB. Since the straight lines AD and AF are equal by construction, it follows that, if the equals AB and AC are taken away from them, the remainders BD and CF are equal [Margin: d — Common Notion 3]. Therefore the two sides BD and DC of triangle BDC are equal to the two sides CF and FB of triangle CFB, each to each — namely BD to CF, and DC to FB, as has been proved. Moreover, the angles D and F contained by those sides are equal, as was also shown. Therefore the angle DBC will be equal to the angle FCB, and the

angle BCD to the angle CBF [Margin: e — Elements I.4]; for both the former pair and the latter stand opposite equal sides, and they lie above the common base BC of each triangle, BDC and CFB.

Now if from the whole equal angles ABF and ACD (which we have already proved equal in the former triangles) the equal angles CBF and BCD are subtracted (which we have likewise just proved equal in the latter triangles), there will remain the angles ABC and ACB above the base BC [Margin: f — Common Notion 3], equal to one another — while the angles DBC and FCB, which lie below the same base BC, are also equal. Therefore both the angles above the base are equal to one another, and the angles below it are equal to one another; and consequently, in isosceles triangles the angles at the base, and so forth. Which was to be demonstrated.

Diagram. The figure for Proposition 5 (the "bridge of asses"). An isosceles triangle ABC with apex A and base vertices B and C; the equal sides are produced below the base to D and E, a point F is taken on AE with $AF = AD$, and the cross-lines BF and CD are drawn.

- A (apex).
- B (left base vertex); C (right base vertex) [glyph of C faint on the leaf, but required by the construction].
- D (lower-left, on AB produced); F (lower-middle, on AE with $AF = AD$); E (lower-right, on AC produced).
- The lines BF and CD cross between the base and the produced ends.

SCHOLIUM.

This proposition is true also of equilateral triangles, since in any equilateral triangle two sides equal to one another can be found — even though Euclid seems to have accommodated it only to isosceles triangles. For, given two sides AB and AC of triangle ABC equal, then — whether the remaining side BC is also equal to them, as happens in an equilateral triangle, or unequal, as occurs in an isosceles one — it necessarily follows both that the angles above the base are equal to one another and that the angles below it are likewise equal, as is clear from the demonstration just given. This theorem is apt to seem rather difficult and somewhat obscure to beginners, on account of the multitude of lines and angles to which they are not yet accustomed. Nevertheless, if the force and demonstration of the preceding theorem are weighed carefully, the present one will be grasped by anyone without much labor — provided only that he remembers that the angles of the triangles were proved equal in the preceding

theorem because they stand opposite equal sides. And the very fact that Campanus [Campanus of Novara] did not supply this is the reason why his demonstration appears confused and rather obscure.

Moreover, the truth of this theorem, in both its parts, can also easily be demonstrated by superposition, just as proposition 4 was demonstrated. For let there again be, in triangle ABC, two equal sides AB and AC, produced as far as one pleases up to D and E. I say both that the angles ABC and ACB above the base BC are equal to one another, and that the angles DBC and ECB below the same base are equal. For if we conceive the triangle ABC in our mind as laid upon the triangle ACB (so that the same triangle serves as though it were two), in such a way that the straight line AB is laid upon AC, the point B will fall on C because of the equality of the sides AB and AC. This being so, the line AC will fall upon the line AB because of the equality — or rather the identity — of the angle A; and the point C will fall on the point B[?] [the printed letter is unclear; the geometry requires B], because of the equality of the sides AC and AB. Therefore the angle ABC will coincide with the angle ACB, and the angle DBC with the angle ECB [Margin: a — Common Notion 8]; and consequently both the former and the latter will be equal to one another.

Diagram. The superposition figure for the alternative proof. A triangle with apex A and base D (lower-left) and E (lower-right); B and C mark the points partway down the two sides (B on AD, C on AE), joined by the segment BC drawn across the figure.

- A (apex); B (on the left side); C (on the right side); D (lower-left); E (lower-right).

COROLLARIUM.

From this fifth proposition it is clear that every equilateral triangle is also equiangular — that is, that the three angles of any equilateral triangle are equal to one another. For let ABC be an equilateral triangle. Since the two sides AB and AC are equal, the two angles B and C will be equal [Margin: a — Elements I.5]. Again, since the two sides AB and BC are equal, the angles C and A will also be equal. Therefore all three angles A, B, and C will be equal. Which was to be shown.

Diagram. An equilateral triangle ABC — A (apex), B (lower-left), C (lower-right) — illustrating that an equilateral triangle is equiangular.

THEOR. 3. PROPOS. 6.

[Margin: vi — proposition 6]

[Proposition — Euclid's enunciation] If two angles of a triangle are equal to one another, then the sides subtended under the equal angles will also be equal to one another.

[Clavius's demonstration] In triangle ABC let the two angles ABC and ACB upon the side BC be equal. I say that the two sides opposite them, AB and AC, are also equal. For if they are not believed to be equal, then — the said angles being nonetheless equal — one will be greater than the other; so let AB, if it be possible, be greater than AC. From AB let there be cut off at D a straight line BD equal to the straight line AC [Margin: b — Elements I.3] (BD being said to be less than AB), and let the straight line CD be drawn. Now consider the two triangles ACB and DBC. In them the two sides AC and CB of triangle ACB are equal to the two sides DB and BC of triangle DBC, each to each — namely AC to DB (for we cut off from AB, by the adversary's own concession, a segment DB equal to AC) and CB to BC, since it is one and the same. Moreover, the angles ACB and DBC contained by those sides are equal, by hypothesis. Therefore the triangles ACB and DBC will be equal [Margin: c — Elements I.4] — the whole to the part, which is impossible. Therefore the sides AB and AC will not be unequal, if the angles B and C upon the side BC are equal — lest we grant that the whole is equal to the part; rather, they will be equal. Therefore, if two angles of a triangle, and so forth. Which was to be demonstrated.

Diagram. The reductio figure for Proposition 6. Triangle ABC with apex A and base vertices B (lower-left) and C (lower-right). On side AB a point D is taken just below A, with $BD = AC$, and the line CD is drawn, forming triangle DBC within triangle ABC.

- A (apex); D (on AB, just below A); B (lower-left); C (lower-right).

SCHOLIVM.

This theorem is the converse of the first part of the preceding one. For there it was demonstrated that if two sides of a triangle are equal to one another, the angles at the base are also equal; here, on the other hand, that if the angles at the base are equal, the sides opposite those angles are also equal. No one ought to find it strange that mathematicians sometimes convert propositions — so that at one time, from some granted antecedent, they collect a consequent by demonstration, while at another time, conversely, from the consequent now

granted they infer that antecedent by another demonstration, as we see Euclid do in these two neighboring propositions. It should not, I say, seem strange, since in mathematical matters antecedent and consequent are not always reciprocal. For in necessary propositions, such as geometrical propositions are, the predicate may sometimes be more universal than the subject, to speak with the logicians; and in that case the proposition cannot be converted. For the proposition "Every man is an animal" is necessary, yet it cannot be converted universally, since not every animal is a man. The same can happen in necessary geometrical propositions, and of this I will now offer just one such example. Euclid demonstrates, at proposition 16 of this book [Elements I.16], that if one side of any triangle is produced, the exterior angle is greater than either of the two interior and opposite angles; and in that proposition antecedent and consequent are in no way reciprocal. For it does not follow that, if in any rectilinear figure one side is produced and the exterior angle is greater than each of the interior opposite angles, that figure is a triangle — since it might also be a quadrilateral, as we shall show at proposition 16 of this book. In the same way many other propositions cannot be converted. For this reason the geometer must first demonstrate that a given proposition can be converted — that is, that its antecedent and consequent are reciprocal — before he collects the antecedent from the granted consequent. Euclid, however, does not convert all the propositions that can be converted, but only those whose conversion is most needed; yet we shall take pains to convert nearly all those that seem to offer any usefulness.

COROLLARIUM.

It follows from this proposition that every equiangular triangle — that is, one all of whose angles are equal — is equilateral. This is indeed the converse of the corollary of the fifth proposition, as is clear. For let the three angles of triangle ABC be equal. I say that it is equilateral. Since the two angles B and C are equal, the sides AB and AC will be equal [Margin: a — Elements I.6]. Again, since the two angles A and B are equal, the sides AC and BC will also be equal; and therefore all three sides AB, BC, AC are equal. Which was to be shown.

Diagram. An equilateral triangle with apex C, base vertices A (lower-left) and B (lower-right), illustrating that an equiangular triangle is equilateral.

EX PROCLO. [*From Proclus.*]

We shall be permitted to convert the second part of the fifth proposition as well, in this way:

[Proposition] If, when the two sides of any triangle are produced, the angles below the base are made equal, then those two sides will also be equal to one another.

[Demonstration] For let the sides AB and AC of triangle ABC be produced to D and E, and let the angles DBC and ECB below the base BC be made equal. I say that the sides AB and AC are also equal to one another. On CE produced as far as one pleases, let CF be cut off equal to BD [Margin: b — Elements I.3], and let the straight lines BF, FD, and DC be drawn. Then consider the triangles DBC and FCB. In them the sides DB and BC are equal to the sides FC and CB, each to each — namely DB to FC by construction, and BC to CB, since it is one and the same; and the angles DBC and FCB contained by those sides are equal by hypothesis. Therefore both the bases CD and BF, and the angles BCD and CBF upon those bases (since they stand opposite the equal sides BD and CF), will be equal [Margin: c — Elements I.4]. Therefore, when these equal angles BCD and CBF are subtracted from the angles FCB and DBC by hypothesis, the remaining angles FCD and DBF will be equal [Margin: a — Common Notion 3]. Now consider again the triangles DBF and FCD. In them, since the sides DB and BF are equal to the sides FC and CD, each to each — namely DB to FC by construction, and BF to CD, as was just shown — and since the angles DBF and FCD contained by those sides are equal, as was also just demonstrated, the angle BDF upon the base DF of triangle DBF will be equal to the angle CFD upon the same base FD of triangle FCD [Margin: b — Elements I.4]; for these stand opposite equal sides. Since, then, in triangle ADF the two angles ADF and AFD are equal, as we have now shown, the sides AD and AF will be equal [Margin: c — Elements I.6]. And if from these the straight lines BD and CF, equal by construction, are taken away, there will remain AB and AC, the sides of triangle ABC, equal [Margin: d — Common Notion 3]. Which was to be shown.

Diagram. The figure from Proclus. Triangle ABC with apex A and base vertices B (left) and C (right), the base BC drawn across; the sides AB and AC are produced below the base to D (below B) and E (below C). On CE a point F is taken with CF = BD, and the lines BF, FD, and DC are drawn, crossing below the base.

- **A** (apex); **B** (left base vertex); **C** (right base vertex) [glyph faint on the leaf — required by the construction]; **D** (lower-left, on AB produced); **F** (on CE); **E** (lower-right, on AC produced).

THEOR. 4. PROPOS. 7.

[Proposition — Euclid's enunciation] On the same straight line, and having the same endpoints as two given straight lines, two other straight lines equal respectively to those two — each to each — cannot be constructed meeting at a different point on the same side as the two lines originally drawn.

[Clavius's demonstration] Upon the straight line AB let two straight lines AC and BC be constructed to some point C. I say that upon the same straight line AB, toward the same side as C, it is impossible to construct at another point, say D, two other straight lines equal to the lines AC and BC, each to each — namely AC to AD, which have the same endpoint A, and BC to BD, which likewise have the same endpoint B. For suppose, if it be possible, that the lines AC and AD are equal to one another, and the lines BC and BD equal to one another as well. Then the point D will either lie on one of the lines AC or BC (so that AD falls on the line AC itself, or BD on BC itself), or inside the triangle ABC, or outside it.

First, let the point D lie on one of the lines AC or BC — say on AC, so that AD is a part of AC. Then, since the lines AC and AD, having the same endpoint A, are said to be equal, the part AD will be equal to the whole AC — which is impossible.

Next, let the point D lie inside triangle ABC; and, the line CD having been drawn, let the lines BC and BD be produced up to E and F. Since in triangle ACD the sides AC and AD are assumed equal, the angles ACD and ADC upon the base CD will be equal [Margin: a — Elements I.5]. But the angle ACD is less than the angle DCE [Margin: b — Common Notion 9], being a part less than the whole; therefore the angle ADC will also be less than that same angle DCE. Hence the angle CDF, being a part of ADC, will be much less than that same angle DCE. Again, since in triangle BCD the sides BC and BD are assumed equal, the angles CDF and DCE below the base CD will be equal [Margin: c — Elements I.5]. But it was shown that the same angle CDF is much less than the angle DCE. Therefore the same angle CDF is both less than the angle DCE and equal to it — which is absurd.

Lastly, let the point D lie outside triangle ABC. Then either it will be in such a position that one line falls upon another, as in the earlier figure — provided that for D you understand C, and for C you understand D — from which again a part will be found equal to the whole, which is absurd. Or it will be in such a position that the two later lines enclose the two earlier ones, as in the latter figure, provided that again for D you understand C, and for C, D. On this supposition we shall fall into the same absurdity, namely that the angle DCF is both less than the angle CDE and equal to it, as is evident. Or finally the point D will lie outside

triangle ABC in such a way that one of the later lines, namely AD, cuts one of the earlier ones, namely BC. Then, the line CD having been drawn, since in triangle ACD the sides AC and AD are assumed equal, the angles ACD and ADC upon the base CD will be equal [Margin: d — Elements I.5]. And accordingly, since the angle ADC is less than the angle BDC [Margin: e — Common Notion 9], a part less than the whole, the angle ACD will also be less than that same angle BDC. Hence the angle BCD, being a part of the angle ACD, will be much less than that same angle BDC. Again, since in triangle BDC the sides BC and BD are assumed equal, the angles BCD and BDC upon the base CD will be equal [Margin: a — Elements I.5]. But it has just been shown that the angle BCD is much less than the angle BDC. Therefore the same angle BCD is both less than the angle BDC and equal to it — which is absurd. Therefore AC and AD are not equal to one another, nor BC and BD to one another. Therefore, upon the same straight line, two other straight lines equal to two given straight lines, and so forth. Which was to be demonstrated.

Diagram. The general setup for Proposition 7. Two pairs of straight lines drawn to the base AB from two different upper points: AC and BC meeting at C, and AD and BD meeting at D, with C and D close together at the top and A (lower-left), B (lower-right) as the common endpoints of the base.

- **C** (upper); **D** (upper, near C); **A** (lower-left); **B** (lower-right).

- **F** (top-left); **E** (top); **C** (below E); **D** (below C, interior); **A** (lower-left); **B** (lower-right).

Diagram. The case where D lies outside the triangle and one line falls on another. A triangle on base AB (A lower-left, B lower-right) with D at the apex and C just below D on the near side.

- **D** (apex); **C** (below D); **A** (lower-left); **B** (lower-right). [Margin: c — Elements I.5]

Diagram. The case where the line AD cuts the side BC. A triangle on base AB (A lower-left, B lower-right) with D at the top and C below; a line from A crosses BC, meeting it at a point marked E.

- **D** (top); **C** (below D); **A** (lower-left); **B** (lower-right); **E** (intersection on BC) [a second E-like mark appears near the top; reading uncertain]. [Margin: d — Elements I.5; e — Common Notion 9; a — Elements I.5]

SCHOLIVM. [The heading is printed **SHOLIVM** — the C is dropped in the source; read *Scholium*.]

It is possible for the two lines AD and BD to be equal to the two lines AC and BC, each to each — AD to BC, and BD to AC — as the last figure indicates. But in this case those lines that are equal to one another do not proceed from the same point, as is clear: for only AC and AD share the same endpoint A, and likewise only BC and BD share the endpoint B; and Euclid excellently demonstrated that it is impossible for AC and AD to be equal to one another in such a way that BC and BD are also equal to one another. Rightly, therefore, are these words set in the proposition: "having the same endpoints as the two lines originally drawn." Again, the two lines AD and BD taken together may be equal to the two lines AC and BC taken together, as can be seen in the same figure; but Euclid does not show this to be impossible. For he said that the two cannot each be equal to each, and so on.

By the same reasoning, from A and B, below AB, the base of triangle ABC — that is, toward the contrary side — two straight lines AD and BD may be drawn meeting at some point, in such a way that AD, issuing from the point A, is equal to AC, and BD, issuing from B, is equal to BC, as is evident in the figure set beside. Not without reason, therefore, did Euclid add: "on the same side." Finally, two lines AC and AD may be equal to one another, sharing the same endpoint A; but on this supposition it can in no way come about that the remaining two, BC and BD, having the same endpoint B, are also equal to one another, as appears in this figure and was demonstrated by Euclid. Aptly, therefore, was it said in the proposition: "two other straight lines equal to two given straight lines, each to each," and so on. So that the aim Euclid set himself in this proposition may be plainly understood, each single word of the proposition must be weighed carefully.

Diagram. The first scholium figure. A rhombus-like figure with the diagonal AB drawn across: it shows AD and BD equal to AC and BC crosswise.

- **C** (top); **A** (left); **B** (right); **D** (bottom).

Diagram. The second scholium figure. A triangle on base AB (A lower-left, B lower-right) with two upper points C (left) and D (right); the lines AD and BC cross, showing two lines from A and B meeting at points on the same side.

- C (top-left); D (top-right); A (lower-left); B (lower-right).

THEOR. 5. PROPOS. 8.

[Margin: viij.]

[Euclid, Elements I.8 — enunciation] If two triangles have two sides equal to two sides, each to each, and also have the base equal to the base, then they will also have the angle contained by the equal straight lines equal to the angle.

[Clavius's demonstration] Let AB, AC be two sides of the triangle ABC, equal to the two sides DE, DF of the triangle DEF — each to each, namely AB to DE and AC to DF; and let the base BC also be equal to the base EF. I say that the angle A is equal to the angle D — the angles, that is, which are each contained by the said sides. For if the base BC be conceived in the mind as laid upon the base EF, [Margin: a — Book I, common notion 8] neither will exceed the other, but the point B will coincide with the point E, and the point C with the point F, since these bases are posited equal to one another. Next, if the triangle ABC be imagined to fall upon the triangle DEF, the point A will fall either upon the very point D or elsewhere. If the point A falls upon the very point D, the sides of the triangles will mutually coincide, since they are posited equal; [Margin: a — Book I, common notion 8] and therefore the angle A will be equal to the angle D, since neither exceeds the other.

But if the point A be said to fall elsewhere, say at G — in whatever way this may happen, that is, whether onto the side ED, or within the triangle EDF, or outside, as appears in the figures — then EG (which is the same as BA) will always be equal to ED, and FG (which is the same as CA) equal to FD, because the sides of the one triangle are posited equal to the sides of the other. But that this cannot be the case has already been demonstrated, [Margin: b — Book I, Prop. 7] since both the straight lines EG, ED possess the same endpoint E, and the straight lines FG, FD the same limit F. Therefore the point A will not fall anywhere other than upon the point D; and consequently the angle A will be equal to the angle D. Therefore, if two triangles have two sides equal to two sides, etc. Which was to be demonstrated.

Diagram. A horizontal strip of four small triangles illustrating the cases of the superposition argument.

- First triangle: apex A (top), base B (lower-left) to C (lower-right) — the triangle ABC.

- Second, third, and fourth triangles: each is triangle DEF (apex **D**, base **E** lower-left to **F** lower-right), with the additional point **G** marking where the superimposed vertex **A** is supposed to fall — successively on the side **ED**, then inside the triangle, then outside it.
- Labels present: **A**, **B**, **C**, **D**, **E**, **F**, **G**.

[Scholium] [Margin: heading printed "SHOLIVM" — the **C** is omitted]

As you see, this proposition converts the first part of the fourth proposition. For just as there, from the equality of the angles contained by the equal sides, the equality of the bases was inferred, so here Euclid concludes from the equality of the bases the equality of the angles comprehended by the equal sides. We can in the same way, from the first and third part of the conclusion of the fourth proposition, infer the whole antecedent of it, so that the theorem may be stated in this form:

[Restated theorem — enunciation] If two triangles have their bases equal, and the angles set upon the bases equal, each to each, then they will also have the remaining sides equal, each to each — namely those subtended by the equal angles — and the remaining angles included by these sides equal.

[Demonstration] For let the base **BC** be equal to the base **EF**, and the angle **B** to the angle **E**, and the angle **C** to the angle **DFE**. I say that the side **AB** is also equal to the side **DE**, and the side **AC** to the side **DF**, and the angle **A** to the angle **D**. For if the base be laid upon the base, [Margin: a — Book I, common notion 8] their extremities will mutually coincide, and likewise the lines of the equal angles. Therefore all will coincide, and consequently all will be equal to one another. This same theorem, which we have here proposed — which indeed seems to convert the fourth proposition more properly than Euclid's does — Euclid will demonstrate differently in the first part of proposition 26, as we shall note in that place.

[Corollary]

Moreover, from the antecedent of this eighth proposition it can be gathered not only that the angles contained by the equal sides are equal, but also that the remaining angles, which are set at the bases, are equal each to each — as the angle **B** to the angle **E**, and the angle **C** to the angle **F**; indeed that the whole triangle is equal to the whole triangle, as is clear from the same superposition of one triangle upon the other. For both the said angles and the whole triangles will mutually coincide, as is evident. This too can be gathered from the fourth proposition, once it has been demonstrated that the angles comprehended by the

equal sides are equal. For it will follow from this — since the sides too are equal — that both the remaining angles and the whole triangles are equal, as was demonstrated in proposition 4.

FROM PROCLUS.

The followers of Philo [*Philonis familiares* — Philo of Byzantium's circle] demonstrate this same eighth theorem by an affirmative demonstration, in this way. For, the same antecedent being posited, let the base BC be understood to be laid upon the base EF in such a way that the triangle ABC falls on the opposite side, and not upon the triangle DEF — such as is the triangle AEF. Then either the two sides, namely DF and FA, constitute one straight line — which will happen if the two angles C and F are right angles — or they do not. If they do constitute one straight line, say DA, the proposition will be concluded thus. Since in the triangle AED the two sides AE, DE are posited equal (for AE is now the same straight line as AB, which by hypothesis is equal to the straight line DE), [Margin: a — Book I, Prop. 5] the angles A and D upon the base AD will be equal, which was to be shown.

But if neither DF, FA nor DE, EA form a straight line, let a straight line DA be drawn from D to A, which will fall either within the triangles or outside them. Let it first fall within — which happens when the angles at E and F are acute. Since therefore in the triangle AED the two sides AE, DE are posited equal, [Margin: b — Book I, Prop. 5] the two angles EAD, EDA at the base DA will be equal. By the same reasoning, since the two sides AF, DF are equal by hypothesis, the two angles FAD, FDA upon the base DA will be equal. If therefore these equals be added to those equals, [Margin: c — Book I, common notion 2] the whole angles

Diagram. Upper of two figures for Philo's affirmative proof. Triangle ABC (apex **A** upper-left, base **B** lower-left to **C**) set point-to-point at **E** against triangle DEF (apex **D** upper-right, side to **F** at right), with the reflected vertex **A** placed below and the straight line DA drawn — the case where DF, FA lie in one straight line.

- Labels present: A, B, C, D, E, F, and a second A (lower vertex).

- Labels present: A, B, C, D, E, F, and a second A (lower vertex).

the whole angles EAF, EDF will be equal. Which was to be shown. Next, let the straight line DA fall outside the triangles — which finally happens when the

angles at F are obtuse. Since therefore in the triangle AED the two sides AE, DE are posited equal, [Margin: d — Book I, Prop. 5] the angles EAD, EDA at the base DA will be equal. By the same reasoning, since the two sides AF, DF in the triangle AFD are equal by hypothesis, the angles FAD, FDA upon the base DA will be equal. Therefore, these being subtracted from the former, [Margin: e — Book I, common notion 3] the angles EAF, EDF will remain equal — which was what was proposed to be demonstrated.

Diagram. Upper of two figures continuing Philo's proof — the case where DA falls outside the triangles. Triangle ABC (apex A, base B–C) meeting triangle DEF (apex D, with E, F) at E, and the reflected vertex A below, DA drawn outside.

- Labels present: A, B, C, D, E, F, and a second A.

PROBL. 4. PROPOS. 9.

[Margin: ix.]

[Euclid, Elements I.9 — enunciation] To bisect a given rectilineal angle [*bifariam facere*].

[Clavius's demonstration] Let BAC be the rectilineal angle to be bisected — that is, to be divided into two equal angles. On the straight line AB take any point D, and from AC [Margin: a — Book I, Prop. 3] cut off a straight line AE equal to AD, and draw the straight line DE. Then upon DE [Margin: b — Book I, Prop. 1] construct an equilateral triangle DFE, and draw the straight line AF, dividing the angle BAC into the angles BAF, CAF. I say that these angles are equal to one another. For since the sides DA, AF of the triangle DAF are equal to the sides EA, AF of the triangle EAF, each to each — because DA is equal to EA by construction, and AF is common — and the base DF is also equal to the base EF, because the triangle DFE was constructed equilateral: [Margin: c — Book I, Prop. 8] the angle DAF will be equal to the angle EAF, and therefore the angle BAC is bisected, which was to be done.

Diagram. The construction for bisecting angle BAC. Apex A at top; rays descending to B (lower-left) and C (lower-right). Point D on ray AB and point E on ray AC; below them the equilateral triangle DFE with vertex F at the bottom; the straight line AF drawn through, bisecting the angle.

- Labels present: A, B, C, D, E, F.

[Scholium]

But if in place of the equilateral triangle we construct an isosceles triangle, we shall nonetheless demonstrate the same thing. This can also be done in the next three propositions that follow.

[Practice]

More quickly than can be told, any rectilineal angle, such as BAC, will be bisected in this way. From the centre A, with some compass-opening, cut off equal straight lines AD, AE of any magnitude whatever. Then, without changing the compass (though you could vary it if you wished), from the centres D and E describe two arcs cutting each other at F. The straight line drawn AF will then bisect the angle BAC. For if the straight lines DF, EF were drawn, they would be equal, being the radii of equal circles. From this, as before, it will be demonstrated that the angle DAF is equal to the angle EAF. But we have not drawn the said lines, so that the bare practice might be shown — which we shall observe in the other practices too, as far as may be, lest a multitude of lines cast darkness over us and breed confusion.

Diagram. The practical bisection by arcs. Apex A; on the two rays the points D and E; two arcs struck from D and E crossing at F below; the rays continuing to B and C.

- Labels present: A, B, C, D, E, F.

But if ever a rectilineal angle contained by very short lines, and placed at the edge of some plane, must be bisected, we shall describe from D and E two arcs mutually intersecting at F *above* the angle A — because below the points D and E there is no space in which they could be drawn. For a straight line drawn out from F through A as far as B will bisect the angle A, as before, as appears in the adjoining figure.

Diagram. The edge-of-plane case. Point F at the top (where two arcs cross); the vertex A below it; the points D and E at the bottom; the bisecting line running down through A.

- Labels present: F, A, D, E (with B, the far endpoint of the produced bisector).

[Scholium]

From this it is plainly gathered that any rectilineal angle can be divided also into 4 equal angles, into 8, into 16, into 32, into 64, and so on, always proceeding by doubling. For once any rectilineal angle has been divided into two equal angles, if each of these be again bisected we shall have 4 equal angles; and if these singly be again bisected, we shall obtain 8 equal angles, and so on. Euclid nowhere taught by what method a rectilineal angle can be divided into any given number of equal parts, because up to that day this had been demonstrated by no one. From Pappus of Alexandria, however, we shall teach it, by means of a certain curved or bent line, at the end of Book 6. Meanwhile, if anyone should wish to divide any proposed rectilineal angle into any number of equal parts by rough rule of thumb (as it is said, by "native wit" [*rudī Minerva*]), he will have to use the compass — attempting, as it were, and often repeating the practice itself, until he reaches the desired end — in this manner. Let the rectilineal angle BAC be divided into 5 equal angles. From the centre A describe an arc of a circle BC, at any interval, cutting the straight lines AB, AC at B and C. Then, by means of the compass (widening its legs now more, now less, until they have the due distance), divide the arc into as many equal parts as the proposed angle is to be divided into — as in the example proposed, into five parts, at the points D, E, F, G. For if straight lines be drawn to these points from A, the angle BAC will be divided into five equal angles. For since the intervals BD, DE, etc., taken with the compass are equal, they will all be equal to one another. Therefore the two sides BA, AD of the triangle BAD [Margin: a — Book I, definition 15] will be equal to the two sides EA, AD of the triangle EAD, each to each, since all proceed from the centre out to the circumference. And the base BD is also equal to the base DE, as was said: [Margin: b — Book I, Prop. 8] therefore the angle BAD will be equal to the angle EAD. By the same reasoning it will be demonstrated that the angle EAD is equal to the angle EAF, and so of the rest. But it will be gathered more briefly, from proposition 27 of the third book, that all the angles at A are equal to one another, because the circumferences BD, DE, etc., were all taken equal to one another.

Let no one be surprised that we sometimes exhibit practices whose demonstrations depend on later propositions. For this we do, as we said above at definition 10, with the intent that, so far as may be, each matter be treated in its proper place — the division of any rectilineal angle into any number of equal parts, that is, in the place where Euclid teaches the division of the same angle into two equal parts; and the division of a straight line into any number of equal parts where Euclid divides that same line into two; and so of each. For such practices do not always require the following demonstrations, but only that it be proved that what was required has been rightly effected by them. Therefore he who, not content with the bare practice, requires a demonstration, will be able to go back

to any practice once he has carefully grasped the demonstrations necessary for it. For we shall always cite, in the demonstrations of our practices, those propositions which must be brought to bear on the matter — just as in the preceding practice we cited proposition 27 of the third book.

Diagram. The five-fold division of angle BAC. Apex **A** at top; an arc **B...C** below; on the arc the division points **D, E, F, G**; straight lines fanning from A to each division point.

- Labels present: A, B, C, D, E, F, G.

PROBL. 5. PROPOS. 10.

[Margin: x.]

[Euclid, Elements I.10 — enunciation] To bisect a given finite straight line.

[Clavius's demonstration] Let AB be a given finite straight line, to be bisected — that is, divided into two equal parts. [Margin: a — Book I, Prop. 1] Let an equilateral triangle ABC be described upon AB, and let its angle C be bisected [Margin: b — Book I, Prop. 9] by the straight line CD, and let the straight line CD cut the straight line AB at D. I say that the straight line AB is bisected at D. Since the two sides AC, CD of the triangle ACD are equal to the two sides BC, CD of the triangle BCD, each to each — namely AC to BC, since both are sides of the equilateral triangle, and CD is common — and the angle ACD is also equal to the angle BCD by construction: [Margin: c — Book I, Prop. 4] the base AD will be equal to the base BD. Therefore we have bisected the given straight line AB at D, which was what had to be done.

Diagram. The construction for bisecting the segment AB. Equilateral triangle with apex **C** at the top and base **A** (lower-left) to **B** (lower-right); the point **D** on the base with the line CD drawn from the apex.

- Labels present: A, B, C, D.

[Practice]

From the centre A, with any interval that nevertheless exceeds half the line AB, describe two arcs, one above, one below; and from the centre B, with exactly the same interval, draw two other arcs, which cut the former at C and D. For the straight line drawn CD will bisect the straight line AB at E. For if from A and B four straight lines be drawn to C and D, these will all be equal to one another, since they fall from the centres to the circumferences of equal circles — for the

arcs of the circles were described with the same interval. Since therefore the sides AC, CD are equal to the sides BC, CD, each to each, and the base AD to the base BD, [Margin: d — Book I, Prop. 8] the angle ACD will be equal to the angle BCD. Again, since the sides AC, CE are equal to the sides BC, CE, each to each, and the angle ACE to the angle BCE, as was shown, [Margin: a — Book I, Prop. 4] the base AE will be equal to the base BE.

Diagram. The practical bisection by intersecting arcs. The segment **A–E–B** horizontal (E the midpoint); above it the intersection point **C**, below it the intersection point **D**, where the arcs struck from A and B cross; the line CD drawn vertically through E.

- Labels present: A, B, C, D, E.

Now if the line to be bisected is placed at the edge of some plane, so that below it there is no space in which two intersecting arcs can conveniently be drawn, then, having described above it two arcs intersecting each other at C, we shall describe on the same side two other arcs intersecting each other at D — whether this be done below the point C, as in the adjoining figure, or above C. For the straight line drawn out through C, D will bisect the straight line AB at E.

Diagram. The edge-of-plane bisection (drawn with dotted arcs). Intersection point **C** at the top, a second intersection **D** lower down, and the segment **A–E–B** at the bottom, with the line through C and D meeting AB at the midpoint E.

- Labels present: A, B, C, D, E.

[Scholium]

It is clear that the same straight line AB can be divided in the same way into 4 equal parts, and into 8, 16, 32, etc., just as we said in the preceding proposition about the division of a rectilineal angle. But by what method any proposed straight line is to be divided into any number of equal parts, we shall set forth most fully at proposition 40 of this book. And the same thing we shall afterward accomplish far more easily at proposition 10 of Book 6, where we shall bring forward various and not unpleasant practices. For there seems to be the more proper place for this matter, since practices of this kind are almost all more easily demonstrated by the proportions of lines. Nor indeed, until that place, shall we ever need the division of a line into more than two equal parts.

PROBL. 6. PROPOS. 11.

[Margin: xj.]

[Euclid, Elements I.11 — enunciation] Given a straight line, from a given point on it, to erect a straight line at right angles [i.e., a perpendicular].

[Clavius's demonstration] Let AB be the given straight line, and C the point on it from which we are bidden to erect upon AB a line at right angles, that is, a perpendicular. From the point C [Margin: a — Book I, Prop. 3] take a straight line CD, and cut off CE equal to it. Then upon DE [Margin: b — Book I, Prop. 1] construct an equilateral triangle DEF, and from F draw the straight line FC to C, which I say is perpendicular to AB. Since the sides DC, CF of the triangle DCF are equal to the sides EC, CF of the triangle ECF, each to each — namely DC to EC by construction, and CF common — and the base DF is also equal to the base EF, because of the equilateral triangle: [Margin: c — Book I, Prop. 8] the angles at C contained by the said sides will be equal. [Margin: d — Book I, definition 10] Therefore each will be called a right angle, and so FC is a straight line perpendicular to AB. Given a straight line, therefore, from a given point on it, etc. Which was to be done.

Diagram. The construction of a perpendicular at C. The straight line running **A–D–C–E–B** (C the given point, D and E cut off equal on either side); above C the vertex F (apex of the equilateral triangle DEF), reached by dotted construction arcs; the line FC erected perpendicular.

- Labels present: A, B, C, D, E, F.

[Practice]

From the point C cut off on either side equal lines CD, CE, and from D and E describe two arcs cutting each other at F. For the straight line drawn FC will be the perpendicular. The demonstration is the same as Euclid's, if only the straight lines DF, EF be drawn, which will be equal because of the equal circles described from D and E, which intersect each other at the point F. But if the given point on the straight line be its extremity, the line must be produced straight and continuous, on the side of the given point, so that from it a perpendicular line may be erected according to the given practice. Thus, if the given line be AC and the given point C its extremity, AC must be prolonged to B, and equal lengths CD, CE taken, etc. But if a perpendicular is to be set up on some line, not indeed at an assigned point, but anywhere at all, this will be effected by this method. From two points A and E, whatsoever, of the proposed line, describe both above and below two arcs intersecting each other at C and D. For the straight line drawn CD will be perpendicular to AB — that is, it will make the two angles at E right, or equal. This you will prove no otherwise than as we demonstrated above at the practice by

which we divided a line into two equal parts. For by the 4th proposition the angles at E will be equal, inasmuch as they stand upon equal bases AE, BE, and are set opposite the equal sides AC, BC, which from C would be drawn to the points A and B.

Diagram. The practical perpendicular at a point. The line **A–D–C–E–B** with the given point C; the arcs struck from D and E crossing at **F** above; FC erected.

- Labels present: A, B, C, D, E, F.

Diagram. The perpendicular erected anywhere on a line. Intersection point **C** at the top, **D** at the bottom (arcs struck from two points of the line), the line **A–E–B** across the middle, and CD the perpendicular through E.

- Labels present: A, B, C, D, E.

(Continuing Proclus's additions to Proposition 11 — how to erect a perpendicular when the given point is the very endpoint of the line.)

If the given point on the line happens to be its endpoint, and the line cannot conveniently be extended, we can still draw a perpendicular from the given point without extending the line, by this method. Let AB be the straight line and A the point. From C, any point taken within the line, erect the perpendicular CD, as Euclid taught; and cut off CE equal to AC [Margin: a — *Elements* I.3]. Then bisect the angle C by drawing the straight line CF [Margin: b — *Elements* I.9]. Next, from E again, as Euclid taught, draw EG perpendicular to CD, meeting the straight line CF at G. Then the straight line GA, once drawn, will be perpendicular to AB. For since the sides AC, CG of triangle ACG are equal to the sides EC, CG of triangle ECG, each to each, and the angles contained by these sides are likewise equal, by construction, the angles A and E, which lie opposite the common side CG, will be equal [Margin: c — *Elements* I.4]. But E is a right angle by construction; therefore A too will be a right angle, and so AC is perpendicular to AB [Margin: d — *Elements* I, Def. 10].

Diagram. Construction for erecting a perpendicular from the endpoint of a line (Proclus's method). A rectangular framework stands on the baseline AB (solid horizontal). Dotted lines show the auxiliary construction: a diagonal from the upper-left down toward B, a horizontal line across the top, and a vertical on the right.

- A (bottom-left, on baseline AB): the given endpoint
- B (bottom-right, on baseline AB): far end of the line

- C (foot of the right-hand vertical, on AB near B): the point taken within the line
- D (top-right): upper end of the perpendicular CD
- E (right-hand vertical, below D): point with $CE = AC$
- F (top-left): end of the bisector CF
- G (upper-left): where EG meets CF; GA is the required perpendicular

SCHOLIUM

We shall erect a perpendicular from a given point more briefly — whether that point is an endpoint or not — in this way. Let AB be the given line and A a point on it. From a center C taken outside the line, wherever you please (provided that the straight line AB, when extended, does not pass through C), and with a radius reaching as far as A, describe an arc of a circle cutting AB at D. Then from D through C draw a straight line cutting the arc at E. The straight line EA, once drawn, will be perpendicular to AB. For angle A is a right angle, since it stands in the semicircle DAE, as we shall show in Proposition 31 of Book III.

You will find yet another construction, for when the given point is at the endpoint of the line, in the scholium to Proposition 31 of this Book.

Diagram. A semicircle standing on the diameter DE, with the required perpendicular EA drawn to the baseline AB.

- A (bottom-left, on line AB and on the circle): foot of the perpendicular
- B (right end of the baseline): far end of the given line
- C (center, upper): center of the arc
- D (bottom-right, on AB): where the arc first cuts AB
- E (top): the point where DC produced meets the arc; EA is perpendicular to AB

PROBL. 7. PROPOS. 12.

[Margin: xij.]

Enunciation.—To draw a perpendicular straight line to a given infinite straight line from a given point that is not on it.

Demonstration.—Let AB be a straight line of unlimited extent, and let C be a point outside it, from which a perpendicular is to be drawn to the straight line AB. With center C and any radius, describe a circle cutting AB at D and E — the radius chosen must be just large enough to reach across the straight line AB, otherwise it

would not cut it. Bisect the straight line DE at F [Margin: a — *Elements* I.10], and draw the straight line CF, which I say is perpendicular to AB. For if CD and CE are drawn, the two sides DF, FC of triangle DFC will be equal to the two sides EF, FC of triangle EFC, each to each, by construction; and the base CD is equal to the base CE, since these are drawn from the center C to the circumference. Therefore the angle DFC will be equal to the angle EFC [Margin: b — *Elements* I.8], and so each is a right angle. Thus CF has been drawn perpendicular, which was to be done.

Diagram. A circle with center C, cut by the horizontal line AB at D and E; F is the midpoint of DE, and CF is the perpendicular dropped from the external point.

- A (far left, on line AB): one end of the given line
- B (far right, on line AB): other end
- C (top center): the given external point / center of the circle
- D (left intersection of circle and AB)
- E (right intersection of circle and AB)
- F (center, on AB below C): midpoint of DE; CF is perpendicular to AB

SCHOLIUM

Euclid rightly appended the qualification "infinite." For if the line were finite, a perpendicular could not always be drawn to it from a given point outside it. For instance, if the finite line were BE and the point C, no circle could be described from C cutting BE in two points, and hence no perpendicular could be drawn from C to BE. For this reason, then, Euclid requires the given straight line to be infinite — that is, to have no determinate magnitude — so that a perpendicular can be dropped at least to the line produced. For that is what happens here: if BE is produced until the circle described from C cuts the whole of BA produced at D and E, and so on.

PRAXIS

With C made the center and any radius, describe two arcs cutting the given line at A and B. Then from A and B, with the same radius (or a different one, if you prefer), let two more arcs be described cutting each other at D. For the straight line CD, drawn so as to cut AB at E, will be perpendicular to AB. The demonstration of this operation does not differ from the one given in the praxis of Proposition 10; for the angles at E will be right angles [Margin: a — *Elements* I.4], being equal to one another.

Diagram. A vertical line CD crossing the horizontal AB at E, with the crossing arcs marked at C and D (small "x" intersections above and below).

- A (left, on AB)
- B (right, on AB)
- C (top): upper arc-intersection
- D (bottom): lower arc-intersection
- E (center, on AB): foot of the perpendicular CD

We shall accomplish the same thing in this way. From any point A on the given line, with a radius reaching to C, describe an arc of a circle. Then from any other point B, with a radius reaching to the same C, describe another arc cutting the first at C and D. The straight line CD drawn so as to cut AB at E will be perpendicular to AB. The demonstration is the same as the previous one. It is not necessary, however, that the radius BC be equal to the radius AC, as appears in this figure; yet the operation will be easier and shorter if the same radius is always used.

Diagram. A vesica (lens) formed by two intersecting arcs; the line CD through the two intersection points crosses AB at E.

- A (left, on AB)
- B (right, on AB)
- C (top): upper intersection of the arcs
- D (bottom): lower intersection
- E (center, on AB): foot of the perpendicular

Diagram. A pair of lens-figures drawn side by side, illustrating the case where the two radii (BC and AC) are unequal, so the two arc-pairs intersect at different points. Each half shows the labels C (top), E (center, on the baseline), and D (bottom), with A and B on the baseline. [The paired construction repeats the same five letters A, B, C, D, E in each half.]

When the given point C is too close to the straight line AB, we must proceed thus. With center C and any radius, cut the straight line AB at the two points A and B. From these, with any larger radius — greater than AC or BC — describe two arcs both above and below, intersecting each other at D and E. For the straight line DCE, which when produced necessarily passes through the point E, will be perpendicular to the straight line AB at F. We shall demonstrate this as follows, drawing the straight lines AD, BD, AC, BC. Since the two sides DA, DC of triangle ACD are equal to the two sides DB, DC of triangle BCD, and likewise the bases AC,

BC are equal, the angles at D will be equal [Margin: a — *Elements* I.8]. Therefore, since the two sides DA, DF of triangle ADF are equal to the two sides DB, DF of triangle DBF, and they contain equal angles at D as we have shown, the angles at F will be equal [Margin: b — *Elements* I.4], and so they are right angles, and so on.

Diagram. Two arcs crossing above and below the line AB, with the perpendicular DCF descending through the intersections; dotted lines mark triangle ACD (and its mirror).

- A (left, on AB)
- B (right, on AB)
- C (center, above F): the given point, close to AB
- D (top): upper arc-intersection
- E (bottom): lower arc-intersection (through which DCF passes when produced)
- F (on AB below C): foot of the perpendicular

(Continuing Proposition 12 — further constructions for special positions of the point and line.)

Now if the given point lies next to the edge of some plane, so that the given line cannot be extended, we shall proceed thus. From any point B — which appears to be placed roughly opposite the given point C, that is, nearly at the extremity of the given line AB — describe two arcs above and below the line AB, with radius BC. Then from a point A somewhat removed from the point B already taken (and the farther apart the points A and B are, the more conveniently the arc-intersections will be found), describe two other arcs with radius AC, cutting the earlier ones at C and D. For the straight line CD will be perpendicular to the given straight line AB.

But if, with a point given that is not near the edge of the plane on which the line lies, the line itself lies at the edge of the plane, so that two arcs cannot conveniently intersect below the line — whether the given point C is close to the line AB or not — we shall solve the problem in this way. With radius AC, taking A anywhere, describe from C an arc cutting the straight line AB at D; and from A and D describe two arcs toward the point C, intersecting each other at E. For the straight line drawn from E through C, cutting AB at F, will be perpendicular to AB, as was demonstrated above for the case when the point C was near the line AB.

Diagram. Two figures. The upper shows the line AB with a right-angle bracket: C above and D below at the right (the perpendicular CD). The lower shows a

vertical construction with C (given point) above the baseline, E at top from the intersecting arcs, and the perpendicular meeting AB at F, with arc-marks at the crossings.

- A (left, on AB)
- B (right end)
- C (given point, above AB / upper-right of the first figure)
- D (on AB, where the arc from C cuts it; also lower-right of the first figure)
- E (top, intersection of the arcs from A and D)
- F (on AB): foot of the perpendicular EC produced

As for how we should proceed when the given point lies next to one edge of the plane and the given line runs near the other edge — so that we may neither extend the line nor conveniently make two arcs intersect at D below the given straight line AB — we shall teach this in the scholium to Proposition 31 of this Book.

We shall also accomplish this in the following way. In the figure of the scholium to Proposition 11, let a perpendicular have to be drawn to the straight line AB from the point E, at the extremity of the line, as it were. Draw any straight line ED, and bisect it at C [Margin: a — *Elements* I.10 [?]; the printed digit is ambiguous]. With center C and passing through E, describe an arc of a circle cutting the given straight line at A. (Should it not cut it, the line must be produced until it is cut by the arc.) For the straight line EA will be perpendicular to AB, since the angle A, standing in a semicircle, is a right angle [Margin: b — *Elements* III.31].

Diagram. A semicircle on diameter DE; the perpendicular EA is drawn from E to the baseline AB.

- A (bottom-left, on AB and on the circle)
- B (right end of baseline)
- C (center, upper): center of the arc, midpoint of ED
- D (bottom-right, on AB)
- E (top): the given point from which EA descends

THEOR. 6. PROPOS. 13.

[Margin: xiiij.]

Enunciation.—When a straight line standing on a straight line makes angles, it will make either two right angles or angles equal to two right angles.

Demonstration.—Let the straight line AB, standing on the straight line CD, make two angles ABC, ABD. If AB is perpendicular to CD, the said angles will be two right angles [Margin: c — *Elements* I, Def. 10]. But if AB is not perpendicular, it will make one angle obtuse and the other acute. I say, then, that these two are equal to two right angles. For draw BE from B perpendicular to CD [Margin: d — *Elements* I.11], so that the two angles EBC, EBD are right angles. Now since the right angle EBD is equal to the two angles DBA, ABE [Margin: e — Axiom 19], then, adding the common right angle EBC, the two right angles EBD, EBC are equal to the three angles DBA, ABE, EBC [Margin: f — Axiom 2]. Again, since the angle ABC is equal to the two angles ABE, EBC [Margin: g — Axiom 19], then, adding the common angle ABD, the two angles ABC, ABD are equal to the three angles DBA, ABE, EBC [Margin: a — Axiom 2]. But we have shown that these same three are also equal to the two right angles EBD, EBC; and things equal to the same thing are equal to one another [Margin: b — Axiom 1]. Therefore the two angles ABC, ABD are equal to the two right angles EBD, EBC. So, when a straight line standing on a straight line makes a line, and so on. Which was to be shown.

Diagram. The line AB stands on the base line CD at B; BE is the auxiliary perpendicular to CD.

- A (top): upper end of the standing line AB
- B (center of the base line): foot where AB stands
- C (left end of the base line CD)
- D (right end of the base line CD)
- E (upper-left): end of the perpendicular BE

SCHOLIVM

This proposition seems to rest on a certain common notion of the mind. For by however much the angle ABC exceeds the right angle EBC, by just so much is the remaining angle ABD fallen short of by the right angle EBD. For as the excess there is the angle ABE, so here the deficit is that same angle ABE. Hence the angles ABC, ABD are proved equal to two right angles, since the one gains above a right angle exactly as much as the other loses.

THEOR. 7. PROPOS. 14.

[Margin: xiv.]

Enunciation.—If, with any straight line and at a point on it, two straight lines not lying on the same side make the adjacent angles equal to two right angles, the two straight lines will be in a straight line with one another.

Demonstration.—At the point C of the straight line AB, let two straight lines CD, CE be drawn on opposite sides, making with AB the two angles ACD, ACE either right angles or equal to two right angles. I say that CD and CE are set in a straight line, so that DCE is one straight line. For if DCE is not straight, then DC produced straight and continuous through C will fall either above CE, so as to make the straight line DCF, or below CE, so as to make the straight line DCG. If it falls above: since AC stands on the straight line DCF, the two angles ACD, ACF will be equal to two right angles [Margin: a — *Elements* I.13]; but the two angles ACD, ACE are also assumed equal to two right angles, and all right angles are equal to one another [Margin: b — Axiom 12]. Therefore the two angles ACD, ACF will be equal to the two angles ACD, ACE. So, taking away the common angle ACD, the angles ACF, ACE will remain equal to one another [Margin: c — Axiom 3] — the part to the whole, which is absurd. Therefore DC produced will not fall above CE; nor will it fall below, for by the same reasoning the angles ACE, ACG would be proved equal. Therefore DC produced will become the same as CE; and consequently, if with any straight line and at a point on it, and so on. Which was to be demonstrated.

Diagram. A fan of lines meeting at C on the line AB (A above, B below); CD runs left, while CE and the false continuations CF, CG spread to the right.

- A (top): upper part of the line AB through C
- B (just below C): lower part of AB
- C (center): the point on AB
- D (left): end of CD
- E (right): end of CE
- F (upper-right): false continuation DCF (above CE)
- G (lower-right): false continuation DCG (below CE)

SCHOLIVM

This proposition is the converse of the preceding. For in that one it was proved that if DCE is straight, the angles ACD, ACE are equal to two right angles. In this one it is demonstrated that if the said angles are equal to two right angles, the straight lines DC, EC are one straight line.

(Continuing the commentary on Proposition 14.)

Euclid rightly added to this proposition the words "and not on the same side." For, as Porphyry says, it can happen that two lines are drawn to some point of a given line on the same side, making with the given line two angles equal to two right

angles, which nevertheless do not form one straight line, precisely because they are not drawn to opposite sides. For let the point C be given on the line AB. Draw CD perpendicular to AB [Margin: d — *Elements* I.11], and bisect the right angle ACD by the straight line CE [Margin: e — *Elements* I.9 [?]; the printed digit reads like "11"]. Then from D, any point on the straight line CD, draw DE perpendicular [to CD] [Margin: f — *Elements* I.11]. Produce ED toward D and take DF equal to the straight line DE [Margin: g — *Elements* I.3], and draw the straight line FC. Now since the sides ED, DC of triangle EDC are equal to the sides FD, DC of triangle FDC, each to each, and the angles they contain are equal, namely right angles, the base EC will be equal to the base CF, and the angle ECD equal to the angle FCD [Margin: a — *Elements* I.4]. But the angle ECD is half a right angle (for the right angle ACD has been bisected). Therefore FCD too will be half a right angle. Hence CF makes with AC the angle ACF, composed of a right angle and half a right angle; and CE makes with the same AC the angle ACE, also half a right angle. Therefore the two angles ACF, ACE, which the straight lines CF, CE make on the same side with AB, are equal to two right angles — and yet CF, CE are not one straight line, because they are not drawn to opposite sides but to the same side.

Diagram. Porphyry's counter-example: at C on the line AB, the perpendicular CD, its bisector CE, and the auxiliary triangle giving CF, all falling on the same side.

- A (top-left): upper end of the line AB
- B (bottom-left): lower end of AB (AB roughly vertical on the left)
- C (center-left): the point on AB
- D (center-right): foot of the perpendicular direction CD
- E (top-right): end of the bisector CE
- F (bottom-right): end of the line CF (with DF = DE)

THEOR. 8. PROPOS. 15.

[Margin: xv.]

Enunciation.—If two straight lines cut one another, they will make the vertical angles equal to one another.

Demonstration.—Let the two straight lines AB, CD cut one another at the point E, however placed. I say that the angles they make at the vertex E are equal to one another — namely the angle AED to the angle BEC, and the angle AEC to the angle BED. Since the straight line DE stands on the straight line AB, the two angles AED, DEB will be equal to two right angles [Margin: b — *Elements* I.13]. Again, since the straight line BE stands on the straight line CD, by the same reasoning the two

angles CEB, BED will be equal to two right angles. Now since all right angles are equal to one another [Margin: c — Axiom 12], the two angles AED, DEB will be equal to the two angles DEB, BEC. Therefore, taking away the common angle DEB, the angle AED will remain equal to the angle BEC [Margin: d — Axiom 3]. By the same reasoning it will be confirmed that the angles AEC, BED are equal to one another. For the two angles AEC, CEB, which are equal to two right angles [Margin: e — *Elements* I.13], will be equal to the two angles DEB, BEC, which are equal to two right angles. Therefore, taking away the common angle BEC, the angles AEC, BED will remain equal to one another [Margin: f — Axiom 3]. So, if two straight lines cut one another, and so on. Which was to be shown.

Diagram. Two straight lines AB and CD crossing at E, forming the vertical-angle "X."

- A (top-left)
- B (bottom-right) — line AB
- C (bottom-left)
- D (top-right) — line CD
- E (center): the point of intersection

COROLLARIVM I.

From the demonstration of this theorem Euclid infers (following the view of Proclus, since other copies do not contain this corollary) that two straight lines cutting one another make, at the point of section, four angles equal to four right angles. For in the demonstration it was shown that both the two angles AED, DEB and the two angles AEC, CEB are equal to two right angles, by Proposition 13. Therefore all four angles set at E together amount to twice two right angles. Hence they are equal to four right angles.

COROLLARIVM II.

By the same reasoning we shall infer that all the angles set about one and the same point, however many they be, are equal to just four right angles. For if from E any number of other lines are drawn, those four angles set at E will merely be divided into more parts, which all taken together are exactly equal to their wholes [Margin: a — Axiom 19]. Since, then, those four angles are equal to four right angles by the first corollary, all the others taken together will likewise be equal to only four right angles. From this it is clear that the whole space surrounding any point in a plane is equivalent to four right angles, as many authors assert — because all the angles that can be set about that point are equal

to four right angles. In the same way it is established that any number of straight lines cutting one another make, at the point of section, angles equal to four right angles.

EX PROCLO.

Enunciation.—If, with any straight line and at a point on it, two straight lines not taken on the same side make the vertical angles equal, the straight lines will be in a straight line with one another.

Demonstration.—From the point C of the straight line AB, let two straight lines CD, CE go out on opposite sides, making the angles ACE, BCD equal to one another (or else the two angles ACD, BCE). I say that the two lines CD, CE make one straight line. For since the angle ACE is equal to the angle BCD, then, adding the common angle BCE, the two angles ACE, ECB will be equal to the two angles DCB, BCE [Margin: b — Axiom 2]. But the angles ACE, ECB are equal to two right angles [Margin: c — *Elements* I.13]. Therefore the two angles DCB, BCE are also equal to two right angles. Hence CD, CE will be one straight line [Margin: a — *Elements* I.14]. This, as you see, is the converse of Proposition 15.

Diagram. The straight lines meeting at C form the vertical-angle "X"; CD and CE are shown to lie in one straight line.

- A (top-left)
- B (bottom-right)
- C (center): the point on AB
- D (bottom-left)
- E (top-right)

EX PELETARIO.

Enunciation.—If four straight lines going out from one point make the pairs of opposite angles equal to one another, then any two opposite lines will be joined into a straight and continuous line.

Demonstration.—From the point A let four lines AB, AC, AD, AE be drawn, making the two opposite angles BAE, CAD equal to one another, and likewise the two opposite angles BAC, DAE equal to one another. I say that BA, AD make one straight line, and so do CA, AE. Since the angles BAE, CAD are equal, if to them are added the equal angles BAC, DAE, the two angles BAE, BAC will be equal to the two angles CAD, DAE [Margin: b — Axiom 2]. Therefore both this pair and that are half of the four angles set about the point A. But these four are equal to four

right angles, by the second corollary of the preceding proposition. Therefore the two angles BAE, BAC are equal to two right angles; and so CA, AE will make one straight line [Margin: c — *Elements* I.14]. In the same manner it will be shown that BA, AD make one straight line. For by the same reasoning the two angles BAE, EAD will be equal to the two angles DAC, CAB. Hence, as before, the proposition will be concluded. Peletier, however, demonstrates this same thing by an argument leading to what cannot be — a *reductio ad absurdum*. We, nonetheless, have with very good reason set our own direct demonstration before his.

Diagram. Four straight lines radiating from the central point A to B, C, D, E, with BAD forming one straight line and CAE the other.

- A (center): the common point of origin
- B (top-left)
- C (top-right)
- D (bottom): opposite B, so that BAD is straight
- E (bottom-left): opposite C, so that CAE is straight

THEOR. 9. PROPOS. 16.

[Margin: xvj (16)]

(*Enunciation.*) In any triangle, if one of its sides is produced, the exterior angle is greater than either of the interior and opposite angles.

(*Demonstration.*) Let side BA of triangle ABC be produced to D. I say that the exterior angle DAC is greater than the interior and opposite angle ABC, and likewise greater than the interior and opposite angle ACB. Bisect AC at E [Margin: a — I.10], and from B, through E, draw the line BEF so that the segment EF cut off is equal to the straight line EB [Margin: b — I.3]; then draw the line FA. Now the sides CE, EB of triangle CEB are equal to the sides AE, EF of triangle AEF, each to each, by the construction; and the angles at E contained by these sides are equal to one another [Margin: c — I.15], being vertical angles about the point E. Therefore the base CB will be equal to the base AF, and angle ECB to angle EAF [Margin: d — I.4]. But the exterior angle DAC is greater than angle EAF — the whole being greater than its part. Therefore the exterior angle DAC is greater than the interior and opposite angle ACB.

Now if side CA is produced to G, and AB is bisected at H, and the line CHI is drawn so that HI is equal to the straight line HC, and the line IA is drawn, it will be

shown by exactly the same reasoning that the exterior angle GAB is greater than the interior and opposite angle ABC. But angle DAC is equal to angle GAB [Margin: e — I.15], since the lines BD and CG cut one another at A. Therefore angle DAC is also greater than the interior and opposite angle ABC. And this same angle DAC was likewise shown to be greater than the interior and opposite angle ACB. Therefore, in any triangle, when one side is produced, and so on. Which was to be demonstrated.

Diagram. The construction figure for Proposition 16. A triangle ABC lies at the center, with side BA produced upward to D and side CA produced upward-left to G; two auxiliary lines cross the figure.

- G (top left): endpoint of side CA produced
- A (top center): apex of the triangle, the common vertex
- D (top right): endpoint of side BA produced
- I (far left): endpoint of the line CHI (with HI = HC)
- H (center-left): midpoint of AB
- E (center): midpoint of AC
- F (right): endpoint of the line BEF (with EF = EB)
- B (bottom left): base vertex
- C (bottom right): base vertex

SCHOLIUM.

Euclid did not say that the exterior angle DAC is greater than the interior angle BAC adjacent to it, but only that it exceeds in magnitude either of the interior and opposite angles ACB, ABC. For an exterior angle can be equal to its adjacent interior angle — namely when the exterior angle is right, since then the adjacent angle is necessarily right as well. It can also be smaller, namely when it is acute; for on that supposition the adjacent angle will be obtuse. Only when the exterior angle is obtuse, then, will it exceed its adjacent interior angle, since that adjacent angle will then necessarily be acute. All of this is easily gathered from Proposition 13, by which an exterior angle together with its adjacent interior angle is equal to two right angles.

As for what we undertook to demonstrate in the scholium to Proposition 6 of this book — namely that this proposition cannot be converted, since an exterior angle can be greater than any interior and opposite one — we shall now resolve it by the case of a quadrilateral figure, one side of which is produced, in which the exterior angle is greater than any interior and opposite one.

Let ABCD be a quadrilateral figure whose angle BAD is constructed obtuse and whose angle ABC is constructed right, on this condition: that the sides AB, DC, produced toward the parts B and C, meet at a point E, and likewise the sides DA, CB, produced toward the parts A and B, meet at a point F. This will come about if an obtuse-angled triangle ADE is constructed, and, DA being produced toward A, a perpendicular FB is drawn from any point F to AE, cutting side DE at C. I say that, if AD is produced to G, the exterior angle CDG is greater than any of the three interior angles BAD, ABC, BCD opposite to it. For since ADE is a triangle, the exterior angle EDG is greater than the interior opposite angle DAE [Margin: a — I.16]. Again, since DAB is obtuse and greater than the right angle ABC, EDG will also be much greater than ABC. Finally, since in triangle CDF the exterior angle CDG is greater than the interior and opposite angle FCD [Margin: b — I.16], it is manifest that in the quadrilateral ABCD the exterior angle CDG is greater than the interior and opposite angles BAD, ABC, BCD. Therefore this Proposition 16 cannot be converted, since its antecedent and consequent are not reciprocal, as has been demonstrated.

Diagram. The quadrilateral figure of the scholium. Quadrilateral ABCD is embedded in triangle ADE, whose base is the horizontal line FADG; the perpendicular FB rises to meet side DE at C.

- E (top left): the meeting point of AB and DC produced
- C (upper center): the point where the perpendicular FB meets DE
- B (left, below E): the foot on the perpendicular
- F (bottom left): the point from which the perpendicular is dropped
- A (bottom center-left): obtuse-angle vertex of the quadrilateral
- D (bottom center): vertex
- G (bottom right): endpoint of AD produced

EX PROCLO.

It follows from this proposition that from the same point to one and the same straight line no more than two equal straight lines can be drawn. For if it were possible, let three equal straight lines AB, AC, AD be drawn from A to the line BC. Then since the sides AB, AC are equal, the angles ACB and ABC on the base BC will be equal [Margin: a — I.5]. Again, since the sides AB, AD are equal, the angles ADB and ABD on the base BD will be equal [Margin: b — I.5]. Therefore, since each of the angles ACD and ADB is equal to angle ABC [Margin: c — Ax. 1 (pron.)], angle ADB will be equal [to angle ACB] [?] — an exterior angle equal to the interior and opposite one — which is absurd, since by this Proposition 16 the exterior is

greater than the interior. Therefore no more than two equal straight lines, drawn between one another as equals, can be drawn from A to BC. Which was the thing proposed.

Diagram. The tall narrow figure for Proclus's corollary. From apex A three lines descend to the base line BC, meeting it at closely spaced points.

- A (apex): the external point
- B (base, left): base endpoint
- D (base, center-right): point where the third line AD meets the base
- C (base, right): base endpoint

PROBL. 10. PROPOS. 17.

[Margin: xvij (17)]

(Enunciation.) In any triangle, any two of its angles, taken in any combination, are less than two right angles.

(Demonstration.) Let ABC be a triangle. I say that the two angles ABC and ACB are less than two right angles; likewise the two angles CBA and CAB; and likewise the two angles BAC and BCA. For let any two sides, namely CB and CA, be produced to D and E. Since, then, the exterior angle ABD is greater than the interior and opposite angle ACB [Margin: d — I.16], if the common angle ABC is added, the two angles ABD, ABC will be greater than the two angles ABC, ACB [Margin: e — Ax. 4 (pron.)]. But ABD, ABC are equal to two right angles [Margin: f — I.13]. Therefore ABC, ACB are less than two right angles.

By the same reasoning the angles CBA and CAB will be less than two right angles. For since the exterior angle ABD is greater than the interior and opposite angle CAB [Margin: g — I.16], then, adding the common angle ABC, the two angles ABD, ABC will be greater than the two angles CAB, CBA [Margin: h — Ax. 4 (pron.)]. And since those two are equal to two right angles [Margin: i — I.13], these other two will be less than two right angles.

In just the same way we shall show that the two angles BAC, BCA are less than two right angles. For since the exterior angle BAE is greater than the interior and opposite angle BCA [Margin: m — I.16], if the common angle BAC is added, the two angles BAE, BAC will be greater than the two angles BCA, BAC [Margin: n — Ax. 4 (pron.)]; and therefore, since those two are equal to two right angles

[Margin: o — I.13], these two will be less than two right angles. Therefore in any triangle, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 17. Triangle ABC has side CB produced beyond B to D and side CA produced beyond A to E.

- E (top): endpoint of side CA produced
- A (apex): the upper vertex
- D (bottom left): endpoint of side CB produced
- B (bottom, right of D): base vertex
- C (bottom right): base vertex

EX PROCLO.

From this it is evident that from the same point to the same straight line no more than one perpendicular can be drawn. For if it were possible, let two perpendiculars AB, AC be drawn from A to the straight line BC. Then in triangle ABC the two interior angles B and C will be equal to two right angles, since they are both right — which is absurd. For any two angles in any triangle have been shown to be less than two right angles [Margin: a — I.17]. Therefore no more than one perpendicular can be drawn from A to BC. Which was the thing proposed.

Diagram. A small figure showing the assumed pair of perpendiculars. From apex A two lines descend to the horizontal base, meeting near a point marked C.

- A (apex): the external point
- B (base): one foot (barely distinguished from C on the short base)
- C (base right): the other foot

COROLLARIVM I.

It is also clear from this that in every triangle having one right or obtuse angle, the remaining angles are acute, as we noted at Definition 26 of this book. For since, by this proposition, any two angles are less than two right angles, it is necessary that, if one is right or obtuse, each of the rest be acute — otherwise we should have to admit two right angles in a triangle, or angles greater than two right angles.

COROLLARIVM II.

It also follows from this proposition that, if a straight line makes unequal angles with another straight line — one acute and the other obtuse — the perpendicular

dropped from any point of it to that other line falls on the side of the acute angle. For let the straight line AB make with the straight line CD unequal angles, namely ABD acute and ABC obtuse, and from the point A let a perpendicular AD be dropped to CD at any point. I say that AD falls on the side of the acute angle ABD. For if it does not fall on the side of angle ABD, let it fall, if possible, on the side of the obtuse angle ABC. Then the two angles ABC and ACB — the one obtuse, the other right — in triangle ABC would be greater than two right angles; but they are also less than two right angles [Margin: b — I.17], which is absurd. Therefore the perpendicular drawn from A to CD does not fall on the side of the obtuse angle. Hence it falls on the side of the acute angle.

Diagram. The figure for Corollary II. An obtuse triangle rises from the horizontal line CD, with apex A and the perpendicular from A to the line.

- A (apex): the point from which the perpendicular is dropped
- C (base left): endpoint of the line CD
- B (base center): the point of intersection on CD
- D (base right): the assumed foot of the perpendicular

COROLLARIVM III.

By the same reasoning it becomes manifest from this proposition that all the angles of an equilateral triangle, and the two angles of an isosceles triangle above its base, are acute. For since both any two angles in an equilateral triangle and the two above the base in an isosceles triangle are equal to one another [Margin: c — I.5], and since at the same time both those two and these are less than two right angles [Margin: d — I.17], each of them will be less than a right angle, that is, acute. For if it were right or obtuse, both together would be equal to, or greater than, two right angles.

THEOR. 11. PROPOS. 18.

[Margin: xvij (18)]

(Enunciation.) The greater side of any triangle subtends the greater angle.

(Demonstration.) In triangle ABC let side AC be greater than side AB. I say that angle ABC, subtended by the greater side AC, is greater than angle ACB, which is subtended by the lesser side AB. For from AC let AD be cut off equal to AB [Margin: a — I.3], and let the line BD be drawn. Since, then, the two sides AB, AD are equal by construction, the angles ABD, ADB will be equal [Margin: b — I.5].

But angle ADB is greater than angle ACB [Margin: c — I.16]. Therefore angle ABD is also greater than angle ACB. And since the whole angle ABC is still greater than angle ABD [Margin: d — Ax. 9 (pron.)], angle ABC will be much greater than angle ACB. By the same reasoning, if side AC is supposed greater than side BC, you will show that angle ABC is greater than angle BAC — namely, if a line equal to CB is cut off from CA, and so on. Therefore the greater side of any triangle subtends the greater angle. Which was to be demonstrated.

Diagram. The figure for Proposition 18. Triangle ABC with apex A; the point D lies on side AC, and BD is drawn.

- A (apex): the upper vertex
- D (on side AC): the point where AD (= AB) is cut off
- B (bottom left): base vertex
- C (bottom right): base vertex

COROLLARIVM.

From this it follows that all three angles of a scalene triangle are unequal, as we noted at Definition 15 of this book. For let ABC be a scalene triangle whose greatest side is AC, whose least is BC, and with AB holding the middle place. I say that all its angles are unequal. For since side AC is supposed greater than side AB, by this proposition angle B will be greater than angle C. By the same reasoning angle C will be greater than angle A, since side AB is also supposed greater than side BC. Therefore all three angles are unequal — B the greatest, A the least, and C holding the middle place between the two.

Diagram. A small right-angled scalene triangle.

- A (apex): upper vertex
- B (bottom left): base vertex
- C (bottom right): base vertex

THEOR. 12. PROPOS. 19.

[Margin: xix (19)]

(Enunciation.) In any triangle the greater angle is subtended by the greater side.

(Demonstration.) In triangle ABC let angle B be greater than angle C. I say that side AC, subtending the greater angle B, is greater than side AB, which subtends the lesser angle C. For if side AC is not greater than side AB, it is either equal to it

or less. If AC be said to be equal to AB, then angle B will be equal to angle C [Margin: a — I.5]; but it is also greater, by hypothesis, which is absurd. But if AC be said to be less than side AB, then angle B, subtended by the lesser side AC, will be less than angle C, subtended by the greater side AB; yet it is supposed greater, which is even more absurd. Since, therefore, side AC is neither equal to side AB nor less than it, it is greater. By the same reasoning it will be proved that side AC is greater than side BC, if angle B is granted greater than angle A. Therefore in any triangle the greater angle is subtended by the greater side. Which it was proposed to demonstrate.

Diagram. The plain triangle for Proposition 19. A tall triangle with apex A over base BC. (Faint mirrored letters visible around the figure are show-through from the facing folio.)

- A (apex): the vertex at the greater angle
- B (bottom left): base vertex at the greater angle
- C (bottom right): base vertex at the lesser angle

COROLLARIVM.

It follows from this proposition that, of all the straight lines drawn from any point to a straight line, the one that is perpendicular is the least. For let lines AD, AE, AF, and others be drawn from the point A to the straight line BC, of which AD alone is perpendicular to BC — and no other can be, since from the same point to the same straight line only one perpendicular can be drawn, as we demonstrated after Proposition 16 from Proclus. I say that AD is the least of them all. For in triangle AED, since the two angles ADE, AED are less than two right angles [Margin: b — I.17], and ADE is set right, AED will be acute. Therefore side AE will be greater than side AD [Margin: c — I.19].

Diagram. The figure for the corollary on the least (perpendicular) line. From apex A several lines descend to the base line BC, meeting it at the points F, E, D in order; AD is the perpendicular.

- A (apex): the external point
- B (base left): endpoint of the base
- F (base): foot of line AF
- E (base): foot of line AE
- D (base): foot of the perpendicular AD
- C (base right): endpoint of the base

In the same way we shall show that all the other straight lines are greater than the straight line AD; and hence the perpendicular AD will be the least of all.

EX PROCLO.

We can also demonstrate this same theorem by a direct, affirmative demonstration, without the aid of the preceding one — provided, however, that the following theorem is first demonstrated:

(Enunciation.) If an angle of a triangle is bisected, and the straight line that bisects the angle, drawn to the base, divides it into unequal parts, then the sides containing that angle will be unequal — the greater being the one that coincides with the greater segment of the base, the lesser being the one that coincides with the lesser segment.

(Demonstration.) In triangle ABC let angle BAC be bisected by the straight line AD, which cuts the base BC into unequal parts, and let DC be the greater segment. I say that side AC is greater than side AB. For let AD be produced to E [Margin: a — I.3] so that DE is equal to AD. Then from the greater segment DC let the straight line DF be cut off equal to the lesser segment DB, and through F, from E, let the straight line EFG be produced. Since, then, the sides AD, DB of triangle ADB are equal to the sides ED, DF of triangle EDF, each to each, by construction — and the angles ADB, EDF contained by these sides are equal [Margin: b — I.15] — the bases AB and EF will be equal, and angle FED equal to angle BAD [Margin: c — I.4]. But angle CAD is also equal to angle BAD, by hypothesis. Therefore the angles CAD, GEA of triangle AGE will be equal [Margin: d — Ax. 1 (pron.)]; and hence the sides AG, EG will be equal [Margin: e — I.6]. But the straight line AC is greater than AG; therefore AC is also greater than EG. And since EG is greater than EF, AC will be much greater than EF. Since, then, it has been demonstrated that the straight line EF is equal to the straight line AB, side AC will be greater than side AB. Which was to be shown.

Diagram. The figure for Proclus's theorem. Triangle ABC with apex A; the bisector AD meets base BC at D and is produced downward to E; the line EFG crosses through F.

- A (apex): the bisected-angle vertex
- G (right, on side / on EFG produced): endpoint of the line EFG
- F (center): point on the base region where DF (= DB) ends and EFG passes
- B (bottom left): base vertex
- D (base center): point where the bisector meets the base

- C (base right): base vertex
- E (bottom, below D): endpoint of AD produced ($DE = AD$)

With this theorem established, Proposition 19 will be demonstrated as follows. In triangle ABC let angle ABC be greater than angle C. I say that side AC is greater than side AB. For let the straight line BC (upon which the said unequal angles are set) be bisected at D; from A, through D, let the straight line ADE be produced [Margin: f — I.3] so that DE is equal to AD, and let the line BE be drawn. Since, then, the sides AD, DC of triangle ADC are equal to the sides ED, DB of triangle EDB, each to each, by construction — and the angles ADC, EDB contained by these sides are equal [Margin: g — I.15] — the bases AC and BE will be equal, and angle ACD equal to angle EBD [Margin: a — I.4]. And since angle ACD is supposed less than angle ABC, angle EBD will also be less than that same angle ABC. Hence angle ABE will be divided by the straight line BD into unequal parts. If, then, it is bisected by the straight line BF, BF will fall above ED, because angle ABD is greater than angle EBD [Margin: b — Ax. 9 (pron.)]. And since EF is greater than ED — and ED was set equal to AD — EF will be greater than AD. But AD is still greater than AF [Margin: c — Ax. 9 (pron.)]. Therefore EF will be much greater than AF. And so, since the straight line BF, bisecting angle ABE, cuts the base AE unequally at F — the greater segment being EF and the lesser AF — by the theorem just demonstrated from Proclus, side BE will be greater than side AB. But BE was shown to be equal to side AC. Therefore side AC will also be greater than side AB. Which was to be demonstrated.

Diagram. The figure for the direct demonstration of Proposition 19. Triangle ABC with apex A; base BC is bisected at D and AD produced to E, with BF drawn and F marked on line AE.

- A (apex): the vertex
- F (center): the point where BF meets AE
- B (bottom left): base vertex
- D (base center): midpoint of BC
- C (bottom right): base vertex
- E (bottom, below D): endpoint of AD produced ($DE = AD$)

SCHOLIUM.

This Proposition 19 is the converse of Proposition 18, as is evident. Campanus [Campanus of Novara], however, entirely inverts the order of these two propositions, so that the one that with us is 18 is 19 with him, and vice versa. He

demonstrates both by reduction to the impossible, whereas Euclid confirmed Proposition 18 directly and affirmatively, as is clearly plain from what has been said.

We can also convert the theorem demonstrated from Proclus, in this way:

(Enunciation.) If two sides of a triangle are unequal, the straight line that bisects the angle contained by them will cut the base into unequal parts, and the greater segment will be next to the greater side.

(Demonstration.) Let the two sides AB, AC of triangle ABC be unequal — AC the greater and AB the lesser. And let the straight line AD, bisecting angle BAC, cut the base BC at D. I say that segment DC is greater than segment DB. For if it is not greater, it is either equal or less. If it be said to be equal, produce AD to E [Margin: a — I.3] so that DE is equal to DA, and draw the line EC. Since, then, the sides AD, DB are equal to the sides ED, DC, each to each — namely ED by construction and DC by the adversary's hypothesis — and the angles at D contained by these sides are equal [Margin: b — I.15], the base AB will be equal to the base EC, and angle BAD to angle CED [Margin: c — I.4]. But angle CAD was also set equal to angle BAD. Therefore the angles CED, CAD will be equal; and hence side AC is equal to side EC [Margin: d — I.6]. Since, then, it has been shown that side AB is also equal to side EC, the sides AC, AB will be equal [Margin: e — Ax. 1 (pron.)] — which is absurd, since AC was supposed greater than AB. Therefore segment DC will not be equal to segment DB. But if DC be said to be less, and DB greater, then by Proclus's theorem side AB will be greater than side AC; yet it was supposed less, which is much more absurd. Therefore DC will not be less than DB. Hence it must necessarily be greater. In the same way this theorem can also be demonstrated.

Diagram. The figure for the converse (POTERIMVS) theorem. Triangle ABC with apex A; the bisector AD meets base BC at D and is produced downward to E, with EC drawn.

- A (apex): the bisected-angle vertex
- B (bottom left): base vertex
- D (base center): point where the bisector meets the base
- C (bottom right): base vertex
- E (bottom, below D): endpoint of AD produced ($DE = DA$)

(Enunciation.) If a straight line bisecting an angle of a triangle also bisects the base, the two sides containing the angle will be equal to one another; and if the sides are equal, the straight line that bisects the angle will also bisect the base.

(Demonstration.) First, let the straight line AD, bisecting angle BAC, also bisect the base BC at D. I say that the sides AB, AC are equal to one another. We shall demonstrate this by the same reasoning by which, in the preceding theorem, it was shown that side AC is equal to side AB when segment DC is set equal to segment DB — provided you construct the figure in the same way. For since the sides AD, DB are equal to the sides ED, DC [Margin: a — I.15], and the angles at D contained by these sides are equal [Margin: b — I.4], the bases AB, EC will be equal, and angle CED equal to angle BAD — that is, to angle CAD. Therefore AC will be equal to EC [Margin: c — I.6], that is, to AB.

Next, let the sides AB, AC be equal, and let the straight line AD, cutting the base BC at D, bisect angle BAC. I say that segment DC is equal to segment DB. For since the sides AD, AB are equal to the sides AD, AC, each to each, and the angles at A contained by these sides are also equal by hypothesis, the bases BD, DC will be equal [Margin: d — I.4].

Diagram. The figure for the PRIMVM theorem. Triangle ABC with apex A; AD bisects both the angle and the base BC at D and is produced downward to E.

- A (apex): the bisected-angle vertex
- B (bottom left): base vertex
- D (base center): midpoint of the base
- C (bottom right): base vertex
- E (bottom, below D): endpoint of AD produced

Theorem 13. Proposition 20.

[Margin: xx (proposition index)]

In every triangle two sides, taken in any way whatever, are greater than the remaining side.

Demonstration (Clavius). Let ABC be a triangle. I say that any two of its sides — say AB and AC together — are greater than the remaining side BC. Let one of them, say CA, be produced to D, and let the straight line AD be made equal to the other, unproduced side AB [Margin: c, 3. primi = Elem. I.3]; and let the straight line DB be drawn. Since, then, the two sides AB and AD are equal to one another by construction, the angles ABD and ADB are equal to one another [Margin: f, 5. primi = Elem. I.5]. But the angle CBD is greater than the angle ABD [Margin: g, 9. pron. = Axiom 9, the whole is greater than the part]; therefore the angle CBD is also greater than the angle ADB. So in triangle CBD the side CD, which lies

opposite the greater angle, will be greater than the side BC, which lies opposite the smaller angle CDB [Margin: h, 19. primi = Elem. I.19].

Now the two sides AB and AC together are equal to CD — for if to the equals AB and AD the common AC is added, the wholes become equal [Margin: i, 2. pron. = Axiom 2], namely the line composed of AB and AC and the line composed of AD and AC. Therefore the two sides AB and AC together are also greater than the side BC. In the same way it will be shown that any other two sides are greater than the remaining one. Therefore in every triangle two sides are greater than the remaining side, and so on. Which was to be demonstrated.

Diagram. The main figure for Proposition 20. A triangle with apex D at the top; from D two lines descend to B (bottom-left) and to C (bottom-right). Point A lies on the right-hand descending line (the side CA produced to D), so that CA extended reaches D with AD = AB. The line DB is drawn across the interior.

- D (top apex): endpoint of CA produced, with AD = AB
- A (on the right side, between D and C): the triangle's upper-right vertex
- B (bottom-left vertex)
- C (bottom-right vertex)

From Proclus.

This theorem is demonstrated otherwise by the associates of Hero [Hero of Alexandria] and Porphyry [Porphyry], without producing any side, in the following way. Suppose we must prove that the two sides AB and AC of triangle ABC are greater than the side BC. Let the angle BAC contained by those sides be bisected by the straight line AD [Margin: a, 9. primi = Elem. I.9]. Since in triangle CDA the side CD is produced to B, the exterior angle BDA will be greater than the interior and opposite angle CAD [Margin: b, 16. primi = Elem. I.16]; hence it is also greater than the angle BAD. So in triangle ABD the side AB, opposite the greater angle ADB, will be greater than the side BD, which is opposite the smaller angle BAD [Margin: c, 19. primi = Elem. I.19]. By the same reasoning it will be shown that the side AC is greater than CD, because the angle CDA is greater than the angle BAD — that is, than the angle CAD [Margin: d, 16. primi = Elem. I.16] — and so on. Therefore the two sides AB and AC will be greater than the side BC. And the same reasoning holds for any two sides, provided the angle they contain is bisected.

Diagram. The small figure for the Proclus alternative. A triangle with apex A at the top; its base runs B (left) — D (middle) — C (right). The line AD is the bisector of angle BAC, meeting the base at D.

- A (top apex): vertex of the bisected angle
- B (bottom-left base endpoint)
- D (foot of the bisector, on the base between B and C)
- C (bottom-right base endpoint)

Theorem 14. Proposition 21.

[Margin: xxj (proposition index)]

If on one side of a triangle two straight lines be constructed internally from its extremities, these constructed lines will be less than the remaining two sides of the triangle, but will contain a greater angle.

Demonstration (Clavius). In triangle ABC let two straight lines BD and CD be constructed inside the triangle upon the extremities B and C of the side BC, meeting at the point D. I say that BD and CD together are less than the two sides BA and CA together, but that the angle BDC is greater than the angle BAC. For let one of the interior lines, namely BD, be produced to the point E on the side CA.

Since in triangle BAE the two sides BA and AE are greater than the side BE [Margin: e, 20. primi = Elem. I.20], if the common EC is added, BA and AC will be greater than BE and EC [Margin: a, 4. pron. = Axiom 4]. Again, since in triangle CED the two sides CE and ED are greater than the side CD [Margin: b, 20. primi = Elem. I.20], if the common DB is added, CE and EB will be greater than CD and DB [Margin: c, 4. pron. = Axiom 4]. But it has already been shown that AB and CA are greater than BE and EC. Therefore BA and CA are much greater than BD and CD — which was the first point proposed.

Moreover, since the angle BDC is greater than the angle DEC — an exterior angle greater than the interior one [Margin: d, 16. primi = Elem. I.16] — and the angle DEC is likewise greater than the angle BAC, for the same reason, the angle BDC will be much greater than the angle BAC — which was the second point proposed. So, if on one side of a triangle two lines are constructed from its extremities, and so on. Which was to be shown.

Diagram. The main figure for Proposition 21. A triangle with apex A; B at bottom-left, C at bottom-right. From B and C two interior lines run to the point D inside the triangle; the line BD is produced beyond D to E, which lies on the side AC.

- A (top apex)
- E (on the side AC, below A): where BD produced meets CA
- D (interior point): where BD and CD meet
- B (bottom-left vertex)
- C (bottom-right vertex)

Scholium.

How rightly Euclid said that those two lines constructed inside the triangle must be drawn from the extremities of one side can be clearly understood from what we shall presently demonstrate from Proclus: namely, that in right-angled triangles, or even obtuse-angled ones [amblygonia, obtuse-angled], two lines can be constructed inside the triangle upon one side, about the right or the obtuse angle — one drawn from the extremity of that side, the other from any point near the other extremity of the same side — which are greater than the remaining two sides of the triangle. Likewise, that in scalene triangles two straight lines can in the same way be constructed inside the triangle upon the greatest side, which contain a smaller angle, and so on.

From Proclus.

Let there be a triangle having, for example, the angle ABC obtuse. I say that from the extremity C, and from any point — say D — near the other extremity B of the side BC, two lines can be drawn inside the triangle to some point, which are greater than the two sides BA and AC. For let the straight line DA be drawn. Since in triangle ABD the two angles ABD and ADB are less than two right angles [Margin: e, 17. primi = Elem. I.17 — printed digit at the scan floor], and ABD is assumed obtuse, ADB will be less than a right angle, and therefore less than the angle ABD. Hence the side AD will be greater than the side AB [Margin: a, 19. primi = Elem. I.19]. From DA let the straight line DE be cut off equal to AB [Margin: b, 3. primi = Elem. I.3], and let the remaining line AE be bisected at F [Margin: c, 10. primi = Elem. I.10].

If, then, a straight line CF is drawn from the extremity C to F, the two constructed straight lines CF and DF inside the triangle will be greater than the two sides BA and AC. For in triangle AFC the two sides AF and FC are greater than the side AC [Margin: d, 20. primi = Elem. I.20]; but AF is equal to FE by construction, so CF and FE together are likewise greater than the side CA. So if the equals ED and AB are added, the straight lines CF and FD become greater than the sides CA and AB [Margin: e, 4. pron. = Axiom 4]. Which is what was proposed. But if a straight line

were drawn to F from the extremity B, the two constructed straight lines CF and BF would be less than the two sides CA and AB, as Euclid demonstrated.

Diagram. The first Proclus figure, an obtuse triangle. A at top-left, B at bottom-left (the obtuse angle is at B), C at bottom-right. D is a point on BC near B; DA is drawn; DE (with $DE = AB$) is cut off along DA; the line CF runs from C to F. Dotted compass-arcs near the top mark the bisection.

- A (top-left apex)
- B (bottom-left vertex, obtuse angle)
- C (bottom-right vertex)
- D (on BC, near B)
- E (on DA, between A and D)
- F (bisection point of AE) [?] — indicated by dotted construction arcs; the letter itself is not clearly legible

Diagram. The second Proclus figure, a scalene triangle. A at top; B at bottom-left; the greatest side BC runs to the bottom-right vertex; D lies on BC near B (with $BD = AB$); AD is drawn; E is a point on AD; CE is drawn from C.

- A (top apex)
- B (bottom-left vertex)
- D (on BC, near B)
- E (on AD)
- C (bottom-right vertex) [?] — faint in the scan

But concerning the construction of two lines inside a triangle that are greater than, or equal to, two sides, we shall show more from Pappus [Pappus of Alexandria] at proposition 34 of this book [Margin: 34. huius lib. = Prop. 34 of this book].

Problem 8. Proposition 22.

[Margin: xxij (proposition index)]

From three straight lines equal to three given straight lines, to construct a triangle. But any two of them, taken in every way, must be greater than the remaining one; for in every triangle two sides, taken in any way, are greater than the remaining one.

Demonstration (Clavius). Let three straight lines A, B, and C be given, any two of which are greater than the remaining one (otherwise no triangle could be

constructed from them, as is clear from Proposition 20, in which it was shown that any two sides of a triangle are greater than the remaining one); and let it be required to construct a triangle having its three sides equal to the three given lines. From any assumed straight line DE, of unlimited length, let DF be cut off equal to the line A [Margin: a, 3. primi = Elem. I.3]; from the remainder FE let FG be cut off equal to B; and from the remainder GE let GH be cut off equal to C.

Then, with center F and radius FD, let the circle DIK be described. Likewise, with center G and radius GH, let another circle HIK be described, which will necessarily cut the former at the points I and K. (For since the two lines FD and GH are supposed greater than FG: if from FE a line FL is taken equal to FD, and from GD a line GM equal to GH, the point M will fall between L and D. For if the point M fell at L, then GL and FL — that is, GH and FD — would be equal to the line FG; but if M fell between G and L, then those same two, FL and GM — that is, DF and GH — would be less than FG; and each of these is contrary to the hypothesis. This is evident from the appended figures.)

From either intersection — namely from K — let the straight lines KF and KG be drawn to the points F and G, and the triangle FGK will have been made, whose sides, I say, are equal to the given lines A, B, and C. For since FK is equal to FD [Margin: b, 15. def. = Elem. I, def. 15], and A is by construction equal to that same FD, the side FK will be equal to the line A [Margin: a, 1. pron. = Axiom 1]. Again, since GK is equal to GH, and C to that same GH, the side GK will likewise be equal to the line C. And it was laid down by construction that the remaining side FG is equal to the remaining line B. Therefore all three sides FK, FG, GK are equal to the three given lines A, B, C. We have thus constructed a triangle from three straight lines equal to three given straight lines. Which was to be done.

Diagram. The first case of the construction. Across the top, three reference segments are drawn with end-serifs and labelled A, B, and C (the three given lines). Below, a horizontal baseline carries the points D (left), F, G, and H, with E at the right end. Two circles are drawn: one centered at F through D, the other centered at G through H; they intersect at K (above the baseline) and at I (below it), and the point M is marked near the center of the baseline. The chords KF and KG close the constructed triangle FGK.

- A, B, C (three reference segments at top): the three given lines
- D, F, G, H (points along the baseline, left to right); E (right end of the baseline)
- K (upper intersection of the two circles)
- I (lower intersection of the two circles)

- M (auxiliary point near the center of the baseline); L referenced in the text [?] — not clearly resolved in the scan

Diagram. The second case (the contrary case where point M would coincide with L). Two circles rest on a common baseline carrying the points D, F, G, and H (with E to the right); the circles meet near the center, where the auxiliary points L and M are marked.

- D, F, G, H (baseline points, left to right)
- L, M (auxiliary points near the center where the circles meet) [?] — small and faint in the scan

Diagram. The third case (the contrary case where point M would fall between G and L, so that the circles fail to reach). Two circles on a common baseline with points D, F, G, H and the auxiliary points L, M near the center.

- D, F, G, H (baseline points, left to right)
- L, M (auxiliary points near the center) [?] — small and faint in the scan

Praxis.

Take a straight line DE equal to any one of the given lines, say B, which we now wish to be the base. Then from D, with radius equal to A, describe an arc; likewise from E, with radius equal to C, another arc cutting the former at F. If then the straight lines DF and EF are drawn, a triangle will have been made having its three sides equal to the three given lines. For the side DF will equal the line A, because of the radius A that was used; the side EF will equal C, because of the radius C that was used; and the side DE was taken equal to the line B from the outset.

Diagram. The praxis figure. A triangle stands on the base DE (D at bottom-left, E at bottom-right), with apex F at the top formed by two intersecting arcs struck from D and from E. To the side, the three given lines are shown as reference segments A, B, and C.

- D (bottom-left, base endpoint)
- E (bottom-right, base endpoint)
- F (apex, intersection of the two arcs)
- A, B, C (reference segments for the three given lines)

Scholium.

By this technique we shall construct, for any given triangle, another entirely equal to it — both as to its sides and angles and as to its area. For let ABC be any triangle, to which an equal one in every respect is to be constructed. I regard its sides as three given straight lines AB, BC, CA, any two of which are greater than the remaining one [Margin: b, 20. primi = Elem. I.20]. Then I take a straight line DE equal to one side, namely BC; and from D, with radius equal to the side AB, I describe an arc, and another from E, with radius equal to the remaining side CA, which cuts the former at F, and so on.

Diagram. The scholium figure. On the left stands the given triangle ABC (A at the apex, B at bottom-left, C at bottom-right). On the right, an equal triangle is being constructed on the base DE (D, E), its apex F reached by dotted arcs struck from D and E.

- A, B, C (the given triangle: apex, bottom-left, bottom-right)
- D, E (base of the constructed triangle)
- F (apex of the constructed triangle, at the intersection of the dotted arcs)

Problem 9. Proposition 23.

[Margin: xxiiij (proposition index)]

On a given straight line, at a given point on it, to construct a rectilineal angle equal to a given rectilineal angle.

Demonstration (Clavius). Let AB be the given straight line, C the given point on it, and DEF the given angle. It is required, then, to construct at the point C on the line AB an angle equal to the angle E. On the lines ED and EF let two points G and H be taken at random, and let them be joined by the straight line GH. Then let a triangle CIK be constructed [Margin: a, 22. primi = Prop. 22] having its three sides equal to the three lines EG, GH, HE — so that CI equals EG, CK equals EH, and IK equals GH. (This will easily be done if CI is taken equal to EG, CL equal to EH, and IM equal to GH; then, from the centers C and I, with radii CL and IM, let circles be described cutting one another at K, and so on.)

I say that the angle C is equal to the angle E. For since the two sides CI and CK are equal to the two sides EG and EH respectively, and the base IK equals the base GH, by construction, the angle C will be equal to the angle E [Margin: b, 8. primi = Elem. I.8]. We have thus made at C an angle equal to the angle E, and so on. Which was to be done.

Diagram. The main figure for Proposition 23 (labels small and near the scan floor). On the left is the given angle at vertex E, its sides carrying the points G and H, which are joined by GH (F at the lower end of one side). On the right runs the given line, drawn as a long diagonal from A (top) to B (bottom), with the given point C on it; at C the triangle CIK is constructed (points I and K), together with the auxiliary points L and M of the fuller construction.

- A (top of the given line); B (bottom of the given line)
- C (the given point on AB)
- E (vertex of the given angle); G, H (points on the sides of the given angle, joined by GH); F (lower endpoint of an angle-side)
- I, K (vertices of the constructed triangle at C); M (auxiliary point) [?]; L referenced in the text [?]
- Several peripheral letters are at the scan floor**

Praxis.

The practical construction of this problem does not differ from the one we gave in the preceding problem, since a triangle must be constructed equal to another in order that an angle equal to the given angle may be produced — as is evident. You will, however, carry out the problem more easily by the following technique. Let AB be the given line, C the point on it, and E the given angle. With center E and any radius, describe an arc GH; and with the same radius, from center C, describe an arc IK; and with the compass, take the arc IK equal to the arc GH. For the straight line CK, when drawn, will make at C an angle equal to the angle E. For if the lines IK and GH were drawn, they would be equal, since we took both distances IK and GH with the compass unchanged. Since, then, the two sides IC and CK are equal to the two GE and EH — because of the equal radii with which the arcs were described — the angles ICK and GEH will be equal [Margin: a, 8. primi = Elem. I.8].

For the rest, by what method a straight line can be drawn from a point taken outside a given line, so as to make with the given line an angle equal to a given rectilineal angle, we shall teach at proposition 31 of this book [Margin: 31. huius lib. = Prop. 31 of this book].

Diagram. The praxis figure for Proposition 23 (small labels near the scan floor). Two small angle-figures: on the left, the angle constructed at C (with A above, the arc IK, and points I, K, B, D); on the right, the given angle at E (with A above, the arc GH, and points G, H, F).

- Left figure: C (vertex), A (above), I, K (ends of the arc), B, D
- Right figure: E/A (vertex region), G, H (ends of the arc), F
- Several peripheral letters are at the scan floor**

Theorem 15. Proposition 24.

[Margin: xxiv (proposition index)]

If two triangles have two sides equal to two sides respectively, but one has the angle contained by the equal straight lines greater than the other's, then they will also have the base greater than the base.

Demonstration (Clavius). Let the two sides AB and AC of triangle ABC be equal to the two sides DE and DF respectively — namely AB to DE and AC to DF — but let the angle A be greater than the angle EDF. I say that the base BC is greater than the base EF. At the line DE and at its point D, let the angle EDG be constructed equal to the angle A [Margin: b, 23. primi = Elem. I.23] (and DG will fall outside the triangle DEF, since the angle EDF is assumed smaller than the angle A); and let DG be made equal to DF — that is, to AC. Then, when the straight line EG is drawn [Margin: c, 3. primi = Elem. I.3], it will fall either above the line EF, or on it, or below it.

First case. Let it first fall above EF, and let the straight line FG be drawn. Since the sides AB and AC are equal to the sides DE and DG respectively, and the angle A equals the angle EDG by construction, the base BC will be equal to the base EG [Margin: d, 4. primi = Elem. I.4]. Again, since the two sides DF and DG are equal to one another, the angles DFG and DGF will be equal [Margin: e, 5. primi = Elem. I.5]. But the angle DGF is greater than the angle EGF [Margin: f, 9. pron. = Axiom 9]; therefore the angle DFG is also greater than that same angle EGF, and so the whole angle EFG is much greater than that same angle EGF. So in triangle EFG the side EG will be greater than the side EF [Margin: a, 19. primi = Elem. I.19]. But EG has been shown equal to BC; therefore BC is also greater than EF. Which is what was proposed.

Second case. Next, let EG fall on EF itself. Then, since again, as before, the base EG is equal to the base BC [Margin: b, 4. primi = Elem. I.4], and EG is greater than EF [Margin: c, 9. pron. = Axiom 9], BC will also be greater than EF. Which is what was proposed.

Third case. Third, let EG fall below EF, and let the straight lines DF and DG be produced to H and I, and let the straight line FG be drawn. Then again, as before, the base EG will be equal to the base BC [Margin: d, 4. primi = Elem. I.4]. Then,

since the two sides DF and DG are equal to one another by construction, the angles GFH and FGI below the base FG will be equal [Margin: e, 5. primi = Elem. I.5]. But the angle FGI is greater than the angle FGE [Margin: f, 9. pron. = Axiom 9]; therefore the angle GFH is also greater than that same angle FGE, and so the whole angle EFG is much greater than that same angle FGE. So in triangle EFG the side EG will be greater than the side EF [Margin: g, 19. primi = Elem. I.19]. But EG has been shown equal to BC; therefore the base BC is also greater than the base EF. So, if two triangles have two sides equal to two sides, and so on. Which was to be shown.

Diagram. The figure for the first two cases. On the left stands triangle ABC (A at the apex, B at bottom-left, C at bottom-right). On the right stands triangle DEF (D at the apex, E at bottom-left, F below), with the constructed line DG (G to the lower-right) and EG drawn so as to fall above EF.

- A, B, C (the first triangle: apex, bottom-left, bottom-right)
- D (apex of the second triangle)
- E (bottom-left of the second triangle)
- F (base point of the second triangle)
- G (constructed point, lower-right, with $DG = DF$)

Diagram. The figure for the third case (small labels near the scan floor). On the left, triangle ABC (A apex, B bottom-left, C bottom-right). On the right, triangle DEF with DG, the sides DF and DG produced to H and I, EG falling below EF, and FG drawn.

- A, B, C (the first triangle)
- D (apex of the second triangle); E, F, G (base region); H, I (points where DF and DG are produced) [?] — H and I are small and faint in the scan

Scholium.

Should anyone perhaps ask why, in Proposition 4, Euclid concluded from the fact that two sides of one triangle, each to each, together with the angles contained by those sides, are equal, not only the equality of the bases but also of the triangles and of the remaining angles; whereas here, from the fact that two sides of one triangle are equal to two sides of another, each to each, but the angles contained by those sides are unequal, he gathers only the inequality of the bases, and not of the triangles and remaining angles — to this it must be answered that Euclid, a most skilled geometer, did so of necessity.

For from the premise of this theorem the inequality of the bases always follows, so that the base of the triangle whose angle contained by the assumed sides is greater exceeds the base of the other, whose angle is smaller, as has been demonstrated; but it is not necessary that the former triangle be greater than the latter. For, as we shall demonstrate most clearly from Proclus at proposition 37 of this first book [Margin: 37. huius 1. libri = Prop. 37 of Book I], a triangle having the greater angle is sometimes equal to the triangle having the smaller angle, sometimes less than it, and sometimes greater. It could not therefore be inferred universally, from the fact that one triangle's angle is greater than another's, that the triangle is also greater — since it is sometimes equal, sometimes less, and sometimes greater. The same can be said of the remaining angles.

For in the first figure of this theorem the angle ABC is always less than the angle DEF; since the angle DEG (which is equal to the angle ABC by Proposition 4) is less than that same angle DEF [Margin: a, 9. pron. = Axiom 9], being a part relative to the whole. In the second figure, however, the angle ABC is indeed equal to the angle DEF, by Proposition 4; but the angle ACB is less than the angle DFE, since the angle DFE is greater than the angle DGF — an exterior angle greater than the interior and opposite one [Margin: b, 16. primi = Elem. I.16] — and the angle DGF is equal to the angle ACB. Finally, in the third figure the angle ABC is indeed greater than the angle DEF, because the angle DEG (being equal, by Proposition 4, to the angle...

(Continuation of the scholium on Proposition 24.)

(since angle DFE is greater than angle ABC), it is greater than the same angle DEF — the whole greater than the part [Margin c: Axiom 9 (the whole is greater than its part)]. But angle ACB is less than the same angle DFE. For if the straight line EF is produced so as to cut the straight line DG at K, angle DFE will be greater than angle DKE [Margin d: I.16], the exterior greater than the interior; and angle DKE is in turn greater than angle DGE, again an exterior greater than the interior and opposite. Therefore angle DFE will be much greater than angle DGE, which by Proposition 4 is equal to angle ACB. The same is clear from the second part of Proposition 21 [Margin: cf. *Elements* I.21], for the interior lines DF, EF contain a greater angle than the exterior lines DG, EG contain. Hence nothing certain could be concluded about the inequality of the remaining angles, since one is now greater than the other, now less, and now equal.

Diagram. A composite figure accompanying the discussion above. On the left is a triangle with apex **A** (top), **B** (lower left), and **C** at the base, with **E** just to the right of **C**. On the right is a construction from **D** (top) with the lines running down to

labelled points **F, K, G, H, I** (the points where the produced lines DG, EF, etc. meet).

- A (upper left): apex of the left triangle
- B (lower left): base vertex
- C, E (base of left triangle): base vertices
- D (top right): apex of the right construction
- F, K, G, H, I (right, descending): intersection points of the produced straight lines

Since in triangle DEF the two angles E and F are always less than two right angles [Margin a: I.17], at least one of them will necessarily be acute. Therefore, if on the side of the acute angle (as in the first figure, on the side of angle DFE; in the second and third, on the side of angle DEF) an angle EDG is constructed equal to angle A, and the rest is carried out as stated in the proposition, then the straight line EG, once drawn, will always fall beyond the point F. For since angle DFE is acute, its adjacent angle — formed by producing the side EF — will be obtuse [Margin b: I.13]. Hence, when the straight line DG is produced cutting the side EF extended at H, the straight line DH will be greater than the side DF [Margin c: I.19], since it is opposite the obtuse angle in triangle DFH; and consequently the straight line EG, which cuts off DG equal to DF, will necessarily fall beyond F. For if it passed through F, or fell short of it, it would cut off from DG a line greater than the side DF — namely, either DH or something greater than DH. If this is observed, the first case of the proposition will suffice; and this was perhaps the reason why Euclid, in Theon's [Theon of Alexandria] edition, was content with the first case alone.

Diagram. Two triangles illustrating the acute-angle case. On the left, triangle with apex **A** (top), **B** (lower left), **C** (base). On the right, triangle **D** (top), **E** (lower left), **F** (base), with construction lines drawn down to the right toward the point where DG cuts EF extended.

- A (top left): apex
- B, C (base left triangle)
- D (top right): apex
- E, F (base of right triangle)

Problem 16. Proposition 25.

[Margin: XXV]

(Euclid's enunciation.) If two triangles have two sides equal to two sides, each to each, but the base of the one greater than the base of the other, then they will also have the angle contained by the equal straight lines greater in the one than in the other.

(Clavius's demonstration.) Let the two sides AB, AC of triangle ABC be equal to the two sides DE, DF of triangle DEF, each to each — that is, AB to DE and AC to DF — while the base BC is greater than the base EF. I say that angle A is greater than angle D. For if angle A is not greater than angle D, it will be either equal or less. If it is said to be equal, then, since the two sides about A are also equal to the two sides about D, each to each, by hypothesis, the base BC will also be equal to the base EF [Margin a: I.4] — which is absurd, for the base BC was assumed to be greater than the base EF. But if angle A is said to be less than angle D, then, because of the equality of the sides about those angles, the base EF will be greater than the base BC [Margin b: I.24] — which is still more absurd, since EF was assumed to be less than BC. Therefore angle A, since it can be neither equal to angle D nor less, must be greater. So if two triangles have two sides equal to two sides, and so on. Which was to be shown.

Scholium

This theorem is the converse of the preceding one. For in that one it was demonstrated, from the greater angle, that the base corresponding to it is greater; whereas in this one it was shown, from the greater base, that the angle corresponding to it is greater. These two theorems — namely, 24 and 25 — differ greatly from those set out in Propositions 18 and 19. For in Proposition 19 it was demonstrated that in one and the same triangle the greater side corresponds to the greater angle; but in Proposition 24 the same was shown for two different triangles, two of whose sides are equal to the two sides of the other, and so forth. You will find the same distinction between Propositions 18 and 25.

Menelaus of Alexandria [Menelaus of Alexandria], as Proclus [Proclus] reports, demonstrates this same theorem directly [ostensively], by the following reasoning. With the same triangles set out, from the greater base BC cut off a straight line BG equal to the smaller base EF [Margin c: I.3]. Construct also an angle GBH equal to angle DEF [Margin d: I.23], and let BH be equal to BA [Margin e: I.3], and therefore to DE. Then, with the straight line AH drawn, let another straight line be drawn through G, from H, cutting AC at I. Now since the two sides BA, BH are equal, the angles BAH, BHA will be equal [Margin f: I.5]. Again, since the sides BG, BH are equal to the sides EF, ED, each to each, and angle GBH is equal to angle DEF by construction, the base HG will be equal to the base DF [Margin a: I.4] — and therefore to AC — and angle GHB equal to angle EDF. And since the straight line HI is greater than HG [Margin b: Axiom 9] (which was shown equal to AC), HI will also be greater than AC; but AC is still greater than AI [Margin c: Axiom 9]. Therefore HI is much greater than AI. Hence angle IAH will be greater than angle IHA [Margin d: I.18]. Therefore, adding the two angles BAH, BHA, which were shown to be equal, the whole angle BAC becomes greater than the whole angle BHG [Margin e: Axiom 4 (if equals are added to unequals, the wholes are unequal)]; but angle BHG was demonstrated to be equal to angle D. Therefore angle BAC will also be greater than angle D — which is what was proposed. And if it should happen that the straight line AH falls outside the triangle, the equal angles BAH, BHA must be subtracted, and so on, so that the remaining angle BAC becomes greater than the remaining angle BHG. But when the straight line AH passes through the point B, nothing need be added or subtracted, as is evident.

Diagram. Menelaus's construction: a kite-shaped figure with apex **A** at the top and vertex **H** at the bottom, the left vertex **B** and the right vertex **C**, with **G** on the base and **I** on side AC near C, and the diagonals/lines AH, BH, and the line through G to I crossing in the interior.

- A (top): apex
- B (left): base vertex
- C (right): base vertex
- G (on base BC)
- I (on AC, near C)
- H (bottom): apex of the lower triangle

Hero [Hero of Alexandria], drawing on the same Proclus, demonstrates it this way. With the same triangles set out, let the smaller base EF be produced to G, so that EG is equal to the greater base BC [Margin f: I.3]. Then, with D as centre and

DF as radius, describe a circle, and let ED be produced to H on the circumference. Now since DH is equal to DF [Margin g: I, Def. 15 (definition of the circle)], DH will also be equal to AC. Therefore, adding the equals DE, AB, the lines AC, AB together will be equal to the whole HE [Margin h: Axiom 2]; but AC, AB together are greater than BC [Margin i: I.20], and therefore greater than EG. So HE will also be greater than EG. Hence the circle described from centre E with radius EG will cut the straight line EH — and thus the circumference of the first circle — at the points I and K; and to K let the straight lines DK, EK be drawn. Now since the two sides AB, AC are equal to the two sides DE, DK, each to each (for DK is equal to DF by the definition of the circle, and DF was assumed equal to the side AC), and the base BC is equal to the base EK (since EK is equal to EG by the definition of the circle, and EG was by con-

Diagram. Hero's construction: at the left a small triangle, and to the right two overlapping circles with several labelled points along a horizontal diameter and around the circumferences. Legible labels include the small triangle's apex [?] and base points, and the circle-points **D** and **E** (the two centres) on the diameter, with **H** at the far right / bottom of a circle, and **F**, **K**, **I** among the upper circumference points. Several peripheral labels are at the scan floor and could not be resolved.

- (small triangle, left): apex [?]; base points A, B [?]
- D (centre of first circle, on the diameter)

- F, H (on the circumferences) [?]
- I, K (intersection points of the two circles) [?]

(Continuation of Hero's demonstration, from Proposition 25 scholium.)

struction made equal to the base CB.) Therefore angle BAC will be equal to angle EDK [Margin a: I.8]; but angle EDK is greater than angle EDF [Margin b: Axiom 9]. Therefore angle A will turn out to be greater than angle EDF as well — which is what was proposed. And this demonstration is more general than the earlier one, since it fits all cases.

Theorem 17. Proposition 26.

[Margin: xxvj]

(Euclid's enunciation.) If two triangles have two angles equal to two angles, each to each, and one side equal to one side — either the side that lies between the equal angles, or the side that subtends one of the equal

angles — then they will also have the remaining sides equal to the remaining sides, each to each, and the remaining angle equal to the remaining angle.

(*Clavius's demonstration.*) Let the two angles B and C of triangle ABC be equal to the two angles E and EFD of triangle DEF, each to each — that is, B to E and C to EFD — and let, first, the side BC, which lies between angles B and C, be equal to the side EF, which lies between angles E and EFD. I say that the remaining sides AB, AC are also equal to the remaining sides DE, DF, each to each — that is, AB to DE and AC to DF, namely those that subtend the equal angles — and the remaining angle A equal to the remaining angle D. For if the side AB is not equal to the side DE, let DE be the greater, and from it cut off a straight line EG equal to the straight line AB [Margin c: I.3], and draw the straight line GF. Now since the sides AB, BC are equal to the sides GE, EF, each to each, and the angles B and E are equal by hypothesis, angle C will be equal to angle EFG [Margin d: I.4]. But angle C was assumed equal to angle EFD. Therefore angle EFG will be equal to the same angle EFD — the part to the whole — which is absurd. So the side AB is not unequal to the side DE, but equal. Consequently, since the sides AB, BC are equal to the sides DE, EF, each to each, and the contained angles B and E are equal, the bases AC, DF will also be equal, and the remaining angles A and D equal [Margin a: I.4]. Which is what was proposed.

Diagram. Two large triangles. Left triangle: **A** (apex), **B** (lower left), **C** (lower right). Right triangle: apex **D** (malformed glyph in the scan), **E** (lower left), **F** (lower right), with **G** marked on the side DE and the line GF drawn.

- A (apex, left); B, C (base, left)
- D (apex, right)
- E, F (base, right)
- G (on side DE, near the apex)

Next, let the sides AB, DE, which subtend the equal angles C and EFD, be equal to one another. I say again that the remaining sides BC, CA are equal to the remaining sides EF, FD, each to each — that is, BC to EF and CA to FD — and the remaining angle A equal to the remaining angle D. For if the side BC is not equal to the side EF, let EF be the greater; from it take EG equal to BC [Margin b: I.3], and draw the straight line DG. Now since the sides AB, BC are equal to the sides DE, EG, each to each, and the contained angles B and E are equal by hypothesis, angle C will be equal to angle EGD [Margin c: I.4]. But angle C was assumed equal to angle EFD. Therefore angle EGD will also be equal to the same angle EFD — an exterior angle equal to the interior and opposite — which is absurd [Margin d:

I.16]; for it is in fact greater. So the side BC is not unequal to the side EF. Whereupon, as before, the conclusion will follow from Proposition 4 of this book. Therefore, if two triangles have two angles equal to two angles, and so on. Which was to be demonstrated.

Diagram. Two smaller triangles. Left: **A** (apex), **B** (lower left), **C** (lower right). Right: **D** (apex), **E** (lower left), **F** (lower right), with **G** marked below F on EF (its extension) and the line DG drawn.

- A (apex, left); B, C (base, left)
- D (apex, right); E, F (base, right)
- G (on EF / its extension)

Corollary

It follows from the demonstration of this theorem that the whole triangles are also equal in area. For if the sides AB, BC are equal to the sides DE, EF, as was shown, and by hypothesis they contain equal angles B, E, then the whole triangles will also be equal to one another [Margin e: I.4].

Scholium

The first part of this theorem is the converse of Proposition 4, with respect to that part in which, from the equality of the sides and of the angles contained by them, the equality of the bases and of the angles upon the bases was inferred. For in the first part of this theorem it was demonstrated, from the equality of the bases BC, EF and of the angles upon those bases, that the remaining sides of the one triangle are equal to the remaining sides, and the remaining angle to the remaining angle, and so on. This indeed we have already demonstrated by another method at Proposition 8 of this book, as we noted there.

Diagram. A small pair of triangles for the scholium. Left: **A** (apex), **B** (lower left), **C** (lower right). Right: **D** (apex), **E** (lower left), **F** (lower right), with **G** marked at the upper right near D.

- A (apex, left); B, C (base, left)
- D (apex, right); E, F (base, right)
- G (near apex D)

Here a certain theorem must be demonstrated, one that is thoroughly necessary and highly useful in geometrical matters, namely:

In an equilateral or isosceles triangle, a straight line drawn from the angle contained by the two equal sides, which bisects either that angle or the base, is perpendicular to the base; and if it bisects the angle, it will also bisect the base; but if it bisects the base, it will also bisect the angle. And conversely: a perpendicular line drawn to the base bisects both the base and the angle.

Let there be, in triangle ABC, two equal sides AB, AC, and let the straight line AD first bisect the angle A. I say that AD is perpendicular to BC and bisects the base BC. For since the two sides AB, AD are equal to the two sides AC, AD, and contain equal angles by hypothesis, the bases BD, CD will also be equal, and the angles at D — and therefore right angles [Margin a: I.4].

Next, let the straight line AD bisect the base BC. I say that AD is perpendicular to BC and bisects angle A. For since the two sides BD, DA are equal to the two sides CD, DA, and the base AB is equal to the base AC by hypothesis, the angles at D will also be equal [Margin b: I.8] — and therefore right angles — and consequently, by the corollary to Proposition 8 of this book, the angles at A will be equal.

Now let the straight line AD be perpendicular to BC. I say that it bisects both the base BC and the angle A. For the angles B, C upon the base BC will be equal [Margin c: I.5]. And so, since the two angles ABD [and ADB] are equal to the two angles D, C of triangle ACD, each to each, and the side AD, opposite the equal angles B, C, is common, the remaining sides BD, CD will also be equal, and the remaining angles at A equal [Margin a: I.26]. Which was to be demonstrated.

Diagram. A large isosceles triangle: apex **A** (top), with the base **B** (lower left) — **D** (foot of the line from A, on the base) — **C** (lower right), and the straight line AD drawn from the apex to the base.

- A (apex): vertex of the equal sides
- B (lower left), C (lower right): base vertices
- D (on base BC): foot of AD

But this theorem too is true:

A triangle in which a straight line drawn from one of its angles to the base, and perpendicular to it, bisects either the base or the angle, has the two sides containing that angle equal. And if the base is bisected, the angle will also be bisected; but if the angle is bisected, the base too will be divided in half.

(Continuation of the scholium.)

In the same triangle ABC, let AD, perpendicular to BC, first bisect the base BC. I say that the sides AB, AC are equal, and the angles at A equal. For since the two sides BD, DA are equal to the two sides CD, DA, and contain equal angles — namely right angles — the bases AB, AC will also be equal, and the angles at A [Margin b: I.4]. Which is the first point.

Next, let the perpendicular AD bisect angle A. I say that the sides AB, AC are equal, and so are the straight lines BD, CD. For since the two angles D, A of triangle ABD are equal to the two angles D, A of triangle ACD, and the side AD lying between them is common, the sides AB, AC and the sides BD, CD will also be equal [Margin c: I.26]. Which is the second point.

Theorem 18. Proposition 27.

[Margin: xxvij]

(Euclid's enunciation.) If a straight line falling on two straight lines makes the alternate angles equal to one another, then those straight lines will be parallel to one another.

(Clavius's demonstration.) On the two straight lines AB, CD let the straight line EF fall, making the alternate angles AGH, DHG equal to one another. I say that the lines AB, CD are parallel. For if they are not parallel, they will eventually meet if produced indefinitely; for if they never met, they would be parallel, by the definition of parallels. Let them then meet, toward B and D, at the point I. Now since GIH is a triangle (for AB is continued as a straight line, and likewise CD, as far as the point I), and angle AGH was assumed equal to angle DHG, the exterior angle AGH will be equal to the interior and opposite angle DHG — which is absurd [Margin a: I.16], since the exterior is greater than the interior. But if AB, CD are said to meet toward A and C, at the point K, then again, by the same reasoning, the exterior angle DHG will be equal to the interior and opposite angle AGH — which is absurd. Therefore the lines AB, CD will not meet. Hence they will be parallel. In the same way, if the alternate angles BGH, CHG are assumed equal, it will be demonstrated that the lines AB, CD are parallel. So if a straight line falling on two straight lines, and so on. Which was to be shown.

Diagram. The two straight lines AB and CD crossed by the transversal EF, extended to form an "hourglass" figure. Along the upper line: **A, G** (where EF crosses AB), **B**; along the lower line: **C, H** (where EF crosses CD), **D**; the transversal running **E** (top) to **F** (bottom); with **I** at the right (where AB, CD would meet if produced toward B, D) and **K** at the left (toward A, C).

- E (top of transversal), F (bottom of transversal)
- A, G, B (upper line AB; G on the transversal)
- K, C, H, D (lower line CD; H on the transversal)
- I (right, the hypothetical meeting point toward B, D)

Scholium

It is necessary that the lines said to be parallel lie in the same plane, as is clear from the definition. Therefore it is not enough that two alternate angles be equal to one another for the two lines to be proved parallel, unless it is granted that they lie in one and the same plane. For it can happen that a straight line falling on two straight lines not in the same plane makes the alternate angles equal. Let CD be perpendicular to the straight line AB, which lies in the plane below; and from C, in another plane, let another perpendicular CE be drawn to CD, so that the point E is understood to be aloft. Once this is set up, it is clear that the straight line CD, falling on the straight lines CE, AB, makes the two alternate angles ECD, ADC equal, since they are right angles; and yet CE, AB are not parallel, because they do not lie in the same plane. Euclid, however, did not append this condition — "lying in the same plane" — to the proposition, just as he did not in what follows; because, since in the first six books he deals with plane figures only, as we said above, everything must necessarily be understood to lie in the same plane. But in the eleventh book, and the others that follow it, he will always give notice that certain lines lie in the same plane, or in different planes, because in those books solids are discussed, in which different planes can be considered. The same must be said of points lying outside lines and surfaces, and so on.

Diagram. A right-angle figure illustrating the out-of-plane case. **A—D—B** lie along the horizontal line (in the plane below); **C** stands above D, and **E** is at the upper left, so that CD is perpendicular to AB, and CE is a second perpendicular to CD rising out of the plane.

- A, D, B (the horizontal line AB, with D the foot of the perpendicular)
- C (above D)
- E (upper left, "aloft" — in a second plane)

Theorem 19. Proposition 28.

[Margin: xxvii]

(Euclid's enunciation.) If a straight line falling on two straight lines makes the exterior angle equal to the interior and opposite angle on the same

side, or the interior angles on the same side equal to two right angles, then the two straight lines will be parallel to one another.

(*Clavius's demonstration.*) On the two straight lines AB, CD let the straight line EF fall, making first the exterior angle EGA equal to the interior and opposite angle on the same side, GHC. I say that the straight lines AB, CD are parallel. For since angle GHC is assumed equal to angle EGA, and angle HGB is equal to that same angle EGA [Margin a: I.15], the alternate angles GHC, HGB will be equal [Margin b: Axiom 1 (things equal to the same thing are equal to one another)]. Hence the straight lines AB, CD will be parallel [Margin c: I.27]. The same will be shown if the exterior angle EGB is assumed equal to the interior angle GHD.

Next, let the straight line EF make the interior angles on the same side — namely AGH, CHG — equal to two right angles. I say again that the straight lines AB, CD are parallel. For since the angles AGH, CHG are assumed equal to two right angles, and the angles AGE, AGH are also equal to two right angles [Margin a: I.13], the two angles AGH, CHG will be equal to the two angles AGE, AGH. Taking away the common angle AGH, the angle AGE will remain equal to the exterior angle on the same side. Therefore, as was already shown, the straight lines AB, CD will be parallel. The same will be shown if the two angles BGH, DHG are assumed equal to two right angles. So if a straight line falling on two straight lines makes the exterior angle, and so on. Which was to be demonstrated.

Diagram. Two horizontal straight lines cut by a transversal. Upper line: A—E—G—B; lower line: C—F—D; the transversal runs from E on the upper line down through G and F to the lower line.

- A, E, G, B (upper line AB; E and G lie on it)
- C, F, D (lower line CD; F lies on it)

Scholium

Long ago we rejected the thirteenth "pronunciatum" [the parallel postulate] from the number of the Principles. Since, then, the following Proposition 29 — together with many others — rests upon it so heavily that without its aid it cannot be demonstrated, it will be worthwhile to confirm it here, by a geometrical demonstration, from the theorems and problems demonstrated up to now that in no way depend upon it — as we promised in the exposition of that axiom. In the first place we shall present Proclus's [Proclus] demonstration; then we shall demonstrate the same proposition ourselves more accurately and more evidently. Proclus, then, before demonstrating it, premises two things. The first is:

[This opening continues Clavius's scholium on Euclid's parallel postulate (the thirteenth pronunciatum). The page begins in the middle of an inserted lemma on the unbounded divergence of two rays.]

[Inserted lemma — unbounded ray divergence]

Lemma. If two straight lines making an angle are drawn out from a single point and produced infinitely, their distance will exceed every finite magnitude.

Let two straight lines AB and AC go out from point A, making the angle A. Now points D and E are farther apart from each other than F and G; likewise points B and C are farther apart than D and E; and so on in succession, if the straight lines AB, AC are produced further. It is therefore clear that their outermost points stand at an infinite distance from one another, provided the lines themselves are produced infinitely. For if they were not separated by an infinite distance, their distance could be increased, and hence the lines could be produced still further — which is absurd, since they are assumed to have already been produced infinitely. Therefore, if the said lines AB, AC are produced infinitely, their distance will exceed every finite distance. Aristotle too made use of this pronouncement in Book I of *On the Heavens* [*De caelo* I], where he proved that the world is not infinite.

Diagram. A small angle-figure at the upper right. The vertex is A (at the right), and two straight rays diverge leftward from A.

- A (vertex, right): common origin of the two rays.
- Upper ray, from A outward (right to left): F (nearest A), D (middle), B (farthest).
- Lower ray, from A outward (right to left): G (nearest A), E (middle), C (farthest).
- The farthest point of the upper ray is printed as a malformed glyph resembling "3" [?: read as **B** from the text, which names points B and C as the outermost].

Now, that the straight lines AB, AC diverge more the farther they are drawn out — a point Proclus [Proclus] assumed without demonstration when he said, in the preceding figure, that points D and E are farther apart than F and G, and likewise B and C farther than D and E, and so on — we shall demonstrate as follows.

From points C and D, taken anywhere on the straight line AC, drop the perpendiculars CB and DE to AB. These measure the distances of points C and D from the line AB, since they are the smallest of all the straight lines drawn from C

and D to AB, as we showed in the corollary to Proposition 19. I say that CB is greater than DE, and hence that the line AC is farther from the line AB at the more remote point C than at the nearer point D. For if CB is not greater than DE, it will be either equal or less. Suppose first it is equal. Cut off BF on AE equal to it, so that point F falls either between A and E, or on E, or finally between E and B; and draw the straight line FC. Since, then, the two sides AE, ED of triangle AED are equal to the two sides FB, BC of triangle FBC, each to each, and they contain equal angles — namely right angles — the bases AD, FC and the angles DAE, CFB will also be equal to one another. [Margin: a — 4. pri. (Euclid I.4)] Therefore the exterior angle CFB will be equal to the interior angle DAE, which is absurd. [Margin: b — 16. primi (I.16)] Alternatively, since the exterior angle CFB is equal to the interior DAE, the lines AC, FC will be parallel [Margin: c — 27. primi (I.27)] — which is likewise absurd, since they meet at C.

Next, suppose CB is less than DE, if that be possible. Produce BC and make BG equal to DE, and join the straight line FG. Since, then, the two sides AE, ED of triangle AED are equal to the two sides FB, BG, each to each, and they contain equal angles, the bases AD, FG and the angles EAD, BFG will also be equal to one another. [Margin: d — 4. primi (I.4)] Therefore the exterior angle BFG will be equal to the interior EAD, which is absurd. Or, since the exterior angle BFG is equal to the interior EAD, the lines AC, FG will be parallel to one another [Margin: a — 27. prim. (I.27)] — which is absurd, since they cut one another at H. Consequently BC will be greater than ED, since it can be neither equal nor less, as has been demonstrated.

Diagram. A right triangle standing on the horizontal base A–B, illustrating the divergence argument.

- A (bottom left): vertex of the angle; origin of the two diverging lines.
- Base (left to right): A, F, E, B.
- B (bottom right): foot of the perpendicular BG.
- G (top): apex, top of the perpendicular erected at B.
- C (right, just below G): point on the line AC; foot of perpendicular CB.
- D (middle left, on the rising line): point on the line AC nearer A; foot of perpendicular DE.
- H (middle): intersection point where the lines FG and AC cross (the "cut one another at H").
- The rising line A→G is the ray AC; the perpendiculars DE and CB (and BG) drop to / rise from the base AB.

SECOND [lemma], which Proclus premises, is of this kind.

Lemma. If a certain straight line cuts one of two parallel straight lines, it will also cut the other when it is produced.

Let there be two parallels AB, CD, and let a straight line EF cut AB at G. I say that the straight line EF, if produced, will also cut CD. Since the two straight lines GB, GF make an angle at point G, then, if they are produced infinitely, they will exceed every finite distance; and hence also the distance by which the parallel AB is separated from the parallel CD, since this distance is finite (otherwise the lines would not be parallel). Therefore, once the distance of GB from GF has become greater than that which lies between the parallels, the straight line GF, produced, must have cut the straight line CD. For as long as GF is contained between the two parallels, it will be removed from GB by a smaller distance than CD is from that same GB, as is evident. With these points set out, then, this theorem — which occurs in Euclid as the thirteenth pronouncement — will readily be demonstrated.

Diagram. Two parallel horizontal lines with an oblique transversal.

- A (upper line, left) — B (upper line, right): the parallel AB.
- C (lower line, left) — D (lower line, right): the parallel CD.
- E (upper left, on the transversal): upper end of the transversal.
- G: point where the transversal cuts the upper parallel AB.
- F (on the lower line): point where the transversal EF meets / cuts the lower parallel CD.
- The transversal runs E–G–F.

[Euclid's thirteenth pronunciatum — the parallel postulate]

Pronouncement. If a straight line falling on two straight lines makes the interior angles on the same side less than two right angles, the two straight lines, produced infinitely, will meet one another on that side where the angles are less than two right angles.

[The following is Proclus's proof of the postulate, which Clavius reports.]

Onto the straight lines AB, CD let the straight line EF fall, making the interior angles toward the sides B and D — namely BGH, DHG — less than two right angles. I say that the straight lines AB, CD converge toward these same sides B and D. For since the two angles BGH, DHG are supposed to be less than two right angles, while the two angles DHG, DHF are equal to two right angles [Margin: a —

13. primi (I.13)], the two angles DHG, DHF will be greater than the two angles DHG, BGH. Taking away the common angle DHG, then, the angle DHF will remain greater than the angle BGH. [Margin: b — 5. pron.] If, therefore, at the straight line FG and at the point G an angle KGH is constructed equal to the angle DHF [Margin: c — 23. pri. (I.23)], GK will fall above GB, and, being produced, will cut the straight line AB. [Margin: d — 11. pron.] Now since the falling line EF makes the exterior angle DHF equal to the interior and opposite angle KGH, the straight lines IK, CD will be parallel. [Margin: e — 28. primi (I.28)] But the straight line AB cuts IK at G; therefore, produced, it will also cut CD, as has been demonstrated, toward the sides B and D — namely at point L, which was what was proposed.

Diagram. Two nearly-horizontal straight lines crossed by a transversal, with an auxiliary constructed line.

- A (upper line, far left) with I just below it (left end of the constructed line IK).
- Upper line runs A ... G ... K (K at the right); this is the line IK (through G) / AB.
- G: point on the upper line where the transversal and the constructed line meet.
- E: point on the transversal, above G.
- K (upper right): end of the constructed line, terminus of angle KGH.
- Lower line: C (far left) ... through F/H ... to D and B (at the right); this is CD.
- F, H (lower-middle): F on the transversal, H the point where the transversal cuts the lower line CD.
- Labels read on the figure: A, I, G, E, K (upper); C, F, H, D, B (lower).

By this reasoning, then, Proclus attempts to demonstrate the thirteenth axiom. But since the principle he premised in the first place seems just as doubtful and obscure as that axiom itself, we shall put forward a more careful demonstration — provided we first make clear wherein lies the difficulty, or obscurity, of that principle assumed by Proclus.

In the judgment of Proclus and of other geometers, it must not be conceded without demonstration that two straight lines which continually approach one another do at last, at some point, meet — however true this may be. Such are two straight lines onto which a falling line makes the two interior angles on the same side less than two right angles, one of which is right and the other acute; for these approach one another toward those sides where the two angles are less than two right angles, as we shall shortly demonstrate. This must not be conceded without

proof, because there can be given, in the same plane, two lines — one straight and the other curved (namely either a hyperbola [Hyperbole] or a conchoid line [linea conchoideos, the conchoid]) — continually approaching one another more and more, which nevertheless never meet, even though both are produced to infinity. The former of these was demonstrated by Apollonius of Perga [Apollonius of Perga], the latter by Nicomedes [Nicomedes].

Likewise it does not seem right to admit without demonstration — although it is perfectly true — that two straight lines making an angle exceed every finite magnitude when both are produced to infinity, even though they continually diverge more and more from one another, as we demonstrated above. For there can be exhibited, in the same plane, two lines enclosing an angle — one straight and the other curved, the curve which Nicomedes calls the conchoid — continually diverging from one another more and more, whose distance nevertheless never exceeds or even equals any given straight line, however both may be extended to infinity. For let a straight line AB be given. I say that a straight line and a curve can be described such that one continually recedes from the other, yet their distance

never equals the straight line AB, nor exceeds it, however far both be produced. For let the straight line AB be produced, as far as you please, to C; through B draw BD perpendicular to AC; and with C as pole and AB as interval let the conchoid line AE be described — a curved line, that is, which becomes ever closer to the straight line BD yet never meets it, as is delivered by Nicomedes. Then through A erect the straight line AI perpendicular to AC, which will be parallel to BD [Margin: a — 28. primi (I.28)]. Finally, from any two points H, I on AI, drop perpendiculars HG, ID to BD, which will be parallel [Margin: b — 28. primi], and therefore equal to one another [Margin: c — 34. primi (I.34)], and will make right angles at H, I [Margin: d — 29. primi (I.29)]. For let us now admit — in order to show what is proposed — all the demonstrations of Euclid, as if they did not depend on the thirteenth axiom, or even if they do depend on it, let them nevertheless be granted, just as if that axiom had already been demonstrated before Proposition 29 of this book, where its use first begins to appear — as indeed we shall demonstrate, just before Proposition 29. And so, since FG is greater than ED, as Nicomedes demonstrated, FH (the remainder) will be less than EI (the remainder). Therefore the lines AI, AE are farther apart at points I, E than at points H, F; and thus we shall prove that they continually diverge more and more, the farther they are extended. Nevertheless their distance will always be less than the straight line AB — that is, than the perpendicular dropped from

the line AI to the line BD — since the curved line AE never reaches the line BD, as Nicomedes demonstrated.

Diagram. The conchoid figure: a straight top line, a straight bottom line, and the curved (conchoid) line rising toward the top.

- Top line (left to right): A, H, I — this is the perpendicular AI.
- Bottom line (left to right): B, G, D — this is the line BD.
- C (below B, at bottom left): the pole from which the conchoid is described.
- The curved conchoid line AE runs from A obliquely toward E (upper right); F lies on it.
- F (middle), E (middle right): points on the conchoid.
- Perpendiculars HG and ID drop from H, I on the top line to G, D on the bottom line.

[Margin (left of figure): a — 28. primi; b — 28. primi; c — 34. primi; d — 29. primi]

I know that this principle of Proclus is entirely true for straight lines, and that, if all the demonstrations of Euclid which depend on the thirteenth axiom be conceded, it could easily be demonstrated in this way. Let two straight lines AB, AC contain the angle A, and let a straight line D of any magnitude be given. I say that the distance of the straight lines AB, AC, produced to infinity, exceeds the magnitude D. For from any point E taken on the line AB, drop a perpendicular EF to AC. If this is greater than D, the proposition is established. But if it is not greater, take its multiple that is next greater than D — namely G. Then, taking AB as such a multiple of AE as G is of EF, drop from B the perpendicular BC to AC, which I say is greater than the given straight line D. For since AB is to BC as AE is to EF [Margin: c — 4. sexti (VI.4)] — this by the corollary to Proposition 4 of Book 6 of Euclid, the triangles ABC, AEF being similar because of the parallel lines BC, EF [Margin: f — 28. primi (I.28)] — then, by alternation, as AB is to AE, so BC is to EF. Therefore BC will be the same multiple of EF as AB is of AE, that is, as G is of EF. Since, then, BC and G are equal multiples of EF, they will be equal to one another. But by construction G is greater than D. Therefore BC also — the distance of point B from point C — will be greater than the given straight line D. Which was the proposition.

Diagram. A right triangle with two separate reference segments drawn above it.

- Above the triangle, two horizontal reference segments: G (upper, the longer, marked with a division tick) and D (lower, shorter).
- A (bottom left): vertex of angle A.

- Base A–F–C (left to right); C at the bottom right.
- B (top right): apex; BC is the perpendicular at C.
- Hypotenuse A→B; E lies on it.
- E (on the hypotenuse), with perpendicular EF dropped to F on the base AC.

[Margin (left of figure): c — 4. sexti; f — 28. primi]

But this demonstration has no force without the properties of parallel lines, which rest on that thirteenth axiom; and therefore that principle of Proclus cannot be assumed for demonstrating the thirteenth axiom, lest the principle be begged in the course of demonstrating it. This being so, we have taken diligent pains to demonstrate that very axiom of Euclid solely from those things which are demonstrated before Proposition 29 of the first book. For before Proposition 29 there is no use of that axiom in Euclid. I have been told that this was also done in a certain Arabic Euclid, but I have never been given the opportunity to read that demonstration, though I have insistently demanded it again and again from the man who possesses that Arabic Euclid. For this reason we have devised the demonstration that follows. But first some preliminary matters must also be premised, which, although they are necessarily required for demonstrating what we propose, are nevertheless far more evident and easier than that axiom of Euclid, so that, with all doubt excluded, we may lend them a firm assent. Let the first be of this kind.

I.

Lemma I. A line, all of whose points are equally distant from a straight line lying in the same plane with it, is straight.

For if all the points of the line AB are equally distant from the straight line DC — that is, if all the perpendiculars dropped to DC, such as AD, EH, FG, BC, are equal (for any perpendicular, being the smallest of all the lines drawn from the same point to the straight line DC, measures the distance of the point from which it is drawn, by the corollary to Proposition 19 of this book) — then AB will be a straight line. And this can be clearly established from the definition of a straight line. For if all the points of the line AB are equally distant from the straight line DC, its points will lie evenly between one another — that is, no intermediate point in it will jut up or down from the extremities, nor bend this way or that, and nothing crooked will be found in it, but it will always extend evenly between its points, just like the straight line DC. Otherwise, not all its points would have an equal distance from the straight line DC, which is contrary to the hypothesis. Nor indeed can it be conceived in thought that any line other than a straight one

could have all its points at an equal distance from a straight line lying in the same plane with it. This principle is such that, once it alone is granted, together with those things which have been shown up to Proposition 29 of this book, we shall demonstrate the thirteenth axiom — a principle so clear that it is known by the natural light, and no one of sound mind could deny it. Or at any rate it is beyond all controversy such that anyone assents to it far more readily than to that thirteenth axiom of Euclid.

Diagram. A rectangular figure: a top line AB and a bottom line DC joined by equal perpendiculars.

- Top line (left to right): A, E, F, B.
- Bottom line (left to right): D, H, G, C.
- Perpendiculars: AD, EH, FG, BC — all equal — joining the top points to the bottom points.

The very same thing holds for a circular line. For a curved line surrounding a circular line, all of whose points are equally distant from the circular line — that is, from which all the straight lines falling to the circular line at equal angles are equal — is itself also circular; so that it takes on the nature of the circular line, from which it is always separated by an equal distance, just as a line always equidistant from a straight line takes on the nature of the straight line to which it is always equidistant, and is therefore straight, as we said. That such a curved line about a circular line is also perfectly circular we shall easily show, if we first demonstrate that a straight line drawn from the center of a circle makes two equal angles with the circumference, and conversely, that a straight line which makes equal angles with the circumference passes through the center.

Let there be, then, a circle ABCDEF whose center is G. I say that the straight line GC, drawn from the center, makes both the interior angles GCB, GCD and the exterior angles ICB, ICD equal to one another. For if IG is produced to A, and the semicircle ABC about the diameter AC is imagined to be turned around, it will coincide with the semicircle AEC, since semicircles of the same circle are equal to one another. But if anyone should say that one semicircle cuts the other, a straight line would have to be drawn from the center G cutting both circumferences, and it would follow that a part is equal to the whole — namely a radius drawn to the inner circumference equal to a radius drawn to the outer circumference — which is absurd. Therefore the angles at C, both interior and exterior, will coincide, and hence be equal. Now let the straight line HAK make equal angles at A. I say that it passes through the center. For if it does not pass through, let the straight line GA be drawn from the center G to A, which, by what

was just demonstrated, will make the angles GAB, GAF equal. Then the angles KAB, KAF are not equal — which is contrary to the hypothesis.

Diagram. Two concentric curves: an inner circle ABCDEF and an outer curved (inflexed) line HLIMNO, with connecting radii through the center G.

- G (center): center of the circle; K is a labeled point just to the left of G, near the center.
- Inner circle points (counterclockwise): A (top), B (left), C (bottom), D (lower right), E (right), F (upper right).
- Outer inflexed line, point for point outside the inner circle: H (top, outside A), L (left, outside B), I (bottom, outside C), M (lower right, outside D), N (right, outside E), O (upper right, outside F).
- The vertical diameter runs I – G – A (bottom to top through the center).
- Connecting lines run from each outer point through its inner point toward the center: HA, LB, IC, MD, NE, OF.
- The line HAK is drawn making equal angles at A.
- All labels read on the tile: outer H, L, I, M, N, O; inner A, B, C, D, E, F; center G; and K. (No labels flagged.)

This having been shown, let the inflexed line HLIMNO surround the circular line ABCDEF, and let all its points be equally distant from it — that is, let all the straight lines falling from that line onto the circular line, and making equal angles, be equal to one another, such as are HA, LB, IC, MD, NE, OF. For since, as has been demonstrated, these pass through the center, they will be the smallest of all the lines falling from the points H, L, I, M, N, O onto the convex periphery (for this was demonstrated by Euclid, Proposition 8 of Book 3, which depends solely on the propositions preceding Proposition 29 of this book, so that it may most rightly be transferred here), and thus they will measure the distances of those points from the underlying circular line. I say that the line HLIMNO is circular. For since all those lines, as we just showed, pass through the center G, if to the equal lines HA, OF are added the equal lines AG, FG, the whole lines HG, OG will be equal; and by the same reasoning all the other lines drawn from the inflexed line HLIMNO to G will be equal both to the straight lines HG, OG and to one another. By the definition of a circle, therefore, the inflexed line is circular. Which was to be demonstrated. From this first [lemma], which we premised, the second follows — namely:

II.

Lemma II. If a straight line is moved transversely over another straight line, always keeping right angles with it at its [lower] end, its other end will describe a straight line as well.

For if, in the previous figure, the straight line AD, perpendicular to DC, is moved transversely over the straight line DC, keeping with it at D always right angles — that is, not tottering or wavering, but always advancing evenly — the end A will describe a straight line as well, namely AB. This follows from what we premised in the first place, since all the points of the described line AB are equally distant from the straight line DC, namely by the straight line AD. From this it follows that this line is straight, since, as was said there, its middle parts do not jut up from the extremities but lie evenly between them, seeing that none of them recedes from the straight line CD, up or down, more or less than any other. This is also evident from what we wrote concerning the definition of a straight line. For since the two points D, A are carried by exactly similar motions (in that the straight line AD does not totter or waver in its motion, but the points D, A advance equally fast and always keep an equal distance between themselves), they will describe similar lines, as we taught in that same definition. Since, then, the point D describes the straight line DC, the line AB, which point A describes, will also be straight. Nor can anyone imagine that, if a straight line is moved transversely, uniformly and without any tottering this way or that, its two end-points would describe two lines differing from one another; rather, such a line as the one end describes, such must the other end also describe, on account of that uniform and even motion of both end-points. This principle is as clear and evident as the preceding one.

The very same thing holds entirely for a circular line. For in the same way a straight line flowing transversely over a circular line evenly — keeping, that is, at its end always equal angles with the circular line, without wavering or bending this way and that — describes with its other end a circular line, so that the described line takes on the nature of the underlying circular line, from which it is always equally distant: just as the straight line AD, flowing transversely over the straight line DC evenly — keeping, that is, at its end D always right angles with it, so that it never inclines, bending or tottering this way and that — traces out with its other end A the straight line AB, so that the described line AB takes on the nature of the underlying straight line DC, from which it always recedes equally. That a straight line flowing transversely over a circular line evenly describes with its other end a circular line as well, we shall easily demonstrate. For in the latter

figure let the straight line HA be moved transversely over the periphery ABCDEF evenly, always making at its end A equal angles with it. I say that the line HLIMNO, described by the other end H, is likewise circular. For since the straight line HA, in every position of that imagined motion, makes equal angles with the periphery ABCDEF, it comes about that, produced, it falls upon the center G, as we showed above. Therefore, adding the equal straight lines HA, OF to the equal straight lines AG, FG, the whole straight lines HG, OG, and all the others, will be equal to one another; and consequently, by the definition of a circle, HLIMNO will be the circumference of a circle. Which was to be shown. Hence follows the third [lemma].

III.

Lemma III. If to a straight line two mutually equal perpendicular straight lines are erected, and their end-points are joined by a straight line, then the perpendicular dropped from any point of this [joining] straight line to the first straight line will be equal to either of the prior perpendiculars.

Let there be erected to the straight line AB two mutually equal perpendiculars AC, BD; and, the straight line CD having been drawn, let the perpendicular EF be dropped from any point E of it to AB. I say that EF is equal to each of AC, BD. For if it is not equal, it will be either greater or less. Cut off, then, FG equal [to AC]: if the straight line AC is imagined to be moved transversely along the straight line AB, always making right angles with it, the point C will describe a straight line passing through G, as was shown above — namely CGD. Then the two straight lines CED, CGD will enclose a surface. Which is absurd. Therefore EF is equal to each of AC, BD. Which was to be shown. From this we shall demonstrate the fourth, which follows.

Diagram. A rectangular figure with a lens (vesica) shape formed by two lines CED and CGD between C and D.

- Top line (left to right): C, E, D — with E in the middle.
- G (upper apex, above the line CD): apex of the described curve; label read as G [?: the blackletter apex glyph is somewhat abraded but reads G].
- G (center, below E, on the vertical): point on the perpendicular EF.
- Bottom line (left to right): A, F, B.
- Sides: AC (left) and BD (right) are the equal perpendiculars; EF is the perpendicular dropped from E to F.

- The two lines CED (through E) and CGD (through G) bulge apart and enclose a surface.

IV.

Lemma IV. If to a straight line two mutually equal perpendicular straight lines are erected, and their end-points are joined by a straight line, this [joining] straight line will make a right angle with each perpendicular.

Let there be erected to the straight line AB two mutually equal perpendiculars AC, BD, and let the straight line CD be drawn. I say that each of the angles C, D is a right angle. For let the straight line AB be bisected at E; at E erect the perpendicular EF to AB; and join the straight lines AF, BF. Since, then, the two sides AE, EF of triangle AEF are equal to the two sides BE, EF of triangle BEF, each to each, and they contain equal angles — namely right angles [Margin: a — 4. pri. (I.4)] — the bases AF, BF, and the angles FAE, FBE as well as AFE, BFE, will also be equal to one another. Taking away, then, the equal angles FAE, FBE from the equal right angles CAE, DBE, the remaining angles CAF, DBF...

Diagram. A rectangle with an inscribed isosceles triangle from the midpoint of the base.

- Top line (left to right): C, F, D — with F in the middle.
- Bottom line (left to right): A, E, B — with E in the middle.
- Sides AC (left) and BD (right) are the equal perpendiculars; CD the top joining line.
- EF is the perpendicular erected at the midpoint E, rising to F.
- Diagonals FA and FB are drawn from F to the base ends, forming triangles AEF and BEF.

[Margin: a — 4. pri. (I.4)]

Euclid, *Elements* Book I — Clavius's commentary (continued)

[Conclusion of Lemma IV — that the angles C, D are right]

CAF, DBF. And so, since the two sides CA, AF of the triangle CAF are equal to the two sides DB, BF of the triangle DBF, and they enclose equal angles, as we have shown, [Margin: a — *Elements* I.4] the bases CF, DF will also be equal, and so will

the angles C, D, as well as CFA, DFB, to one another. If, then, to the equal angles CFA, DFB the angles AFE, BFE (shown to be equal) are added, the whole angles CFE, DFE become equal, and hence right. And since the perpendicular EF is equal to each of AC, BD — as we showed in the preceding theorem — the two lines AC, EF, drawn perpendicular to AE, will be equal to each other [?]. Therefore, just as was proved a moment ago concerning the angles C, D, the angles C and EFC will be equal to one another. But EFC has been shown to be right. Therefore C too will be right, and consequently so will the angle D, which has been shown equal to C.

We shall, however, demonstrate that the angles C, D are right by another method, once the following theorem has first been premised.

[Theorem: converging and diverging lines]

If a straight line falling upon two other straight lines makes with one of them an interior right angle, and with the other, on the same side, an acute angle, then those two lines, produced toward the side where the acute angle lies, will always be less distant from each other; but toward the other side they will always be more distant from each other.

Let the straight line AB, falling on the lines AC, BD, make the angle ABD right and the angle BAC acute. I say that the lines AC, BD, produced toward C, D, are always less distant from one another, but more distant if they are produced toward E, F.

Diagram. A figure of two nearly-horizontal straight lines cut by a transversal AB, with a zigzag staircase of alternating perpendiculars between them.

- Upper line (left → right): E, O, M, A, G, I, C
- Lower line (left → right): F, P, N, L, B, H, K, D
- A: point on the upper line where the transversal AB meets it (acute angle BAC)
- B: point on the lower line where the transversal AB meets it (right angle ABD)
- Toward C, D (right side): the perpendiculars BG, GH, HI, IK, KC drop alternately from lower to upper line and back, forming the converging staircase
- Toward E, F (left side): the perpendiculars AL, LM, MN, NO, OP, PE (and EF) rise alternately, forming the diverging staircase

For [Margin: b — *Elements* I.12] let the perpendicular BG be drawn from B to AC. By Corollary 2 to Proposition 17 of this book it will fall toward the side of the

acute angle BAC, and therefore the angle GBD, being part of the right angle ABD, will be acute. So when the perpendicular GH is dropped from G to BD, it too will fall toward the side of the acute angle GBD, by the same corollary; and therefore the angle HGC, being part of the right angle BGC, will be acute. Again, then, when the perpendicular HI is drawn to AC, by the same corollary it will fall toward the side of the acute angle HGC, and so the angle IHD, being part of the right angle GHD, will be acute. And so on to infinity: if from I the perpendicular IK is drawn to BD, and from K the perpendicular KC to AC, and from C the perpendicular CD to BD, and so forth, they will all fall toward the sides of the acute angles, one after another.

Now since in the triangle ABG the angle BAG is acute and AGB is right, [Margin: c — *Elements* I.19] the line AB will be greater than BG. And in the triangle BGH the line BG, being opposite the right angle GHB, is greater than GH; and in the triangle GHI the line GH is greater than HI. And so on continually: the lines nearer to AB will always be greater than those farther off, and there will be no end to this decrease of the perpendiculars. Therefore the line AC is less distant from the line BD at G than at A, and at I less than at G, and at C less than at I, and so on — seeing that the perpendiculars AB, GH, IK, CD, which decrease in order as we have shown, are the least of all the lines falling from the points A, G, I, C onto the line BD (as is clear from the corollary to Proposition 19 of this book), and consequently they measure the distances of those points from the same line BD. It is therefore established that the lines AC, BD, produced toward C, D, become continuously less distant from one another — which was the first point.

Again, let the perpendicular AL be erected from A on AC [Margin: d — *Elements* I.11]. It will divide the obtuse angle BAE into the right angle EAL and the acute angle LAB — that is, it will fall between AB and AE — and the angle ALB will be acute, since both ABL and ALB [Margin: e — *Elements* I.17] are less than two right angles while ABL is right; and consequently the angle ALF will be obtuse. By the same reasoning the perpendicular LM, erected on BF at L, will fall between LA and LF, and will make the angle LMA acute and LME obtuse. Likewise the perpendicular MN, erected on AE at M, will fall between ML and ME, and will make the angle MNB acute and MNF obtuse. And so on to infinity: if from N the perpendicular NO is erected to BF, and from O the perpendicular OP to AE, and from P the perpendicular PE to BF, and from E the perpendicular EF to AE, and so forth, it will divide all the obtuse angles one by one, one after another.

Now since in the triangle ABL the angle ABL is right and ALB [Margin: f — *Elements* I.19] acute, AL will be greater than AB; and in the triangle ALM the line

LM, opposite the right angle LMA, is greater than AL; and in the triangle LMN the line MN, opposite the right angle MNL, is greater than ML; and so on continually: the lines that are farther from AB will always be greater than those nearer to it, to infinity. Hence the line AE is more distant from the line BF at M than at A, and at O more than at M, and at E more than at O, and so on — since the perpendiculars AL, ML, ON, EP [?] (which, as was shown, increase in order) are the least of all the lines falling from the points A, M, O, E onto the line BF. It is therefore clearly established that the lines AC, BD, produced toward E, F, become continuously more distant from one another — which was the second point.

But if some obstinate person should want to maintain that the line AL, which is perpendicular to AC, does not meet DB when produced, that will establish all the more strongly the very thing proposed for demonstration. For the line DB, beyond the point B, will be much more distant from the line CA than at the point B — inasmuch as AL, which is perpendicular to AC, does not meet DB, whereas GB, likewise perpendicular to the same AC, does meet DB at B, and so on.

[Alternative proof that the angles C, D are right]

This being so, we shall demonstrate without difficulty that in the figure above the angles C, D are right. For if the angle C, say, is not said to be right, it will be either acute or obtuse. Suppose first it is acute. Since, then, the line CA, falling on the lines AB, CD, makes the angle CAB right and C acute, the lines CD, AB produced toward D, B will always be less distant from each other — that is, the perpendiculars dropped from CD onto AB will become smaller in order than CA, as was just demonstrated. The perpendicular DB is therefore less than CA, which is absurd, since it is assumed equal to it. So the angle C is not acute; and by the same reasoning neither will the angle D be acute.

Next suppose the angle C is obtuse. Since the line CA, falling on the lines CD, AB, makes the angle CAB right and C obtuse, the lines CD, AB produced toward D, B will always be more distant from each other — that is, the perpendiculars dropped from CD onto AB will increase continually, as we have just shown. The perpendicular DB is therefore greater than CA, which is absurd, since it is assumed equal. So the angle C is not obtuse; and by the same reasoning neither will the angle D be obtuse. But it has not been shown acute either. Each, therefore, is right — which was to be shown.

From what has been demonstrated we shall now easily demonstrate Axiom 13, in this way.

V.

If another straight line, falling on two straight lines, makes the interior angles on the same side less than two right angles, then those two straight lines, produced to infinity, will meet each other on the side where the angles are less than two right angles.

This is Axiom 13 in Euclid, according to our commentaries; in other editions it is the eleventh — the one we have undertaken to demonstrate. Let the straight line AB, falling on the lines AC, BD, make the interior angles ABD, BAC on the same side less than two right angles. I say that the lines AC, BD, produced toward C, D, meet.

Diagram. A "staircase" figure of congruent right triangles built between a vertical transversal AB and an oblique line AC, used to prove Axiom 13 for the case where one interior angle is right.

- Vertical line AB (top → bottom): A, F, G, H, B, I (A at top; I falls below B)
- Oblique line AC (top → bottom): A, E, K, L, C (equal segments $AE = EK$, $KL = AK$, $LC = AL$ — successive doublings)
- Produced points (beside E, K, L respectively): M, N, O (with $EM = EF$, $KN = KG$, $LO = LH$; the joins MK, NL, OC are drawn)
- Horizontal line BD: B (left), D (right)
- The perpendiculars EF, KG, LH, CI are drawn to AB and produced to M, N, O

Suppose first that one of the angles — namely ABD — is right, and the other, BAC, acute. Taking any point E on the line AC [Margin: g — *Elements* I.12], drop from it a perpendicular EF to the line AB; take FG equal to AF, GH equal to AG, and HI equal to AH, so that AG is double AF, AH double AG, and AI double AH.

And since, if along the line AF equal segments are continually cut off, some part will fall beyond the point B — because the finite line AB is at last exhausted by the continual removal of one and the same quantity, seeing that the line AF can be so multiplied (by taking equal parts along AB continuously) that it eventually exceeds the finite line AB. This Euclid frequently assumes in Book 5 and the following books, where, given two unequal magnitudes having a ratio to one another, he usually requires the smaller to be so multiplied until it exceeds the larger. It happens all the more if to AF an equal FG is cut off, and then GH is taken equal to the whole AG (not to AF alone), and HI to the whole AH (not to AF or AG alone), and so on: some part will at last fall beyond the point B. Let the point I,

then — which terminates the third double in the present example — be set beyond the point B.

Take also on the line AC the segment EK equal to AE, KL equal to AK, and LC equal to AL, so that there are as many parts on AC as on AB; and let the lines KG, LH, CI be drawn and produced, together with EF, so that EM, KN, LO become equal to EF, KG, LH respectively; and finally let the lines MK, NL, OC be joined. Now since the two sides KE, EM of the triangle KEM are equal by construction to the two sides AE, EF of the triangle AEF, each to each, and they contain equal vertical angles at E [Margin: I.15], the base MK will be equal to the base AF and the angle M to the angle F [Margin: I.4]. But FG is also equal to AF, and the angle F is right by construction. Therefore MK and FG will be equal to each other [Margin: Common Notion 1], and the angle M too will be right. And so, since at FM two equal perpendiculars FG, MK have been raised, the angle G will be right by the preceding theorem.

Again, since the two sides LK, KN of the triangle LKN are equal by construction to the two sides AK, KG of the triangle AKG, and they contain equal vertical angles at K [Margin: I.15], the base NL will be equal to the base AG and the angle N to the angle G [Margin: I.4]. But GH is also equal to AG by construction, and the angle G is right, as was just shown. Therefore NL and GH will be equal to each other [Margin: Common Notion 1], and the angle N too will be right. Consequently, by the preceding theorem, the angle H will also be right. By the same reasoning we shall show that the angle I is right, and so on, if there were more parts of the line AB. But the angle B is also right by hypothesis; therefore the lines IC, BD [Margin: g — *Elements* I.28] are parallel; and so BD produced will cut the line AC beyond C, and thus at that point of section the lines AC, BD will meet. Which was to be demonstrated.

[Axiom 13 — the case where neither interior angle is right]

Next, let neither of the angles ABD, BAC be right, but ABD acute and BAC either acute or obtuse. Since the two angles ABD, BAC are assumed less than two right angles, while the two angles ABD, DBE [Margin: h — *Elements* I.13] are equal to two right angles, the latter two will be greater than the former two. So when the common angle ABD is removed, the remaining angle DBE will be greater than the remaining angle BAC. [Margin: a — *Elements* I.23] Construct at A, on the line AB, an angle BAF equal to the angle DBE. The line AF will fall above the line AC, since AF makes a greater angle with AB than AC does. Now since the exterior angle DBE is equal to the interior and opposite angle BAF on the same side, [Margin: b — *Elements* I.28] the lines AF, BD will be parallel to each other.

Diagram. A figure showing the transversal AB meeting the lines AC, BD, with the auxiliary line AF (parallel to BD) and the perpendicular AG dropped to BD, used to prove that the lines meet when neither interior angle is right.

- H: upper left, on the line H–A–F drawn across the top
- F: upper right, endpoint of AF (with AF parallel to BD)
- Apex (top center): the point A, where the transversal and the constructed lines meet [label A not clearly legible on the leaf]
- E: lower left, on the lower line (angle DBE)
- G: lower center, foot of the perpendicular dropped from A onto BD
- D: lower right, on the lower line
- B (on the lower line, between E and G) and C (endpoint of AC, toward the lower right) belong to the construction but are not clearly legible at this resolution

Also drop from A to BD [Margin: c — *Elements* I.12] the perpendicular AG, which, by Corollary 2 to Proposition 17 of this book, will fall toward the side of the acute angle ABD; and the angle GAF too will be right. For if it be said to be acute, then the line AG, falling on the lines AF, BD, would make the angle AGD right and GAF acute, and consequently — as we demonstrated just above — the lines AF, BD, produced toward F, D, would at last meet; which is absurd, since they have been shown to be parallel. And if the angle GAF be said to be obtuse, then GAH will be acute; and so, from what was just demonstrated, the lines AF, BD, produced toward H, B, would meet, which is absurd, since they have been shown to be parallel. So the angle GAF is neither acute nor obtuse. It is therefore right, and consequently its part GAC is acute. Now since the line AG, falling on the lines AC, BD, makes the angle G right and GAC acute, the lines AC, BD, produced toward C, D, will meet, as we demonstrated just above. Therefore, if the line AB, falling on the lines AC, BD, makes two angles less than two right angles, neither of the angles ABD, BAC being right, the lines AC, BD, produced toward C, D, will meet. Which was to be shown.

And if it should happen that the line AC lies between AB and the perpendicular AG, it is clearly established that the lines AC, BD meet, since AC would then cut the base BG of the triangle ABG. To grasp this more easily, you may draw the line AC between AB and AG.

[Remark: the postulate is demonstrable]

Although, once our principle is granted, this thirteenth axiom has been excellently demonstrated by us — and by Proclus too, if his principle (harder, indeed, than ours) be admitted — so that it can with full right be reckoned among the theorems and not among the first principles, nevertheless, so as not to alter Euclid's order in any respect, we shall use it in all the propositions whose demonstrations depend on it, as though it were a postulate. But let us now return to the series of Euclid's propositions.

THEOR. 20. PROPOS. 29. [Margin: xxix.]

A straight line falling on parallel straight lines makes the alternate angles equal to one another; and the exterior angle equal to the interior and opposite angle on the same side; and the interior angles on the same side equal to two right angles.

Let the straight line EF fall on the parallels AB, CD.

Diagram. The standard figure for Proposition 29: two parallels AB, CD cut by the transversal EF.

- Upper parallel AB: A (left), B (right)
- Lower parallel CD: C (left), D (right)
- Transversal EF: E (upper end), F (lower end)
- G: intersection of the transversal with AB
- H: intersection of the transversal with CD

I say first that the alternate angles AGH, DHG are equal to one another. For if they are not equal, let one — say AGH — be the greater. Then since the angle AGH is greater than the angle DHG, if the common angle BGH is added, [Margin: a — Common Notion 4] the two angles AGH, BGH will be greater than the two DHG, BGH. But the two AGH, BGH [Margin: b — *Elements* I.13] are equal to two right angles. Therefore the two DHG, BGH are less than two right angles. And so, since they are interior and on the same side, B and D, [Margin: c — Common Notion 13 (the postulate)] the lines AB, CD will meet on that side — which is absurd, since they are assumed parallel. So the angle AGH is not greater than the angle DHG; nor is it less, for by the same reasoning it would be shown that the lines meet toward A and C. Therefore the alternate angles AGH, DHG are equal. And the same reasoning holds for the alternate angles BGH, CHG.

I say secondly that the exterior angle AGE is equal to the interior and opposite angle CHG on the same side. For the alternate angle CHG is equal to BGH, as was

shown; and to the same BGH [Margin: d — *Elements* I.15] the angle AGE is equal. Therefore the angles AGE, CHG [Margin: e — Common Notion 1] will also be equal to one another. In the same way it will be demonstrated that the angle BGE is equal to the angle DHG.

I say thirdly that the interior angles on the same side, AGH, CHG, are equal to two right angles. For it was shown that the exterior angle AGE is equal to the interior angle CHE [recte: CHG]; if the common angle AGH is added, [Margin: a — Common Notion 2] the two angles AGE, AGH will be equal to the two CHG, AGH. But the two AGE, AGH [Margin: b — *Elements* I.13] are equal to two right angles. Therefore the two angles CHG, AGH will also be equal to two right angles. In the same way the angles BGH, DHG will be equal to two right angles. Therefore a straight line falling on parallel straight lines makes the alternate angles equal, and so on. Which was to be demonstrated.

SCHOLIUM

This present theorem is the converse of the two preceding theorems, as is evident.

THEOR. 21. PROPOS. 30. [Margin: xxx.]

Straight lines parallel to the same straight line are also parallel to one another.

Let the straight lines AB, CD be parallel to the same straight line EF. I say that AB, CD are also parallel to one another. Since all these lines are assumed to lie in the same plane (for Proposition 9 of the eleventh book will treat of lines in different planes), the straight line GH drawn across will cut them all — namely AB at I, CD at K, and EF at L.

Diagram. Three parallel lines cut by one transversal GH, for Proposition 30.

- Upper parallel AB: A (left), I (crossing), B (right)
- Middle parallel EF: E (left), L (crossing), F (right) [left-hand label of the middle line is faint]
- Lower parallel CD: C (left), K (crossing), D (right)
- Transversal GH: G (upper end), H (lower end)

Now since AB is assumed parallel to EF, [Margin: c — *Elements* I.29] the angle AIL will be equal to the alternate angle FLI. Again, since CD is also assumed parallel to EF, [Margin: d — *Elements* I.29] the angle DKI will be equal to the same angle FLI — namely as interior to exterior, or exterior to interior. Therefore the angles AIL,

DKI [Margin: e — Common Notion 1] will also be equal to one another. And since they are alternate, [Margin: f — *Elements* I.27] the lines AB, CD will be parallel to each other. Therefore straight lines parallel to the same straight line are also parallel to one another. Which was to be demonstrated.

SCHOLIUM

But if someone should say that the two lines AI, BI are parallel to the line CD and yet are not parallel to each other, the reply is that AI, BI are not two lines but only parts of one line. For one must conceive any parallels as produced to infinity; and it is clear that AI produced coincides with BI. For this reason the proposition could have been stated more generally, thus:

Diagram. Three parallel lines cut by a transversal GH, illustrating the scholium to Proposition 30.

- Upper parallel AB: A (left), I (crossing), B (right)
- Middle parallel CD: C (left), K (crossing), D (right)
- Lower parallel EF: E (left), L (crossing), F (right)
- Transversal GH: G (upper end), H (lower end)

Straight lines parallel to the same straight line are also parallel to one another; or else, when they meet each other, they constitute one and the same line.

Diagram. Two lines AB, AC meeting at A, both parallel to DE, with the transversal AF, illustrating that they lie in one straight line.

- B (left) — A (apex, upper right) — C (short segment to the right): the lines AB and AC meeting at A
- Lower line DE: D (left), F (center, where AF meets DE), E (right)
- AF: drawn from A down to F on DE

For let two straight lines AB, AC, meeting at A, be parallel to DE. I say they are set in a straight line. From the point A let the straight line AF be drawn, cutting DE at F, in any manner. Since AB, DE are parallel, [Margin: a — *Elements* I.29] the alternate angles BAF, AFE will be equal. So when the common angle CAF is added, [Margin: b — Common Notion 2] the two angles at A will be equal to the two angles CAF, AFE. But these two [Margin: c — *Elements* I.29] are equal to two right angles, since they are interior between the two parallels AC, DE. Therefore the two angles at A will also be equal to two right angles; and consequently [Margin: d — *Elements* I.14] AB, AC are set in a straight line. Which was the thing proposed.

PROBLEMA 10. PROPOSITIO 31. [Margin: xxxj.]

Through a given point, to draw a straight line parallel to a given straight line.

Through the point A a line is to be drawn parallel to the line BC.

Diagram. The construction for Proposition 31: through A, a parallel FE to the given line BC.

- Upper line FAE (the parallel drawn through A): F (left), A (the given point), E (right)
- Lower line BC (given): B (left), D (center, foot of AD), C (right)
- AD: the auxiliary line from A to D on BC

From A draw a line AD to BC, in any way, making any angle ADB; and at A construct the angle EAD equal to it [Margin: e — *Elements* I.23]. I say that the line EA, extended to F as far as you please, is parallel to BC. For since the alternate angles ADB, DAE are equal by construction, [Margin: f — *Elements* I.27] the lines BC, EF will be parallel. Therefore through a given point we have drawn a straight line parallel to a given straight line, and so on. Which was to be done.

SCHOLIVM

Now the given point must be situated in such a place outside the given line that this line, when produced, does not meet it. This is plainly gathered from the very construction of the problem. For from the given point a line must be drawn making some angle with the given line, which could not happen if the point lay in a straight line with the given line itself. And just as from one and the same point only one perpendicular — not several — can be drawn to the same straight line, as we showed at Proposition 17 from Proclus, so too through the same point only one parallel — not several — can be drawn to a given straight line. For if two were drawn, they would meet [Margin: a — *Elements* I.30] at that same point, which is absurd, since they are parallel to one another — because they are parallel to one and the same line to which they are said to be drawn parallel.

Moreover, from this problem together with the one contained in Proposition 23, we shall easily construct a parallelogram one of whose angles is equal to a given rectilinear angle, and whose sides containing that angle are equal to two given straight lines.

Diagram. The construction of a parallelogram DEGF with a given angle and given sides.

- Parallelogram vertices: D (bottom left), E (bottom right), G (top right), F (top left)
- Given straight lines shown separately at the lower left: A (upper segment), B (lower segment)
- Given rectilinear angle: C (at the left)

For let the straight lines A, B be given, and let it be required to construct a parallelogram having an angle equal to the given rectilinear angle C, with the sides about that angle equal to the given lines A, B. Take a straight line DE equal to the line A; [Margin: b — *Elements* I.23] make the angle EDF equal to the angle C, [Margin: c — *Elements* I.3] and the line DF equal to the line B. Then through E [Margin: d — *Elements* I.31] draw the line EG parallel to DF, and through F the line FG parallel to DE, cutting EG at G. Since, then, both the sides DF, EG and the sides DE, FG are parallel by construction, [Margin: e — Definition 35] DEGF will be a parallelogram. And since by construction it has the angle D equal to the given angle C, and the sides DE, DF about the said angle D equal to the given lines A, B, what was proposed will have been done.

By similar reasoning, from this problem and Proposition 23, we shall draw from a point given outside a given straight line a straight line that makes with the given line an angle equal to a given rectilinear angle — as we promised at Proposition 23.

Diagram. From the point A outside BC, a line AB making with BC an angle equal to the given angle D.

- Given rectilinear angle: D (upper left)
- A: the given point (upper right)
- F: endpoint of EF (to the right)
- Lower line BC: B (left), E (center, the chosen point), C (right)
- AB: drawn through A parallel to EF, meeting BC at B; EF: the angle CEF constructed at E

For let the point A be given outside the line BC, and let the rectilinear angle D be given; and let it be required to draw from A to the line BC a straight line that contains with it an angle equal to the given angle D. Take any point E on the line BC and [Margin: a — *Elements* I.23] construct at it an angle CEF equal to the angle D. If, then, the line EF passes through the given point A, what was ordered will have been done. But if it does not pass through A, [Margin: b — *Elements* I.32] draw through A a line AB parallel to EF, cutting BC at B. I say that the angle ABC is equal to the angle D. For since AB, EF are parallel, [Margin: c — *Elements* I.29] the

angle CEF, as exterior, is equal to the interior and opposite angle ABC on the same side. And since the angle D is also equal to the angle E by construction, [Margin: d — Common Notion 1] the angles ABC and D will be equal to one another — which was proposed.

It does not seem out of place to show here that Euclid, at Proposition 26 — in order to demonstrate the equality of the sides in two triangles from the equality of two angles and one side — rightly prescribed that that side must either be adjacent to the equal angles or else subtend an equal angle. For unless one of these two conditions is present, nothing will be concluded.

Diagram. The counterexample triangle ABC with DE drawn parallel to AC, showing why the side-condition in Proposition 26 is needed.

- A: apex (top)
- B: bottom left; C: bottom right
- D: point on AB
- E: point on BC (near C)
- DE: drawn inside the triangle, parallel to AC

For let there be a triangle ABC, with the sides AB, AC greater than the side BC. Cut off BD equal to BC, [Margin: e — *Elements* I.31] and draw DE parallel to AC; [Margin: f — *Elements* I.29] then the angle BED will be equal to the angle C. And so the two angles B, C of the triangle ABC are equal to the two angles B, E of the triangle DBE, each to each, and the side BC is equal to the side DB — and yet the remaining sides...

(Clavius's commentary — scholium to Proposition 31, continued from the previous pages.)

the remaining sides are not equal to the remaining sides. For BE is less than BC, and so cannot be equal either to side AC or to side AB, since these sides are assumed to be greater than side BC. The reason is this: in triangle ABC the side BC lies adjacent to the said angles, whereas in triangle DBE the side DB is opposite one of those angles—namely the angle DEB, which is equal to angle C.

Again, let there be a triangle FGH, and let the sides FG and FH once more be greater than the side GH, with FH greater than FG. Cut off HI equal to FG [Margin: g — *Elements* I.31], and draw IK parallel to FG [Margin: h — I.29]. Then the angle HKI will be equal to angle G. Therefore the two angles H and G of triangle FGH are equal to the two angles H and K of triangle IKH, each to each, and the side FG is equal to the side IH; and yet the remaining sides are not equal to the remaining

sides. For HK is less than HG, and so cannot be equal either to side HG or to side FH, since FH is assumed to be even greater than GH. The reason is this: in triangle FGH the side FG is opposite angle H, whereas in triangle IKH the side IH is opposite angle K—which is not assumed equal to angle H, but is equal to angle G [Margin: i — I.18], and G is greater than H, because we assumed side FH greater than side FG. We have postponed this demonstration to this place on account of the properties of parallel lines, on which it depends.

Diagram. Two triangles sharing the base region and the right-hand vertex, illustrating the I.26 counter-example. The outer triangle FGH has its apex F at the top, with G at the lower left and H at the lower right. Inside it a second triangle IKH is drawn (with dashed construction lines): I lies on side FH just below F, K lies on the base near G, and IK is drawn parallel to FG.

- F (apex, top): outer-triangle vertex
- I (upper, on FH near F): vertex of inner triangle IKH (HI cut off equal to FG)
- G (lower left): outer-triangle vertex
- K (lower, near G): vertex of inner triangle IKH
- H (lower right): shared vertex of both triangles

Praxis

(Practical constructions for Proposition 31 — drawing a parallel through a point.)

Suppose a parallel to BC is to be drawn through the point A. Draw a straight line AD to BC at any inclination, and from D and A, with any one and the same radius, describe two arcs on opposite sides—one toward B, the other toward C. Then, with the compass, cut off from the second arc an arc GH equal to the arc EF. If now a straight line is drawn from A through H [Margin: k — I.27], it will be parallel to BC; for the alternate angles EDF and HAG are equal, as is established from the construction of Proposition 23, and so on.

Diagram. Construction of a parallel to BC through A by equal arcs. The lower line runs from B (left) to C (right); the transversal AD is drawn obliquely from A down to D on BC. From D an arc is described (endpoints E and F) and from A an equal arc (endpoints G and H); the line AH is the parallel drawn through A.

- A (upper line, left): the given point through which the parallel is drawn
- H (top, arc endpoint): end of the arc centred at A; the parallel AH passes through it
- G (on AD below A): arc endpoint at A (angle HAG)

- E (on BC, left of D): arc endpoint at D (angle EDF)
- D (on BC): foot of the transversal AD
- B (lower line, left) / C (lower line, right): endpoints of the given line
- F: second endpoint of the arc centred at D, on segment AD [?] (label not clearly legible on the leaf)

By another method a parallel to the given line BC will be drawn through the same point A in this way. From center A, with any radius, describe an arc cutting BC at the point D; and with the same radius, from D, mark off a point E on the same straight line BC. Then, with the same radius, from A and E describe two arcs cutting each other at F. For once the straight line AF is drawn, it will be parallel to the straight line BC. Since the same radius was assumed, AF is equal to DE, and AD equal to EF (were these lines drawn); therefore AF, being opposite DE, will be parallel to it, as we shall demonstrate later at Proposition 34.

Diagram. A pair of horizontal lines forming the parallelogram-based construction. The upper line carries A (left) and F (right), where two arcs cross; the lower line runs from B (left) through D and E to C (right). AF is drawn equal and parallel to DE.

- A (upper line, left): the given point
- F (upper line, right): intersection of the two arcs
- B (lower line, left) / C (lower line, right): endpoints of the given line BC
- D (lower line): where the arc from A cuts BC
- E (lower line): point marked off from D at the same radius

But if the point A is close to the straight line BC, the desired parallel is drawn more conveniently by this rule. From A, take a point D on BC at any distance; and from any point of the same line BC—namely E, which should however be somewhat distant from D (for the greater the distance between D and E, the more easily and accurately the parallel is drawn)—describe an arc toward A with the same radius. Then, from A with the radius DE, describe another arc cutting the former at F. For when AF is rightly drawn it will be parallel to BC, as before, because AF is equal to DE by the same radius, and AD equal to EF, were these lines drawn, and so on.

Diagram. The same construction adapted to a point A near the line. Upper line with A (left) and F (right, arc intersection); lower line from B (left) through D and E to C (right).

- A (upper line, left): the given point, close to BC

- F (upper line, right): intersection of the two arcs
- B (lower line, left) / C (lower line, right): endpoints of BC
- D (lower line): point taken on BC
- E (lower line): the more distant point on BC

But we have set out a far easier method of drawing a parallel to a given line through a given point in our *Astrolabe*, Book 1, Lemma 4 (Clavius, *Astrolabium* I, lemma 4).

From these constructions we shall easily draw, from the end point of some line, a line perpendicular to that given line—even if the line cannot be produced—which we promised in the scholium to Proposition 11. Let AB be the straight line from whose end point B a perpendicular is to be raised. Taking any point C, cut off CB equal to CA, and from A and B, with any radius, describe two arcs cutting each other at D; then draw the straight line DC, which will be perpendicular to AB, as we wrote at Proposition 11. Next, through B draw a parallel to CD, according to the construction of this Proposition 31 just explained: from CD cut off any segment CE; from B, with radius CE, describe an arc, which is cut at F by another arc described from E with radius CB; and draw the straight line BF. For this will be parallel to CD, as is clear from the construction of this Proposition 31. Therefore, since the angle ACD is equal to the interior angle CBF [Margin: l — I.29], and since ACD is a right angle, CBF will also be a right angle, and consequently BF will be perpendicular to AB.

Diagram. Raising a perpendicular at the endpoint B of AB. Along the baseline lie A (left), C (middle, with $CA = CB$), and B (right). Above, D is the intersection of the arcs from A and B (so $DC \perp AB$); E is taken on CD, and F is where the arcs of radius CE and CB meet, so that BF is parallel to CD and hence perpendicular to AB.

- D (top): intersection of the arcs from A and B; $DC \perp AB$
- E (middle, on CD): point cut off on CD
- F (middle, right): intersection of the constructing arcs; BF passes through it
- A (baseline, left) / C (baseline, middle) / B (baseline, right): the line AB with C such that $CA = CB$

Similarly, if a straight line AB is given, and a point C outside it—near the edge of the plane in which the line lies—we shall draw from C a perpendicular to AB, without either producing the line or extending the plane below AB, as we promised at Proposition 12, in this way. Take a point D anywhere on AB, and cut off on either side DA and DB equal to each other; from A and B, with any radius,

describe two arcs cutting each other at E; then draw the straight line ED, which by the construction of Proposition 11 will be perpendicular to AB. Next, through C draw a parallel to DE, according to the construction of this Proposition 31: from the given point C, with any radius, describe an arc cutting DE at F; with the same radius, from D toward C, describe another arc, which is intersected at G by another arc drawn from C with radius DF. For the straight line drawn from C through G, cutting AB at H, will be parallel to DE, by the construction of this Proposition 31. Therefore, as we wrote just now, CH will be perpendicular to AB, just as ED is perpendicular to the same.

Diagram. Dropping a perpendicular from an external point C to AB. Along the baseline lie A, D, B, and H (left to right), with $DA = DB$. E lies above D, where the arcs from A and B meet, so $ED \perp AB$. C is the external point (upper right); F is where an arc from C cuts DE, and G is the intersection of the constructing arcs, so that the line CGH is parallel to DE and hence $CH \perp AB$.

- E (top): intersection of the arcs from A and B; $ED \perp AB$
- C (upper right): the given external point
- F (middle, left, on DE): where an arc from C cuts DE
- G (middle, right): intersection of the two constructing arcs; CH passes through it
- A / D / B / H (baseline, left to right): AB with D its chosen point ($DA = DB$) and H the foot of the perpendicular CH

Theorem 22. Proposition 32.

[Margin: xxxij.]

(*Euclid, enunciation.*) In any triangle, when one side is produced, the exterior angle is equal to the two interior and opposite angles. And the three interior angles of a triangle are equal to two right angles.

[p. 56]

(*Clavius's demonstration.*) In triangle ABC, let the side BC be produced to D. I say first that the exterior angle ACD is equal to the two interior and opposite angles A and B together. For draw from C a line CE parallel to the straight line AB [Margin: b — I.31]. Then, since the straight line AC falls upon the parallels AB and CE, the alternate angles A and ACE will be equal [Margin: a — I.29]. Again, since the straight line BD falls upon the same parallels, the exterior angle DCE will be equal to the interior angle B [Margin: b — I.29]. Therefore, adding the equals ACE and A, the whole angle ACD—which is composed of the two angles DCE and ACE—

becomes equal to A and B together [Margin: c — common notion 2 (pronuntiatum 2)]. Which is what was proposed.

I say secondly that the three interior angles of the same triangle—A, B, and ACB—are equal to two right angles. For since the exterior angle ACD, as was shown, is equal to the two interior angles A and B, if the common angle ACB is added, the two angles ACD and ACB will be equal to the three angles A, B, and ACB [Margin: d — common notion 2]. But the two angles ACD and ACB are equal to two right angles [Margin: e — I.13]. Therefore the three interior angles A, B, and ACB are also equal to two right angles. Therefore, in any triangle, when one side is produced, and so on. Which was to be demonstrated.

Diagram. The triangle for Proposition 32. Triangle ABC has its apex A at the top; the base runs from B (lower left) to C, and BC is produced beyond C to D (lower right). From C a line CE is drawn upward to the right to E, parallel to AB.

- A (apex, top): vertex whose interior angle is under consideration [?] (label partly obscured by an arrowhead on the tile)
- B (lower left): base vertex
- C (base, right of B): vertex at which the side is produced
- D (lower right): the point to which BC is produced
- E (upper right): endpoint of CE, drawn parallel to AB

Scholium

Since it was demonstrated in Proposition 16 that the exterior angle of any triangle is greater than either of the interior and opposite angles, whereas here the same exterior angle is shown to be equal to those two interior angles together, it is clear that either one of the interior and opposite angles is exceeded by the exterior angle by the amount of the other interior and opposite angle. Thus, in the triangle proposed, the interior angle A is exceeded by the exterior angle ACD by the interior angle B; and the interior angle B is exceeded by the same exterior angle ACD by the interior angle A—since the angle ACD has been shown in this place to be equal to A and B together. Again, since it was demonstrated in Proposition 17 that any two angles of a triangle, taken in any way, are less than two right angles, while here all three are equal to two right angles, it is clear that the two fall short of two right angles by the remaining angle of the triangle. Thus, in the same triangle, the two angles A and B fall short of two right angles by the angle ACB, to which that deficit is equal.

Moreover, that every triangle has its three angles equal to two right angles was, as Eudemus [Eudemus of Rhodes] reports, first of all demonstrated by the Pythagoreans in this way. Let there be a triangle ABC, and through the point A [Margin: a — I.31] draw a line DE parallel to BC. Then, since the alternate angles DAB and ABC are equal [Margin: b — I.29], if the equal angles EAC and ACB are added (for these too are alternate), the two angles DAB and EAC will be equal to the two angles ABC and ACB [Margin: c — common notion 2]. Therefore, adding the common angle BAC [Margin: d — I.2 (pronuntiatum)], the three angles DAB, BAC, CAE will be equal to the three angles ABC, BAC, ACB. But the angles DAB, BAC, CAE are equal to two right angles, as is established from Proposition 13. Therefore in triangle ABC also the angles ABC, BAC, ACB are equal to two right angles—which is what was proposed.

From this, moreover, we shall easily conclude that the exterior angle ACF, if the side BC is produced, is equal to the two interior and opposite angles ABC and BAC. For since the angles ABC, BAC, ACB are equal to two right angles, as was shown [Margin: e — I.13], and the angles ACF and ACB are also equal to two right angles, the angles ABC, BAC, ACB will be equal to the angles ACF and ACB. Therefore, removing the common angle ACB, the angle ACF remains equal to the two angles ABC and BAC [Margin: f — common notion 3 (pronuntiatum 3)].

Diagram. The Pythagorean demonstration. Triangle ABC has apex A; through A the line DAE is drawn parallel to the base BC (D on the left, E on the right). The base runs from B (lower left) through C, with BC produced beyond C to F (lower right), forming the exterior angle ACF.

- D (top left): endpoint of the parallel through A (angle DAB)
- A (apex): vertex of the triangle
- E (top right): endpoint of the parallel through A (angle EAC)
- B (lower left): base vertex
- C (base): base vertex
- F (lower right): point to which BC is produced (exterior angle ACF)

The first part of Euclid's proposition can also easily be converted; that is: if from one angle of a triangle a straight line is drawn so that the exterior angle equals the two interior and opposite angles, then that line is set in a straight line with the side. For from C draw the straight line CD, and let the angle ACD be equal to the two angles ABC and BAC. I say that BC and CD lie in a straight line. Since the angle ACD is equal to the angles ABC and BAC, if the common angle ACB is added, the angles ACD and ACB will be equal to the angles ABC, BAC, ACB [Margin: g —

common notion 2]. But ABC, BAC, ACB are equal to two right angles [Margin: h — I.32]. Therefore the angles ACD and ACB will also be equal to two right angles. Therefore BC and CD constitute one straight line [Margin: i — I.14].

How Many Right Angles All the Interior Angles of Any Rectilineal Figure Are Equivalent To

(An additional proposition by Clavius.) By two methods, from this Proposition 32, we shall gather how many right angles the interior angles of any rectilineal figure are equivalent to; the first of these is as follows.

(Enunciation.) All the angles of any rectilineal figure are equal to twice as many right angles as the number giving the figure's rank among the rectilineal figures.

That is: all the angles of the first rectilineal figure are equal to twice one right angle, that is, to two right angles; the angles of the second rectilineal figure are equal to twice two right angles, namely four right angles; the angles of the third rectilineal figure are equal to twice three right angles, namely six right angles; and so with the rest. The rank that any rectilineal figure holds among the rectilineal figures is indicated by the number of its sides or angles, less two—since two straight lines do not enclose a surface, and therefore do not form a figure, but at least three straight lines are required to constitute a figure. From this it follows that the triangle, since it has three sides and as many angles, is the first among the rectilineal figures; for when two is subtracted from three, one remains. Thus a figure having 20 sides or angles will be the eighteenth among rectilineal figures, since two subtracted from 20 leaves 18. The same judgment is to be made about the other figures. Accordingly, a figure contained by 20 sides, being the eighteenth, will have 20 angles equivalent to 36 right angles—namely twice 18 right angles, as was said. Likewise all 10 angles of a figure contained by 10 sides will be equivalent to 16 right angles, since such a figure is the eighth among the rectilineal figures. This will be demonstrated in the following way. Every rectilineal figure is divided into as many triangles as its rank among the figures—that is, as many as it has angles or sides, less two. For from any one of its angles straight lines can be drawn to all the opposite angles; only to the two neighboring angles can they not be drawn. Therefore it will be divided into as many triangles as it has angles, less those two. Thus you see that a triangle cannot be divided into other triangles; a quadrilateral can be cut into two; a pentagon into three; a hexagon into four, and so on. Since, then, the angles of these triangles constitute all the angles of the proposed rectilineal figure, and all the angles of any triangle are equal to two right angles, it is clear that all the angles of

any rectilineal figure are equal to twice as many right angles as the number of triangles into which it is divided—that is, as its rank among the rectilineal figures. This is indeed clearly seen in the figures shown.

Diagram. A row of four unlabelled rectilineal figures illustrating division into triangles by diagonals drawn from a single vertex: a triangle (undivided), a quadrilateral (split into 2 triangles by one diagonal), a pentagon (split into 3), and a hexagon (split into 4). No point-labels are printed.

[p. 57]

all the angles of any rectilineal figure are equal to twice as many right angles as the number of triangles into which it is divided—that is, as its rank among the rectilineal figures. This is indeed clearly seen in the figures shown.

The second method, by which the value of the angles of any rectilineal figure is found, is this.

(Enunciation.) All the angles of any rectilineal figure are equal to twice as many right angles, less four, as it contains sides or angles.

That is: the angles of any triangle are equal to twice three right angles less four—namely two right angles. Likewise, the angles of a figure containing 20 sides will be equivalent to twice 20 right angles less four—namely 36 right angles—and so on. The demonstration is as follows. If from any point taken inside the figure straight lines are drawn to all the angles, as many triangles are produced as the figure contains sides or angles. Then, since the angles of any triangle are equal to two right angles [Margin: a — I.32], all the angles of those triangles will be equal to twice as many right angles as there are sides bounding the figure. But the angles of those triangles that meet at the point taken inside the figure do not belong to the angles of the proposed rectilineal figure, as is evident. Therefore, if these are taken away, the remaining triangle-angles—those that constitute the angles of the proposed figure—will likewise be equal to twice as many right angles, less those formed at the assumed point, as the figure contains sides or angles. Now all those angles about the said point, however many they are, are equal to just four right angles, as we gathered from Proposition 15. For this reason the angles of every figure are equal to twice as many right angles, less four, as the figure contains angles or sides—which is what was proposed.

Diagram. A row of unlabelled rectilineal figures illustrating the second method—division into triangles from a single interior point: a figure divided into triangles

about an interior point, then a quadrilateral (4 triangles), a pentagon (5 triangles), and a hexagon (6 triangles). No point-labels are printed.

Furthermore, from this second method it is clear that, if the several sides of any rectilineal figure are produced in order toward the same side, all the exterior angles together are equal to four right angles. For any exterior angle, together with the interior angle next to it, equals two right angles [Margin: b — I.13]; and so all the exterior angles together with all the interior angles will be equal to twice as many right angles as the figure contains sides or angles. But the interior angles alone are equal to twice as many right angles less four, as we demonstrated. Therefore, if the interior angles are taken away, the exterior angles will remain equal to just four right angles—the four, namely, by which the interior angles fall short, so that the interior and exterior together make up twice as many right angles as there are sides bounding the figure. For example: in any triangle the interior and exterior angles together are equal to six right angles. Since, then, the interior angles are equal to two right angles [Margin: c — I.32], the exterior alone will be equal to just four right angles. In a quadrilateral, the exterior and interior angles together are equal to eight right angles. Since, then, the interior angles alone are equal to four right angles, as we showed, the exterior alone will also be equal to four right angles. In a pentagon, or five-angled figure, the interior and exterior angles are equal to 10 right angles. But since the interior angles amount to six right angles, as we demonstrated, the exterior angles will remain equal to just four right angles. All of this may be seen in the figures shown; and the reasoning is the same in all other figures.

Diagram. A small schematic strip beside the text, showing rectilineal figures (a triangle and further polygons) with their sides produced in order, so that the exterior angles are marked at each vertex—illustrating that the exterior angles together make four right angles. The figures are drawn schematically; no point-labels are clearly legible on the leaf.

From Campanus

(A demonstration drawn from Campanus of Novara.) If the individual sides of a pentagon are produced in both directions, so that any two meet outside the pentagon, five angles will be formed by the meeting sides, equal to just two right angles.

In the pentagon ABCDE, let the sides, produced in both directions, meet at the points F, G, H, I, K. I say that the five angles F, G, H, I, K are equal to just two right angles. For in triangle BHK, since the side HB is produced to F, the exterior angle

FBK will be equal to the two interior and opposite angles H and K [Margin: d — I.32]. By the same reasoning, in triangle AIG the exterior angle FAG will be equal to the two interior and opposite angles I and G. Therefore the two angles FBA and FAB are equal to the four angles G, H, I, K. Adding, then, the common angle F [Margin: e — common notion 2], the three angles A, B, F of triangle ABF will be equal to the five angles F, G, H, I, K. But the angles A, B, F of triangle ABF are equal to two right angles [Margin: f — I.32]. Therefore the five angles F, G, H, I, K are also equal to two right angles. Which is what was proposed.

Diagram. A five-pointed star (pentagram). The inner pentagon has vertices A, B, C, D, E; each side, produced in both directions, meets a neighbouring produced side at the outer star-points F (top), G (right), H (lower right), I (lower left), and K (left). The construction triangles ABF, BHK, and AIG referred to in the text are formed by these produced sides.

- F (top apex): star-point (vertex of triangle ABF)
- A (upper left, inner): pentagon vertex
- B (upper centre, inner): pentagon vertex
- G (right): star-point
- C (centre-right, inner): pentagon vertex
- D (lower centre, inner): pentagon vertex [?] (printed glyph ambiguous; position corresponds to the fifth pentagon vertex D)
- E (left-centre, inner): pentagon vertex
- K (far left): star-point [?] (printed glyph ambiguous between K and R; text names it K)
- I (lower left): star-point
- H (lower right): star-point

Corollary I

From this Proposition 32 it follows that the three angles of any triangle taken together are equal to the three angles of any other triangle taken together, since both those three and these are equal to two right angles [Margin: g — I.32]. Hence, if two angles of one triangle are equal to two angles of another triangle, the remaining angle of the one will also be equal to the remaining angle of the other, and the triangles themselves will be equiangular.

Corollary II

It is also established that, in every isosceles triangle whose angle contained by the equal sides is a right angle, each of the remaining angles is half a right angle. For

the remaining two together make one right angle, since all three are equal to two right angles [Margin: h — I.32], and that third one is assumed to be a right angle. Therefore, since the two remaining angles are equal to each other [Margin: i — I.5], each of them will be half a right angle. But if the angle contained by the equal sides is obtuse, each of the others is less than half a right angle, for the remaining two together will be less than one right angle, and so on. Finally, if the said angle is acute, each of the remaining two is greater than half a right angle, since the remaining two together will be greater than one right angle, and so on.

Corollary III

It is also clear that any angle of an equilateral triangle is two-thirds of one right angle, or a third of two right angles. For the two right angles to which the three angles of an equilateral triangle are equal [Margin: k — I.32], divided into three angles, make two-thirds of one right angle each.

Euclid, *Elements*, Book I — Clavius's Commentary (continued)

COROLLARY IV

It is also clear that if from one angle of an equilateral triangle a perpendicular is dropped to the opposite side, two scalene triangles are formed. Each of them has one right angle, at the foot of the perpendicular; a second angle equal to two-thirds of a right angle — namely the angle that is also an angle of the equilateral triangle; and, finally, a remaining angle equal to one-third of a right angle.

SCHOLIUM

Moreover, from the third corollary a method can be derived for dividing a right angle into three equal angles. Let ABC be a right angle. On the straight line AB construct an equilateral triangle ABD [b: *Elements* I.1]. Since, by the third corollary, the angle ABD makes two-thirds of the right angle ABC, the angle CBD will be one-third of that same right angle. Now bisect the angle ABD by the straight line BE [c: *Elements* I.9]; then each of the angles ABE and EBD will likewise be one-third of a right angle. The right angle ABC is thus divided into three equal angles — which is what was proposed.

Diagram. A small figure illustrating the trisection of a right angle. The right angle ABC stands on the base, with an equilateral triangle ABD raised on AB and the bisector BE drawn.

- A (bottom-left): endpoint of the base line
- B (bottom, right of A): vertex of the right angle ABC
- C (upper right): endpoint of the vertical arm of the right angle
- D (top): apex of the equilateral triangle ABD
- E (left, interior): point on the bisector BE of angle ABD

THEOREM 23. PROPOSITION 33

[Margin: xxxij.]

Straight lines that join equal and parallel lines toward the same parts are themselves also equal and parallel.

Let AB and CD be equal and parallel straight lines, and let the straight lines AC and BD join them toward the same parts. I say that AC and BD too are equal and parallel. Draw the straight line AD. Since AD falls upon the parallels AB and CD, the alternate angles BAD and CDA are equal [d: *Elements* I.29]. Therefore the two sides BA and AD of triangle BAD equal the two sides CD and DA of triangle CDA, each to each, and the angles contained by these sides are likewise equal; so the bases BD and AC are equal, and the angle ADB equals the angle DAC [a: *Elements* I.4]. Since, then, these are alternate angles between the straight lines AC and BD, those lines are parallel [b: *Elements* I.27]. And it has already been proved that they are equal. Therefore straight lines that join equal and parallel lines, and so forth. Which was to be demonstrated.

Diagram. A parallelogram-like figure with the diagonal AD drawn. The equal, parallel lines AB and CD are joined by AC and BD.

- A (top-left)
- B (top-right)
- C (bottom-left)
- D (bottom-right)

The diagonal runs from A to D.

SCHOLIUM

Euclid said that equal and parallel lines must be joined *toward the same parts*, so that the joining lines are themselves both equal and parallel. For if they were joined toward opposite parts — say at A and D, and again at B and C — the joining lines would never be parallel, but would always cut one another; nor would they be equal, except very rarely, as will be clear from the following proposition.

THEOREM 24. PROPOSITION 34

[Margin: xxxiv.]

In parallelogrammic areas the opposite sides and the opposite angles are equal to one another; and the diameter bisects them.

Let ABCD be a parallelogram, of the kind we defined in Definition 35. I say that the opposite sides AB and DC are equal to one another, and likewise the opposite sides AD and BC; that the opposite angles B and D are equal to one another, and likewise the opposite angles DAB and DCB; and finally that, when the diameter AC is drawn, the parallelogram itself is bisected.

Since AB and DC are parallel, the alternate angles BAC and DCA are equal [c: *Elements* I.29]. Again, since AD and BC are parallel, the alternate angles BCA and DAC are also equal [d: *Elements* I.29]. And so, since the angles BAC and BCA of triangle ABC equal the two angles DCA and DAC of triangle ADC, each to each, and the side AC, which lies between these angles, is common to both triangles, the straight line AB equals the opposite straight line DC, and the straight line BC equals the opposite straight line AD [e: *Elements* I.26] — which is the first point. For the same reason the angle B equals the angle D. And since, if to the equal angles BAC and DCA the equal angles DAC and BCA are added, the whole angles BAD and BCD are likewise made equal [a: Common Notion 2], the second point is established — namely, that the opposite angles are equal. Finally, since the two sides AB and BC of triangle ABC equal the two sides CD and DA of triangle CDA, each to each, and the angle B equals the angle D, as we have just shown, the triangles ABC and CDA are equal [b: *Elements* I.4]; and therefore the parallelogram ABCD is bisected by the diameter AC, which was the third point proposed. Therefore, in parallelogrammic areas, the opposite sides and angles are equal to one another, and so forth. Which was to be demonstrated.

Diagram. A parallelogram with the diameter AC drawn.

- A (top-left)

- B (top-right)
- D (bottom-left)
- C (bottom-right)

The diameter runs from A to C.

SCHOLIUM

Euclid aptly said that only the *parallelograms* are bisected by the diameter, and not the *angles* as well. For only in the square and the rhombus are the angles too bisected by the diameter; but in the oblong [Latin: *altera parte longius* — "longer on one side"] and in the rhomboid they are divided into unequal parts. All of this will be clear if we first show that these four figures — the square, the oblong, the rhombus, and the rhomboid — are parallelograms. This we shall demonstrate by the three following theorems, of which the first is this:

Every quadrilateral having its opposite sides equal is a parallelogram.

In quadrilateral ABCD let the opposite sides AB and DC be equal, and likewise the opposite sides AD and BC. I say that ABCD is a parallelogram — that is, that the lines AB and DC are parallel, and likewise the lines AD and BC. When the diameter AC is drawn, the two sides AB and BC of triangle ABC will equal the two sides CD and DA of triangle CDA, each to each, the base AC being common. Therefore the angle B will equal the angle D [c: *Elements* I.8]. Again, since the sides AB and BC equal the sides CD and DA, each to each, and the angles B and D have been shown equal, the angle

Diagram. A quadrilateral with the diameter AC drawn.

- B (top-left)
- A (top-right)
- C (bottom-left)
- D (bottom-right)

The diameter runs from A to C.

BAC will equal the alternate angle DCA, and the angle BCA the alternate angle DAC. Therefore AB and DC are parallel, and likewise AD and BC [a: *Elements* I.27] — which is what was proposed.

From this it is established that the rhombus and the rhomboid are parallelograms, since their opposite sides are equal to one another, as is clear from their definitions. By the same reasoning the square will be a parallelogram,

since it has its opposite sides equal — indeed all four of its sides are equal to one another, by its definition. This theorem, moreover, converts the first part of Proposition 34, as is evident.

The second theorem is this:

Every quadrilateral having its opposite angles equal is a parallelogram.

In quadrilateral ABCD let the opposite angles A and C be equal, and likewise the opposite angles B and D. I say that ABCD is a parallelogram — that is, that the lines AB and DC are parallel, and likewise the lines AD and BC. For if to the equal angles A and C the equal angles B and D are added [b: Common Notion 2], the two angles A and B will equal the two angles D and C, and therefore the angles A and B will make half of the four angles A, B, C, and D. Since these four angles equal four right angles, as we demonstrated at Proposition 32, the two angles A and B equal two right angles. Therefore AD and BC are parallel [c: *Elements* I.28]. For the two angles A and D will likewise equal the two angles B and C. From this too it is clear that the rhomboid is a parallelogram, since its opposite angles are equal, by definition. Similarly the square and the oblong; for their opposite angles too are equal, being right angles, from their definitions.

Diagram. A small parallelogram (drawn as an oblong).

- A (top-left)
- B (top-right)
- D (bottom-left)
- C (bottom-right)

This theorem converts the second part of Proposition 34, as is plain. The third part, however, cannot be converted. For a trapezium too can be bisected by a diameter and yet not be a parallelogram. Let ABCD be an oblong or a rhomboid, which has been shown to be a parallelogram; in it, when the diameter AC is drawn, construct on AC a triangle AEC equal to triangle ABC but in reverse order, so that the side CE equals the side AB, and AE equals CB, as we taught in the scholium to Proposition 22; and let the trapezium AECD be formed. Now since the triangle ABC equals the triangle ADC — because the diameter AC bisects the parallelogram [d: *Elements* I.34] — the triangle AEC will also equal the triangle ADC; and accordingly the trapezium AECD is bisected by the diameter AC.

Diagram. Two figures (the oblong case and the rhomboid case), each showing the parallelogram ABCD with the diameter AC and the added triangle AEC forming the trapezium AECD.

- A (top-left)
- B [?] (top-right)
- C (bottom-right)
- D (bottom-left)
- E (right side, between B and C): apex of the constructed triangle AEC

But if any quadrilateral is bisected by *each* of its two diameters, it will be a parallelogram, as we shall show at Proposition 39. This indeed cannot happen in any trapezium.

The third theorem is of this kind:

Every quadrilateral having all its angles right is a parallelogram.

In quadrilateral ABCD let all four angles be right. I say that it is a parallelogram — that is, that the lines AB and DC are parallel, and likewise AD and BC. Since the two angles A and B equal two right angles (being themselves two right angles), AD and BC are parallel [c: *Elements* I.28]. In the same way AB and DC are parallel; and thus ABCD is a parallelogram, which is what was proposed.

Diagram. A square.

- D (top-left)
- C (top-right)
- A (bottom-left)
- B (bottom-right)

From this it is again established that the square and the oblong are parallelograms, since all their angles are right, as is clear from their definitions.

Having in this way demonstrated that the square, the oblong, the rhombus, and the rhomboid are parallelograms, we shall easily show that the angles of the square and of the rhombus are bisected by the diameter, but that the angles of the oblong and of the rhomboid are not bisected, as we noted a little earlier. Let ABCD be a square or a rhombus, with the diameter AC. Since the two sides BA and AC of triangle BAC equal the two sides DA and AC of triangle DAC, each to each, and the base BC equals the base DC (for these figures are equilateral), the angles BAC and DAC are equal [f: *Elements* I.8]. Therefore the angle BAD is bisected. In the same way we shall demonstrate that the remaining angles are bisected by the diameter.

Diagram. Two small figures (the square and the rhombus), each with a diagonal drawn.

- A (top-left)
- B (top-right)
- D (bottom-left)
- C (bottom-right)

Again, let ABCD be an oblong or a rhomboid, with the diameter AC, and let AB be the greater side. Since in triangle ABC the side AB is greater than the side BC, the angle BCA is greater than the angle BAC [g: *Elements* I.18]. But the angle BCA equals the alternate angle DAC [h: *Elements* I.29], because BC and AC are parallel (for ABCD has been shown to be a parallelogram). Therefore the angle DAC too will be greater than the angle BAC. And for this reason the angle BAD is divided unequally by the diameter AC. The same reasoning holds for the other angles. Hence Euclid aptly said, in the third part of this proposition, that only the parallelograms are bisected by the diameter, and not the angles as well.

Diagram. Two small figures (the oblong and the rhomboid), each with a diagonal drawn.

- A (top-left)
- B (top-right)
- D (bottom-left)
- C (bottom-right)

In nearly the same way we shall show that the two diameters in a square and in an oblong are equal, but that in a rhombus and a rhomboid they are unequal — the greater being the one that divides the acute angles, the lesser the one that divides the obtuse angles. Let ABCD be a square or an oblong, with the diameters AC and BD, which I say are equal. Since the two sides AB and BC of triangle ABC equal the two sides AB and AD of triangle BAD, each to each, and the angle ABC equals the angle BAD (each being right), the base AC equals the base BD [i: *Elements* I.4]. And accordingly the diameters in a square and in an oblong are equal.

Diagram. Two figures (the square and the oblong), each with both diameters drawn, meeting at the centre E.

- A (top-left)
- B (top-right)

- D (bottom-left)
- C (bottom-right)
- E (centre): intersection of the diameters AC and BD

Diagram. Two figures (the rhombus and the rhomboid), each with both diameters drawn, meeting at E.

- A (top-left)
- B (top-right)
- E (centre): intersection of the diameters AC and BD
- C (bottom, left figure) / (bottom-right)
- D (bottom)

Again, let ABCD be a rhombus or a rhomboid, with the diameters AC and BD, and let the angle BAD be the greater and ABC the lesser. For they are not equal; otherwise each would be right, since both together equal two right angles [a: *Elements* I.29] — which is absurd, and contrary to the definitions of the rhombus and rhomboid. I say that the diameter BD is greater than the diameter AC. Since the two sides AB and AD of triangle BAD equal the two sides AB and BC of triangle ABC, each to each, and the angle BAD is greater than the angle ABC, the base BD will be greater than the base AC [b: *Elements* I.24] — which is what was proposed. From this it is clear why, in Proposition 33, Euclid asserted that only those lines are equal which join equal parallels toward the same parts, as we noted there. For in the rhombus and rhomboid the straight lines AC and BD are unequal, even though they join the equal parallels AB and DC, because they do not join them toward the same parts, as is evident.

In every parallelogram, nevertheless, the diameters bisect one another. For the two angles EAD and EDA of triangle AED equal the alternate angles ECB and EBC of triangle BEC, each to each [c: *Elements* I.29]; and the side AD equals the side BC opposite to it in the parallelogram ABCD [d: *Elements* I.34], each of which lies between equal angles. Therefore AE will equal CE, and DE will equal BE [e: *Elements* I.26]. And so each diameter is bisected at the point E.

We shall also demonstrate the converse of what we have just said, namely:

Every quadrilateral in which the diameters bisect one another is a parallelogram.

In quadrilateral ABCD let the diameters AC and ED [recte: BD] bisect one another at E. I say that ABCD is a parallelogram. Since the sides AE and EB of triangle AEB equal the sides CE and ED of triangle CED, and the angles contained at the vertex

E are also equal [f: *Elements* I.15], the bases AB and CD are equal, and the angle ABE equals the alternate angle CDE [g: *Elements* I.4]. Therefore the straight lines AB and CD are parallel [h: *Elements* I.27]. By the same reasoning AD and CB are shown to be parallel. Therefore ABCD is a parallelogram.

Diagram. A small parallelogram with both diameters drawn, meeting at E.

- A (top-left)
- B (top-right)
- E (centre): intersection of the diameters
- D (bottom-left)
- C (bottom-right)

And so, if one wishes to construct a parallelogram readily, let him draw two lines AC and BD intersecting one another at E in any manner whatever. For if he cuts off EA and EC equal to one another, and likewise EB and ED equal to one another, the lines AB, BC, CD, and DA, when drawn, will form a parallelogram, as has here been demonstrated. But if the angles at E are right, and all four lines EA, EC, EB, and ED are equal to one another, the parallelogram so formed will be a square, because the eight angles at A, B, C, and D are each half a right angle, as will easily be demonstrated by Propositions 5 and 32 of this book.

This theorem too may be referred to here:

A straight line that bisects the diameter of a parallelogram in any way whatever also bisects the parallelogram; and a straight line that bisects the parallelogram in any way whatever also bisects the diameter.

In parallelogram ABCD let the straight line EF bisect the diameter AC at the point G. I say that the parallelogram is divided in half. Since the angle EAG equals the alternate angle FCG [i: *Elements* I.29], and the angle EGA equals the angle FGC [k: *Elements* I.15]; and since the side AG equals the side CG by hypothesis — each of which lies between equal angles — the sides EG and FG are also equal [l: *Elements* I.26]. Therefore, since the sides AG and GE equal the sides CG and GF, and the contained angles are also equal, the triangles AGE and CGF are equal [m: *Elements* I.4]. So, when the common area BCGE is added, the triangle ABC equals the trapezium BCFE [n: Common Notion 2]. But the triangle ABC is half of the parallelogram ABCD [o: *Elements* I.34]. Therefore the trapezium too is half of the same parallelogram; and accordingly the straight line EF bisects the parallelogram.

Diagram. A large parallelogram ABCD with the diameter AC and the bisecting line EF, together with an auxiliary line for the converse.

- A (top-left)
- E (top, between A and B)
- B (top-right)
- G (interior, upper): point where EF meets the diameter AC
- H (interior, lower): auxiliary point used in the converse
- D (bottom-left)
- F (bottom, left of centre)
- I (bottom, centre-right)
- C (bottom-right)

Now let EF bisect the parallelogram; I say that the diameter AC too is bisected at G. For if the diameter AC is *not* bisected at G [p: *Elements* I.10], let it be bisected at some other point, say H, through which let the straight line EHI be drawn. Then, as we have just demonstrated, EICB will be the trapezium that is half of the parallelogram ABCD, and thus equal to the trapezium EFCB, which is also supposed to be half of the same parallelogram — a part equal to the whole, which is absurd. Therefore AC is bisected at G and at no other point, which was what was proposed.

From this it is easily gathered how, if a point is marked on some side of any parallelogram — or even inside the parallelogram, or outside it, provided it does not lie on the diameter unless it bisects the diameter — a line ought to be drawn from that point so as to bisect the parallelogram. For if the diameter is drawn, and from the given point a straight line is drawn through the midpoint of the diameter, what is proposed will be accomplished. For instance, if the point is E, on the side AB, one must draw the straight line EF through G, the point at which the diameter AC is bisected; and so with other points.

Peletier [Jacques Peletier] also demonstrates here a not-unpleasing problem, namely:

Between two infinite straight lines that form an angle, to place a straight line equal to a given line, which shall make with one of them an angle equal to any given angle. But this given angle, together with the angle contained by the given lines, must be less than two right angles.

Let the two infinite straight lines AB and AC contain the angle BAC; let D be any given finite straight line, and E a given angle, on this condition: that the two

angles E and BAC are less than two right angles. It is required, then, to place between the straight lines AB and AC a straight line equal to the given line D, making with one of them — namely with AC — an angle equal to the given angle E. Make the angle CAF equal to the angle E [q: *Elements* I.23]; and, F A having been produced to G, let AG be equal to the straight line D [r: *Elements* I.3]. Through G draw GB parallel to AC, cutting AB at B [s: *Elements* I.31]. Then through B draw BC parallel to AG, cutting AC at C. I say that the straight line BC, placed between the straight lines AB and AC, is equal to the straight line D, and that the angle BCA equals the angle E. For since it is a parallelogram, by con-

Diagram. Peletier's construction. At the left stand the given angle E and the given finite line D; at the right the two infinite lines AB and AC meet at A, with the constructed parallelogram AGBC.

- E (upper left): the given angle
- D (left): the given finite straight line
- G (top, left of B): point on the line FA produced, with AG equal to D
- B (top-right): point where GB (parallel to AC) meets AB
- A (centre-left): vertex where the infinite lines AB and AC meet
- C (bottom-right): point where BC (parallel to AG) meets AC
- F (bottom, below A): point on line AC through which the angle CAF equal to E is made

(Continuation of the demonstration begun on the previous page.)

by construction, ACBG [is a parallelogram], and so the line BC will be equal to the line GA.[Margin a: *Elements* I.34] But GA is equal, by construction, to the line D. Therefore BC too will be equal to the line D. Again, since the angle BCA is equal to the alternate angle CAF,[Margin b: *Elements* I.29] and the angle E is also equal, by construction, to that same angle CAF, the angles E and BCA will be equal — which is what was proposed. Moreover, anyone can see from the construction why the two given angles must be less than two right angles; for otherwise triangle ABC would not be formed, if the angles BAC and BCA were equal to, or greater than, two right angles, as is clear from Proposition 17 or 32.

SCHOLIUM II.

It will not be out of keeping with our plan to add here some remarks about lines drawn inside a triangle, which Pappus of Alexandria [Pappus] demonstrates in Book 3 of his *Mathematical Collections* — as we undertook to do at Proposition 21. First, then, in every triangle that is not equilateral, and is not an isosceles triangle

whose base is smaller than either of its [equal] sides, one can construct from the two endpoints of the base not only two straight lines within the triangle whose sum is greater than the sum of the two sides — as Proclus [Proclus] showed for right-angled or obtuse-angled triangles at Proposition 21 — but even two lines whose sum is equal to it.

For let ABC be the first triangle, with side AB greater than side AC, and let BD be half of the two sides AB and AC together. Take any point E between A and D, and draw EF parallel to BC; from any point G draw GH parallel to AB, and join GC.

Diagram. A scalene triangle with apex at the top and a circular arc swung across its lower right. Labelled points:

- A (apex, top)
- D (near the apex, upper left of A)
- E (just below, between D and F)
- F (near the apex, upper right of A)
- B (lower-left vertex)
- H (on the base, immediately right of B)
- K (on the base, toward the centre — where the arc cuts CH)
- G (on the right-hand slant, below the apex)
- C (right-hand vertex)
- I (below and right, the far end of the drawn arc)

Now since EA and AF together are greater than EF, [Margin c: Elements I.20] and likewise CF and FG are greater than GC, the lines EA, AC, FG together will be greater than EF and GC together; and when the common FG is removed, EA and AC together will be greater than EG and GC together, and therefore much greater than GC alone. Let GC then be produced, and let GI be made equal to EA and AC together. And since BE is greater than EA and AC together — because BE exceeds BD, the half of BA and AC together, whereas EA and AC together fall short of the half of those same lines, namely by DA and AC together — BE will also be greater than GI, which is equal to EA and AC together. Since, then, GH is equal to BE [Margin d: Elements I.34] in the parallelogram BEGH, GH too will be greater than GI. If, therefore, a circle is described with centre G and radius GI, it will cut the line GH, and consequently will first cut CH itself at K. Join GK. I say that GH and GK together are equal to AB and AC together; for GH is equal to BE, and GI — that is, GK — is equal to EA and AC together. And this can be done in infinitely many ways, according as the point E is taken farther from D, and the point G

farther from the point E; that is, according as both AD and EF can be divided at infinitely many points.

Next, let ABC be an isosceles triangle whose base BC is greater than either side. With centre B, through A, describe the arc AD cutting the line BC at D; draw any line BF cutting the arc at E and the side AC at F; through any point G of EF draw GH parallel to BC; through any point I of GH draw IK parallel to BF; join the line IC; and cut off AL equal to EG.

Diagram. An isosceles triangle with apex at the top and a large circular arc swept across the lower part of the figure. Labelled points:

- A (apex, top; L marked just beside it on side AB)
- L (on AB, close below A)
- E, G, F, H (a cluster along EF / GH in the upper middle, left to right)
- I (on the segment GH)
- B (lower-left vertex)
- K, N (on the base, right of B)
- D (on the base, toward the centre)
- C (right-hand vertex)
- M (far right, where IC is produced to M)

Then BG will be equal to AB and AL together, while LC is less than BE (or AB), and for that reason much less than BG. And since IK is equal to BG[Margin e: Elements I.34] in the parallelogram BGIK, IK too will be equal to AB and AL together, and greater than LC. Now since GF and FH are greater than GH,[Margin f: Elements I.20] and HC and HI greater than IC, the lines GF, FC, HI together will be greater than GH and IC; and when the common HI is removed, the remaining GF and FC together will be greater than GI and IC together; and therefore, when the common BG is added, BF and FC together will become greater than BG, GI, IC together. But BA and AC together are greater than BF and FC.[Margin g: Elements I.20] Therefore BA and AC together will be much greater than BG, GI, IC together. Since, then, BG is equal to BA and AL together, the remaining LC will be greater than the remaining GI and IC together, and therefore much greater than IC alone. Let IM (with IC produced) be made equal to LC. And since IK has been shown to be greater than LC — that is, than IM — if with centre I, through M, an arc of a circle is described, it will cut the line IK, and consequently will first cut CK itself at N. Join IN. I say that IK and IN together are equal to AB and AC together; for IK is equal to AB and AL together, and IN — that is, IM — is equal to LC. And this too

can be done in infinitely many ways, since BF can be drawn in infinitely many ways, and both EF and GH can be divided in infinitely many ways.

It is clear, moreover, that if within the same triangle ABC two straight lines are drawn enclosing the lines HG, GK in the first triangle, or the lines KI, IN in the second,[Margin h: Elements I.21] their sum will be greater than sides AB and AC together — since they would be greater than the lines HG, GK in the first triangle, or the lines KI, IN in the second.

But in an equilateral triangle, or in an isosceles triangle whose base is smaller than either side, it can be shown as follows that no two lines can be constructed inside whose sum is greater than, or equal to, the two sides together — rather, whatever interior lines are drawn are smaller. For in triangle ABC, whose two sides AB, AC are equal, and whose base BC is not greater but either equal or smaller — so that angle A is not greater than angle B or C,[Margin i: Elements I.5 or 18] but either equal or smaller — let two lines DE, EF be constructed at random, which I say are together smaller than the two sides AB and AC together.

Diagram. A tall triangle with apex A and base along the bottom, with several lines (cevians) drawn from near the apex to points on the base. Labelled points:

- A (apex, top)
- H (below A, on side AC)
- G (below H)
- E (below G — the meeting-point of the interior lines)
- B (base, left end)
- D (base)
- F (base)
- C (base, right end)

For let DE be produced, cutting side AC at G, and join the line GB. Since, then, the two angles ABC and C are equal,[Margin k: Elements I.5] and ABC is greater than angle GBC, C too will be greater than angle GBC. But the angle GDB is also greater than angle C,[Margin l: Elements I.16] being exterior to the interior [angle].

Therefore angle GDB will be much greater than angle GBC;[Margin m: Elements I.19] and consequently side GB will be greater than side GD. And since angle BGA is greater than angle C,[Margin n: Elements I.16] exterior to interior, and angle C is either equal to angle A or greater, as [we shall] show—

—it will follow that angle BGA is also greater than angle A. Therefore side AB will be greater than side GB.[Margin a: Elements I.19] But the line GB has been shown

to be greater than GD, and consequently much greater than DE. Therefore side AB will be much greater still than DE. By the same reasoning, if FE is produced, cutting AC at H, and the line HB is joined, we shall show that side AB — and consequently AC too — is greater than FE. Therefore sides AB and AC together are greater than the two lines DE and EF together. But if FE, produced, were to cut side AB, we should demonstrate in the same way that side AC is greater than the line EF.

Now, if it seems marvellous to those unacquainted with geometry that, in the triangles we have described, interior lines can be drawn whose sum is greater than, or equal to, the two sides together, it will surely seem still more marvellous that within those same triangles two lines can be constructed, each of which singly is greater than, or equal to, each single side. Let there first be constructed, in triangle ABC, individual lines each greater than the individual sides — the triangle whose side AB is not less than side AC, while side BC is greater than either side AB or AC. With centre B describe the arc of a circle AD; take any point E between the arc AD and the side AC, and draw the line BE [Margin b: Elements I.21] cutting the arc at F, such that BE is greater than BF — that is, than BA — and join EC.

Diagram. A triangle with apex A and a circular arc (centre B) swept across the lower right. Labelled points:

- A (apex, top)
- F (near the apex, on line BE where it meets the arc)
- E (just below F, between the arc AD and side AC)
- B (lower-left vertex)
- H (on the base, near B)
- G (on the base, near H — where the arc from E cuts CB)
- D (on the base, toward the centre — foot of arc AD)
- C (right-hand vertex)
- K (far right, on the produced line EC / arc)
- I [?] (a small point on line EH where it meets the arc; not clearly resolvable on the woodcut)

Now since BE and EC together are less than AB and AC together, [Margin: Elements I.21] and BE is greater than AB, EC will be much less than AC. Let EC, then, be produced, and let EK be made equal to AC, and hence less than EB; and from E, through K, describe an arc of a circle, which will cut EB, and consequently will first cut CB itself at G. Finally, taking any point H between B

and G, join the line EH cutting the arc at I; and what was proposed will be done. For BE is greater than BA, and EH is greater than EI — that is, than EK, or AC.

Next, let there be constructed, within the same triangle, individual lines each equal to the individual sides. Let the same construction be made, omitting the line EH, but let the arc KG cut the line EB at H. Suppose side BA greater than side AG; then BE will be a line greater than AB, since it is greater than BF, which is equal to AB. Then, taking EI equal to AB, the point I will fall between B and H — since EB is greater than AB, and EH is less than AB.

Diagram. A triangle with apex A and a large circular arc across the lower part of the figure. Labelled points:

- A (apex, top)
- H, F, E (a cluster near the apex, along line BE)
- B (lower-left vertex)
- L (on the base, close to B, where the arc from E cuts BC)
- G (on the base, near L)
- D (on the base, toward the centre)
- C (right-hand vertex)
- K (far right, on the produced line / arc)
- I [?] (small point on EB, taken so that $EI = AB$; not clearly resolvable on the woodcut)

From E, through I, describe an arc of a circle cutting BC at L, and join the lines EL, EG; and what was proposed will be done. For EL is equal to EI — that is, to AB — and EG is equal to EK — that is, to AC.

Besides these, Pappus demonstrates that within the same triangles we have described two lines can be constructed that are greater than the two sides and that have a given ratio to those sides — which someone might well find incredible. But this cannot be demonstrated here, since it depends on ratios.

FROM PROCLUS.

Proposition (from Proclus). In every rectilinear figure having an even number of sides, if it is equilateral and equiangular, any two opposite sides will be parallel to one another.

Clavius's demonstration. "Opposite sides" are called those two which have an equal number of sides on either hand: thus in the hexagon ABCDEF the opposite sides will be AB and ED, since toward the parts A and E there are two sides, just

as toward the parts B and D. In the octagon ABCDEFGH the opposite sides will be AB and FE, since toward the parts A and F there are three sides, just as toward the parts B and E. And so in the other equilateral figures with an even number of sides: on either hand of the opposite sides there will be as many sides as there are in half the number of sides, less one. Thus in the quadrangle there will be one, in the hexagon two, in the octagon three, in the decagon four, in the twelve-sided figure five, and so on. I say, then, that any opposite sides are parallel — AB, namely, to ED in the hexagon; AB to FE in the octagon; and likewise for the rest.

Diagram. A regular hexagon. Labelled vertices:

- A (top left)
- B (top right)
- C (right)
- D (bottom right)
- E (bottom left)
- F (left)

Diagram. A regular octagon, illustrating the opposite sides AB and FE. The woodcut labels are small and faint; on it I can read the vertices A and B (across the top edge) and F, G, E toward the lower left, while the remaining vertices C, D, H are too indistinct to resolve with confidence. Per the text the vertices are lettered A B C D E F G H in order.

- A [?] (top left)
- B (top right)
- C [?]
- D [?]
- E (lower left region)
- F (lower left region)
- G (left)
- H [?]

For let the two extremities of the opposite sides be joined, toward the same parts, by a straight line — such as BD in the hexagon and BE in the octagon. And since, as we demonstrated at Proposition 32,[Margin c: Elements I.32] the six angles of a hexagon are equal to eight right angles, the three angles B, C, D of that hexagon will be equal to four right angles, because all the angles are supposed equal. But the angles BCD, CBD, CDB of triangle BCD are equal to two right angles. Therefore the remaining angles ABD, EDB will be equal to two right angles. Hence AB and

ED will be parallel.[Margin d: Elements I.28] Again, since the eight angles of an octagon are equal to twelve right angles, its four angles B, C, D, E will be equal to six right angles. But the four angles of the quadrilateral BCDE are equal to four right angles. Therefore the two remaining angles ABE, FEB will be equal to two right angles,[Margin e: Elements I.28] and so AB and FE will be parallel. In the same way it will be demonstrated, in all other figures of this kind, that the two angles standing at the straight line that joins the extremities of the opposite sides are equal to two right angles. For in the decagon that line cuts off a pentagon, whose angles are equal to six right angles; but five angles of a decagon are equal to eight right angles. Removing the six, then, two right angles remain. In the equilateral and equiangular figure of twelve sides the same line will cut off a hexagon, whose angles are equal to eight right angles; but six angles of the whole figure are equal to ten right angles. Removing the eight, then, two right angles remain, and so on.

Although every equiangular figure with an even number of sides has its opposite sides parallel, as we have shown, nevertheless only a quadrilateral figure that has its opposite sides parallel is customarily called a *parallelogram* by Euclid [Euclid] and the other geometers; and for that reason, in the Definitions, we said that a parallelogram is a quadrilateral figure, and so forth.

THEOREM 25. PROPOSITION 35. [Margin: XXXV.]

Euclid's enunciation. Parallelograms constructed on the same base and between the same parallels are equal to one another.

Clavius's demonstration. Between the two parallels AB, CD, on the base CD, let there stand two parallelograms CDEA, CDBF. (Parallelograms are said to be between the same parallels when two opposite sides are parts of the parallels, as is seen in the example proposed.) I say that these parallelograms are equal to one another — not as to their angles and sides, but as to their area, or capacity. For, first, the point F will fall between A and E.

Diagram. Two overlapping parallelograms on the common base CD, between the parallels AB and CD. Labelled points, along the upper parallel from left to right: A, F, E, B; along the lower parallel: C (left), D (right).

- A (upper line, left)
- F (upper line, between A and E)
- E (upper line)
- B (upper line, right)

- C (lower line, left)
- D (lower line, right)

Since, then, in parallelogram CDEA the line AE is equal to the opposite line CD, [Margin a: Elements I.34] and FB is equal to that same CD as its opposite in parallelogram CDBF, AE and FB will be equal to one another. [Margin b: Common Notion 1] Removing, then, the common FE, AF will remain equal to EB. [Margin c: Common Notion 3] But AC is also equal to ED, its opposite in parallelogram CDEA; [Margin d: Elements I.34] and the angle BED is equal to the angle FAC, exterior to interior. [Margin e: Elements I.29] Therefore triangle FAC will be equal to triangle BED. [Margin f: Elements I.4] Adding, then, the common trapezium CDEF, [Margin g: Common Notion 2] the whole parallelogram CDEA will become equal to the whole parallelogram CDBF. Which is what was proposed.

Let the point F fall, secondly, on the point E. I say again that the parallelograms CDEA, CDBE are equal. For, as before, the lines AE, EB will be equal, and likewise the angles BED, EAC; and hence the triangles EAC, BED [will be] equal. [Margin h: Elements I.4] Adding, then, the common triangle CDE, [Margin i: Common Notion 2] the parallelograms CDEA, CDBE will become equal.

Diagram. The second case: a figure on base CD in which the two upper vertices coincide, with crossed lines forming two triangles. Labelled points: E and B along the top, C and D along the bottom. (The top-left vertex A, required by parallelogram CDEA, is not clearly resolvable on the woodcut.)

- A [?] (top left)
- E (top, centre-left)
- B (top right)
- C (bottom left)
- D (bottom, centre)

Let the point F fall, thirdly, beyond E, so that the line CF cuts the line DE at G. Since, then, as before, the lines AEFB are equal, if the common EF is added, [Margin k: Common Notion 2] the whole AF will be equal to the whole EB, and likewise the angles BED, FAC will be equal; and hence triangle FAC [will be] equal to triangle BED. [Margin l: Elements I.4] Removing, then, the common triangle EGF, [Margin m: Common Notion 3] the trapezium AEGC will remain equal to the trapezium FGDB. And so, adding the common triangle CDG, the whole parallelogram CDEA will become equal to the whole parallelogram CDBF. Therefore parallelograms constructed on the same base and between the same parallels are equal to one another. Which was to be demonstrated.

Diagram. The third case: two parallelograms on base CD whose upper sides overlap, the line CF crossing DE at G. Labelled points along the top, left to right: E, F, B; the crossing-point G in the middle; C and D along the bottom. (The top-left vertex A is not clearly resolvable on the woodcut.)

- A [?] (top left)
- E (top left)
- F (top, centre)
- B (top right)
- G (interior, where CF meets DE)
- C (bottom left)
- D (bottom, centre)

SCHOLIUM.

We shall easily convert this proposition, in this way: *Equal parallelograms constructed on the same base and toward the same parts will be between the same parallels.*

Let there be two equal parallelograms ABCD, CDEF on the same base CD and toward the same parts. I say that the line AB, produced, lies in a straight line with EF, and that therefore the parallelograms are between the same parallels. For otherwise AB, when produced, will fall either below EF or above it. Let it fall first below, as AH does. Then the parallelogram CDGH will be equal to the parallelogram ABCD; [Margin n: Elements I.35] but the parallelogram CDEF is supposed equal to that same parallelogram ABCD. Therefore the parallelograms CDEF, CDHG would be equal — the whole and the part — which is absurd. Therefore AB will not fall below EF.

Diagram. Two parallelograms sharing the base region, with diagonals drawn, illustrating the case in which AB produced falls below EF. Labelled points: along the upper line A, B (left) and E, F (right); the interior points G, H; along the lower line D (left) and C (right).

- A (upper line, left)
- B (upper line, right of A)
- E (upper line, right)
- F (upper line, far right)
- G (interior, left of centre)
- H (interior, right of centre)

- D (lower line, left)
- C (lower line, right)

Let AB, secondly, when produced, fall above EF. Then FE, extended, will fall below AB. Therefore, as before, the parallelograms ABCD, CDHG will be equal — the whole and the part — which is absurd. The same absurdity would follow if CF, DE were produced as far as AB extended. And the same demonstration will fit all the cases that can occur — that is, whether the point F lies beyond B or not, as is evident. Therefore AB will not fall above EF; but neither below, as was demonstrated. Therefore, when produced, it lies in a straight line with EF; and consequently the parallelograms ABCD, CDEF are between the same parallels.

Diagram. A small inset figure for the second case of the scholium (AB produced above EF), with diagonals drawn. Labelled points: A, B across the top; H, G, E, F across the middle; D, C along the bottom.

- A (top left)
- B (top, right of A)
- H (left)
- G (middle)
- E (middle right)
- F (far right)
- D (bottom left)
- C (bottom, right of D)

THEOREM 26. PROPOSITION 36. [Margin: XXXVI.]

Euclid's enunciation. Parallelograms constructed on equal bases and between the same parallels are equal to one another.

Clavius's demonstration. Let there be two parallelograms ACEF, GHDB on the equal bases CE, HD, between the same parallels AB, CD. I say that they are equal. For let the extremities of the lines CE, GB be joined, toward the same parts, by the straight lines CG, EB.

Diagram. Two parallelograms on equal bases CE and HD, between the parallels AB and CD, with the connecting lines CG, EB drawn. Labelled points: along the upper line, left to right, A, F, G, B; along the lower line, left to right, C, E, H, D.

- A (upper line, left)
- F (upper line)

- G (upper line)
- B (upper line, right)
- C (lower line, left)
- E (lower line)
- H (lower line)
- D (lower line, right)

Since, then, the line CE is supposed equal to the line HD, and GB is equal to that same HD[Margin o: Elements I.34] as its opposite in parallelogram GHDB, CE and GB will be equal to one another;[Margin p: Common Notion 1] and they are also parallel, by hypothesis. Therefore CG, EB, which join them, will also be parallel[Margin q: Elements I.33] and equal, and so CEBG will be a parallelogram. Thus, since the parallelograms ACEF, GCEB are between the same parallels and on the same base CE,[Margin r: Elements I.35] the parallelogram ACEF will be equal to the parallelogram GCEB. Again, since the parallelograms GCEB, GHDB are between the same parallels and on the same base GB,[Margin s: Elements I.35] the parallelogram GHDB will also be equal to that same parallelogram GCEB. Therefore the parallelograms ACEF, GHDB will be equal to one another.[Margin t: Common Notion 1] Therefore parallelograms constructed on equal bases and between the same parallels [are equal to one another], and so forth. Which was to be shown.

(Marginal citations are keyed by the letters a, b, c... that stand at the corresponding step in the text. In them "primi" means "of Book I" — i.e. Elements I.n — and "pron." means pronunciatum, a common notion / axiom. They are rendered below verbatim inside [Margin ...].)

SCHOLIVM [to Prop. 36]

The converse of this theorem is twofold, in this manner.

(Converse, enunciation — Clavius.) Parallelograms that are equal, stand on equal bases, and are set up toward the same side lie between the same parallels. And parallelograms that are equal and lie between the same parallels, if they do not have the same base, stand on equal bases.

(Demonstration.) First, let there be two equal parallelograms ABCD and EFGH, on the equal bases BC and FG, and set up toward the same side. I say that they lie between the same parallels — that is, that AD, when produced, meets EH in one straight line. For otherwise it would fall either below EH or above it; and on that supposition it would follow that a whole and a part are equal, exactly as was said

in the converse of the preceding proposition, and as the figure readily shows. The equal bases are to be understood as given on the same straight line BG.

Diagram. Two adjoining/overlapping parallelograms on a common base-line, illustrating the converse of Prop. 36 (equal parallelograms on equal bases).

Readable labels:

- Along the base (line BG): B (far left), C, F, G (far right)
- Along the top: A, D, and E, H
- K (upper region, above the base near the construction) and I, E (interior/base construction points)

[Several of the interior and upper labels sit very small at this resolution — the construction points I and K in particular are not fully resolved.]

(Second part.) Secondly, let the same equal parallelograms lie between the same parallels AH, BG. I say that the bases BC, FG are equal. For if one of them, say BC, be claimed the greater, cut off BI equal to the straight line FG [Margin a: 3.primi], and draw IK parallel to CD [Margin b: 31.primi]. Then the parallelogram ABIK will be equal to the parallelogram EFGH [Margin c: 36.primi], and therefore to the parallelogram ABCD — a part equal to the whole, which is absurd. So BC is not greater than FG; and by the same reasoning it will not be smaller either. Therefore the bases BC, FG are equal.

The following theorem too is easily demonstrated from this.

(Second converse, enunciation — Clavius.) If two parallelograms between the same parallels have unequal bases, the one whose base is greater will be the greater. And conversely, if two parallelograms between the same parallels are unequal, the base of the greater will be the greater.

(Demonstration.) For in the latter figure let there be parallelograms BD, FH between the parallels AH, BG, and let base BC be greater than base FG. I say that parallelogram BD is greater than parallelogram FH [Margin d: 3.primi]. Cut off the straight line BI equal to FG [Margin e: 31.primi], and draw IK parallel to AB [Margin f: 36.primi]. Then the parallelograms BK, FH, on the equal bases BI, FG, will be equal. Since therefore BD is greater than BK [Margin g: 9.pron.], the same BD will be greater than FH.

Again, let the parallelograms BD, FH be unequal, and let BD be the greater. I say that base BC is greater than base FG. For if it were equal, the parallelograms would be equal [Margin h: 36.primi], which is absurd, since BD is supposed the greater. And if it were smaller, the parallelogram FH would be greater than BD,

as we have just shown — which is far more absurd, since BD is supposed greater than FH. Therefore the base BC, being neither equal to FG nor smaller, will be greater than FG, which is what was proposed.

Diagram. The large "latter figure": two tall parallelograms between the parallels AH (top) and BG (base), for the comparison of unequal bases. Readable labels:

- Top line (AH): A (far left), D, E, H (far right)
- Base line (BG): B (far left), C, F, G (far right)
- Construction points I (on the base near C) and K — small and only partly resolved at this resolution.

THEOR. 27. PROPOS. 37.

[Margin: XXXVII.]

(*Euclid — enunciation.*) Triangles set up on the same base and between the same parallels are equal to one another.

(*Demonstration — Clavius.*) Between the parallels AB, CD, and on the base CD, let two triangles ACD, BCD be set up. (A triangle is said to be set up between two parallels when its base is part of one of them and the opposite vertex touches the other.) I say that these triangles are equal. Through D draw DE parallel to the straight line AC [Margin i: 31.primi], and DF parallel to BC. Then the parallelograms ACDE, BCDF will stand on the same base CD and between the same parallels [Margin k: 35.prim.]. But the triangles ACD, BCD are the halves of these, since the diagonals AD, BD bisect the parallelograms ACDE, BCDF [Margin l: 34.primi]. Therefore the triangles ACD, BCD will be equal [Margin m: 7.pron.]. Therefore triangles on the same base, etc. Which was to be demonstrated.

Diagram. The Prop. 37 figure: two triangles on the common base CD between parallels. Labels (top line, left to right): E, A, B, F; (base): C, D. The diagonals cross, forming the two parallelograms ACDE and BCDF.

SCHOLIVM [to Prop. 37]

The converse of this proposition will be demonstrated by Euclid at prop. 39. Furthermore, from this proposition we shall easily demonstrate, along with Proclus [Proclus], the following: that triangles whose two sides are equal to the two sides of another, each to each, while the angle contained by those sides in the one is greater than the corresponding angle in the other, are sometimes equal and sometimes unequal — which is what we promised at prop. 24. For let there be two triangles ABC, DEF, with sides AB, AC equal to the sides DE, DF, and angle

A greater than angle EDF; and let these two angles first be equal to two right angles. I say the triangles are equal. Produce ED to H and FD to I [Margin n: 23.prim.]; and make angle EDG equal to angle A [Margin o: 17.prim.], toward the acute angle DFE (for one of the angles DEF, DFE will always be acute, since both together are less than two right angles) [Margin p: 3.prim.]; and let DG equal the straight line DF, that is AC; and draw the straight lines EG, GF. EG will always fall beyond the acute angle DFE, as we showed at the end of the scholium to prop. 24. Now since the angles A and EDF are supposed equal to two right angles, and angle EDG has been made equal to angle A, the angles EDG, EDF will also be equal to two right angles [Margin q: 13.prim.]; but the angles EDG, GDH are likewise equal to two right angles [Margin r: 3.pron.]. Therefore the angles EDG, EDF are equal to the angles EDG, GDH. So, taking away the common angle EDG, the angle EDF will remain equal to angle GDH; and angle EDF is equal to angle GDH. But it is also equal to angle GDH [Margin s: 15.prim.]... [the two remaining angles EDF and GDH being equal]; and so angle GDH is the half of the whole angle GDI. Again, since the sides DG, DF are equal, the angles DFG, DGF are equal; and these, being equal to the exterior angle GDI, each of them — namely DGF — is the half of angle GDI. But it has been shown that angle GDH is the half of the same GDI [Margin t: 5.prim.]. Therefore the angles GDH, DGF will be equal [Margin u: 32.prim.]; and since they are alternate between EH, FG, EH and FG will be parallel [Margin x: 7.pron.]. And [triangles DEG, DEF] will be equal, since they have the same base DE and lie between the same parallels [Margin y: 27.prim.]. And since triangle DEG is equal to triangle ABC — because the sides DE, DG are equal to the sides AB, AC, and angle A is equal to angle EDG [Margin z: 37.prim.] — triangle ABC will also be equal to triangle DEF [Margin a: 4.prim.], which is what was proposed.

Diagram. The scholium's first-case figure (angles equal to two right angles): a plain triangle ABC at the left (A apex; B, C base), and at the right the construction on triangle DEF with ED produced to H and FD produced to I, the added lines DG, EG, GF, and the intersection point K. Readable labels — left: A, B, C; right: D, E, F, G, H, I, and K (near F). At this resolution the crowded right-hand cluster (H, I, G, K in particular) is only partly resolved.

(Case 2.) Next, let the angles A and EDF be greater than two right angles. I say that triangle ABC, which has the greater angle, is less than triangle DEF. Produce ED to H and FD to I [Margin a: 23.prim.]; make angle EDG equal to angle A [Margin b: 3.prim.], and let DG equal DF, that is AC; and draw the straight lines EG, GF. Now since the angles A and EDF are supposed greater than two right angles, the angles EDG, EDF will also be greater than two right angles; but the angles EDG, GDH are

equal to two right angles [Margin c: 13.primi]. Therefore the angles EDG, EDF are greater than the angles EDG, GDH. So, taking away the common EDG, angle EDF remains greater than angle GDH. And since angle EDF is equal to angle HDI [Margin d: 15.primi], HDI too will be greater than GDH; and so GDH is less than the half of angle GDI. Again, since the sides DG, DF are equal, the angles DFG, DGF are equal [Margin e: 5.primi]; and since they are equal to the exterior angle GDI [Margin f: 32.primi], each of them — namely DGF — is the half of angle GDI. But it has been shown that angle GDH is less than the half of the same GDI. Therefore DGF will be greater than GDH. Cut off from angle DGF the angle DGK equal to the alternate angle GDH [Margin g: 23.primi]. Then GK will be parallel to DE [Margin h: 27.prim.] and will cut the straight line EF. From D to K, where GK cuts the straight line EF, draw the straight line DK. Then triangle DEG will be equal to triangle DEK [Margin i: 37.primi]. And since triangle DEG is equal to triangle ABC — because the sides DE, DG are equal to the sides AB, AC, and angle A is equal to angle EDG [Margin k: 4.prim.] — triangle ABC will also be equal to triangle DEK. Since therefore DEK is less than triangle DEF [Margin l: 9.pron.], the triangle ABC too will be less than triangle DEF. Which is what was proposed.

Diagram. The scholium's second-case figure (angles greater than two right angles): a small triangle ABC at the left (A apex; B, C base), and a right-hand construction on triangle DEF with the produced lines to H and I, the added line DG, and the point K on EF. Readable labels — left: A, B, C; right: D, E, F, H, I, K, G. The right cluster is crowded and small; H, I, K are not all fully resolved.

(Case 3.) Thirdly, let the angles A and EDF be less than two right angles. I say that triangle ABC, which has the greater angle, is greater than triangle DEF. Produce ED to H and FD to I [Margin m: 23.prim.]; make angle EDG equal to angle A [Margin n: 3.primi], and let DG equal DF, that is AC; and draw the straight lines EG, GF. Now since the angles A and EDF are supposed less than two right angles, the angles EDG, EDF will also be less than two right angles. But the angles EDG, GDH are equal to two right angles [Margin o: 13.primi]. Therefore EDG, EDF are less than EDG, GDH; and, the common EDG being taken away, EDF remains less than GDH. But EDF is equal to HDI [Margin p: 15.primi]. So HDI too will be less than GDH; and thus GDH is greater than the half of angle GDI. And since DGF is the half of the same angle GDI, as was shown above, GDH will be greater than DGF. Make the angle DGK equal to angle GDH [Margin q: 23.primi], drawing the straight line GK, which will cut the straight line EF produced at K; and draw the straight line DK. Then, as before, GK will be parallel to DE [Margin r: 27.prim.], and triangle DEG will be equal to triangle DEK [Margin s: 37.primi]. But again DEG is equal to ABC [Margin t: 4.primi]. Therefore ABC too is equal to DEK

[Margin u: 9.pron.]. And so, since DEK is greater than DEF, ABC too will be greater than DEF. Which was to be demonstrated.

Diagram. The scholium's third-case figure (angles less than two right angles): a large triangle ABC at the left (A apex; B, C base), and to the right the construction on triangle DEF with ED, FD produced to H and I, the added lines DG, EG, GF, and the intersection K on EF. Readable labels — left: A, B, C; right: D, E, F, G, H, I, K. The upper labels H, I and the point K are small and only partly resolved.

From all this it is clear why Euclid, in prop. 24, concluded only the inequality of the bases and not of the triangles, as we noted there.

THEOR. 28. PROPOS. 38.

[Margin: XXXVIII.]

(*Euclid — enunciation.*) Triangles set up on equal bases and between the same parallels are equal to one another.

(*Demonstration — Clavius.*) Between the parallels AB, CD, and on the equal bases CE, FD, let the triangles ACE, BFD be set up. I say they are equal. Draw EG parallel to AC, and DH parallel to BF [Margin x: 31.primi]. Then the parallelograms ACEG, BFDH will be equal [Margin y: 36.primi]. Since therefore the triangles ACE, BFD are the halves of these [Margin z: 34.prim.], they will be equal to one another [Margin a: 7.pron.]. Therefore triangles on equal bases, etc. Which was to be shown.

Diagram. The Prop. 38 figure. Top line (left to right): A, G, B, H. Base line (left to right): C, E, F, D. The zig-zag internal lines form the two parallelograms ACEG and BFDH and the two triangles ACE, BFD on the equal bases CE, FD.

SHOLIVM [to Prop. 38]

[Printed "SHOLIVM" — the initial C is dropped; see anomalies.]

The converse of this will be shown by Euclid at prop. 40.

Moreover, from this proposition it follows that, if from any vertex of a given triangle a straight line is drawn bisecting the opposite side, the triangle too is bisected. For in triangle ABC let the straight line AD be drawn from vertex A, bisecting side BC at D. I say that triangle ABC is also bisected. For if a parallel to BC is drawn through A, the two triangles ABD, ADC will lie between the same parallels and on equal bases [Margin b: 38.primi]; therefore they will be equal.

EX PELETARIO [From Peletier]

(Problem — enunciation.) From any given point on one side of a proposed triangle, to draw a straight line that bisects the given triangle.

(Solution.) Let ABC be the triangle, and D the given point on side BC. We must, then, draw a straight line from D that bisects the triangle. Now if the point D bisects the side BC, then the straight line DA, drawn to A, will bisect the triangle, as was shown in this scholium. But if D does not bisect BC, let BC be bisected at E [Margin c: 10.primi]. Then from D to the opposite vertex A draw the straight line DA, and through E draw EF parallel to DA [Margin d: 31.primi], cutting AC at F. If now the straight line DF is drawn, the triangle will be bisected by the line DF. For, drawing the straight line EA, the triangles EFA, EFD will be equal [Margin e: 38.primi], since they stand on the same base EF and between the same parallels EF, AD. Adding therefore the common triangle CFE, the whole triangles AEC, CDF will be equal [Margin f: 2.pron.]. But AEC is the half of the whole ABC, as was shown. Therefore CDF too is the half of the same triangle ABC, which was to be proved.

Diagram. The "Colligitur" scholium figure: a triangle with apex A and base B–D–C, D being the midpoint; a dotted horizontal line through A marks the parallel to BC. Labels: A, B, C, D.

Diagram. The Peletier figure: triangle with apex A; base line B, D, E, C (left to right); F on side AC; internal lines DA and EF (parallel to DA). Labels: A, F, B, D, E, C.

But if the point D falls in the other half EC, we shall carry out the problem in the same way; only then the triangle will be cut off toward the B side, and the trapezium toward the C side, as the present figure sufficiently shows. The demonstration is the same, provided the letter B in it is changed to C and C to B. We shall, however, propose this problem in a much more general form at the end of Book VI.

Diagram. The Peletier figure for the alternative case (point D in the other half): triangle with apex A; base line B, E, D, C (left to right); F on side AC; the internal construction lines. Labels: A, F, B, E, D, C.

THEOR. 29. PROPOS. 39.

[Margin: XXXIX.]

(*Euclid — enunciation.*) Equal triangles set up on the same base and toward the same side are also between the same parallels.

(*Demonstration — Clavius.*) Let there be two equal triangles ABC, DBC on the same base BC and toward the same side. I say they are set up between the same parallels — that is, that the straight line AD, when drawn, is parallel to BC. For if it is not, draw through A a parallel to BC [Margin a: 31.primi], which will fall either above AD or below it. Let it first fall above, as AE, meeting BD produced at E; and draw the straight line EC. Now since AE, BC are parallel, triangle EBC will be equal to triangle ABC [Margin b: 37.primi]; but by hypothesis triangle DBC too is equal to the same triangle ABC. Therefore the triangles DBC, EBC will be equal [Margin c: 1.pron.] — a part and a whole, which is absurd. And if the parallel drawn through A falls below AD, as AF, then, drawing the straight line FC, by the same reasoning the triangles BFC, BDC will be equal — a part and a whole — which is absurd. Therefore AD will be parallel to BC. Therefore equal triangles on the same base, etc. Which was to be shown.

Diagram. The Prop. 39 figure: base BC with the two equal triangles ABC (apex A) and DBC (apex D) toward the same side; AE the parallel meeting BD produced at E; AF the parallel falling below. Readable labels: A, E, B (upper area), B, C (base), D, F. Several of the small internal labels (D, F and the direction of E) are only partly resolved at this resolution.

SHOLIVM [to Prop. 39]

[Printed "SHOLIVM" — the initial C is dropped; see anomalies.]

From these Campanus [Campanus of Novara] infers the following theorem.

(*Theorem — enunciation.*) A straight line bisecting two sides of a triangle will be parallel to the remaining side.

(*Demonstration.*) Let the line DE bisect the sides AB, AC of triangle ABC at D and E. I say DE is parallel to the side BC. For since the triangles ADE, BDE stand on the equal bases AD, DB and between the same parallels — if through E a parallel to AB were drawn — triangle BDE will be equal to triangle ADE [Margin d: 38.primi]; and by the same reasoning triangle CED will be equal to the same triangle ADE. This is also established from the scholium of the preceding proposition: for the straight line ED will bisect triangle AEB, and the same line DE will likewise bisect triangle ADC, since by hypothesis the bases AB, AC are bisected by the line DE. Therefore the triangles DBE, ECD will be equal [Margin e: 1.pron.]; and they have the same base DE and are set up toward the same side.

Therefore they will lie between the same parallels [Margin f: 39.primi], and hence DE, BC will be parallel. Which is what was proposed.

Diagram. The Campanus scholium figure: triangle ABC (apex A; B, C base) with D, E the midpoints of AB, AC; the line DE and the crossing internal lines to B and C. Labels: A, D, E, B, C.

That which we promised at the end of the second theorem in the scholium to prop. 34 we shall now easily demonstrate from this proposition. Namely:

(Theorem — enunciation.) Every quadrilateral that is bisected by both of its diagonals is a parallelogram.

(Demonstration.) For let the quadrilateral ABCD be bisected by both diagonals AC, BD. I say it is a parallelogram. Since the triangles ADC, BDC are halves of the same quadrilateral ABCD [Margin g: 7.pron.], they will be equal to one another. And so, since they have the same base DC and are toward the same side, they will lie between the same parallels [Margin h: 39.primi]; and therefore the straight lines AB, DC are parallel. In no other way we shall show that AD, BC are parallel. Therefore ABCD is a parallelogram. Which is what was proposed.

Diagram. The "OMNE quadrilaterum" figure: a quadrilateral (parallelogram) with the two diagonals AC, BD drawn. Labels: A (top-left), B (top-right), C (bottom-right), D (bottom-left).

THEOR. 30. PROPOS. 40.

[Margin: XXXX.]

(Euclid — enunciation.) Equal triangles set up on equal bases and toward the same side are also between the same parallels.

(Demonstration — Clavius.) Let there be two equal triangles ABC, DEF on the equal bases BC, EF (placed on the same straight line) and set up toward the same side. I say they lie between the same parallels — that is, that the straight line drawn from A to D is parallel to the straight line BF. For if it is not, the parallel to BF drawn through A will fall either above AD or below it. Let it first fall above, meeting ED produced at G; and draw the straight line GF. Now since AG, BF are parallel, triangle EFG will be equal to triangle ABC [Margin i: 38.primi]; but triangle DEF too is supposed equal to the same triangle ABC. Therefore the triangles DEF, GEF will be equal [Margin k: 1.pron.] — a part and a whole — which is absurd. And if the parallel drawn through A falls below AD, as AH, then, drawing the straight line HF, by the same argument the triangles HEF, DEF will

be equal — a part and a whole — which is absurd. Therefore AD is parallel to BF. Therefore equal triangles on equal bases, etc. Which was to be demonstrated.

Diagram. The Prop. 40 figure: base line B, C, E, F (the collinear equal bases BC, EF); triangle ABC (apex A) and triangle DEF (apex D); AG the parallel meeting ED produced at G; AH the parallel below (H interior near D). Readable labels — top: A, D, G; base: B, C, E, F; and H. The top cluster D, G and the interior H are small; not all fully resolved.

SCHOLIVM [to Prop. 40]

[The initial S–C–H–O is set with a decorative dotted ring for the O.]

This proposition is the converse of prop. 38 in one way. But it can be converted in another way, just as we converted prop. 36 in its scholium — namely:

Clavius, *Opera Mathematica*, Tomus I — Commentary on Euclid, Book I (folios 67–69)

(This batch continues Clavius's scholium on Euclid I.37–40, extending the results on parallelograms and triangles to trapezia, then a theorem on bisecting the two parallels in a triangle, and finally the problem of dividing a line into any number of equal parts. Throughout, the theorem-enunciations set in capitals are Clavius's own within the scholium; the italic passages are his demonstrations. Marginal notes are Clavius's citations: "primi" (also "pri."/"prim.") = a proposition of Euclid's Elements Book I; "pron." = one of the pronuntiata, i.e. the common notions/axioms. The reference numerals are given as printed.)

Theorem. Equal triangles between the same parallels, if they do not stand on the same base, will be constructed on equal bases.

Demonstration. Let ABC and DEF be equal triangles between the parallels AD and BF, standing on the bases BC and EF, which I say are equal. For if they are not equal, let BC be the greater. Cut off, then, the straight line CG equal to EF [Margin: a — Elements I.3], and draw the straight line GA; then triangle AGC will be equal to triangle DEF [Margin: b — Elements I.38]. But triangle ABC is also assumed equal to that same triangle DEF; therefore triangles AGC and ABC will be equal [Margin: c — Common Notion 1] — a part and the whole, which is absurd. Hence the bases BC and EF are not unequal, but equal. Which is what was proposed.

The following theorem, too, will be proved with little trouble.

Theorem. If two triangles between the same parallels have unequal bases, the one whose base is greater will be the greater. And conversely, if two triangles between the same parallels are unequal, the base of the greater will be greater.

Diagram. Two triangles standing between two parallel lines. The upper parallel runs through A (left apex) and D (right); the lower parallel carries, from left to right, B, G, C, E, F. Triangle ABC and triangle AGC share the apex A; triangle DEF has apex D. The straight line CG is cut off equal to EF, and GA is drawn.

- A (upper parallel, left): apex of triangles ABC and AGC
- D (upper parallel, right): apex of triangle DEF
- B (lower parallel, far left): base endpoint
- G (lower parallel): endpoint of the cut-off segment CG
- C (lower parallel): shared base endpoint
- E (lower parallel): base endpoint of triangle DEF
- F (lower parallel, right): base endpoint of triangle DEF

Demonstration. For let there be, in the adjoining figure, between the parallels AD and BF, the triangles ABC and DEF, with base BC greater than base EF. I say that triangle ABC is greater than triangle DEF. For when the straight line CG has been cut off equal to EF [Margin: d — Elements I.3] and the straight line AG drawn, the triangles AGC and DEF, standing on the equal bases GC and EF, will be equal [Margin: e — Elements I.38]. Since, then, triangle ABC is greater than triangle AGC [Margin: f — Common Notion 9], that same triangle ABC will be greater than DEF.

Again, let the triangles ABC and DEF be unequal, with ABC the greater. I say that base BC is greater than base EF. For if it be called equal, triangle ABC will be equal to triangle DEF [Margin: g — Elements I.38], which is absurd, since ABC is assumed the greater. But if it be thought smaller, then triangle DEF will be greater than triangle ABC, as we have just shown — which is far more absurd, since ABC is assumed the greater. Therefore the straight line BC will be greater than EF, since it has been shown neither equal nor smaller. Which is what was proposed.

Now the results demonstrated so far concerning parallelograms and triangles set between the same parallels can also easily be demonstrated of trapezia described between the same parallels, in nearly the same order, as follows.

I.

Theorem. Trapezia in the same parallels and on the same base, whose opposite bases are equal to one another, are equal to one another; and trapezia that are

equal, in the same parallels and on the same base, have their opposite bases equal.

(Definition.) Trapezia are said to be in the same parallels when their two opposite sides are parallel and are parts of the same parallels.

Diagram. Two trapezia sharing the base CD, set between the parallels AB (upper) and CD (lower). Along the upper parallel, from left to right: A, E, F, B. Along the lower parallel: C (left), D (right). The diagonals EC and FD are drawn, crossing between the parallels, so that the interior resembles a "W" within the outer trapezium. Trapezium ACDE and trapezium FCDB are formed.

- A (upper parallel, far left): vertex of trapezium ACDE
- E (upper parallel): opposite-base endpoint (AE)
- F (upper parallel): opposite-base endpoint (FB)
- B (upper parallel, far right): vertex of trapezium FCDB
- C (lower parallel, left): shared base endpoint
- D (lower parallel, right): shared base endpoint

Demonstration. Between the parallels AB and CD, then, on the same base CD, let two trapezia ACDE and FCDB be set up, whose opposite bases AE and FB are equal. I say that they are equal to one another. For when the straight lines EC and FD have been drawn, the triangles ECD and FCD, on the same base CD and between the same parallels, will be equal to one another [Margin: h — Elements I.37], as will the triangles ACE and FDB, on the equal bases AE and FB and between the same parallels [Margin: i — Elements I.38]. If, then, to the equal triangles ECD and FCD there be added the equal triangles ACE and FDB, the whole trapezia ACDE and FCDB will be equal to one another [Margin: k — Common Notion 2].

Now let the trapezia ACDE and FCDB be equal. I say that the opposite bases AE and FB are also equal. For again the triangles ECD and FCD will be equal [Margin: l — Elements I.37]. If, then, from the equal trapezia these be taken away, the remaining triangles ACE and FDB will be equal [Margin: m — Common Notion 3]. Hence, as we show in this scholium, the bases AE and FB will be equal.

II.

Theorem. Trapezia in the same parallels and on the same base, whose opposite bases are unequal, are themselves unequal, and the greater is the one whose base is greater; and unequal trapezia in the same parallels and on the same base have

their opposite bases unequal, and the greater base belongs to the greater trapezium.

Demonstration. As in the same figure: if base AE be said to be greater than base FB, I say that trapezium ACDE is greater than trapezium FCDB. For again the triangles ECD and FCD are equal [Margin: n — Elements I.37]; but triangle ACE is greater than triangle FDB, as we demonstrated in this scholium [Margin: o — Common Notion 4], because base AE is assumed greater than base FB. Therefore the whole trapezium ACDE will be greater than the whole trapezium FCDB.

Again, if trapezium ACDE be said to be greater than trapezium FCDB, I say that base AE is greater than base FB. For again the triangles ECD and FCD are equal [Margin: p — Elements I.37]. Hence the remaining triangle ACE is greater than the remaining triangle FDB [Margin: q — Common Notion 5]; and therefore, as was shown in this scholium, base AE will be greater than base FB. Which was to be shown.

III.

Theorem. Trapezia in the same parallels and on equal bases, whose opposite bases are equal, are equal; and equal trapezia in the same parallels and on equal bases have their opposite bases equal.

Diagram. Two trapezia between the parallels AB (upper) and CD (lower), standing on the equal bases CE and GD. Along the upper parallel, from left to right: A, F, H, B. Along the lower parallel, from left to right: C, E, G, D. The straight lines FC and HD are drawn, so that two triangles (FCE and HGD) point upward. Trapezium ACEF and trapezium HGDB are formed.

- A (upper parallel, far left): vertex of trapezium ACEF
- F (upper parallel): apex/opposite-base endpoint (AF)
- H (upper parallel): apex/opposite-base endpoint (HB)
- B (upper parallel, far right): vertex of trapezium HGDB
- C (lower parallel, far left): base endpoint
- E (lower parallel): division point (base CE)
- G (lower parallel): division point (base GD)
- D (lower parallel, far right): base endpoint

Demonstration. Between the parallels AB and CD, on the equal bases CE and GD, let two trapezia ACEF and HGDB be set up, whose opposite bases AF and HB are likewise equal. I say that the trapezia are equal. For when the straight lines FC and HD have been drawn, the triangles FCE and HGD, on the equal bases CE and

GD, will be equal [Margin: r — Elements I.38], as will the triangles ACF and BDH, on the equal bases AF and BH and between the same parallels, equal to one another. Therefore the whole trapezia will be equal [Margin: s — Common Notion 2].

Now let the trapezia ACEF and HGDB be equal, on the equal bases CE and GD. I say that the opposite bases AF and BH are also equal. For again the triangles FCE and HGD, on the equal bases CF [recte: CE] and GD, are equal [Margin: t — Elements I.38]; and when these are taken away from the equal trapezia, the remaining triangles ACF and BDH will be equal [Margin: u — Common Notion 3]; and therefore, as we showed a little earlier in this scholium, the bases AF and BH will be equal.

IV.

Theorem. Trapezia in the same parallels and on equal bases, whose opposite bases are unequal, are unequal, and the greater is the one whose base is greater; and unequal trapezia in the same parallels and on equal bases have their opposite bases unequal, and the greater base belongs to the greater trapezium.

Demonstration. As in the same figure: if base AF be said to be greater than base HB, then trapezium ACEF will be greater than trapezium HGDB. For again the triangles FCE and HGD, on the equal bases CE and GD, are equal [Margin: a — Elements I.38]; but triangle ACF is greater than triangle BDH, as shown above [Margin: b — Common Notion 4], because base AF is assumed greater than base BH. Therefore the whole trapezium ACEF will be greater than the whole trapezium HGDB.

Again, if trapezium ACEF be assumed greater than trapezium HGDB, then base AF will be greater than base BH. For again the triangles FCE and HGD, on the equal bases CE and GD, are equal [Margin: c — Elements I.38]; and when these are taken away from the unequal trapezia, the remaining triangle ACF will be greater than the remaining triangle BDH [Margin: d — Common Notion 5]; and therefore, as was shown in this scholium, base AF will be greater than base BH. Which was to be demonstrated.

Moreover, the following theorem does not seem one to be omitted here, since by it we shall with little trouble divide any straight line into any number of equal parts — a task we undertook to carry out at this place in the scholium to Proposition 10 of this book. For although the same could be demonstrated, and indeed more easily, by the proportions of lines, as we shall show in Book 6, it is nonetheless pleasant to understand that the same can be accomplished, with no

labor, by the propositions demonstrated so far, without the aid of proportions. The theorem, then, is as follows.

Theorem. If in a triangle a straight line be drawn parallel to one of the sides, then a straight line drawn from the opposite angle and bisecting either of the parallels also bisects the other.

Diagram. The first case: triangle ABC with apex A at the top. The base BC carries B (left), F (middle), C (right); the parallel DE, drawn across higher up, carries D (left), G (middle), E (right). The cevian AF runs from A through G on DE to F on BC, meeting both at right angles.

- A (apex): the opposite angle
- D (left end of parallel DE): on side AB
- G (middle of DE): where AF meets DE
- E (right end of parallel DE): on side AC
- B (base, left): base endpoint
- F (middle of base): where AF meets BC
- C (base, right): base endpoint

Diagram. The second case (angles at F not right): triangle ABC, apex A. Base B (left), F (middle), C (right); parallel DE with D (left), G (middle), E (right). To the right, the constructed point H, with the straight lines AH, HF, FD, FE drawn, and angle AGH constructed equal to angle AGD.

- A (apex): the opposite angle
- D, G, E (on parallel DE, left to middle to right)
- H (right, beyond E): constructed point, where angle AGH = angle AGD and GH = GD
- B, F, C (base, left to middle to right)

Demonstration. In triangle ABC let DE be parallel to BC, and let the straight line AF cut either BC or DE into two equal parts, at F or at G. I say that it bisects the other as well.

First, let the angles at F be right. [Margin: e — Elements I.29] Granting this, the angles at G will also be right. If, then, BC is bisected, angle A will also be bisected, by what we demonstrated in the scholium to Proposition 26 of this book; and therefore the straight line AG, being perpendicular to the base DE of triangle ADE and bisecting angle A, will also bisect the base DE, as we showed in the same place — which is what was proposed. But if DE be assumed bisected, then by the

same scholium to Proposition 26 of this book angle A is also bisected; and therefore the straight line AF, being perpendicular to the base BC and bisecting angle A, will also cut the base BC into two equal parts, which is what was proposed.

Next, let the angles at F not be right, but AFC obtuse and AFB acute. [Margin: f — Elements I.29] Granting this, AGE will also be obtuse and AGD acute, since these are equal to those, as external to internal. If, then, BC is bisected, let there be constructed on the acute angle AGD an angle AGH equal to it [Margin: g — Elements I.23], with the straight line GH equal to GD [Margin: h — Elements I.3], and let the straight lines AH, HF, FD, FE be drawn. Now since both the whole triangles ABF and ACF are equal, by the scholium to Proposition 38 of this book [Margin: i — Elements I.38], and likewise the triangles cut off, DBF and ECF, on account of the equal bases BF and CF, the triangles ADF and AEF will also be equal [Margin: k — Common Notion 3]. Again, since the two sides AG, GD of triangle AGD are equal to the two sides AG, GH, and they contain the equal angles AGD, AGH by construction, the triangles AGD and AGH will also be equal [Margin: l — Elements I.4]. By like reasoning, since the two sides DG, GF are equal to the two sides HG, GF by construction, and they contain the equal angles DGF, HGF — for since by construction the angles AGD, AGH are equal, the remainders of the two right angles, DGF and HGF, will be equal [Margin: m — Elements I.13]; for both AGD together with DGF, and AGH together with HGF, are equal to two right angles — the triangles DGF and HGF will also be equal [Margin: n — Elements I.4]; and therefore the whole triangles ADF and AHF will be equal [Margin: o — Common Notion 2]. But triangle AEF has been shown equal to that same triangle ADF. Therefore the triangles AHF and AEF will also be equal to one another [Margin: p — Common Notion 1]; and on that account they will lie between the same two parallels — that is, when the straight line EH is drawn, it will be parallel to the common base AF [Margin: q — Elements I.39]. Therefore the triangles HGF and EGF, between the same parallels and on the same base FG, will also be equal to one another [Margin: r — Elements I.37]. But triangle HGF has been shown equal to triangle DGF. Therefore the triangles DGF and EGF will also be equal to one another; and on that account the base DG too will be equal to the base GE, as was demonstrated in this scholium — which is what was proposed.

Diagram. The case in which DE is assumed bisected: triangle ABC, apex A. Parallel DE with D (left), G (middle), E (right), and the constructed point H at the far right; base B (left), F (middle), C (right). The straight lines AH, HG, GB, GC are drawn.

- A (apex)
- D, G, E (on parallel DE, left to right)
- H (far right): constructed point
- B, F, C (base, left to right)

Demonstration. But if DE be assumed bisected, let there be constructed an equal angle [Margin: s — Elements I.23], and let the straight lines AH, HG, GB, GC be drawn [Margin: t — Elements I.3]. Now since both the triangles [AGB, AGH?] and the triangles DGB, EGC, on account of the equal bases DG, EG [Margin: u — Elements I.38], [are respectively equal], the whole triangles AGB and AGC will also be equal [Margin: x — Common Notion 2]. Again, since the two sides AF, FB are equal to the two sides AF, FH, and they contain the equal angles AFB, AFH by construction, the triangles AFB and AFH will also be equal [Margin: y — Elements I.4]. By like reasoning, since the two sides GF, FB are equal to the two sides GF, FH, and they contain the equal angles GFB, GFH by construction, the triangles GFB and GFH will also be equal [Margin: z — Elements I.4]; and when these are taken away from the equal triangles AFB, AFH, the remaining triangles AGB and AGH will be equal [Margin: a — Common Notion 3]. But triangle AGC has been shown equal to that same triangle AGB. Therefore the triangles AGC and AGH will also be equal to one another [Margin: b — Common Notion 1]. Hence they will also lie between the same parallels — that is, when the straight line CH is drawn, it will be parallel to AF [Margin: c — Elements I.39]; and on that account the triangles GHF and GFC will be equal to one another [Margin: d — Elements I.37]. But triangle GHF has been shown equal to triangle GBF. Therefore the triangles GFC and GFB will also be equal to one another [Margin: e — Common Notion 1]; and so, as we demonstrated in this scholium, the bases FC and FB will also be equal. Which is what was proposed.

Diagram. The "Aliter" (alternative) case: triangle ABC, apex A. Parallel DE with D (left), G (middle), E (right); the base carries B (left), H, F, C (right), so that the reductio-point H lies on BC between B and F. The straight lines FD, FE are drawn.

- A (apex)
- D, G, E (on parallel DE, left to right)
- B (base, far left)
- H (base): the assumed bisection point of BC in the reductio
- F (base, middle)
- C (base, far right)

Another way. First let BC be bisected at F. I say that DE too is bisected at G. For if DG and GE are not equal, let DG be the greater, and draw the straight lines FD, FE. Then, by what we demonstrated in this scholium, both triangle ADG will be greater than triangle AEG, and triangle FDG greater than triangle FEG. Therefore the whole triangle ADF will be greater than the whole triangle AEF [Margin: f — Common Notion 4]; and if to these be added the triangles DBF, ECF, ECF — which are equal because of the equal bases BF, CF [Margin: a — Elements I.38] — the whole triangle ABF will be made greater than the whole triangle ACF [Margin: b — Common Notion 4]; and so it will be the greater: but it is also assumed equal. Which is absurd. Therefore DE is bisected at G. Which is what was proposed.

Now let DE be bisected at G. I say that BC too is bisected at F. If not, let BC be bisected at H [Margin: c — Elements I.10], and draw the straight line AH, cutting DE at I. Now since AH cuts BC into two equal parts at H, it will also cut DE itself into two equal parts at I, as we have just shown. Which is absurd, since DE is assumed bisected at G; for it would follow that a part is greater than the whole. For if DI is equal to IE, then since IE is greater than GE, DI will also be greater than GE — that is, greater than DG, which is assumed equal to GE. Therefore BC is bisected at F. Which was to be demonstrated.

This theorem being shown, let us now come to the division of a straight line into any number of equal parts.

Problem. To cut a given finite straight line into any number of equal parts you please.

Diagram. [The page is heavily foxed; the labels below were confirmed at high magnification.] A large triangle with apex C at the top, from which two sides descend, extended slightly above C by a ruled line. Three horizontal transversals cross the figure: an upper one carrying, left to right, A, N, M, L, K, B; a middle one carrying E, I, H, G, F, D; and the base carrying A, N, M, L, K, B. Straight lines run from C through the division points F, G, H, I of the parallel DE down to the points K, L, M, N on AB.

- C (apex): the meeting-point of AC and BD
- A (left end of AB): extremity of the given line
- B (right end of AB): extremity of the given line
- K, L, M, N (on AB, between B and A): the four division points giving parts BK, KL, LM, MN, NA
- D (right end of the parallel DE): the point taken on BC
- E (left end of the parallel DE): where AC meets DE

- F, G, H, I (on DE, between D and E): the equal-part marks DF, FG, GH, HI, IE

Demonstration. Let AB be the given straight line, to be cut into five equal parts. Through the extremity B draw any straight line BC, and, taking any point D on BC — whether below B or above it — draw through D a line DE parallel to AB [Margin: d — Elements I.31], and on it cut off [Margin: e — Elements I.3] five parts equal to one another, DF, FG, GH, HI, IE, yet under this rule: that, when the point D is below B, the straight line DE, composed of the five equal parts, be greater than the given line AB, but smaller when the point D is above B — so that, of course, the straight line AC, drawn through the other extremity A and through E, can meet BD at some point, as at C. And if from C straight lines be drawn through the points F, G, H, I, the given straight line AB will be cut into the five equal parts BK, KL, LM, MN, NA. For since in triangle CBL the straight line DG is parallel to BL — or, in triangle CDG, the straight line BL is parallel to DG — and DG is bisected at F, then BL too will be bisected at K, as we demonstrated in the preceding theorem. And by the same reasoning KM will be bisected at L, just as FH is bisected at G. Therefore the three parts BK, KL, LM are equal to one another, just as the three DF, FG, GH; and so on for the rest.

Another way. At the extremity A of the line AB, which is to be cut into five equal parts, construct any rectilinear angle A, and from the straight line AC cut off [Margin: f — Elements I.3] five parts of any size, equal to one another, AD, DE, EF, FG, GC; and when the straight line CB has been drawn [Margin: g — Elements I.31], draw parallels to it, GL, FK, EI, DH. I say that the straight line AB is cut into five equal parts.

Diagram. [Foxed; labels confirmed at high magnification.] A right-triangle "staircase." The base runs, left to right, A, H, I, K, L, B; the slanting side rises from A through D, E, F, G to the apex C at the top right. From the division points D, E, F, G of the slanting side, lines DH, EI, FK, GL are drawn parallel to the closing side CB, meeting the base at H, I, K, L. The interior points M and N (on the parallels GM, FN drawn to AB) are marked near G and F.

- A (bottom left): the vertex where the angle is constructed
- C (top right): apex
- D, E, F, G (on the slant AC, ascending): equal divisions AD, DE, EF, FG, GC
- H, I, K, L (on the base AB, ascending): division points AH, HI, IK, KL, LB
- B (bottom right): extremity of the given line
- M, N (interior): points on the parallels GM, FN drawn to AB

For when through G and F there have been drawn parallels GM, FN to AB [Margin: h — Elements I.31] — which will also be parallel to one another [Margin: i — Elements I.30] and to BL, parallelograms GB, FL being formed [Margin: k — Elements I.34] — the angles FGN and GCM, external and internal in the parallels GL, CB, will be equal to one another, as will the angles CGM and GFN, external and internal in the parallels GM, FN [Margin: l — Elements I.29]. Now since the two angles C, G of triangle CGM are equal to the two angles G, F of triangle GFN, each to each, and the sides adjacent to them, CG and GF, are equal by construction, the sides GM and FN will also be equal [Margin: m — Elements I.26]; and since these have been shown equal to the straight lines BL, LK, then BL and LK too will be equal to one another. And by the same reasoning we shall show that KI, IH, and HA are equal; and therefore the straight line AB will be divided into five equal parts. Which is what was proposed.

Another way. At the two extremities A, B of the line AB, which is to be divided into five equal parts, construct two equal angles on opposite sides, ABC and BAD. And on each of the lines BC, AD — which, on account of the alternate equal angles A, B, are parallel to one another [Margin: n — Elements I.27] — take four parts wholly equal to one another (namely one fewer than the number of parts into which the line is to be cut), of the sort BE, EF, FG, GC and AH, HI, IK, KD [Margin: o — Elements I.3], and let the straight lines CH, GI, FK, ED be joined, which will be parallel to one another, since they join the extremities of equal parallels [Margin: p — Elements I.31]. I say that the straight line AB is cut into five equal parts.

Diagram. [Foxed; labels confirmed at high magnification.] A rhomboid/parallelogram-like figure formed by the two equal, oppositely-directed lines BC and AD crossing the given line AB. The upper region carries, left to right, C, G, Q, F, P, E, then B at the right; the central line AB carries A (left), then M, N, O; the lower region carries H, I, K, D. Transversals CH, GI, FK, ED are drawn, together with the parallels EP, FQ to AB.

- A (left of central line): extremity of the given line
- B (right): extremity of the given line
- C (upper left): apex of triangle ABC
- D (lower right): apex of triangle BAD
- E, F, G (on BC, from B toward C): equal divisions BE, EF, FG, GC
- H, I, K (on AD, from A toward D): equal divisions AH, HI, IK, KD
- M, N, O (on AB): division points giving AL/LM/MN/NO/OB [with L]
- P, Q (interior): points on the parallels EP, FQ drawn to AB

For when through E and F there have been drawn parallels EP, FQ to AB [Margin: q — Elements I.31] — which will also be parallel to one another [Margin: r — Elements I.30], and equal to NO, MN, parallelograms EN, FM being formed [Margin: s — Elements I.34] — the angles EFP and FGQ, external and internal in the parallels FK, GI, will be equal to the angles GFQ and FEP, external and internal in the parallels QF, PE [Margin: t — Elements I.39]. And so, since the two angles G, F of triangle FGQ are equal to the two angles F, E of triangle EFP, each to each, and the sides adjacent to them, FG and EF, are equal by construction, the sides FQ and EP will also be equal to one another [Margin: u — Elements I.26]; and since these have been shown equal to the straight lines MN, NO, then MN and NO too will be equal to one another. And by the same reasoning OB, NO, MN, LM, AL will all be equal to one another; and therefore the straight line AB will be divided into five equal parts. Which is what was proposed.

This practical construction will be demonstrated more briefly thus. Since the straight lines ED, FK, GI, GH [recte: CH] are parallel — because they join the extremities of equal and parallel lines [Margin: x — Elements I.33] — the straight line BL will be cut into four equal parts, and likewise the straight line AO, as we showed in the preceding practical construction. Therefore all five parts AL, LM, MN, NO, OB will be equal.

Another way. Let an instrument be prepared, suited to the division of lines into equal parts, in this manner. When two parallels CD, EF have been drawn a fairly large distance apart, let there be taken on each any number of parts wholly equal to one another [Margin: y — Elements I.3] — as many on the one as on the other — and let them be joined, at a modest interval, by straight lines, which will be parallel to one another, since they join the extremities of equal parallels [Margin: z — Elements I.33]. If, then, by means of a compass the straight line AB, which is to be divided into five equal parts, be transferred from some point G as far as a point H, so that five intervals of the parallels are enclosed between G and H, the line GH thus drawn will be divided by those parallels into five equal parts [Margin: a — Elements I.3]; and if from these parts equal ones be taken on the given line AB, then AB too will be divided into five equal parts [Margin: b — Elements I.30]. That GH is cut into five equal parts will be demonstrated thus. When through C and N there have been drawn parallels CI, NM to GH [Margin: c — Elements I.34] — which will also be parallel to one another and equal to GK, KL, parallelograms GI, KM being formed [Margin: d — Elements I.29] — the angles CNI, NOM [recte: NKO?], external and internal in the parallels NK, OL, [and the angles] ONM, NCI, external and internal in the parallels NM, CI, will be equal to one another. Therefore, since the two angles N, C of triangle CNI are equal to

the two angles O, N of triangle NOM, each to each, and the sides adjacent to them, CN, NO, are equal by construction [Margin: e — Elements I.26], the sides CI, NM will also be equal to one another; and since these have been shown equal to the straight lines GK, KL, then GK and KL too will be equal to one another. And by the same reasoning all the parts of the straight line GH will be shown equal; and therefore the straight line GH will be divided into five equal parts.

Diagram. [Foxed; labels confirmed at high magnification.] The dividing instrument: a four-sided frame between the two parallels CD (upper, running C...E) and DF (lower, running D...F), ruled with several equally-spaced horizontal lines between them, and crossed by oblique transversals. Upper edge carries C (top left), G, Q, then E (top right); the interior carries N, K on the first interior line, I lower, O and M on the left, L in the middle, H and P lower down; the base carries D (bottom left) and F (bottom right).

- C (top left): corner
- E (top right): corner
- D (bottom left): corner
- F (bottom right): corner
- G, Q (on the upper edge): the transferred segment's endpoints / division marks
- N, K, I, L, M, O, H, P (interior): intersection points of the transferred line GH with the ruled parallels

Diagram. A short horizontal straight line AB marked with four ticks dividing it into five equal segments — the line AB to be divided, shown for transfer by the compass onto the instrument.

- A (left end): extremity
- B (right end): extremity

This practical construction can also be shown more briefly, as follows. Mark off five intervals of the line EF, from E all the way to P, and with the compass transfer the line AB from P to some point of the line CE, say to Q. In this way the line PQ, once drawn, will be divided by the parallels into five equal parts, as was demonstrated in the second construction. Therefore, if the parts of the line PQ—which by construction equals the given line AB—are transferred onto the given line AB, then AB too will be divided into five equal parts. Which is what was proposed.

THEOR. 31. PROPOS. 41.

[Margin: xlj (41)]

Enunciation. If a parallelogram has the same base as a triangle and lies in the same parallels, the parallelogram will be double the triangle.

Demonstration. Between the parallels AB and CD, and on the base CD, let a parallelogram ACDE and a triangle BCD be set up. I say that the parallelogram is double the triangle BCD. For when the diagonal AD is drawn in the parallelogram, the triangles ACD and BCD will be equal [Margin: (a) Elements I.37]; but the parallelogram ACDE is double the triangle ACD, since the triangles ACD and ADE are also equal to one another [Margin: (b) Elements I.34]. Therefore the same parallelogram ACDE will also be double the triangle BCD [Margin: (c) common notion 6 [pronunciatum]]. And so, if a parallelogram has the same base as a triangle, and so on. Which was to be demonstrated.

Diagram. A parallelogram ACDE with the triangle BCD standing on the same base CD in the same parallels AB, CD. The diagonal AD divides the parallelogram; lines from A and from the apex complete the triangle BCD.

- A (top left): upper-left vertex of the parallelogram, on the upper parallel.
- E (top, above D): upper vertex of the parallelogram, on the upper parallel.
- B (top right): apex of the triangle, on the upper parallel.
- C (bottom left): left end of the base.
- D (bottom, middle): right end of the base CD.

SCHOLIUM

Hence it follows that if a triangle has double the base and lies in the same parallels as a parallelogram, the triangle will be equal to the parallelogram. For if the base CD is produced to F so that DF equals CD, and the line FB is drawn, the triangle BCF will be double the triangle BCD [Margin: (d) Elements I.38], since the triangles BCD and BDF are equal. But the parallelogram ACDE is also double the same triangle BCD [Margin: (e) Elements I.41]. Therefore the triangle BCF and the parallelogram ACDE will be equal [Margin: (f) common notion 6].

Diagram. A parallelogram ACDE and a triangle BCF, where the base CF is double the base CD of the parallelogram (D being the midpoint of CF).

- A (top left): upper-left vertex of the parallelogram.
- E (top, above D): upper vertex of the parallelogram.
- B (top right): apex of the triangle BCF.

- C (bottom left): left end of the doubled base.
- D (bottom, middle): midpoint, with $DF = CD$.
- F (bottom right): right end of the base CF.

This same theorem of Euclid's can be demonstrated in the same way if the parallelogram and the triangle have equal bases—though not the same base—and lie in the same parallels, as you see in the parallelogram ACDE and the triangle BFG, whose bases CD and FG are equal. For when the diagonal AD is drawn in the parallelogram, the triangles ACD and BFG will be equal [Margin: (g) Elements I.38]. Since, then, the parallelogram ACDE is double the triangle ACD—because the diagonal AD bisects the parallelogram ACDE [Margin: (h) Elements I.34]—it will also be double the triangle BFG [Margin: (i) common notion 6]. By the same reasoning, if the base FG were doubled and a line drawn to B, the triangle would come out equal to the parallelogram, since this triangle would then be double the triangle BFG as well, and so on.

Diagram. A parallelogram ACDE and a triangle BFG standing in the same parallels on equal but distinct bases CD and FG.

- A (top left): upper-left vertex of the parallelogram.
- E (top, above D): upper vertex of the parallelogram.
- B (top right): apex of the triangle BFG.
- C (bottom left): left end of base CD.
- D (bottom): right end of base CD.
- F (bottom): left end of base FG.
- G (bottom right): right end of base FG.

The converse

The converse of this theorem is twofold, as follows.

Enunciation. If a parallelogram is double a triangle, and they have the same base, or equal bases, and are set up toward the same side, they will lie in the same parallels. And if a parallelogram is double a triangle and lies in the same parallels, the bases will be equal—unless it is the same base.

Demonstration. Let the parallelogram ABCD be double the triangle EBC, whether they have the same base or equal bases. I say that the parallel AD, when produced, falls on the point E. For otherwise it would fall either above E or below it. Hence, as will be shown after the manner of proposition 39 or 40, a part would equal the whole, as the figure also indicates. For the parallelogram ABCD would then also be double the triangle BFC or BGC [Margin: (k) Elements I.41]. Therefore

the triangles EBC and FBC, or the triangles EBC and GBC, would be equal—a part and the whole [Margin: (l) common notion 6]. Which is absurd.

Diagram. A crowded figure for the first converse: a parallelogram ABCD with a triangle EBC on the base, and the alternative apex points F (above E) and G (below E) illustrating the "falls above or below" argument; a second, similar configuration appears to the right. The apex labels are printed close together and overlap.

- A (top left): upper-left vertex of the parallelogram.
- D (top): upper vertex of the parallelogram.
- E (top, on the produced parallel): apex of the triangle EBC.
- F (raised above E): alternative apex position (falls above E).
- G (below E): alternative apex position (falls below E).
- B (bottom left): left end of the base.
- C (bottom): right end of the base.

Next, let the parallelogram ABCD be double the triangle EFG, in the same parallels. I say that the bases BC and FG are equal. For if one of them—say BC—were greater, then, cutting off CH equal to the other and drawing HI parallel to AB [Margin: (m) Elements I.31], we shall prove that the parallelograms ABCD and IHCD are equal, the whole and the part (since each is double the triangle EFG—the one by hypothesis, the other by proposition 41). Which is absurd. We shall show the same if the base FG is said to be the greater. For if FH equal to BC be cut off and the line HE drawn, the triangles EFH and EFG will be equal, the part and the whole (since each is half of the parallelogram ABCD—the one by proposition 41, the other by hypothesis). Which is absurd.

Diagram. A small figure at the lower left for the second converse: the parallelograms ABCD and IHCD and the triangle EFG. The figure is small and faint, and several labels are hard to resolve.

- A (top left): upper-left vertex.
- I (top): upper vertex of the inner parallelogram IHCD. [?]
- D (top): upper vertex.
- E (top right): apex of the triangle EFG.
- B (bottom left): left end of base BC.
- H (bottom): point on the base, with the cut-off segment.
- C (bottom): shared base point.
- F (bottom): left end of base FG.

- G (bottom right): right end of base FG.

The following additional theorems, inserted after proposition 41, are drawn from Proclus.

Enunciation. If a triangle and a trapezium stand on the same base and in the same parallels, and the greater parallel line of the trapezium is the base of the triangle, the trapezium will be less than double the triangle. But if the lesser parallel line of the trapezium is the base of the triangle, the trapezium will be greater than double the triangle.

Demonstration. Between the parallel lines AE and BC, let a trapezium ABCD and a triangle EBC be set up on the same base BC—which base, however, is greater than the other line AD, the parallel side in the given trapezium. I say that the trapezium ABCD is less than double the triangle EBC. For since AD is assumed to be less than BC, take AF equal to BC and draw the line CF, which will be parallel to AB [Margin: (a) Elements I.33]; and so ABCF will be a parallelogram, which is double the triangle EBC [Margin: (b) Elements I.41]. Therefore the trapezium ABCD, being a part of the parallelogram, will be less than double the same triangle EBC. Which is what was proposed.

Diagram. A trapezium ABCD and a triangle EBC on the base BC, with AF taken equal to BC to complete the parallelogram ABCF; here the base BC exceeds the parallel side AD.

- A (top left): left end of the upper parallel.
- D (top): upper vertex of the trapezium.
- F (top): point with AF = BC, completing parallelogram ABCF.
- E (top right): apex of the triangle EBC.
- B (bottom left): left end of the base BC.
- C (bottom): right end of the base BC.

Again, let there be a trapezium and a triangle as before, but let the base BC be less than the other parallel line AD in the given trapezium. I say that the trapezium ABCD is greater than double the triangle EBC. For since AD is greater than BC, cut off DF equal to BC and draw the line BF, which will be parallel to CD [Margin: (c) Elements I.33]; and so BCDF will be a parallelogram, which is double the triangle EBC [Margin: (d) Elements I.41]. Therefore the whole trapezium ABCD, which exceeds the parallelogram BCDF, will be greater than double the same triangle EBC. Which is what was proposed.

Diagram. A trapezium ABCD and a triangle EBC, with DF cut off equal to BC to form the parallelogram BCDF; here the parallel side AD exceeds the base BC.

- A (top left): left end of the upper parallel.
- F (top): point with $DF = BC$.
- D (top): upper vertex of the trapezium.
- E (top right): apex of the triangle EBC.
- B (bottom left): left end of the base BC.
- C (bottom): right end of the base BC.

The same will be concluded if the trapezium and the triangle are set up on equal bases, in such a way that now the base of the trapezium is greater than its opposite parallel side, and now less.

Enunciation. A trapezium having two opposite sides parallel is double the triangle whose base is the one side of the trapezium joining the two parallels, and whose vertex is at the midpoint of the opposite side.

Demonstration. Let ABCD be a trapezium whose two opposite sides AB and DC are parallel, and on the base BC let a triangle EBC be set up, having its vertex E at the midpoint E of the side AD. I say that the trapezium ABCD is double the triangle EBC. For let one side of the triangle running to the vertex, namely BE, be produced until it meets CD, extended to F. Since AB and CF are parallel, the alternate angles BAE and FDE will be equal [Margin: (e) Elements I.29]; and the angles AEB and DEF are also equal, being vertical angles at E [Margin: (f) Elements I.15]; and the side AE of triangle ABE equals the side DE of triangle DEF, by hypothesis. Therefore the remaining sides AB and BE will be equal to the remaining sides DF and FE, each to each, and the remaining angles ABE and DFE will be equal; and hence the triangles ABE and DFE will be equal, by the corollary of proposition 26 of this book [Margin: (g) Elements I.26]. So, adding the common triangle CDE, the triangles ABE and CDE together will be equal to the triangle CEF [Margin: (h) common notion 1]. But the triangle BCE is also equal to the same triangle CEF, since the bases BE and EF have been shown to be equal and the triangles themselves lie between the same parallels—if through C a parallel to BF were drawn [Margin: (i) Elements I.38]. Therefore the triangle CBE will be equal to the triangles ABE and CDE [Margin: (k) common notion 1]; and consequently the triangle CBE will be half of the trapezium ABCD. Which is what was proposed.

Diagram. A trapezium ABCD with AB parallel to DC, and a triangle EBC whose vertex E is the midpoint of the side AD; the side BE is produced to meet CD extended at F.

- A (left): left vertex of the trapezium.
- B (bottom left): lower-left vertex, base end.
- C (bottom right): base end.
- D (right): right vertex of the trapezium.
- E (middle): midpoint of AD, vertex of the triangle.
- F (top right): where BE produced meets CD extended.

PROBLEMA 11. PROPOSITIO 42.

[Margin: xlij (42)]

Enunciation. To construct, in a given rectilineal angle, a parallelogram equal to a given triangle.

Demonstration. Let the given triangle be ABC and the given rectilineal angle D. We must therefore construct a parallelogram equal to the triangle ABC, having an angle equal to angle D. Bisect one side of the triangle, namely BC, at E [Margin: (a) Elements I.10], and make the angle CEF equal to angle D [Margin: (b) Elements I.23], as you please—that is, whether the angle CEF inclines toward C or toward B, whichever seems more convenient. Likewise draw through A a line AF parallel to BC [Margin: (c) Elements I.31], to cut EF at F. Again, through C or B, draw CG parallel to EF, meeting AF produced at G. Then in the angle CEF—which has been made equal to the given rectilineal angle D—there will be constructed the parallelogram CEFG, which I say is equal to the triangle ABC. For when the line EA is drawn: the parallelogram CEFG is double the triangle AEC [Margin: (d) Elements I.41], and the triangle ABC is likewise double the same triangle AEC [Margin: (e) Elements I.38], because the triangles AEC and ABE stand on equal bases EC and BE and in the same parallels, and so are equal. Therefore the parallelogram CEFG and the triangle ABC will be equal to each other [Margin: (f) common notion 6]. And since the angle CEF has been made equal to angle D, the proposition stands. And so, for a given triangle, we have constructed a parallelogram equal to it in a given rectilineal angle. Which was to be done.

Diagram. The triangle ABC with its side BC bisected at E, and the parallelogram CEFG built in the angle CEF; the given angle D is drawn separately to the right.

- A (top left): apex of the triangle.
- F (top): upper vertex of the parallelogram CEFG.
- G (top right): upper vertex of the parallelogram.
- B (bottom left): left end of the base.
- E (bottom, middle): midpoint of BC.

- C (bottom): right end of the base.
- D (right, separate): the given rectilineal angle.

SCHOLIUM

The practical construction of this problem is very easy from the construction itself.

Here Peletarius [Jacques Peletier] adds the following problem, which is the converse of this proposition.

Enunciation. To construct, in a given rectilineal angle, a triangle equal to a given parallelogram.

Demonstration. Let the given parallelogram be ABCD and the given angle G. Make the angle CBE equal to angle G, and let the line BE cut AD, produced to E. Extend BC also to F so that CF equals the line BC, and join EF. I say that the triangle BEF, having the angle EBF equal to the given angle G, is equal to the parallelogram ABCD. For when the line CE is drawn, the parallelogram ABCD is double the triangle BCE [Margin: (g) Elements I.41]; likewise the triangle BEF is double the same triangle BCE [Margin: (h) Elements I.38], since the triangles EBC and ECF are equal. Therefore the parallelogram ABCD and the triangle BEF will be equal to each other [Margin: (i) common notion 6]. Which is what was proposed.

Diagram. The parallelogram ABCD and the triangle BEF, where BE cuts AD produced at E and BC is extended to F; the given angle G is drawn separately to the right.

- A (top left): upper-left vertex of the parallelogram.
- D (top): upper-right vertex of the parallelogram.
- E (top right): where BE meets AD produced; apex of the triangle.
- B (bottom left): common vertex.
- C (bottom): lower-right vertex of the parallelogram.
- F (bottom right): point on BC produced, with CF = BC.
- G (right, separate): the given angle.

The practical construction of this problem of Peletier's is likewise very easy from the construction itself.

THEOR. 32. PROPOS. 43.

[Margin: xliij (43)]

Enunciation. In every parallelogram, the complements of the parallelograms about the diameter are equal to one another.

Demonstration. In the parallelogram ABCD, let there be, about the diameter AC, the parallelograms AEGH and CFGI, and the complements DFGH and EBIG, as we stated in definition 36. I say that these complements are equal to one another. For since the triangles ABC and CDA are equal [Margin: (a) Elements I.34], and likewise the triangles AEG and GHA, then if the latter are subtracted from the former, the trapezia CBEG and CDHG will remain equal [Margin: (b) common notion 1]. But the triangles CGI and CGF are also equal [Margin: (c) Elements I.34]. Therefore, if these are taken away from the trapezia, the complements DFGH and EBIG will remain equal [Margin: (d) common notion 3]. In every parallelogram, then, the complements, and so on. Which was to be shown.

Diagram. A parallelogram ABCD with the diameter AC drawn; about the diameter stand the parallelograms AEGH and CFGI, meeting at G, with the two complements DFGH and EBIG.

- A (top left): upper-left vertex.
- E (top): point on AB.
- B (top right): upper-right vertex.
- H (middle left): point on AD.
- G (center): point on the diameter AC where the inner parallelograms meet.
- I (middle right): point on BC.
- D (bottom left): lower-left vertex.
- F (bottom): point on DC.
- C (bottom right): lower-right vertex.

SCHOLIUM

This theorem is demonstrated in the same way by Proclus even if the two parallelograms about the diameter do not meet at the point G, but either one is set apart from the other, or the two intersect each other. Let one first be at a distance from the other, so that the complements are five-sided figures. Thus, in the parallelogram ABCD, about the diameter AC, let the parallelograms AEFG and CHIK stand. I say that the complements DEFIH and BKIFG are equal. For since the triangles ABC and CDA are equal to one another [Margin: (e) Elements I.34], and likewise the triangles AEF and CHI [recte: CHI; source prints GHI] are equal to the triangles AGF and CKI, the remaining complements DEFIH and BKIFG will be equal [Margin: (f) common notion 3]. Which is what was proposed.

Diagram. A parallelogram ABCD with diameter AC; two smaller parallelograms AEFG and CHIK stand about the diameter but are separated, so that the two complements are pentagons (DEFIH and BKIFG). Several inner labels are crowded and faint.

- A (top left): upper-left vertex.
- B (top right): upper-right vertex.
- E, F (upper area): vertices of the parallelogram AEFG.
- G (mid): vertex of parallelogram AEFG.
- H, I, K (lower area): vertices of parallelogram CHIK.
- D (bottom left): lower-left vertex.
- C (bottom right): lower-right vertex.

Now let the parallelograms AEFG and CHIK, standing about the diameter, cut each other, so that they have the common part ILMF. I say that here too the complements DELH and BGMK are equal. For since the triangles ABC and CDA are equal [Margin: (g) Elements I.34], and likewise the triangles AFG and AFE, the remaining quadrilaterals BCFG and DCFE will be equal [Margin: (h) common notion 3]; and again the triangles IFM and IFL are equal [Margin: (i) Elements I.34]. Therefore, if these are added to the said quadrilaterals, the figures BCIMG and DCILE will be equal [Margin: (k) common notion 2]. Since, then, the triangles CIK and CIH are also equal [Margin: (l) Elements I.34], the remaining complements BGMK and DELH will likewise be equal [Margin: (m) common notion 3]. Which is what was proposed.

Diagram. A parallelogram ABCD with two inner parallelograms AEFG and CHIK that intersect, sharing the common part ILMF; the complements are DELH and BGMK. The figure is small with several overlapping labels.

- A (top left): upper-left vertex.
- G (top): point on the upper edge.
- B (top right): upper-right vertex.
- E (mid left): point on the left edge.
- L, M (center): vertices of the shared inner region ILMF.
- F (center): vertex of the shared inner region.
- I (center): intersection point.
- K (right): point on the right edge.
- D (bottom left): lower-left vertex.
- H (bottom): point on the lower edge.

- C (bottom right): lower-right vertex.

We shall also demonstrate the converse of this theorem, following Peletarius, in this way.

Enunciation. If a parallelogram is divided into four parallelograms such that two opposite ones of them are equal, the remaining two will lie about the diameter.

Demonstration. When two lines EF and GH, parallel to the lines BC and CD and cutting each other at I, are drawn, let the parallelogram ABCD be divided into four parallelograms, of which the two opposite ones BEIH and DFIG are equal. I say that the remaining two, AEIG and CFIH, lie about the diameter—that is, that the diameter drawn from the point C to the point A passes through the point I. For if it does not pass through it, let the diameter CKA cut the line GH at K (if that be possible), and through K [Margin: (n) Elements I.31] let LM be drawn parallel to BC. Then the complements BHKL and DGKM will be equal [Margin: (o) Elements I.43]; but DGKM is greater than DGIF [Margin: (p) common notion 9]. Therefore BHKL will also be greater than DGIF. Since, then, DGIF is assumed equal to BEIH, BHKL will also be greater than BEIH—the part greater than the whole [Margin: (q) common notion 1]. Which is absurd. Therefore the diameter AC does not cut the line GH at K, but passes through the point I. Which is what was proposed.

Diagram. A large leaning parallelogram ABCD divided into four parallelograms by the lines EF and GH crossing at I; the diagonal is drawn, and the point K (on GH) with the line LM illustrates the reductio. The labels are crowded and several overlap near the center.

- A (top left): upper-left vertex.
- E (top): point on the upper edge AB.
- B (top right): upper-right vertex. [?]
- G (left): point on the left edge AD.
- I (center): intersection of EF and GH.
- K (center, near I): where the diameter cuts GH (in the reductio).
- L, M (center/lower): endpoints of LM parallel to BC. [?]
- H (right): point on the right edge BC.
- D (bottom left): lower-left vertex.
- F (bottom): point on the lower edge DC.
- C (bottom right): lower-right vertex.

PROBLEMA 12. PROPOSITIO 44.

[Margin: xliv (44)]

Enunciation. To apply to a given straight line, in a given rectilineal angle, a parallelogram equal to a given triangle.

Demonstration. Let the given straight line be A, the given triangle B, and the given rectilineal angle C. We must therefore construct a parallelogram equal to the triangle B, having an angle equal to angle C and one side equal to the line A. Construct a parallelogram DEFG equal to the triangle B, having the angle EFG equal to angle C [Margin: (a) Elements I.42], and produce GF to H so that FH equals the line A; and through H [Margin: (b) Elements I.31] draw HI parallel to FE, meeting DE produced at I. Then extend from I, through F, the diameter IF, meeting DG produced at K; and through K [Margin: (c) Elements I.31] draw KL parallel to GH, cutting IH produced at L, and produce EF to M. I say that the parallelogram LMFH is the one sought. For it has the side FH equal to the given line A, and the angle HFM equal to the given angle C [Margin: (d) Elements I.15]—since the angle HFM equals the angle EFG, which was made equal to angle C. And finally the parallelogram LMFH is equal to the triangle B [Margin: (e) Elements I.43], since it is equal to the complement DEFG, which was made equal to the triangle B. And so, to a given straight line, for a given triangle, and so on. Which was to be done.

Diagram. The given line A, the given triangle B, and the given angle C at the left; then the construction: the parallelogram DEFG equal to triangle B, extended into the applied parallelogram LMFH along the diameter IF.

- A (top left, segment): the given straight line.
- B (left, triangle): the given triangle.
- C (left, angle): the given rectilineal angle.
- D (top): upper vertex of parallelogram DEFG.
- E (top): upper vertex.
- I (top right): where HI meets DE produced.
- G (middle left): vertex of DEFG.
- F (center): common vertex on the diameter IF.
- H (middle right): point with FH = A.
- K (bottom left): where the diameter meets DG produced.
- M (bottom): point on EF produced.
- L (bottom right): where KL meets IH produced.

SCHOLIUM

But if one should wish the given line A itself to be one side of the parallelogram, it will not be difficult to transfer the parallelogram FMLH onto the line A, from what we taught in the scholium of proposition 31 of this book. For if at N, the extremity of the line A, there be made...

Euclid, *Elements* Book I — Propositions 45–47 (with Clavius's commentary and scholia)

(continuation of the scholium to Proposition 44)

at A, let an angle be made equal to the angle MFH, and let the straight line NO be taken equal to the straight line FM. Then, when the parallelogram is completed, as was taught in the said scholium, what is sought will have been accomplished.

But perhaps we shall carry out this problem more in keeping with Euclid's own intention if we construct the parallelogram upon the given straight line itself, and not upon one equal to it — such as the straight line FH was — and so on. So let the straight line AB again be given, together with the given triangle CDE and the given angle F; and let it be required to construct upon the straight line AB a parallelogram equal to triangle CDE, in the given angle F. We shall do it as follows. One side of the triangle — say DE — being bisected at G, and the straight line CG being drawn (which, by the scholium to Proposition 38 of this book, bisects triangle CDE), let the straight line AB be produced toward the part where the parallelogram must have its angle equal to the given angle F — here, toward A; and let AH be made equal to EG, half of the side DE. Next, at A, [Margin: (f) I.23] let the angle HAI be constructed equal to the angle E — downward, if the parallelogram is to be constructed toward the upper part, but upward if toward the lower. With the straight line AI set equal to EC, let the straight line HI be joined. And since the two sides HA, AI are equal to the two sides GE, EC, each to each, and contain equal angles, [Margin: (g) I.4] the triangles AHI, EGC will be equal. After this, [Margin: (h) I.31] let IK be drawn through I parallel to HB, [Margin: (i) I.23] and at A, toward this parallel, let the angle HAL be constructed equal to the given angle F, and let AL cut the straight line IK at L. [Margin: (k) I.31] Let HM also be drawn through H parallel to AL, cutting IK at M; [Margin: (l) I.41] then the parallelogram AHML will be double the triangle AHI. But triangle CDE is likewise double triangle EGC, since triangles EGC, DGC have been shown to be equal. Therefore, since triangles AHI, EGC have been proved equal, [Margin:

(m) Ax. 7] the parallelogram AHML and the triangle CDE will be equal. Now, with the straight line LK taken equal to the given straight line AB, let KA be drawn and produced until it meets MH (produced) at N; through N let NO be drawn parallel to HB until it meets KB (produced) at O; and finally let LA be produced as far as P, on the straight line NO. I say that the parallelogram ABOP is the one sought. For it has been constructed upon the given straight line AB, and it has the angle BAP equal to the given angle F, [Margin: (n) I.15] since it is equal to the angle HAL, which was made equal to angle F. It is moreover equal to the given triangle CDE, [Margin: (o) I.43] since it is equal to the parallelogram AHML, which was shown to be equal to triangle CDE.

Praxis. The practical construction of this problem does not differ from the construction itself, except that the straight line HI need not be drawn, nor the straight line CG; for these were drawn only for the sake of the demonstration.

Diagram. The large construction figure for the Proposition 44 scholium (parallelogram AHML transformed into the required parallelogram ABOP), a dense network of intersecting lines. Labels read on the leaf:

- N, P (top edge)
- O, E, G, D (upper-right region)
- H (left)
- B (center-right)
- C (lower right); F (lowest right)
- I (lower left), M, L, K (along the lower edge)
- A [?] (a central label near the diagonal intersection is not cleanly resolvable)

Diagram. A small separate parallelogram at the top right of the page (the completed result parallelogram). Legible corner labels: N (top left), A (top), O (lower left). The two remaining corner labels are not legible on the scan, even under magnification — 2 labels unread.

Here Peletier [Jacques Peletier] adds another problem, in this way.

[Peletier — problem] *On a given straight line, to construct a triangle equal to a given parallelogram, in a given rectilineal angle.*

Let the given straight line be AB, the given parallelogram CDEF, and the given angle L. Let CD be produced to G so that DG is equal to CD, and let the straight line GE be joined. Then triangle CEG will be equal to the parallelogram CDEF, as we demonstrated in the scholium to Proposition 41. [Margin: (P) cf. schol. I.41] Now

upon the given straight line AB let a parallelogram ABHI be made equal to triangle CEG — that is, to the parallelogram CDEF — having the angle A equal to angle L; and let AI be produced to K so that IK is equal to AI, and let the straight line BK be joined. I say that the triangle ABK, constructed upon the given straight line AB and having the angle A equal to the given angle L, is equal to the given parallelogram CDEF. For since triangle ABK is equal to the parallelogram ABHI (by the scholium to Proposition 41), which was constructed equal to the parallelogram CDEF, the proposition is established.

Praxis. The practical construction of this problem does not differ from the theoretical construction, and it is not difficult, provided one uses the preceding practical construction, by which the parallelogram ABHI is set up on the given straight line AB, in the given angle A, equal to the triangle ECG.

Diagram. Two adjacent figures for Peletier's problem: at the left, triangle ABK with the parallelogram ABHI (and I produced to K); at the right, the parallelogram CDEF with triangle CEG; the given angle L is shown separately. Labels read on the leaf:

- Left figure: B (apex), H [?] (top left of parallelogram — reads ambiguously), A, I, K (lower edge)
- Right figure: E, F (top), C, D, G (lower edge)
- L (given angle, shown at the side)

PROBLEMA 13. PROPOS. 45.

[Margin: xlv.]

[Euclid, Prop. 45 — enunciation] *On a given straight line, to construct a parallelogram equal to a given rectilineal figure, in a given rectilineal angle.*

Although Euclid states this problem in absolute form, without tying us to any determinate given straight line — as he had done in the preceding Proposition 44 — nevertheless, because in what follows it is frequently applied to a given straight line, it seemed good to state it together with a given straight line. So let the given straight line be EF, the rectilineal figure ABC, and the given angle D. It is required, then, to construct upon the given straight line EF a parallelogram equal to the rectilineal figure ABC and having an angle equal to angle D. Let the rectilineal figure be resolved into the triangles A, B, and C. Then [Margin: (a) I.44] upon triangle A let a parallelogram EFGH be constructed, on the straight line EF, having the angle F equal to angle D. Likewise, upon the straight line GH, a parallelogram GHIK equal to triangle B, having the angle G equal to angle D.

Likewise, upon the straight line IK, a parallelogram IKLM equal to triangle C, having the angle K equal to angle D. And let one proceed in the same way if there are more triangles in the given rectilineal figure; and what is required will be done. For the three parallelo-

Diagram. The Proposition 45 figure: at the left, the rectilineal figure ABC resolved into triangles (interior regions marked A, B, C); at the right, the three parallelograms EFGH, GHIK, IKLM joined into a single oblique strip; the given angle D is shown separately. Labels read on the leaf:

- Rectilineal figure: A [?], B, C (interior regions); D (angle)
- Parallelogram strip: E, H, I, M (upper edge); F, G, K, L (lower edge)

(Proposition 45, commentary continued — p. 74)

grams constructed, which are indeed equal to the given rectilineal figure ABC, make up one whole parallelogram — which is proved as follows. The two angles EFG, HGK [Margin: (b) Ax. 1] are equal to one another, since each is equal to angle D. Adding, therefore, the common angle FGH, the two angles EFG, FGH — [Margin: (c) Ax. 29] which are equivalent to two right angles — [Margin: (d) Ax. 2] will be equal to the two angles HGK, FGH; and hence these angles too will be equal to two right angles. [Margin: (e) I.14] Therefore FG, GK will make one straight line. By the same reasoning we shall show that EH, HI make one straight line, because the two angles EHG, [Margin: (f) I.34] HIK are equal to one another — since they are equal to the equal opposite angles EFG, HGK — [Margin: (g) Ax. 29] and the two angles HIK, IHG are equal to two right angles, and so on. Since, then, EI and FK are parallel, [Margin: (h) I.30] and likewise EF and IK (because each is parallel to the straight line HG), the figure EFKI will be a parallelogram. In the same way it will be shown that the parallelogram IKLM, joined to the parallelogram EFKI, makes up one whole parallelogram EFLM. Therefore upon the given straight line EF we have constructed, equal to the given rectilineal figure ABC, a parallelogram EFLM having the angle F equal to the given angle D. Which was to be done.

Scholium

In the same way, given any number of rectilineal figures, we shall construct a parallelogram equal to them, if they are all resolved into triangles for which equal parallelograms are exhibited, one for each, by Proposition 44 — just as was done in this problem. For since all these parallelograms make up one parallelogram, as was demonstrated here, a parallelogram will have been

constructed equal to the given rectilinear figures. For example, suppose someone considers two given rectilinear figures AB and C; suppose AB is resolved into the triangles A and B; and suppose that for the individual triangles A, B, C, individual parallelograms EG, GI, IL are constructed, upon the straight lines EF, HG, IK, according to the method of this problem, equal to them, by Proposition 44. Then the whole parallelogram EFLM will have been constructed, equal to the two rectilinear figures AB and C. And so for more.

The practical construction of this problem must be sought from the practical construction of the preceding proposition, repeated as often as needed.

To this place may be referred a most useful problem from Peletier, which we shall, however, demonstrate by another and shorter method, in this way.

[Peletier — problem] *Given two unequal rectilinear figures, to find the excess of the greater over the less.*

Let the given rectilinear figures be A and B, and let A be the greater. It is required, then, to find out by what magnitude the rectilinear figure A exceeds the rectilinear figure B. [Margin: (i) I.45] Let a parallelogram CDEF be made, in any angle D, equal to the greater rectilinear figure A. And upon the straight line CD let a parallelogram CDGH be made, in the same angle D, equal to the lesser rectilinear figure B. Since, then, the parallelogram CDEF exceeds the parallelogram CDGH by the parallelogram EFHG, the figure A will also exceed the figure B by the same parallelogram EFHG. Which was the thing proposed.

Diagram. The "excess" figure: at the left, two small oblique parallelograms marked A and B (the two given figures rendered as parallelograms); at the right, a rectangle divided by a vertical line into the parallelogram CDGH and the excess parallelogram EFHG. Labels read on the leaf:

- A, B (the two parallelograms at the left)
- C, H, F (upper edge of the rectangle); D, G, E (lower edge)

PROBLEMA 14. PROPOSITIO 46.

[Margin: xlv.]

[Euclid, Prop. 46 — enunciation] *On a given straight line, to describe a square.*

Let AB be the given straight line, upon which a square must be described.

[Margin: (a) I.11] From A and B let AD, BC be drawn perpendicular to AB, and let them be equal to AB itself, and let the straight line CD be joined. I say that ABCD is

a square. For since the angles A and B are right, [Margin: (b) I.28] AD and BC will be parallel; and they are also equal, since each is equal to AB. Therefore [Margin: (c) I.33] AB and DC are also parallel and equal; and so ABCD is a parallelogram, in which — since AD, DC, CB are equal to AB — all four sides are equal. And all four angles are also right, since C and D [Margin: (d) I.34] are equal to the opposite right angles A and B. Therefore ABCD is a square, by definition; and consequently we have described a square on a given straight line. Which was to be done.

Diagram. The square ABCD erected on AB. Labels read on the leaf: D, C (top edge); A, B (bottom edge).

From Proclus [Ex Proclo]

[Proclus] *The squares of equal straight lines are equal; and the straight lines of equal squares are equal.*

First let the straight lines AB, CD be equal. I say that their squares ABEF, CDGH are equal also. For when the diagonals BF, DH are drawn, the two sides BA, AF of triangle BAF will be equal to the two sides DC, CH of triangle DCH, [Margin: (e) I.4] each to each — since, by the definition of a square, the straight lines AF, CH are equal to the straight lines AB, CD. And the angles A and C are also equal, namely right. [Margin: (f) I.34] Therefore triangles BAF, DCH will be equal. And since these are halves of the squares, the whole squares will be equal too. Which was the thing proposed.

Diagram. Two squares side by side, each with a diagonal drawn: the square ABEF (diagonal BF) and the square CDGH (diagonal DH). Labels read on the leaf: F, E, H, G (upper edge, left to right); A, B, C, D (lower edge, left to right).

Next let the squares ABDE, BCFG be equal. I say that their straight lines AB, BC are equal too. For let the squares be joined at the angle B, so that the straight lines AB, BC are set in a straight line. And since the angles ABG, ABD are right, [Margin: (g) I.14] the straight lines GB, BD will also be set in a straight line. Let the diagonals AD, CG be drawn, and let the straight lines AG, CD be joined. Since, then, the squares ABDE, BCFG are equal, the triangles ABD, BCG, their halves, will be equal too. Adding, therefore, the common triangle BCD, the whole triangle ACD will become equal to the whole triangle GDC. Therefore triangles ACD, GDC, since they have the same base CD and are on the same side of it, [Margin: (h) I.39] are within the same parallels; and so AG, CD are parallel. And since — as we showed in the scholium to Proposition 34 — the diagonal in a square bisects the angles of the square, the angles DAC, GCA will be alternate half-right angles, and therefore equal. For this reason [Margin: (i) I.27] AD, CG are parallel too. Therefore ADCG is

a parallelogram; and consequently [Margin: (k) I.34] the straight lines AD, CG are equal. Since, then, in the triangles ABD, BCG the sides AD, CG are equal, and the angles at which those sides lie are also equal to one another (being half-right, as was shown in the scholium to Proposition 34), [Margin: (l) I.26] the remaining sides will be equal, namely AB to BC, and so on. Which was the thing proposed.

Diagram. The two squares ABDE and BCFG joined at the vertex B, with the diagonals AD, CG and the joining lines AG, CD, drawn tilted. Labels read on the leaf:

- A (top); E (upper right)
- G (left); B (center); D (right)
- F (lower left); C (lower center)

(Scholium to Proposition 46, continued — p. 75)

Scholium

All this could be proved much more briefly by the superposition of one square upon another. For if the straight lines are equal, and one is placed upon the other, they will coincide with one another. Since, then, the angles too are equal — namely right — they will likewise coincide with one another; and so the whole square will coincide with the whole square. But if the squares are equal, they coincide with one another on account of the equality of their angles; therefore the straight lines too are equal — otherwise one square would be greater than the other.

The practical construction of this problem is very easy. For if, at a given straight line AB, at one of its ends — say at A — a perpendicular AD is erected equal to the given straight line AB, and from B and D, at the interval of that same AB, two arcs are described cutting one another at C, and the straight lines BC, DC are joined, a square will have been constructed. For ABCD, since by construction it is a figure of equal sides — and moreover has its opposite sides equal — will be a parallelogram, as we demonstrated at the beginning of the scholium to Proposition 34. Since, then, the angle A is right, [Margin: (m) I.29] B and D will also be right, as well as [Margin: (n) I.34] the opposite angle C, and so on.

THEOR. 33. PROPOS. 47.

[Margin: xlvj.]

[Euclid, Prop. 47 — enunciation (the Pythagorean theorem)] *In right-angled triangles, the square described on the side subtending the right angle is equal to the squares described on the sides containing the right angle.*

In the triangle ABC let the angle BAC be right, [Margin: (a) I.46] and let there be described, on AB, AC, BC, the squares ABFG, ACHI, BCDE. I say that the square BCDE, described on the side BC which is opposite the right angle, is equal to the two squares ABFG, ACHI, which are described on the other two sides — whether these two sides be equal or unequal. For let the straight line AK be drawn [Margin: (b) I.31] parallel to BE, or to CD, cutting BC at L, and let the straight lines AD, AE, CF, BH be joined. And since the two angles BAC, BAG are right, [Margin: (c) I.14] the straight lines GA, AC will be one straight line; and in the same way IA, AB will be one straight line. Again, since the angles ABF, CBE are equal (being right), if the common angle ABC is added, [Margin: (d) Ax. 2] the whole angle CBF becomes equal to the whole angle ABE; and similarly the whole angle BCH equal to the whole angle ACD. Since, then, the two sides AB, BE of triangle ABE are equal to the two sides FB, BC of triangle FBC, each to each — as is clear from the definition of a square — and the angles ABE, FBC contained by these sides are equal, as we have shown, [Margin: (e) I.4] the triangles ABE, FBC will be equal. But the square (or parallelogram) ABFG [Margin: (f) I.41] is double the triangle FBC, since they are between the parallels BF, CG and on the same base BF; and the parallelogram BEKL is double the triangle ABE, since they are between the parallels BE, AK and on the same base BE. Therefore [Margin: (g) Ax. 6] the square ABFG and the parallelogram BEKL will be equal. By the same reasoning it will be shown that the square ACHI and the parallelogram CDKL are equal. [Margin: (h) I.4] For again the triangles ACD, HCB will be equal, and therefore their doubles — namely the parallelogram CDKL and the square ACHI — will be equal. Wherefore the whole square BCDE, which is composed of the two parallelograms BEKL, CDKL, is equal to the two squares ABFG, ACHI. Therefore in right-angled triangles the square, and so on. Which was to be demonstrated.

Diagram. The classic Euclid I.47 "windmill" figure, drawn twice (for the two cases named in the text — legs equal, and legs unequal): triangle ABC with the right angle at A, squares ABFG, ACHI, BCDE on the three sides, the line AK dropped through L on BC to K on DE, and the joining lines AD, AE, CF, BH. Labels read on the leaf (page heavily stained at the head):

- Left figure: G, I (top); F (left); A (right-angle vertex); H (right); B, L, C (middle row); E, K, D (lower edge)

- Right figure (second case): G [?], I (top); F (left); A; H (right); B, L, C (middle); E, K, D (lower edge)

[— duplicated figure with dense labelling on a foxed page; a top-left label on the second figure is not cleanly resolvable]

Scholium

Anyone will easily understand from this theorem that in an obtuse-angled triangle the square of the side opposite the obtuse angle is greater than the two squares together of the other two sides; while in any triangle the square of the side opposite one of the acute angles is less than the two squares together of the other two sides. For if the angle were narrowed until it became right — the sides containing it remaining the same — the opposite side would turn out less; but if the acute angle were widened until it became right — the same sides containing it remaining — the opposite side would become greater, as is evident. Since, then, the square of the side opposite the right angle has here been shown equal to the two squares together of the other two sides, it is clear that the square of the side opposite the obtuse angle is greater than the two squares together of the other two sides, while the square of the side opposite the acute angle is less than the two squares together of the remaining two sides. But by how much the former is greater, and by how much the latter is less, Euclid will demonstrate in Book 2, Propositions 12 and 13.

Since this theorem is most beautiful and has outstanding uses, I judged it worth the effort to try whether it could be demonstrated by other ways, with the construction somewhat varied — which Peletier denied could be done without proportions. So let there again be a triangle ABC whose angle BAC is right, and let the sides BA, CA be produced toward the parts of the right angle, and let AD, AE be made equal to AC, AB; and through C, D, B, E let parallels be drawn to AB, AC, meeting at F, G. And since in the parallelograms CD, BE [Margin: (i) I.34] both the sides DF, FC are equal to the opposite sides AC, AD, and the sides EG, GB to the opposite sides AB, AE, each parallelogram will be equilateral; and moreover all their angles are right. [Margin: (k) I.34] For F, G, being equal to the opposite right angles DAC, EAB, are themselves right; and the angles C, D, B, E are right, because each of C and D together with the right angle DAC, and each of B and E together with the right angle EAB, [Margin: (l) I.29] is equal to two right angles. Therefore CD, BE are the squares of the sides AC, AB. The sides FD, GE being also produced until they meet at H, let there be erected at B and C, perpendicular to BC, the straight lines BI, CK, cutting GH, FH at I, K, and let the straight line IK be joined. And since, if from the right angles IBC, ABG the common angle ABI is taken away,

the remaining angles ABC, GBI are equal — and the right angles BAC, BGI are also equal — the two angles A, B of triangle ABC will be equal to the two angles G, B of triangle GBI, each to each; and the sides AB, GB adjacent to them are equal, on account of the square BE. [Margin: (m) I.26] Therefore both the sides BC, BI and AC, GI will be equal, and the remaining angles C, I equal. In just the same way, in the triangles ABC, FKC, both the sides BC, CK and AB, FK will be equal, and the angles B, K — because the two angles A, C of triangle ABC are equal to the two angles F, C of triangle FKC (since A, F are right, and the two angles C are the remainder of the two right angles once the common angle ACK is removed), and the sides AC, CF adjacent to them are equal, on account of the square CD. Therefore the straight lines BI, CK [Margin: (n) Ax. 1] are also equal to one another; [Margin: (o) I.28] and since they are also parallel, [Margin: (P) I.33] BC, IK will also be equal and parallel. Therefore BCKI is the square of the side BC, since its four sides are equal and all its angles right — for the angles I, K are equal to the opposite right angles C, B. I say, then, that the square CI is equal to the two squares BE, CD,

Diagram. The large figure for the alternative (Peletier-inspired) demonstration of the Pythagorean theorem: the right triangle ABC with its legs produced, the squares CD and BE built outward, the point H where FD, GE meet, the perpendiculars BI, CK, and the joined line IK, together with numerous interior division and intersection points (some on dotted construction lines). Labels read on the leaf (page heavily stained/foxed):

- H (top apex)
- E (upper left); I, T, K (upper row)
- G (far left); R, S, P (middle-upper row)
- D (right)
- A (center)
- M, N [?], O [?] (lower dotted line)
- B, L, C (bottom edge); F (lower right)

[— ~18 labels on a foxed page; the lower-row points on the dotted line are not all cleanly resolvable]

(Continuation of Clavius's commentary on Proposition 47 of Book I — the Pythagorean theorem. The alternative demonstrations begun on the preceding page conclude here; all of the following is Clavius's commentary, not Euclid's own text.)

Diagram. The large combined construction figure for the alternative demonstrations of the Pythagorean theorem. A right triangle sits at the center

(right angle at A), with the three squares erected outward and an outer square **BCKI** built on the hypotenuse; numerous auxiliary lines (several dotted) subdivide the outer square into the two parallelograms discussed in the text. The sheet is foxed, but at native resolution the labels read as follows.

- H (top apex): summit of the upper construction
- E (upper, below H): point on the left slope
- I (left, upper): vertex on the left square
- T (upper middle): division point on the top edge
- K (upper right): outer vertex on the right
- G (left edge): outer vertex on the left
- R (left middle): interior division point
- S (upper center): interior division point
- P (right center): interior division point
- A (center): the right-angle vertex of the triangle
- D (right edge, middle): vertex of the right-hand square
- M (lower left): interior/foot point
- N (lower middle): interior/foot point
- [?] (lower right, between N and C): a small mark; the text calls for point **O** here, but the glyph is not clearly resolvable
- F (right edge, lower): outer point on the right
- B (bottom-left corner): base vertex
- L (bottom middle): base division point
- C (bottom-right corner): base vertex

[Clavius, alternative demonstration — conclusion of the first alternative]

that the squares BE and CD are equal. For when the straight line HTAL is drawn from H through A, it will be parallel to BI and CK. Since GE is equal to BA [Margin: (q) Elements I.34], and EH is equal to AD — that is, to GI, which was shown equal to AC (or AD) — then, adding the common segment EI, the whole HI will be equal to the whole GE, that is, to AB. And since HI and AB are also parallel, BI and AH will likewise be parallel and equal [Margin: (r) Elements I.33]. In the same way AH will be shown parallel and equal to CK. Now the square BE is equal to the parallelogram BH on the same base AB [Margin: (s) Elements I.35], and the parallelogram BT is equal to that same parallelogram BH on the same base BI; therefore the square BE is also equal to the parallelogram BT [Margin: (t) pron. 1 (Common Notion 1)]. Likewise, since the square CD is equal to the parallelogram CH on the same base AC [Margin: (u) Elements I.35], and the parallelogram CT is

equal to that same parallelogram CH on the same base CK, the square CD is also equal to the parallelogram CT [Margin: (x) pron. 1 (Common Notion 1)]. Therefore the whole square BCKI, composed of the two parallelograms BT and CT, is equal to the two squares BE and CD. Which was to be demonstrated.

[Clavius, second alternative demonstration]

Otherwise. In place of the straight line HTAL, let the two straight lines AI and AK be joined, and through A let TAL be drawn parallel to BI and CK. Then, since the square BE is double the triangle ABI on the same base AB, while the parallelogram BT is likewise double that same triangle ABI on the same base BI [Margin: (y) Elements I.41] — for we shall show, as before, that BK, BE, and CD are the squares on the sides BC, AB, and AC — the square BE will be equal to the parallelogram BT [Margin: (z) pron. 6 (Common Notion 6)]. By the same reasoning, since the square CD is double the triangle ACK on the same base AC, while the parallelogram CT is double that same triangle ACK on the same base CK [Margin: (a) Elements I.41], the square CD will also be equal to the parallelogram CT [Margin: (b) pron. 6]. Wherefore, as before, the whole square BCKI, made up of the two parallelograms BT and CT, is equal to the two squares BE and CD. Which was to be shown.

[Clavius, third alternative demonstration]

Otherwise. In place of the straight lines HTAL, AI, and AK, let there be drawn through F and G the lines FM and GP, parallel to BC and IK, cutting AB and CK at N and O, and BI and CE at R and S. Then BR will be equal to KO. For since the angles O and R are right [Margin: (c) Elements I.29], and the angles OKF and RBG are equal — because each was shown above to be equal to the angle ABC — the two angles O and K of the triangle FKO will be equal to the two angles R and B of the triangle GBR, each to each. Moreover the sides FK and BG adjacent to them are equal, because each was shown above to be equal to BC. Therefore the sides KO and BR will also be equal [Margin: (d) Elements I.26]. And so, since the parallelograms BCFN and BCOM on the same base BC are equal [Margin: (e) Elements I.33], and the parallelogram BCPR is equal to the parallelogram IKOM (on account of the straight lines BR and KO shown to be equal — for from this it follows that if one is superimposed on the other they exactly coincide, because of the equality of their sides and angles), both parallelograms BCFN and BCSG will be equal to the whole square BCKI, which is composed of the two parallelograms BCOM and IKOM [Margin: (f) Elements I.35]. Since therefore the square CD is equal to the parallelogram BCFN on the same base CF, and the square BE is equal

to the parallelogram BCSG on the same base BG, both squares CD and BE will also be equal to that same square BCKI. Which was to be demonstrated.

**

[Clavius, scholium on the theorem]

And in this way still other demonstrations can be devised. I consider Euclid's own demonstration the simpler and more direct; yet it is not without pleasure to see that one and the same truth can be confirmed by a variety of demonstrations.

The discovery of this admirable and most beautiful theorem is ascribed to Pythagoras, who — as Vitruvius writes in Book 9 — sacrificed victims to the Muses because they had aided him to so splendid a discovery. Some think he sacrificed a hundred oxen; but if Proclus is to be believed, he offered only one. Perhaps, however — as some maintain — Pythagoras took his occasion from numbers in order to investigate this theorem. For when he had carefully contemplated these three numbers, 3, 4, and 5, and had seen that the square of the greatest is equal to the squares of the other two, he constructed a scalene triangle whose greatest side was divided into 5 equal parts, the least into 3 of the same magnitude, and the remaining side into 4. This done, he considered the angle contained by these two sides and found it to be right. He observed the same in very many other numbers, as in 6, 8, 10, and in 9, 12, 15, and so on. He therefore judged it worth inquiring whether in every right triangle the square of the side opposite the right angle is equal to the squares of the remaining sides, seeing that all triangles whose sides had magnitude according to the said numbers contained one right angle. And so at last, with the greatest delight of mind, he lit upon this marvelous theorem and demonstrated it by a firm argument. Euclid, however, amplified it in a wonderful manner in Book 6, Proposition 31, where he demonstrated not only that the square of the side opposite the right angle is equal to the squares of the other two sides, but also that any rectilinear figure whatever constructed upon the side opposite the right angle — whether it be a triangle, a quadrangle, or the like — is equal to the two figures described upon the remaining sides, provided they are similar to the first and similarly described, as we shall show in that place.

Moreover, since we have made mention of three numbers the square of whose greatest is equal to the squares of the others, it will not be beside the point to explain briefly by what method such numbers are found. Given, then, these three numbers 3, 4, 5: if they are doubled, another three are obtained, 6, 8, 10; if the same are tripled, there arise another three, 9, 12, 15; and if they are quadrupled,

these three are found, 12, 16, 20. In this way as many others as one pleases will be found, if those first three are multiplied by any number whatever. Two rules, however, are handed down by Proclus by which the said numbers are found without any regard to those first three. The first is ascribed to Pythagoras and is of this kind. Take for the least any odd number you please, say 5, from which you will find the others thus. From the square of the number taken — here, from 25 — reject unity. For half of the number remaining, namely 12, will be the second number; and if unity is added to this, the third number, 13, arises. The square of this, therefore, is equal to the squares of the others. And if the odd number taken had been 3, the other two found by this rule would be 4 and 5. The second rule is attributed to Plato and is as follows. Take any even number, say 6. From the square of its half, namely 9, subtract one, and to the same add one, and you will have the remaining two numbers, 8 and 10; the first being 6, that is, the even number taken. If by this rule the even number 10 is taken, the other two will be found to be 24 and 26.

[Clavius, transition to the appended propositions]

From this most celebrated discovery of Pythagoras many things not unpleasant to know may be gathered, theorems as well as problems, of which I have thought it best to bring forward only those that are believed likely to bring great utility to geometrical matters, taking my beginning here.

I.

If in any square a diagonal is drawn, the square described on the diagonal will be double the said square.

In the square ABCD let the diagonal AC be drawn. I say that the square on the diagonal AC is double the square ABCD. For since in the triangle ABC the angle B is right [Margin: (g) Elements I.47], the square on the side AC will be equal to the two squares on the sides AB and BC. And since the squares on the lines AB and BC are equal — because the lines AB and BC are equal — the square on AC will be double either of them, that is, double the square on the line AB; so the square on the diagonal is double the square ABCD. Which is what was proposed.

Diagram. Proposition I: a square with a diagonal.

- A (top-left) and B (top-right): upper vertices
- D (bottom-left) and C (bottom-right): lower vertices
- Diagonal drawn from A to C

II.

The square on the diagonal of an oblong (a figure longer on one side) is equal to the two squares on the unequal sides.

In the oblong ABCD let the diagonal AC be drawn; and since in the triangle ABC the angle B is right [Margin: (h) Elements I.47], the square on the side AC will be equal to the two squares on the unequal sides AB and BC. Which is what was proposed.

Diagram. Proposition II: an oblong (rectangle) with a diagonal.

- A (top-left) and B (top-right): upper vertices
- D (bottom-left) and C (bottom-right): lower vertices
- Diagonal drawn from A to C

III.

If there are two right triangles whose sides opposite the right angles are equal, then the two squares on the remaining two sides of the one triangle will be equal to the two squares on the remaining two sides of the other.

Let the angles A and D of the triangles ABC and DEF be right, and let the opposite sides BC and EF be equal. I say that the two squares on the sides AB and AC taken together are equal to the two squares on the sides DE and DF taken together. For the squares on the lines BC and EF are equal to one another, since the lines themselves are assumed equal. But the squares on the lines AB and AC are equal to the square on the line BC [Margin: (i) Elements I.47], and the squares on the lines DE and DF are equal to the square on the line EF. Therefore the squares on the straight lines AB and AC are equal to the squares on the straight lines DE and DF [Margin: (k) pron. 1 (Common Notion 1)]. Which is what was proposed.

Diagram. Proposition III: two right triangles side by side.

- A (apex of the first triangle, right angle here); B (bottom-left) and C (bottom-right)
- D (apex of the second triangle, right angle here); E (bottom-left) and F (bottom-right)

IV.

Given two unequal squares, to find another two squares which are both equal to each other and, taken together, equal to the two unequal squares proposed taken together.

Let A and B be the sides of two unequal squares. Make a right angle DCE, and let DC be a straight line equal to B, and CE a straight line equal to A. Then draw the straight line DE joining the two points D and E, and upon it construct two half-right angles DEF and EDF [Margin: (l) pron. 13 (Common Notion / axiom 13)], and let the straight lines DF and EF meet at F. Now since in the triangle FDE the angles FDE and FED are equal, the sides DF and EF will also be equal [Margin: (m) Elements I.6], and therefore the squares on those sides equal as well. I now say that these same squares on the lines DF and EF are equal to the squares on the lines A and B — that is, to the squares on the lines CE and CD. For since in the triangle DEF the angles FDE and FED make one right angle, the remaining angle F will be right [Margin: (n) Elements I.32]. Wherefore the squares on the lines DF and EF will be equal to the square on the line DE [Margin: (o) Elements I.47]. But to that same square on the line DE the squares on the lines CD and CE are also equal [Margin: (p) Elements I.47]. Therefore the squares on the lines DF and EF are equal to the squares on the lines DC and EC [Margin: (q) pron. 1]. Which is what was proposed.

Diagram. Proposition IV: the construction on the right angle DCE.

- A and B (two short reference segments at the top): the sides of the two given squares
- C: vertex of the right angle DCE
- D and E: endpoints of the two legs (CD, CE)
- F: point where DF and EF (drawn at half-right angles from D and E) meet

V.

Given two unequal lines, to find that by which the greater is more powerful than the lesser.

The power [potentia] of a straight line is called its square; for a straight line is said to be capable of just as much as its square amounts to. Let there be, then, two unequal lines A and B, and let it be required to know by how much the square of the greater line A exceeds that of the lesser B. On any straight line CD let CE be taken equal to A, and EF equal to B. Then, with center E and radius EC, let a

semicircle CGD be described, and from F let FG be drawn perpendicular to CD. I say that the square on the line A — that is, on the line CE, which is equal to it — is greater than the square on the line B — that is, on the line EF, which is equal to it — by the square on the line FG. For when the line EG is drawn, its square will be equal to the squares on the lines EF and FG [Margin: (r) Elements I.47]; that is, the square on the line EC, being equal to it, will exceed the square on the line EF by the square on the line FG. Which is what was proposed.

Diagram. Proposition V: a semicircle on the diameter, with a perpendicular.

- A and B (two reference segments at the top): the two unequal given lines
- C, E, F, D (along the base line, left to right): C the left end of the diameter, E the center, F between E and D, D the right end
- G (on the arc above F): top of the perpendicular FG drawn up from F

VI.

Given any number of squares whatever, whether equal or unequal, to find a square equal to all of them.

Let the sides of five squares be A, B, C, D, E, and let it be required to find a square equal to all five of them. Make a right angle FGH, and let the line FG be equal to A, and the line GH to B. Then, when the line HF has been drawn, make a right angle FHI, and let HI be equal to C. Again, drawing the line IF, make a right angle FIK, and let IK be equal to D. Finally, drawing the line KF, make a right angle FKL, and let KL be equal to E, and let the line FL be drawn. I say that the square on the line FL is equal to the five squares proposed. For the square on FH is equal to the squares on FG and GH [Margin: (s) Elements I.47], that is, to the squares on A and B. Again, the square on FI is equal to the squares on FH and HI [Margin: (t) Elements I.47], and therefore to the squares on A, B, and C. Likewise the square on FK is equal to the squares on FI and IK [Margin: (u) Elements I.47], and thus to the squares on A, B, C, and D. Finally the square on FL is equal to the squares on FK and KL [Margin: (x) Elements I.47], and therefore to the squares on A, B, C, D, and E. Which is what was proposed.

Diagram. Proposition VI: a spiral of right triangles about the common apex F, with five reference segments A–E at the right.

- F (bottom center): common apex where all the drawn lines meet
- G (bottom-left): vertex of the first right angle (FGH)
- H (left, above G): vertex of the second right angle (FHI)

- I (upper left): vertex of the third right angle (FIK)
- K (top-left) and L (top-right): outer vertices; FL is the final hypotenuse
- A, B, C, D, E (five vertical segments at the right): the sides of the five given squares

VII.

Given any two squares whatever, to adjoin to one of them a figure equal to the other square, in such a way that the whole composite figure is also square.

Let ABCD and EFGH be two squares, and let it be proposed to adjoin to the square ABCD a figure equal to the square EFGH, and so on. Take the straight line BI equal to the line FG, a side of the square EFGH. Then, having drawn the straight line AI and produced the line BA toward A, take BK equal to the line AI, and complete the square BKLM. I say that the figure ADCMLK, adjoined to the square ABCD, is equal to the square EFGH. For since the square on the line AI — that is, the square BKLM — is equal to the squares on the lines AB and BI [Margin: (y) Elements I.47], that is, to the squares ABCD and EFGH, then, if the common square ABCD is removed, there will remain the figure ADCMLK, equal to the square EFGH [Margin: (z) pron. 3 (Common Notion 3)]. Which is what was proposed.

Diagram. Proposition VII: the large square BKLM containing the small square ABCD in its lower-left corner, with the separate square EFGH beside it.

- K (top-left), L (top-right), M (bottom-right), B (bottom-left): the large completed square BKLM
- A (on the left side, above B), D (interior, right of A), C (on the base, right of B): with B, the small square ABCD in the corner
- I (on the base line, to the right of C): endpoint of the diagonal AI drawn from A
- The gnomon remaining when ABCD is removed is the figure ADCMLK
- E (top-left), H (top-right), F (bottom-left), G (bottom-right): the separate given square EFGH

VIII.

Given any two sides whatever of a right triangle, to arrive at the knowledge of the remaining side.

Let the angle A be right in the triangle ABC, and first let the sides AB and AC about the right angle be known, of which let AB be set at 6 palms and AC at 8.

Since, then, the squares on the lines AB and AC — namely the squares of 36 and 64 palms — are equal to the square on the line BC [Margin: (a) Elements I.47], if they are joined together the result is 100 square palms. Therefore the side BC will contain 10 palms; for that is the side, or square root, of 100 palms, as is plain among the arithmeticians. Next, let the sides AB and BC be known, and let AB be 6 palms and BC 10. Since, then, the squares on the lines AB and AC are equal to the square on the line BC [Margin: (b) Elements I.47], if the square on the line AB, which contains 36 palms, is subtracted from the square on the line BC, which is 100 palms, there will remain the square on the line AC, 64 palms. Therefore the side AC will contain 8 palms; for that is the square root of 64 palms. Which is what was proposed. For the rest, rational numbers will not always be found by this art, since not every number has a side, or square root, as is known among the arithmeticians. Hence the side found can very often not be expressed except by what they call a surd root. But of these matters elsewhere.

Diagram. Proposition VIII: a right triangle with its sides marked off in units.

- A (apex, right angle here)
- B (bottom-left) and C (bottom-right)
- Side AB marked 6, side AC marked 8, base BC marked 10 (each side ruled into unit tick-marks)

IX.

If from the angle contained by two unequal sides of a triangle a perpendicular is drawn to the base, falling within the triangle, the base will be cut into unequal parts, and the greater part will be on the side of the greater side. And conversely, if the base is cut by the perpendicular not into two equal parts, the two sides will be unequal, and the greater will be the one adjacent to the greater segment of the base.

Let the perpendicular AD fall first within the triangle ABC, whose side AB is greater than the side AC, dropped to BC — which happens only when each of the angles B and C is acute, as is clear from Corollary 2 of Proposition 17. I say that the segment BD is greater than the segment CD. For since the square on AB together with the squares on AD and BD is equal to the square on AC together with the squares on AD and CD [Margin: (c) Elements I.47], and the square on AB is greater than the square on AC — because the side AB is assumed greater than the side AC — the two squares on AD and BD will also be greater than the two squares on AD and CD. And when the common square on the line AD is taken away, the remaining square on BD will be greater than the remaining square on

CD. Therefore the straight line BD will be greater than the straight line CD; which was the first point.

Next, let the perpendicular AD make the segment BD greater than the segment CD. I say that the side AB is greater than the side AC. For the square on BD will be greater than the square on CD; and when the common square on AD is added, the two squares on BD and AD will be greater than the two squares on CD and AD. Since, then, the square on AB together with the squares on BD and AD is equal to the square on AC together with the squares on CD and AD [Margin: (d) Elements I.47], the square on AB will also be greater than the square on AC, and consequently the side AB will be greater than the side AC. Which is what was proposed.

Diagram. Proposition IX: a triangle with a perpendicular from the apex to the base.

- A (apex)
- B (bottom-left) and C (bottom-right): the base endpoints
- D (foot of the perpendicular AD on the base, between B and C)

[Clavius, closing scholium and transition to the general (Pappus) theorem]

And in this way very many other things could be gathered from this discovery of Pythagoras, which, deliberately — so as not to be tiresome to the reader — we have judged should here be omitted and deferred to another place.

Far more universal than this Pythagorean theorem is the one demonstrated by Pappus [Pappus of Alexandria] for every triangle, whether it be right-angled or not, and concerning any parallelograms whatever constructed upon the sides of the triangle, whether right-angled or not, even if they are not equiangular with one another. Reducing this into the form of a theorem, we have proposed it more clearly in this manner, and — in my judgment — still more generally than Pappus:

In every triangle, any parallelograms whatever described upon two of its sides are equal to a parallelogram set upon the remaining side, one of whose sides is equal and parallel to the straight line drawn from the angle which the two sides contain to the point where the sides of the parallelograms opposite to the sides of the triangle meet, when they are produced toward the parts of that angle.

(The demonstration of this general theorem begins on the following page. Book I of the Elements has not yet ended: the running heads remain "EVCLID. GEOM." /

"LIBER I." throughout, and Proposition 48 — the converse of the Pythagorean theorem — does not appear here.)

(Continuation of Clavius's generalized area theorem — the "Pappus theorem": parallelograms erected on two sides of a triangle are together equal to a parallelogram on the base. The demonstration begins here.)

[Clavius — demonstration]

Let ABC be any triangle, and on the sides AB and AC let there be erected any parallelograms whatever, ABDE and ACFG, whose sides DE and FG — the sides that, within the parallelograms, are opposite to the sides AB and AC taken in the triangle — when produced toward the side of the angle A meet at H; and let the straight line AH be drawn. I say that the parallelograms AD and AF together are equal to a parallelogram described on the base BC, one of whose other sides is equal and parallel to the straight line AH.

For let HA be produced so as to cut BC at L, and through B and C let BI and CK be drawn parallel to AH; and join the straight line IK. Now since BIHA and CKHA are parallelograms, [Margin: a. 34. primi (Elements I.34)] each of BI and CK is equal to AH; and hence [Margin: b. 30. primi (Elements I.30)] BI and CK are equal to one another. And since they are also parallel — because each is parallel to the same line AH — [Margin: c. 33. primi (Elements I.33)] BC and IK are likewise parallel and equal. Therefore BCKI is a parallelogram on the base BC, having its other side BI equal and parallel to AH; and it is to this that the parallelograms AD and AF must be shown equal. [Margin: d. 35. primi (Elements I.35)] Now the parallelograms AD and ABIH are equal, since they have the same base AB and lie between the same parallels AB and HD; [Margin: e. 35. primi (Elements I.35)] and ABIH is equal to the parallelogram IL, since these two likewise have the same base BI and lie between the same parallels BI and LH. Therefore AD too is equal to IL. In the same way we shall show that AF is equal to KL. Therefore the parallelograms AD and AF together are equal to the parallelogram BK. Which was the thing proposed.

[Clavius — Pappus's alternative construction]

Pappus [Pappus of Alexandria] constructs the figure differently. For he takes the straight lines AC, AE and AB, AG set in a straight line, so arranged that the parallelograms AD and AF are equiangular, having their angles AED and AGF [Margin: f. 29. primi (Elements I.29)] equal, as interior angles, to the exterior angle BAC — as this figure of his indicates. But we have set out the matter more generally, as is evident.

Diagram. The principal figure for the generalized area theorem. A triangle ABC stands with its base BC at the bottom (B left, C right) and vertex A at the centre; above it the apex H is formed where the produced sides of the two parallelograms meet. Parallelograms ABDE (on side AB) and ACFG (on side AC) are erected toward H; the line AH is produced downward to L on BC. Lines BI and CK are drawn parallel to AH, and IK is joined.

- H (top apex): meeting point of the produced parallelogram sides
- E (upper left): outer vertex of parallelogram ABDE
- G (upper right): outer vertex of parallelogram ACFG
- A (centre): vertex of the triangle
- I (mid-left): foot of BI $\parallel$ AH
- K (mid-right): foot of CK $\parallel$ AH
- D (lower left): vertex of parallelogram ABDE, near B
- B (bottom left): base vertex
- L (bottom centre): where AH produced meets BC
- C (bottom right): base vertex
- F (far bottom right): vertex of parallelogram ACFG, beyond C

Diagram. Pappus's alternative figure for the same theorem. Same lettering as the principal figure, but with the sides so placed (AC in line with AE, and AB in line with AG) that the two parallelograms are equiangular.

- H (top apex): meeting point of the produced sides
- E (upper left): parallelogram vertex
- G (upper right): parallelogram vertex
- A (centre): vertex of the triangle
- I (mid-left): foot of BI $\parallel$ AH
- K (mid-right): foot of CK $\parallel$ AH
- B (bottom left): base vertex
- L (bottom centre): foot of AH on BC
- C (bottom centre-right): base vertex
- F (bottom right): parallelogram vertex beyond C

THEOR. 34. PROPOS. 48.

[Margin: xxxviii (= 48, in the outer margin beside the heading)]

[Euclid — enunciation]

If the square that is described on one of the sides of a triangle is equal to the squares that are described on the two remaining sides of the triangle, the angle contained by those two remaining sides is a right angle.

[Clavius — demonstration]

Let there be given a triangle ABC, and let the square on the side AC be equal to the squares on the remaining sides BA and BC. I say that the angle ABC is a right angle. For draw BD perpendicular to BA and equal to the straight line BC, and join the straight line AD. Now since, in the triangle ABD, the angle ABD is a right angle, [Margin: g. 47. primi (Elements I.47)] the square on AD will be equal to the squares on BA and BD. But the square on BD is equal to the square on BC, because the lines are equal. Therefore the square on AD will be equal to the squares on BA and BC. And since the square on AC is assumed equal to the squares on BA and BC, [Margin: h. 1. pronunc. (Common Notion 1)] the squares on AD and AC are equal to one another, and consequently the straight lines AD and AC are themselves equal. Now since the sides BA, BD of triangle ABD are equal to the sides BA, BC of triangle ABC, and the base AD has been shown equal to the base AC, [Margin: i. 8. primi (Elements I.8)] the angles ABD and ABC are equal. But the angle ABD is by construction a right angle. Therefore the angle ABC too will be a right angle. If, then, the square described on one of the sides of a triangle [is equal to the squares on the remaining sides], and so on. Which was to be demonstrated.

[Clavius — SCHOLIUM]

This theorem is the converse of the preceding Pythagorean theorem, as is plainly evident.

Diagram. Figure for Proposition 48 (the converse of the Pythagorean theorem). Triangle ABC with A at the lower left, C at the lower right, and B on the upper right; D is above, with BD drawn perpendicular to BA and equal to BC, and AD joined.

- B (upper right of the base region): vertex whose angle is proved right
- A (lower left): vertex
- C (lower right): vertex

TRIANGULORUM COMPARATIONES

[Comparisons of Triangles]

[Clavius — scholium]

Euclid [Euclid] has compared two triangles with one another in nine ways in this book. **First** [Margin: k. 4. primi (Elements I.4)], when two sides are equal to two sides, each to each, and they contain an angle equal to an angle, he gathered the equality of the bases, of the remaining angles, and hence of the whole triangles.

Next [Margin: l. 8. primi (Elements I.8)], when two sides are equal to two sides, each to each, and the base equal to the base, he inferred the equality of the angles contained by those sides. Here we concluded also the equality of the remaining angles, and proved the whole triangles to be equal.

Third [Margin: m. 24. primi (Elements I.24)], when two sides are equal to two sides, each to each, but they contain unequal angles, he showed that the base opposite the greater angle is greater than the base opposite the lesser angle.

Fourth [Margin: n. 25. primi (Elements I.25)], when two sides are equal to two sides, each to each, but the bases are unequal, he demonstrated that the angle opposite the greater base is greater than the angle opposite the lesser base.

Fifth [Margin: o. 26. primi (Elements I.26)], when two angles are equal to two angles, each to each, and one side is equal to one side — whether the side that lies adjacent to the equal angles, or the side that is opposite one of the equal angles — he proved that the remaining sides of the one are equal to the remaining sides of the other,

and the remaining angle to the remaining angle. Here we taught that it follows also that the whole triangles are equal.

Sixth [Margin: a. 37. primi (Elements I.37)], he demonstrated that two triangles set on the same base and between the same parallels are equal.

Seventh [Margin: b. 38. primi (Elements I.38)], he showed that two triangles set on equal bases and between the same parallels are equal.

Eighth [Margin: c. 39. primi (Elements I.39)], he taught that two equal triangles set on the same base and toward the same part lie between the same parallels.

Ninth, finally [Margin: d. 40. primi (Elements I.40)], he proved that two equal triangles set on equal bases in the same straight line, and toward the same part, lie between the same parallels.

And upon these modes of arguing about two given triangles nearly the whole of geometry seems to rest, so that they ought to be committed diligently to memory. But just as, beginning from proposition 26, we excluded in the scholium to proposition 31 two comparisons — namely, when two angles are equal to two angles and one side to one side, yet not the side that lies adjacent to the equal angles nor the side that is opposite one of the equal angles in both triangles, but rather the side that in the one lies adjacent to the equal angles while in the other is opposite one of the equal angles; or the side that in the one is opposite one of the equal angles while in the other is opposite the other of the equal angles — just as, I say, we excluded these two comparisons because from them the equality of the remaining sides does not follow, as we demonstrated in the scholium to proposition 31: so too, in the case of proposition 4, three comparisons must be excluded, from which the equality of the bases can in no way be inferred.

First, then, when two sides are equal to two sides, each to each, and one angle to one angle — the angle that is opposite one of the equal sides — the bases cannot be equal, unless the angle in each triangle that is opposite the corresponding equal side is either less than a right angle or not less than a right angle.

Diagram. Figure for the first excluded comparison. Two triangles share a common baseline. On the left, triangle ABC with apex A over the base points B and C; on the right, the isosceles triangle DFG with apex D over the base points E, F, G. The baseline is lettered, from left to right, B — C — E — F — G.

- A (upper left apex): vertex of triangle ABC
- D (upper right apex): vertex of the isosceles triangle DFG ($DF = DG$)
- B (baseline, far left): base vertex of triangle ABC
- C (baseline): base vertex of triangle ABC
- E (baseline): point to which base GF is produced
- F (baseline): base vertex of the isosceles triangle
- G (baseline, far right): base vertex of the isosceles triangle

[Clavius — demonstration of the first excluded case]

For let DFG be an isosceles triangle having the sides DF and DG equal; let the base GF be produced as far as E, let the straight line ED be joined, and upon triangle DEG let there be constructed an equal triangle ABC, whose sides AB, AC are equal

to DE, DG, and whose base BC is equal to the base EG. Then two sides AB, AC are equal to two sides DE, DF, each to each, and the angles B, E, which are opposite the equal sides AC, DF, are equal; and yet the base BC is greater than the base EF, since BC is equal to EG. The reason is that the angle C is acute, whereas DFE is obtuse. For since [Margin: e. 5. primi (Elements I.5)] the angles DFG and G are equal, and [Margin: f. 17. primi (Elements I.17)] taken together are less than two right angles, each will be less than a right angle, and therefore DFE is greater than a right angle — seeing that [Margin: g. 13. primi (Elements I.13)] the two angles at F are equal to two right angles. But if two sides AB, AC are equal to two sides DE, DG, the angle B equal to the angle E, and each of the angles C, G either less than a right angle or not less, then and only then does it follow that the bases BC, EG are equal, and so on. For if the base BC were less than EG: were AB laid upon DE, then BC would indeed coincide with EG, on account of the equality of the angles B, E, but the point C would fall short of G, say at F. Since, then, the sides DF, DG are equal — because DF is the same as AC, which is equal to DG — [Margin: h. 5. primi (Elements I.5)] the angles DFG and G will be equal, and therefore each less than a right angle, since [Margin: i. 17. primi (Elements I.17)] both together are less than two right angles. Since, then, [Margin: k. 13. primi (Elements I.13)] the two angles at F are equal to two right angles, DFE — that is, C, which does not differ from DFE — will be greater than a right angle. Therefore it is not the case that each of the angles C and G is less than a right angle; rather C is acute and G obtuse, which is contrary to the hypothesis. In the same way, if the base BC be said to be greater than the base EF (the sides AB, AC being set equal to DE, DF, the angle B equal to E, and each of the angles C and F either less than a right angle or not less), the point C will fall beyond F, say at G; and again the angle C — that is, G — will be acute, and DFE obtuse, which is contrary to the hypothesis.

[Clavius — the second excluded case]

Next, when two sides are equal to two sides, each to each, and one angle to one angle, so arranged that the one is opposite one of the equal sides and the other opposite the other, nothing can be concluded either. For let ABC be a triangle whose side AB is greater than the side AC. Then [Margin: l. 18. primi (Elements I.18)] the angle ACB will be greater than the angle ABC. Let the angle ACD be made equal to the angle ABC: then CD will fall above CB. Let there also be described, from A through B, an arc of a circle cutting CD at D, and let the straight line AD be joined. Then two sides AB, AC are equal to two sides AD, AC, each to each, and the angle ABC, opposite the side AC, is equal to the angle ACD, opposite the side AD; and yet the bases BC, DC are not equal. For if they were equal, then

both the two straight lines AB, AD and the two CB, CD would be equal, [Margin: m. 7. primi (Elements I.7)] which is absurd; or else the angles BAC, DAC would be equal, [Margin: n. 8. primi (Elements I.8)] a part equal to the whole, which is absurd.

Diagram. Figure for the second excluded comparison. Triangle ABC with A at the upper right, B at the lower centre, and D at the left; the angle ACD is made equal to angle ABC, and an arc of a circle described from A through B cuts CD at D. Lines AD, AB, AC, DB and DC are drawn.

- A (upper right apex): vertex
- D (left): point where the arc cuts CD
- B (lower centre): vertex
- C (lower right): vertex

[Clavius — the third excluded case]

Lastly, when two sides are equal to two sides, each to each, and the angle contained in the one triangle by those sides is equal to the angle in the other triangle that is opposite one of those sides, nothing can be inferred either. For let ABC be a triangle each of whose sides AC, CB is greater than the side AB, and let BC be greater than AC. Then [Margin: a. 18. primi (Elements I.18)] the angle BAC will be greater than the angle ABC. If, then, the angle ABD be made equal to the angle BAC, BD will fall below BC. Let there also be described an arc of a circle from A through C, which will fall below BC and will cut BD at D. When the straight line AD is joined, then two sides AB, AC will be equal to two sides AB, AD, each to each, and the angle BAC, contained by those sides AB, AC, will be equal to the angle ABD, which is opposite the side AD; and yet the bases BC, BD are not equal. Otherwise both the straight lines AC, AD and BC, BD would be equal, [Margin: b. 7. primi (Elements I.7)] which is absurd; or else the angles BAC, BAD would be equal, [Margin: c. 8. primi (Elements I.8)] the whole and a part, which is absurd.

Diagram. Figure for the third excluded comparison. Quadrilateral-like figure with A at the top, B at the left, C at the right, and D at the bottom; the diagonals cross, an arc of a circle is described from A through C, and the line AC is drawn dashed.

- A (top): vertex from which the arc is described
- B (left): vertex
- C (right): vertex through which the arc passes

- D (bottom): point where the arc cuts BD

[Clavius — conclusion of the scholium]

Rightly, then, did Euclid in proposition 4 prescribe that the angle contained by those sides in the one triangle must be equal to the angle of the other triangle that is likewise contained by those sides; for without this condition nothing can be concluded, as we have demonstrated.

FINIS ELEMENTI PRIMI.

[End of the First Element — Book I]

(Book I ends here. Book II does not begin on these pages: the catchword "EVCLI-" at the foot of the last page points forward to the opening of Book II — presumably its title and Definitions — on the following leaf, beyond this range.)

EUCLID'S ELEMENTS, BOOK TWO

[EVCLIDIS ELEMENTVM SECVNDVM]

DEFINITIONS

I.

[Euclid, Definition] Every rectangular parallelogram is said to be *contained* by the two straight lines that contain the right angle.

[Clavius's commentary] In this second book Euclid treats the powers of straight lines [potentiae linearum rectarum], inquiring how large are the squares of the parts of any divided straight line, and the rectangular parallelograms [contained] under the parts of that same divided line — both among themselves and compared with the square of the whole line, and so on. To carry this out conveniently, he first sets out, in two definitions, the two things most necessary for a right understanding of what is to be demonstrated.

By the first definition he explains under which straight lines any rectangular parallelogram is said to be contained, and what it is for a parallelogram to be contained under two straight lines. To understand this, one must first explain that a parallelogram is called *rectangular* when all its angles are right. Of these there are only two kinds: the square, and the oblong [altera parte longius, "longer

on one side"]. In both, all the angles are right, as is clear from their definitions. Furthermore, in any parallelogram, if only one angle is given to be right, the remaining three will necessarily be right as well. For let angle A in parallelogram ABCD be right. I say that the remaining three angles B, C, D are right too. Since AD and BC are parallel, [Margin: a. Elements I.29] the interior angles A and B are equal to two right angles; but angle A is right, by hypothesis; therefore B will be right too. And since [Margin: b. Elements I.34] each angle is equal to its opposite — angle A to angle C, and angle B to angle D — the angles C and D will be right as well.

Diagram. A tall upright rectangle illustrating Definition I, parallelogram ABCD.

- A (top-left corner)
- B (top-right corner)
- C (bottom-right corner)
- D (bottom-left corner)

Euclid therefore says that any rectangular parallelogram is contained under the two straight lines that contain one of its right angles. Thus the rectangular parallelogram ABCD is said to be contained under the two straight lines AB, AD; or under AD, DC; or under DC, CB; or finally under AB, BC — because any such pair of lines expresses the whole magnitude of the parallelogram: one of them, such as AB or DC, its length, and the other, such as AD or BC, its breadth. Hence, once the two lines containing the right angle of a rectangular parallelogram are given, its whole quantity is at once conceived and understood — namely its length and its breadth. There is this too: such a parallelogram is produced by the imagined motion of one line along the other. For if one conceives in the mind the straight line AB moving downward transversely along the straight line AD, always making a right angle with AD, until point A reaches point D and point B reaches point C, the whole parallelogram ABCD will be traced out. The same will happen if AD is supposed to move transversely along the straight line AB, and so on. For this reason a rectangular parallelogram is with full justice said to be contained under two such straight lines.

Therefore a rectangular parallelogram said to be contained under two straight lines will be the one whose two sides about a single right angle are equal to those two straight lines, each to each. Thus the rectangular parallelogram contained under the straight lines E and F will be the same as parallelogram ABCD, since side AB is equal to line E, and side AD to line F.

Diagram. Two separate horizontal line segments, drawn one above the other, labelled at their left ends. They represent the two given straight lines of the preceding paragraph.

- E (upper segment)
- F (lower segment)

It is clear from what has been said that a rectangular parallelogram contained under two *equal* lines is a square. For since each of those equal lines is equal to the line opposite it, all four sides of the rectangular parallelogram will be equal; and therefore, by the definition of a square, it will be a square.

Likewise it is evident that if two straight lines are equal to two other straight lines, each to each, the rectangular parallelogram contained under the first two is equal to the one contained under the latter two — a rectangular

parallelogram — because both the angles and the sides of the one are equal to the angles and sides of the other. This, however, can also easily be demonstrated in the following way. Let straight lines AB, BC be equal to straight lines DE, EF, each to each. I say that the rectangular parallelogram ABCG, contained under AB, BC, is equal to the rectangular parallelogram DEFH, contained under DE, EF. For when the diagonals AC, DF have been drawn: since the sides AB, BC of triangle ABC are equal to the sides DE, EF of triangle DEF, and the angles B and E are equal — namely right — [Margin: c. Elements I.4] the triangles ABC, DEF will be equal. By the same reasoning triangles AGC, DHF will be equal. Therefore the whole parallelograms ABCG, DEFH will be equal.

Diagram. Two rectangles, one above the other, each divided by a diagonal into two triangles, showing the two equal rectangular parallelograms ABCG and DEFH.

Upper rectangle (ABCG), with diagonal AC:

- A (top-left corner)
- G (top-right corner)
- B (bottom-left corner)
- C (bottom-right corner)

Lower rectangle (DEFH), with diagonal DF:

- D (top-left corner)
- H (top-right corner)
- E (bottom-left corner)

- F (bottom-right corner)

This containing of a rectangular parallelogram under the two straight lines that contain the right angle has a great affinity with the multiplication of one number by another. For just as the number 12 is produced from multiplying 3 by 4, and is arranged into the form of a parallelogram — whence it too is said to be contained under 3 and 4 — so also the parallelogram ABCD, contained under the two straight lines AB, BC (of which the former is 3 palms and the latter 4), consists of 12 square palms. These are produced by drawing line AB, of 3 palms, into line BC, of 4 palms, as the figure shows. This is well known to arithmeticians and geometers, and is demonstrated by Johannes Regiomontanus [Regiomontanus], *On Triangles* [De triangulis] I.16. Hence some say that a rectangular parallelogram is generated by drawing one of two lines about the right angle into the other —

Diagram. A lattice of small open circles (nodes) arranged in a rectangular array, illustrating the product $3 \times 4 = 12$ as an arrangement of units.

- 3 (label at left, the number of one dimension)
- 12 (label at the centre of the array, the product)
- 4 (label at the foot, the number of the other dimension)

Diagram. A rectangle ABCD ruled into a grid of unit squares (3 by 4), illustrating the same product $3 \times 4 = 12$ as an area.

- A (top-left corner)
- D (top-right corner)
- B (bottom-left corner)
- C (bottom-right corner)
- 3 (label at the left side, the length AB)
- 12 (label at the centre, the total area in square palms)

— just as the immediately preceding parallelogram is produced by drawing line AB into line BC, or (what is the same) by drawing line BC into line AB. For the same parallelogram is produced whether the smaller line is drawn into the larger or the larger into the smaller — just as the same number is produced whether the smaller number is multiplied by the larger or the larger by the smaller, as Euclid demonstrates in Book 7, Prop. 16. For this number 12 is produced from multiplying 3 by 4 just as much as from multiplying 4 by 3.

In passing, it also seems right that I warn the reader that Euclid, in this second book and in the others that follow, calls a rectangular parallelogram simply a

"rectangle" — a usage the other geometers observe as well, so that by the name "rectangle" one must always understand a rectangular parallelogram. Again, to avoid repeating the same letters so often, geometers customarily denote a parallelogram — whether rectangular or not — by just two letters, those that lie opposite each other across the diagonal. Thus they call the adjacent parallelogram AC, or BD.

Diagram. A single upright rectangle (drawn with dotted sides), illustrating the practice of naming a parallelogram by the two opposite corner-letters, AC or BD.

- A (top-left corner)
- B (top-right corner)
- D (bottom-left corner)
- C (bottom-right corner)

II.

[Euclid, Definition] In every parallelogrammic space, let each one of the parallelograms that lie about its diagonal, taken together with the two complements, be called a *Gnomon*.

[Clavius's commentary] In parallelogram ABCD — whether it be rectangular or not — let the diagonal AC be drawn; and from any point G on it let the straight lines EF, HI be drawn parallel to the sides of the parallelogram, so that the parallelogram is divided into four parallelograms, of which two, EH and IF, are said to be *about the diagonal*, while the other two, BG and GD, are the *complements*, as is clear from the last definition of Book 1. Thus the figure composed of either parallelogram about the diagonal — say IF — together with the two complements BG, GD, such as the figure EBCDHG, which the arc KLM encloses, is called a Gnomon. By the same reasoning the figure FDABIG, composed of the parallelogram EH about the diagonal together with the two complements BG, GD, will be called a Gnomon.

Diagram. The left of two figures for Definition II — a rectangle ABCD with the diagonal AC drawn, divided by the lines EF and HI (crossing at point G on the diagonal) into four parallelograms; an arc KLM marks off the gnomon.

- A (top-left corner)
- D (top-right corner)
- B (bottom-left corner)
- C (bottom-right corner)

- H (on the top edge; upper end of vertical line HI)
- I (on the bottom edge; lower end of HI)
- E (on the left edge; left end of horizontal line EF)
- F (on the right edge; right end of EF)
- G (interior point on diagonal AC, where EF and HI cross)
- K (on HI, above G)
- L (on HI / near diagonal, below G)
- M (on EF, left of G)
- KLM (the arc enclosing the gnomon)

Diagram. The right of the two figures for Definition II — the same construction shown in an oblique (non-rectangular) parallelogram ABCD, with diagonal AC, the lines EF and HI meeting at G, and the arc KLM marking the gnomon.

- A (top-left corner)
- D (top-right corner)
- B (bottom-left corner)
- C (bottom-right corner)
- H (on the top edge; upper end of HI)
- I (on the bottom edge; lower end of HI)
- E (on the left edge; left end of EF)
- F (on the right edge; right end of EF)
- G (interior point on diagonal AC, where EF and HI cross)
- K (on HI, above G)
- L (below G, near the diagonal)
- M (on EF, left of G)
- KLM (the arc enclosing the gnomon)

But let us now come to the propositions of this second book. In them it will surely be worthwhile to spend much labor understanding them precisely, because of their manifold use both in geometry and in human commerce. For from several of these propositions are demonstrated those admirable rules of Algebra, than which I scarcely believe anything more excellent can be found in the human disciplines: they draw out certain miracles of numbers (so to speak) so abstruse and hidden that the art seems to surpass every human grasp — and yet do so with such ease and delight that nothing seems easier.

From other propositions of this book, in turn, are drawn the demonstrations by which surd numbers (as they are called) are added, subtracted, multiplied, and

divided among themselves — that is, numbers that can in no way be expressed, such as the roots of non-square or non-cubic numbers, which not even by Divine power can be exhibited among numbers, since the thing implies a contradiction (as the philosophers and theologians put it). What could be more wonderful than this? For who would believe that by demonstration one can know what results from the square root of the number 8 added to the square root of the number 18 — when each root is unknown and can by no means be expressed (the former being a little less than 3, the latter a little more than 4) — and yet the sum made from the two is gathered, by force of Proposition 4 of this book, to be the square root of the number 50, which is a little more than 7?

Moreover, from Propositions 12 and 13 of this same book the area and quantity of any triangle is known most exactly; and from that knowledge, in turn, flows and derives the measurement of all magnitudes. Finally, the last proposition of this book reduces every rectilinear figure — even an irregular one, or several of them — to an equal square, with wonderful ease. So that this book truly deserves to be called golden: though very small in bulk, it contains uses that are almost infinite.

EUCLID, GEOMETRY

THEOREM 1. PROPOSITION 1.

[Euclid, enunciation] If there be two straight lines, and one of them is cut into any number of segments: the rectangle contained under those two straight lines is equal to the rectangles contained under the uncut line and each of the segments.

[Clavius's demonstration] Let there be two straight lines, A and BC, of which BC is cut in any manner into any number of segments BD, DE, EC. I say that the rectangle contained under A and BC is equal to all the rectangles taken together that are contained under the undivided line A and each segment — namely the rectangle under A and BD; likewise under A and DE; likewise under A and EC.

For let the rectangle BF be contained under A and BC — that is, let GB be equal to A. This will be so if at BC two perpendiculars BG, CF are erected equal to line A, and line FG is drawn. For BG, CF will be [Margin: a. Elements I.28] parallel, on account of the right angles B, C; and they are also [Margin: b. Axiom 1 (Common Notion 1)] equal to each other, since each is set equal to A. [Margin: c. Elements I.33] Therefore FG, BC will also be parallel and equal to each other; and consequently BF will be a rectangle, contained under A (that is, GB) and BC, by Definition 1 of this book. Next, from D and E draw the lines DH, EI parallel to BG

or CF. So DH, EI, since they are parallel to BG, will [Margin: d. Elements I.30] also be parallel to each other. Again, these same lines, since by construction BH and BI are parallelograms, will [Margin: e. Elements I.34] be equal to BG, and therefore to A.

Diagram. A rectangle BF (with top edge GF and bottom edge BC), divided by the two interior verticals DH and EI into three sub-rectangles (BH, DI, EF). Below and to the left, the separate straight line A is drawn.

- G (top-left corner)
- H (on top edge, above D)
- I (on top edge, above E)
- F (top-right corner)
- B (bottom-left corner)
- D (on bottom edge, first cut)
- E (on bottom edge, second cut)
- C (bottom-right corner)
- A (the separate straight line, drawn below the rectangle at the left)

Since, therefore, line BG is equal to line A, the rectangle BH will be contained under the cut line A and segment BD. By the same reasoning DI will be contained under A and segment DE; likewise EF under A and segment EC. Therefore, since the rectangles BH, DI, EF together are equal to the whole rectangle BF, it is clear that the rectangle contained under A and BC is equal to all the rectangles contained under A and the segments BD, DE, EC. If, then, there be two straight lines, and one of them be cut, and so on. Which was to be demonstrated.

SCHOLIUM.

Since at Book 9, Proposition 14 we shall also demonstrate in numbers the first ten theorems of this second book (which Euclid adapts to lines), provided the numbers are divided as the lines are, it will not be out of place to apply briefly to numbers what is here demonstrated at greater length concerning lines — especially since the multiplication of one number by another corresponds to the drawing of one line into another, as we said above. So, given any two numbers, say 6 and 10, let the latter be divided into three parts, 5, 3, and 2. I say that 60, the number produced from 6 times 10, is equal to the three numbers 30, 18, and 12, which are generated from the multiplication of 6 by 5, by 3, and by 2 — which is clear.

At this point Federico Commandino [Federicus Commandinus] demonstrates two other theorems, which now follow.

[THEOREM — first addition of Commandino]

[Euclid/Commandino, enunciation] If there be two straight lines, and both are cut into any number of segments: the rectangle contained under those two straight lines is equal to the rectangles contained under each segment of the one and each of the segments of the other.

[Clavius's demonstration] Let there be two straight lines AB, AC containing the right angle A, cut into the parts AD, DE, EF, FB [on AB] and AG, GH, HC [on AC]. I say that the rectangle contained under AB, AC is equal to the rectangles contained under AD, AG; AD, GH; AD, HC; DE, AG; DE, GH; DE, HC; EF, AG; EF, GH; EF, HC; FB, AG; FB, GH; FB, HC. Let the rectangle AI be completed, and draw DK, EL, FM parallel to AC (or BI); likewise HN, GO parallel to AB (or CI), which cut the former lines at P, Q, R, S, T, V. Since, therefore, the rectangle AS is contained under AD, AG; and GP under AD, GH; and HK under AD, HC — [Margin: f. Elements I.34] because the lines GS, HP are equal to AD — and likewise the rectangles DT, SQ, PL are contained under DE, AG; DE, GH; DE, HC — [Margin: g. Elements I.34] because DS, SP, PK are equal to AG, GH, HC, and ST, PQ equal to DE — and by the same reasoning the rectangles EV, TR, QM are contained under EF, AG; EF, GH; EF, HC; and also the rectangles FO, VN, RI under FB, AG; FB, GH; FB, HC — it is clear that the rectangle under AB, AC is equal to the rectangles contained under each of the parts AD, DE, EF, FB and each of the segments AG, GH, HC. Which was proposed.

Diagram. The rectangle AI (with sides AB along the bottom and AC up the left), ruled by the interior verticals DK, EL, FM and horizontals HN, GO into a grid of cells (4 columns by 3 rows). Interior cells are lettered P, Q, R (upper) and S, T, V (lower).

Corners:

- A (bottom-left)
- B (bottom-right)
- I (top-right)
- C (top-left)

Bottom edge AB (left to right): A, D, E, F, B Left edge AC (bottom to top): A, G, H, C
Top edge CI (left to right): C, K, L, M, I Right edge IB (top to bottom): I, N, O, B
Interior points/cells: P, Q, R, S, T, V

[THEOREM — second addition of Commandino]

[Euclid/Commandino, enunciation] If there be two straight lines, and both are cut in any way: the rectangle contained under those two straight lines, together with the rectangle contained under one part of the one and one part of the other, is equal to the rectangles contained mutually under the whole lines and the said parts, together with the rectangle contained under the remaining parts.

[Clavius's demonstration] Let there be two straight lines AB, AC containing the right angle A, cut in any way at D and E. I say that the rectangle contained under AB, AC, together with the rectangle contained under the parts AD, EC, is equal to the rectangles contained under AB, EC and under AC, AD, together with the rectangle contained under DB, AE. For let the rectangle AF be completed; through D draw the line DG parallel to AC (or BF); and through E draw the line EH parallel to AB (or CF), cutting DG at I. Since, therefore, the rectangle AF is equal to the rectangles EF, DH, AI: if the common rectangle EG is added, the rectangles AF, EG (namely those contained under the wholes AB, AC and the parts AD, EC) will be equal to the rectangles EF, AG, DH — contained under AB, EC; AC, AD; and DB, AE. Which was proposed.

Diagram. The rectangle AF, with D on the bottom side AB and E on the left side AC; the vertical DG and the horizontal EH cross at the interior point I, dividing the rectangle into four sub-rectangles.

- C (top-left corner)
- F (top-right corner)
- A (bottom-left corner)
- B (bottom-right corner)
- D (on bottom edge AB)
- E (on left edge AC)
- G (on top edge CF, above D)
- H (on right edge BF, level with E)
- I (interior intersection of DG and EH)

(Continuation of the numerical scholium to Proposition 1, from the preceding page.)

The same things are also clear in numbers. For suppose these two numbers 10 and 8 are proposed, of which the first is divided into three parts, 2, 3, 5, and the second into two, 3, 5: it is evident that 80, the number produced from 10 times 8, is equal to the six numbers 6, 10, 9, 15, 15, 25, which are produced from each of the parts 2, 3, 5 multiplied into any of the parts 3, 5, and which added together

make 80 [?], as Federico Commandino's [Federico Commandino] first theorem required.

Again, if the same numbers are cut in any other way — the first, say, into 3, 7, the second into 2, 6 — it is likewise plain that 80, the number produced from 10 times 8, together with 18, the number produced from 3 times 6, is equal to the three numbers 60, 24, 14, which are produced from 10 times 6, from 8 times 3, and from the remaining part 7 into the remaining part 2, since on both sides the total comes to 98, as Commandino's second theorem required.

THEOR. 2. — PROPOS. 2. [Euclid, *Elements* II.2] [Margin: ij.]

Enunciation (Euclid). If a straight line is cut at random, the rectangles contained by the whole and each of the segments are together equal to the square described on the whole.

Demonstration (Clavius). Let the straight line AB be divided at random at C into two parts. I say that the two rectangles contained by the whole AB and the segments AC, CB, taken together, are equal to the square on the whole line AB. For let AD, the square on the line AB, be described, and from C let CF be drawn parallel to AE or BD; [Margin: a — Euclid I.34] CF will be equal to AE — that is, to AB, to which AE is equal by the definition of a square. Since, then, AE is equal to AB, the rectangle AF will be the one contained by the whole AB and the segment AC. Similarly the rectangle CD will be the one contained by the whole AB and the segment CB. Therefore, since the rectangles AF, CD together are equal to the square AD, it is evident that the rectangles contained by AB and the segments AC, CB are equal to the square on the line AB. Therefore, if a straight line is cut at random, and so on. Which was to be demonstrated.

Diagram. The square on AB (the square AD), for Proposition 2. The base runs A (bottom-left) — C (bottom-middle) — B (bottom-right); the top runs E (top-left) — F (top-middle) — D (top-right). The vertical CF divides the square into two rectangles: AF (the left rectangle, on the segment AC) and CD (the right rectangle, on the segment CB).

- A (bottom-left corner)
- C (bottom edge, division point)
- B (bottom-right corner)
- E (top-left corner)

- F (top edge, foot of CF at top)
- D (top-right corner)

Otherwise (ALITER). Let the line D be taken equal to AB. Since AB is divided at C, the rectangle contained by the undivided line D and the line AB — that is, the square on AB — is [Margin: b — Euclid II.1] equal to the two rectangles contained by D and the divided line, that is, by AB and each of the segments AC, CB. Which is what was proposed.

Diagram. Two horizontal reference segments for the alternative proof: the line D (undivided) and the line AB cut at C. Legibly labelled points: D (on the one segment); B and C (on the other, divided, segment). The far endpoint of the divided segment (A) is drawn with an arrowhead terminal and is faint.

- D (undivided segment)
- B (endpoint of divided segment)
- C (division point of divided segment)
- A [?] (opposite endpoint, faint/arrowhead terminal)

SCHOLIUM [printed: SHOLIVM]

Although Euclid states this theorem for a straight line divided into just two parts in any way, the same result is proved by the same means if the line is divided into any number of parts, as these figures make clear. In numbers the same thing is seen as follows. Let the number 10 be divided into two parts, 7 and 3. I say that the numbers 70 and 30, produced by multiplying 10 by 7 and by 3, are together equal to 100, the square of the number 10 itself, as is evident. In the same way, if 10 is divided into several parts — 3, 2, 4, and 1 — the numbers 30, 20, 40, and 10, generated from 10 times 3, 2, 4, and 1, will be equal to 100, the square of the number 10. Federico Commandino demonstrates this theorem here in the same way.

Diagram. A figure illustrating the theorem for a line divided into several parts: a rectangle divided by vertical lines into a row of strips, accompanied by reference line-segments. Legibly along the top edge: G, H, I, K (with B at the top-right corner); along the base: A, C, D, then a further division point, and B at the right. Below the rectangle are two reference segments — one plain, marked L at its left end, and one divided segment carrying marks at C, D, E with an arrowhead terminal and B at the far end. Several interior division-labels are degraded by a diagonal offset-smudge across this region.

- G, H, I, K (top edge, division points of the strips)

- B (top-right and bottom-right corner)
- A (bottom-left corner)
- C, D (base, division points)
- [?] (a further base division point, obscured)
- L (left end of the plain reference segment)
- C, D, E (marks on the lower divided reference segment)

Federico Commandino demonstrates this theorem here in the same way.

[Added theorem — generalization of Proposition 2]

Enunciation. If a straight line is cut into any number of segments, the square described on the whole is equal to the rectangles contained by each of the segments taken with every one of the segments.

Demonstration. Let AB be divided into any number of parts AC, CD, DB. I say that the square described on AB is equal to the rectangles contained by each of the parts AC, CD, DB and every one of the segments AC, CD, DB — that is, to the rectangles contained by AC and AC; AC and CD; AC and DB; CD and AC; CD and CD; CD and DB; DB and AC; DB and CD; DB and DB. For let a line EF be taken equal to AB, and divided into parts EG, GH, HF equal to the parts AC, CD, DB. Then, by what we demonstrated at Proposition 1 of this book, the rectangle contained by AB and EF — that is, the square on AB — will be equal to the rectangles contained by AC and EG; AC and GH; AC and HF; CD and EG; CD and GH; CD and HF; DB and EG; DB and GH; DB and HF. Since, then, the parts AC, CD, DB are equal to the parts EG, GH, HF, the square on AB will also be equal to the rectangles contained by AC and AC; AC and CD; AC and DB; CD and AC; CD and CD; CD and DB; DB and AC; DB and CD; DB and DB. Which is what was proposed.

In numbers the same is evident. For if the number 10 is divided into 2, 3, 5, then 100, the square of the whole, will be equal to these nine numbers — 4, 6, 10, 6, 9, 15, 10, 15, 25 — which are produced from each of the parts 2, 3, 5 multiplied by every one of the parts 2, 3, 5, as is clear.

Diagram. The square on AB for the generalized theorem, AB being divided into three parts. The square is divided into a 3×3 grid of nine rectangles. Along the top edge: A, C, D, B (A at the left, C and D the interior divisions, B at the right). Below is the auxiliary line EF, equal to AB and divided at G, H: E, G, H, F.

- A, C, D, B (top edge of the square — the divisions of AB)
- E, G, H, F (the auxiliary line EF, divided at G and H)

THEOR. 3. — PROPOS. 3. [Euclid, *Elements* II.3] [Margin: iij.]

Enunciation (Euclid). If a straight line is cut at random, the rectangle contained by the whole and one of the segments is equal both to the rectangle contained by the segments and to the square described on the aforesaid segment.

[Book II continues]

Demonstration (Clavius). Let the straight line AB be divided at random at the point C. I say that the rectangle contained by the whole AB and either segment — say AC (whether this segment be the greater or the less) — is equal to the rectangle contained by the segments AC, CB together with the square on the first segment taken, AC. For let the square on the said segment AC be constructed, namely AD; and from B let BF be drawn parallel to AE, until it meets ED, produced, at F. Since, then, AE is equal to the line AC by the definition of a square, the rectangle AF will be the one contained by the whole AB and the segment AC. Again, since CD is by the same reasoning equal to AC, the rectangle CF will be the one contained by the segments AC and CB. Since, then, the rectangle AF is equal to the square AD together with the rectangle CF, it plainly follows that the rectangle contained by the whole AB and the segment AC is equal to the rectangle contained by the segments AC, CB together with the square on the aforesaid segment AC. And so, if a straight line is cut at random, and so on. Which was to be shown.

Diagram. The figure for Proposition 3. A rectangle standing on AB: the base runs A (bottom-left) — C (bottom-middle) — B (bottom-right); the top runs E (top-left) — D (top-middle) — F (top-right). The left portion AD is the square on the segment AC; BF, drawn from B up to F, completes the rectangle AF on the whole AB, while CF (through D) marks off the rectangle CF on the segment CB.

- A (bottom-left corner)
- C (bottom edge, division point)
- B (bottom-right corner)
- E (top-left corner)
- D (top edge, above C)
- F (top-right corner)

Otherwise (ALITER). Let the line D be taken equal to the segment AC. Since AB is divided at C, the rectangle contained by D and AB — that is, by AB and AC — is [Margin: a — Euclid II.1] equal to the rectangle contained by D and CB — that is, by AC, CB — together with the rectangle contained by D and AC, that is, the square on the segment AC. Which is what was proposed.

Diagram. Two horizontal reference segments for the alternative proof: the line D (equal to AC) and the line AB cut at C. Legibly labelled: D (the short upper segment); C and B on the lower, divided segment (its far endpoint drawn with an arrowhead terminal). [Margin: a — Euclid II.1]

- D (upper segment, equal to AC)
- C (division point of lower segment)
- B (endpoint of lower segment)

SCHOLIUM

To fit this theorem to numbers, let 10 be divided into 7 and 3. I say that the number 70, produced from 10 times 7, is equal to the number 21, produced from 7 times 3, together with 49, the square of the first part, 7 — as the thing itself shows. By the same reasoning, the number 30, generated from 10 times 3, will be equal to the number 21, produced from 3 times 7, together with 9, the square of the aforesaid number 3.

THEOR. 4. — PROPOS. 4. [Euclid, *Elements* II.4] [Margin: iv.]

Enunciation (Euclid). If a straight line is cut at random, the square described on the whole is equal both to the squares described on the segments and to twice the rectangle contained by the segments.

Demonstration (Clavius). Let the straight line AB be divided at random at C. I say that the square on the whole line AB is equal to the squares on the segments AC, CB together with the rectangle contained twice by the segments AC, CB. For let the square AD be described on AB, and let the diagonal BE be drawn. Then from C let CF be drawn parallel to BD, cutting the diagonal at the point G; and through G let HI in turn be drawn parallel to AB. The square AD will thus be divided into four parallelograms. Now, since in the triangle ABE the two sides AB, AE are equal, [Margin: a — Euclid I.5] the two angles ABE, AEB will be equal. But [Margin: b — Euclid I.32] the three angles ABE, AEB, BAE of the triangle ABE are equal to two

right angles, and BAE is a right angle; the remaining two, ABE and AEB, will therefore be half-right angles. By the same reasoning you will show that the angles DBE, DEB are half-right. This also follows from what we demonstrated at Proposition 34 of Book 1; for, as was shown there, the diagonal BE bisects the right angles ABD, AED. Since, then, the three angles of the triangle EFG are likewise [Margin: c — Euclid I.32] equal to two right angles, and the angle EFG is a right angle [Margin: d — Euclid I.29] (being equal, as external to internal, to the right angle D), while FEG has been shown to be half-right, the remaining angle EGF will also be half-right, and therefore equal to the angle FEG. [Margin: e — Euclid I.6] The sides EF, FG will therefore be equal; and since these are [Margin: f — Euclid I.34] equal to the opposite sides GH, HE, the parallelogram FH will be a square, all its sides being equal and all its angles right — for, one angle (namely FEH, or F) being right in the parallelogram FH, all four are right, as we demonstrated at Definition 1 of this book. By the same reasoning CI will be a square. Hence CI and FH are the squares on the segments AC, CB, since the side HG is [Margin: g — Euclid I.34] equal to AC. The rectangles AG, DG likewise will be contained by the segments AC, CB, because CG, GI are equal to CB (on account of the square CI), and FG is equal to GH (on account of the square FH, that is, [Margin: h — Euclid I.34] to AC). Consequently, since the square AD is equal to the squares CI, FH together with the rectangles AG, DG, it follows that the square AD on the whole line AB is equal to the squares on the segments AC, CB together with the rectangle contained by those same segments AC, CB taken twice. Therefore, if a straight line is cut at random, the square described on the whole, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 4. The square AD on AB, with the diagonal BE drawn from B (bottom-right) to E (top-left), and divided into four parallelograms by CF (vertical, through the base-point C) and HI (horizontal). The base runs A (bottom-left) — C (bottom-middle) — B (bottom-right); the top runs E (top-left) — F (top-middle) — D (top-right); the horizontal midline runs H (left) — G (centre, on the diagonal) — I (right). The parallelograms CI and FH (about the diagonal) are the squares on the segments; AG and DG are the two equal rectangles.

- A (bottom-left corner)
- C (bottom edge, division point)
- B (bottom-right corner)
- E (top-left corner)
- F (top edge, above C)

- D (top-right corner)
- H (left edge, midpoint)
- G (centre, on the diagonal BE)
- I (right edge, midpoint)

Otherwise (ALITER). Since AB is divided at C, the square on the whole AB is [Margin: i — Euclid II.2] equal to the rectangles contained by the whole AB and the segments AC, CB. But the rectangle contained by AB and AC is [Margin: k — Euclid II.3] equal to the rectangle contained by AC, CB together with the square on the segment AC; likewise the rectangle contained by AB and CB is equal to the rectangle contained by CB, AC together with the square on the segment CB. Therefore the square on AB is also equal to the squares on the segments AC, CB together with the rectangles contained by AC, CB and by CB, AC. Which is what was proposed.

COROLLARIUM I

Hence it is evident that the parallelograms about the diagonal of a square are squares. This follows from the earlier demonstration of this theorem, in which it was shown that the rectangles CI, FH, which lie about the diagonal BE, are squares; for in all other squares the demonstration will be the same. Yet this corollary is to be understood of those parallelograms about the diagonal of a square which have some angle in common with the whole square — of which kind are the said parallelograms CI, FH. For CI has the angle ABD in common with the square, and FH the angle AED.

The same is nonetheless true of any parallelograms about the diagonal of a square, even one produced beyond it, provided they have some angle in common with the square and their sides are parallel to its sides. For about the diagonal AC of the square BD let there stand a parallelogram, whether inside the square or outside, provided only that it has its sides parallel to the sides of the square BD. I say that FH is a square. For since AB, EF are parallel, [Margin: l — Euclid I.29] the angles BAC, FEG will be equal, internal and external; and by the same reasoning the angles BCA, FGE will be equal. But the angles BAC, BCA are half-right, as was already shown. Therefore the angles FEG, FGE will also be half-right; [Margin: m — Euclid I.6] and consequently the sides EF, FG opposite them are equal, [Margin: n — Euclid I.32] and the angle F is right. Therefore, since the sides EF, FG are [Margin: o — Euclid I.34] equal to the opposite sides GH, HE, the parallelogram FH will be equilateral. But it is also right-angled, from what we have shown; for

the single angle F has been demonstrated to be right. Therefore FH will be a square. Which was proposed.

Diagram. The figure for Corollary I: a square with its diagonal, carrying a smaller similar parallelogram (FH) set about that same diagonal. The large square is BD (with the diagonal drawn between corners A and C); the smaller parallelogram about the diagonal is EFGH. Legibly labelled points include E, F, G, H (the smaller parallelogram) and A, B, C, D (the large square). The relative positions of several corner-labels of the two nested figures could not all be resolved with certainty against the offset show-through. [Margin: l — Euclid I.29; m — Euclid I.6; n — Euclid I.32; o — Euclid I.34]

- E, F, G, H (the parallelogram FH about the diagonal)
- A, B, C, D (the large square, diagonal drawn A–C)

COROLLARIUM II

It likewise follows from the demonstration of this Proposition 4 that the diagonal of any square bisects its angles. For it was proved that the angles AEB, DEB are half-right, and so on — which we also demonstrated at Proposition 34 of Book 1.

SCHOLIUM [printed: SHOLIVM]

In numbers this fourth theorem will be exercised thus. Let the number 10 be divided at random into 7 and 3. You see, then, that 100, the square of the whole number, is equal to 49 and 9, the squares of the parts 7 and 3, together with the number 21, produced from 7 times 3, taken twice. For 49, 9, 21, and 21 make 100.

It will be very easy, moreover, to demonstrate from this fourth theorem the following further theorem.

[Added theorem — the doubling of a line and its square]

Enunciation. If one straight line is double another, the square described on the former is quadruple the square described on the latter; and if a square is quadruple another square, the side of the former is double the side of the latter.

Demonstration. Let AB be, first, double the line K. I say that the square on AB is quadruple the square on K. For if AB is bisected at C, and the construction of this fourth theorem is carried out, there will be four parallelograms AG, CI, IF, FH, which are squares and equal to one another, since all their sides are equal and all their angles right, as can easily be demonstrated from Proposition 34 of Book 1. Therefore, since the square AD is equal to the four squares AG, CI, IF, FH, the

square on the line AB will be quadruple the square on the line AC — that is, on the line K, which is equal to AC; for each of them is half of the line AB.

More briefly (BREVIVS). [Margin: p — Euclid II.4] The square on AB is equal to the squares on the lines AC, CB together with the rectangle contained twice by the lines AC, CB. Since the squares on the equal lines AC, CB are equal, and the rectangle contained by the equal lines AC, CB is itself also a square, equal to the square on AC, it follows that the square on AB is quadruple the square on AC, being equal to four squares each equal to the square on AC.

Next, let the square on AB be quadruple the square on K. I say that the side AB is double the side K. For if AB is bisected at C, so that AB is double AC, then, as has already been demonstrated, the square on AB will be quadruple the square on AC. But it was assumed also to be quadruple the square on K. Therefore the squares on the lines K and AC are equal, and so the lines K, AC are equal; but AB, by its construction, is double AC. It will therefore also be double K. All this, however, we shall demonstrate otherwise at Proposition 20 of Book 6.

Diagram. The figure for the doubling theorem: the square AD on AB, with the diagonal EB and the internal divisions CF and HI making the four equal squares AG, CI, IF, FH. The base runs A (bottom-left) — C (bottom-middle) — B (bottom-right); the top runs E (top-left) — F (top-middle) — D (top-right); the horizontal midline runs H (left) — G (centre) — I (right). At the left stands the separate reference segment K, equal to AC. [Margin: p — Euclid II.4]

- A (bottom-left corner)
- C (bottom edge, division point)
- B (bottom-right corner)
- E (top-left corner)
- F (top edge, above C)
- D (top-right corner)
- H (left edge, midpoint)
- G (centre, on the diagonal EB)
- I (right edge, midpoint)
- K (separate reference segment, equal to AC)

Furthermore, from this Proposition 4 a method can be gathered for finding a number which, together with any given number, makes a square number as well. For if 1 is subtracted from the given number, the square produced by multiplying half of the remainder by itself is the number sought. Thus, if the given number is

15, and a square number is sought which, together with the given 15, makes another square number, we subtract 1 from 15 and take half of the remaining 14, namely 7. For the square number 49, produced by multiplying that half by itself, is the number which, together with the given 15, makes up 64, a square number whose side is 8 — that is, a number greater by one unit than 7, the side of the square found. The reason for this is as follows. Since the square AD on the line AB is [Margin: q — Euclid II.4] equal to the two squares FH, CI on the parts AC, CB, together with the rectangle contained twice by AC, CB: if we set the gnomon HBF — which, together with the square FH, makes up the whole square AD — equal to 15 (that being the given number), and set the square CI equal to 1, so that its side CB is also 1, then each of the rectangles AG, DG will be 7, and hence the segment AC will be 7 (so that indeed AC times CB, which is 1, makes 7). The square FH will therefore be 49; and the whole side AB will be 8, greater by one unit than AC, the side of the square FH. This, then, is why, from the given number — that is, from the gnomon HBF — we subtract 1 and set half of the remainder as the side of the square FH that is sought.

But so that fractional numbers may be avoided, the given number should be odd, so that, once 1 is removed, the remaining number can be halved. The rule, however, is true whatever the given number may be.

We shall achieve the same thing if from the given number we take away any square number and divide half of the remainder by the side of the square taken away; the quotient will be the side of the square sought. Thus, if the number 45 is given for the gnomon HBF, we take away the square number 9 for the square CI, whose side is 3. Half of the remainder 36 is 18, for AG; this, divided by 3 — that is, by CG, the side of the square taken away, CI — gives the quotient 6, for the side GH, whose square FH, namely 36, added to the gnomon HBF (that is, to 45), makes the square number 81. But so that fractions may be avoided, the number must be so given that, when some square number is taken away, the remaining number has a half which the side of the square taken away measures exactly.

Conversely, we shall find a square number from which any given number, subtracted, leaves another square number. For if 1 is taken from the given number, and 1 is added to half of the remainder, the side of the square sought will be produced. Thus, if [again] ...

Clavius, *Opera Mathematica*, Tomus I — Commentary on Euclid's *Elements*, Book II

(continuation of the numerical scholium to Proposition 4)

again, let the given number be 15. Take away 1, and the half of the remaining number 14 will be 7; add 1 to this, and 8 will be produced, the side of the square sought. For 49 is a square number whose side is 7, which is always one unit less than the side of the square found. The ground of this rule, too, is easily drawn from the same figure of Proposition 4 of this [book]. For if we set the gnomon HBF — which, subtracted from the square AD, leaves the square FH — equal to 15 (which is of course the given number), and set the square CI equal to 1, and accordingly its side CB equal to 1 as well, then each of the rectangles AG and DG will be 7, and consequently the segment AC will be 7, as was said above, and the whole line AB will be 8, and so on.

[Margin: v.]

THEOR. 5. PROPOS. 5.

[Euclid, *Elements* II.5 — enunciation.] If a straight line is cut into equal and into unequal parts, the rectangle contained by the unequal segments of the whole, together with the square on the [segment] lying between the points of section, is equal to the square described on the half.

[Demonstration.] Let the straight line AB be divided in two at C, and unequally at D, so that the [line] between the sections is the straight line CD — the amount, that is, by which the half CB exceeds the smaller segment DB, or by which the greater segment AD exceeds the half AC. I say that the rectangle contained by the unequal segments AD and DB, together with the square on the straight line CD (which lies between the two sections), is equal to the square on the half CB.

Describe CF, the square on the half CB; and, the diagonal [diámetro] BE having been drawn, from D draw the straight line DG parallel to BF, cutting the diagonal BE at the point H, through which draw IK parallel to BC. Likewise from A draw AL parallel to CE, cutting IK produced at L. Then, by Corollary 1 of the preceding proposition, DI and KG will be squares, and therefore DH will be equal to the straight line DB; [Margin (a): *Elements* I.34] and KH is also equal to CD. Hence the rectangle AH will be contained by AD and DB, and KG will be the square on the straight line CD. What must be proved, therefore, is that the rectangle AH together with the square KG is equal to the square CF.

Now since [Margin (b): *Elements* I.43] the complements CH and FH are equal, if the common square DI is added, the parallelogram DF will be equal to the parallelogram CI. [Margin (c): *Elements* I.36] But AK is also equal to that same CI, since the bases AC and CB are equal. Therefore DF and AK will also be equal to one another; and if the common CH is added to them, the gnomon MNO will be equal to the rectangle AH. Consequently, since the gnomon MNO and the square KG are equal to the rectangle AH, the rectangle AH together with the square KG is equal to that same square CF. Therefore, if a straight line is cut into equal and unequal parts, and so on. Which was to be shown.

Diagram. The figure for Proposition 5. A large rectangle standing on the base line A–C–D–B (read left to right), with the square on the half CB built up at the right and a rectangle adjoined to its left; a semicircular arc is drawn about the central point H, and a diagonal runs from the top-left corner E to the bottom-right corner B. Labelled points:

- E (top-left corner): upper end of the diagonal EB
- G (top edge, middle): division of the top edge
- F (top-right corner)
- M (interior, upper-middle): corner-letter of the gnomon MNO
- L (left end of the middle horizontal)
- K (middle horizontal, left of centre)
- O (middle horizontal, near centre): corner-letter of the gnomon MNO
- H (centre): meeting of the diagonal, the horizontal IK, and the vertical through D
- I (right end of the middle horizontal)
- A (bottom-left corner)
- C (bottom edge, midpoint of AB)
- D (bottom edge, point of unequal section)
- B (bottom-right corner)

[The gnomon is named MNO in the text; M and O are legible on the figure, but a distinct point-letter N is not separately visible.]

SCHOLIUM.

[Scholium to Proposition 5.] Otherwise. We shall demonstrate this theorem together with Francesco Maurolico [Francesco Maurolico], in the manner in which the same result is demonstrated in numbers by the monk Barlaam [Barlaam of Seminara]; and this we shall do, together with the same Maurolico, in

the following propositions up to the eleventh exclusive. You will find these demonstrations adapted to numbers at Proposition 14 of Book 9 [*Elements* IX.14]. We shall therefore carry out our purpose as follows.

Since the square on CB [Margin (d): *Elements* II.4] is equal to the squares on CD and DB together with twice the rectangle contained by DB and CD; and since the rectangle contained by DB and CD, together with the square on DB, [Margin (e): *Elements* II.3] is equal to the rectangle contained by DB and CB — the square on CB will be equal to the remaining square on CD, together with the remaining rectangle contained by DB and CD, and the rectangle contained by DB and CB (that is, by DB and AC). But the rectangle contained by DB and AC, together with that contained by DB and CD, [Margin (f): *Elements* II.1] is equal to the rectangle contained by DB and the whole AD. Therefore the square on CB will be equal to the rectangle contained by AD and DB; that is, the rectangle contained by AD and DB, together with the square on CD, will be equal to the square on CB. Which was to be demonstrated.

Diagram. A small marginal line-diagram accompanying the scholium : a single horizontal straight line marked with points, illustrating AB bisected at C and cut unequally at D. Legible labels along the line: A (left end), C (middle), D (right of C). [The label at the right end (B) is not clearly legible: B?]

Now the same is manifest in numbers. Let the number 10 be divided equally into 5 and 5, and again unequally into 7 and 3, so that the middle number between the sections is 2 — that, namely, by which the half-number 5 exceeds the smaller part 3, and so on. You see, then, that the number 21, produced from 7 times 3, together with 4, the square of the intermediate number 2, is equal to 25, the square of the half-number 5.

From this Proposition 5, too, we shall find, in another way, a square number with which any given number will likewise make up a square number. For if 1 is added to the given number, and 1 is subtracted from the half of the composite number, the remainder will be the side of the square sought. Thus, if the given number is 15, adding 1 makes 16; and if 1 is taken from its half, 8, there remains 7, the side of the square 49 — with which the given number 15 makes up the square number 64, whose side is 8, which is always one unit greater than 7, the side of the square found. The ground of this rule is not difficult, from the demonstration of Proposition 5. For since the rectangle AH, together with the square KG, [Margin (g): *Elements* II.5] is equal to the square CF: if the rectangle AH is set equal to 15, as the given number, while the square DI is set equal to 1, and accordingly its side DB equal to 1 as well, so that 15 is produced from AD into

DB — namely the rectangle AH — then, 1 being added, the whole line AB will be 16; and if 1 is taken from its half, 8, there will remain CD, 7, which is of course the side of the square KG.

Here too, if fractional numbers are to be avoided, the given number must be odd, so that, 1 being added, it may be divided in two.

Conversely, we shall find a square number from which, if the given number be subtracted, the remainder will likewise be a square number. For if 1 is added to the given number, half the composite number will be the side of the square sought. Thus, if the given number is 15, adding 1 makes the half of the composite number 8, the side of the square 64 sought. For if you subtract the given number 15, the remaining number 49 will be a square, whose side, 7, is always one unit less than the side of the square found. The ground of this too is clear from the same figure of Proposition 5. For if the square KG (which, taken from the square CF, leaves the rectangle AH) is set equal to 15, as the given number, and the square DI set equal to 1, and accordingly its side DB equal to 1, then the whole line AB will be 16, and its half CB will be 8, and so on.

[Margin: vj.]

THEOR. 6. PROPOS. 6.

[Euclid, *Elements* II.6 — enunciation.] If a straight line is bisected and some straight line is added to it in a straight line, the rectangle contained by the whole together with the added line and by the added line, together with the square on the half, is equal to the square on the line that is composed both of the half and of the added line, as though described on a single line.

[Demonstration of Proposition 6.] Let the straight line AB be bisected at C, and let BD be added to it in a straight line. I say that the rectangle contained by the whole composite line AD and the added line DB, together with the square on the half CB, is equal to the square on the line CD, which is composed of the half CB and the added line BD.

Describe CE, the square on CD; and, the diagonal DF having been drawn, from B draw the straight line BG parallel to DE, cutting the diagonal DF at the point H, through which draw IK parallel to CD. Likewise from A draw AL parallel to CF, cutting IK produced at L. Then, by Corollary 1 of Proposition 4 of this book, BI and KG will be squares, and therefore the straight line DI will be equal to the straight line DB; [Margin (a): *Elements* I.34] and KH is also equal to the straight line CB. Hence the rectangle AI will be contained by the straight lines AD and DB, and KG

will be the square on the straight line CB. What must be proved, therefore, is that the rectangle AI together with the square KG is equal to the square CE.

Now since the parallelogram AK [Margin (b): *Elements* I.36] is equal to the parallelogram CH — the bases AC and CB being equal — [Margin (c): *Elements* I.43] and since the parallelogram HE is likewise equal to that same CH (complement to complement), AK and HE will be equal to one another. Therefore, the common CI being added, the rectangle AI will be equal to the gnomon MNO. Consequently, since the gnomon MNO and the square KG are equal to the square CE, the rectangle AI together with that same square KG will also be equal to that same square CE. And so, if a straight line is bisected and some straight line is added to it in a straight line, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 6. A large square standing on the base line A–C–B–D (read left to right), where AB is bisected at C and BD is added beyond B; the square is built on CD, with subdivisions marked; a semicircular arc is drawn about the central point H, and the diagonal runs from the top-left corner F down to the bottom-right corner D. Labelled points:

- F (top-left corner): upper end of the diagonal FD
- G (top edge, middle)
- E (top-right corner): [glyph slightly abraded, but required as the corner opposite C of the square CE]
- M (interior, upper-middle): corner-letter of the gnomon MNO
- L (left end of the middle horizontal)
- K (middle horizontal, left of centre)
- O (middle horizontal, near centre): corner-letter of the gnomon MNO
- H (centre): meeting of the diagonal, the horizontal IK, and the vertical through B
- I (right end of the middle horizontal)
- A (bottom-left corner)
- C (bottom edge, midpoint of AB)
- B (bottom edge, point of addition)
- D (bottom-right corner)

[As in the previous figure, the gnomon is named MNO; M and O are legible, but a distinct point N is not separately visible.]

SCHOLIUM.

[Scholium to Proposition 6.] Otherwise. Since the square on CD [Margin (d): *Elements* II.4] is equal to the squares on CB and BD together with twice the rectangle contained by DB and CB — that is, to the squares on CB and BD together with the rectangles contained by DB and CB and by DB and AC (taking AC once for CB, to which it is set equal) — and since the rectangles contained by DB and AC, by DB and CB, and by DB and DB (which is the square on DB) [Margin (e): *Elements* II.1] are equal to the rectangle contained by DB and the whole AD: therefore the square on CD is equal to the remaining square on CB, together with the rectangle contained by DB and AD. That is, the rectangle contained by AD and DB, together with the square on CB, is equal to the square on CD. Which was to be demonstrated.

Diagram. A small marginal line-diagram accompanying this scholium : a single horizontal straight line marked with points, illustrating the line AB with BD added. The legible labels along the line (reading as printed) are D, B, C, A. [Point-order reading uncertain owing to the small type: D?, B?, C?, A?]

Furthermore, if we are willing to consider the matter more attentively, we shall find that this Proposition 6 can most easily be demonstrated by means of the preceding Proposition 5 — a thing which that learned man, most practised in every kind of learning, Maurice Bressius [Maurice Bressius] of Grenoble, once Royal Professor of the mathematical disciplines in the University of Paris, also observed. For let the straight line AB be bisected at C, and let a straight line BD of any length be added to it. I say that the rectangle contained by the whole composite line AD and the added line BD, together with the square on the half CB, is equal to the square on the straight line CD, composed of the half and the added line.

For, added onto AD from the other side, let there be the straight line AE, equal to the added line BD; then the whole ED will be cut equally at C and unequally at B, since EA and AC are equal to DB and BC. The straight line EB will also be equal to the straight line AD, since EB is equal to DB and AB is common to both. [Margin (f): *Elements* II.5] Therefore the rectangle contained by the unequal parts EB and BD, together with the square on the intermediate section CB — that is, the rectangle contained by AD and BD, together with the square on the half CB — will be equal to the square on the half CD; that is, to the square on the line composed of the half CB of the given line AB and of the added line BD. Which is what was proposed.

Diagram. A small marginal line-diagram for the Bressius construction : a single horizontal straight line divided by tick-marks, illustrating ED cut equally at C and unequally at B, with EA added at the left. Legible labels along the line (left to right): E, A, C, B, D.

Now let the number 10 be bisected (so that we may adapt this theorem too to numbers) into 5 and 5, and let the number 2 be added to it. You see, then, that the number 24, which is produced from the whole composite number 12 into the added number 2, together with 25, the square of the half-number, is equal to 49, the square of that number 7 which is composed of the half 5 and the added 2.

Moreover, from this theorem there is gathered a remarkable property of arithmetical proportionality, which consists in the always-equal excess of proportional quantities. For since AD exceeds CD by the magnitude AC (that is, CB), and CD exceeds BD by the same magnitude BC, the three lines AD, CD, BD will have arithmetical proportionality; inasmuch as the first, AD, exceeds the second, CD, by the same excess AC (or CB) by which the second, CD, exceeds the third, BD. Hence, since it has been shown that the rectangle contained by the extremes AD and BD, together with the square on the excess CB, is equal to the square on the mean line CD, it is clearly gathered that in every arithmetical proportionality of three lines, the rectangle contained by the extremes, together with the square on the excess, is equal to the square on the mean line.

For three lines that are arithmetically proportional can always be so joined together as to make up a single line bisected in two (a line, that is, equal to the excess between the first and the third) together with the third. This is plain if three straight lines AD, CD, BD are given. For if from the first, AD, there be cut off DC, equal to the mean, and from this mean DC there be taken away the third DB, then AB (the excess between the first and the third) will be cut in two at C, with the third BD added to it. For since BC, the excess between the mean CD and the third BD, must be equal (on account of the arithmetical proportionality) to AC, namely the excess between the first AD and the mean CD, AB will necessarily be cut in two at C. And the same reasoning holds in the other cases. The same is seen in numbers that have the same excess. For in the numbers 4, 7, 10, which have the same excess 3, the number 40, produced from the extremes 4 and 10, together with 9, the square of the excess 3, is equal to the square number 49, which arises from the mean number 7.

From this Proposition 6, too, we shall find — as from Proposition 4 — a square number with which any given number will make up a square number as well. For if 1 is taken from the given number and the remaining number is bisected,

the square number of this half will be the one that is sought. Thus, if the given number is 15: 1 taken away leaves 14, whose half, 7, will give the square number 49 sought. For 15 with 49 makes the square number 64, whose side, 8, is one unit greater than 7, the side of the square found. The ground of this is manifest from this Proposition 6. For since the rectangle AI, together with the square GK, [Margin (g): *Elements* II.6] is equal to the square CE: if the rectangle AI is set equal to 15, and the square BI equal to 1, and accordingly its side BD equal to 1, then the whole line AD will be 15, since, multiplied into BD (1), it produces the rectangle AI, 15. So, 1 (BD) being taken away, there remains AB, 14, whose half, 7, will give CB, the side of the square KG sought.

It is necessary here too that the given number be odd, so that fractional numbers may be avoided — that is, so that, 1 being taken away, it may be divided in two.

Conversely, we shall find a square number from which, when the given number is subtracted, a square number likewise remains. For if 1 is taken from the given number, and 1 is again added to the half of the remaining number, the side of the square sought will be produced. Thus, if the given number is 15: 1 taken away leaves 14, the half of the remaining number 7; and, 1 being added, the side of the square sought, 8, is produced. For if from its square, 64, you subtract the given number 15, the remainder will be the square number 49, whose side, 7, is always one unit less than the side of the square found...

[printed p. 60 (recte 90)]

(continuation of the scholium to Proposition 6)

found, 8. The reason is that, if the rectangle AI (which, subtracted from the square CE, leaves the square KG) is set equal to 15, and the square BI [equal to 1], and accordingly its side BD equal to 1, then the whole line AD will be 15, as was said. So, 1 (BD) being taken away, AB will be 14; and if 1 is again added to its half CB, which is 7, the side CD, 8, will be produced, which is what is sought, and so on.

[Margin: vij.]

THEOR. 7. PROPOS. 7.

[**Euclid, *Elements* II.7 — enunciation.**] If a straight line is cut in any way, the squares on the whole and on one of the segments — whether the greater or the smaller — both together, are equal both to twice the rectangle contained by the whole and the said segment, and to the square made on the remaining segment.

[Demonstration.] Let the straight line AB be cut in any way at C. I say that the square on the whole AB, and the square on the segment (whether the greater or the smaller) AC, are equal to twice the rectangle contained by the whole AB and the said segment AC, together with the square on the remaining segment CB.

Describe upon AB the square AD; and, the diagonal BE having been drawn, from C draw the straight line CF parallel to AE, cutting the diagonal at the point G, through which draw HI parallel to AB. Then, by Corollary 1 of Proposition 4 of this book, CI and HF will be squares; and since the straight line GH [Margin (a): *Elements* I.34] is equal to the straight line AC, HF will be the square on the segment AC. Again, since AE is equal to AB, the rectangle AF will be contained by the whole AB and the segment AC. By the same reasoning the rectangle HD will be contained by the same straight lines AB and AC, since the straight lines DE and EH are equal to AB and AC, on account of the squares AD and FH. Now since the rectangles AF and FI, together with the square CI — that is, the gnomon KLM together with the square CI — are equal to the square AD, then, if the common square HF is added, the squares AD and HF will be equal to the rectangles AF and DH (each of which is contained by the whole AB and the segment AC), together with CI, the square on the remaining segment CB. Therefore, if a straight line is cut in any way, and so on. Which was to be demonstrated.

Diagram. The first (left) figure for Proposition 7. A square on the base A–C–B, subdivided by a vertical through C and a horizontal HI; the diagonal runs from the top-left corner E to the bottom-right corner B, and a semicircular arc is drawn about the central point G. Labelled points:

- E (top-left corner): upper end of the diagonal EB
- F (top edge, middle)
- D (top-right corner)
- H (left end of the middle horizontal HI)
- G (centre): meeting of the diagonal and the horizontal
- K (middle horizontal, right of centre): corner-letter of the gnomon KLM
- I (right end of the middle horizontal)
- M (interior, lower-middle): corner-letter of the gnomon KLM
- A (bottom-left corner)
- C (bottom edge, point of section)
- B (bottom-right corner)

[The gnomon is named KLM; K and M are legible, but a distinct point L is not separately visible.]

Diagram. The second (right) figure for Proposition 7, of the same construction with the section point taken so that the other segment is the greater. A square on the base A–C–B, with the diagonal from the top-left corner E to the bottom-right corner B and a semicircular arc about the central point G. Labelled points:

- E (top-left corner)
- F (top edge, middle)
- D (top-right corner)
- H (left end of the middle horizontal)
- G (centre)
- K (middle horizontal, right of centre)
- M (interior, lower-middle)
- A (bottom-left corner)
- C (bottom edge, point of section)
- B (bottom-right corner)

[A right-end horizontal label (I) is expected but not clearly legible in this second figure: I?]

SCHOLIVM.

[Scholium to Proposition 7.] Otherwise. Since the square on AB [Margin (b): *Elements* II.4] is equal to the squares on AC and CB together with twice the rectangle contained by AC and CB: if the common square on AC is added, the squares on AB and AC will be equal to twice the square on AC and the square on CB, together with twice the rectangle contained by AC and CB. But the rectangle contained by AC and CB, together with the square on AC, [Margin (c): *Elements* II.3] is equal to the rectangle contained by AB and AC; and therefore twice [that rectangle] is equal to twice the rectangle contained by AB and AC. Therefore the squares on AB and AC are equal to the remaining square on CB, together with twice the rectangle contained by AB and AC. Which was to be demonstrated.

Diagram. A small marginal line-diagram accompanying this scholium : a single horizontal straight line divided by a tick-mark, illustrating AB cut at C. The point-letters are too small to resolve individually: [labels illegible — A?, C?, B?].

In numbers, however: let the number 10 be divided in any way into 6 and 4. Then 100, the square number of the whole number 10, and 36, the square number of the part 6, are equal to the number 120 (which is made twice from the whole 10 into the part 6) together with 16, the square number of the other part 4, as is evident. So likewise 100, the square number of the whole number 10, and 16, the

square number of the part 4, are equal to the number 80 (which is made twice from the whole 10 into the part 4) together with 36, the square number of the other part 6.

EX FEDERICO COMMANDINO.

(From Federico Commandino [Federico Commandino].)

[Enunciation.] If a straight line is cut into unequal parts, the squares on those parts are equal to the rectangle contained twice by the said parts, together with the square on the line by which the greater part exceeds the smaller.

[Demonstration.] Let the straight line AB be cut into unequal parts AC and CB, and let AC be the greater part; and let a line AD be set equal to the smaller part CB, so that DC is the excess by which the part AC exceeds the part CB. I say that the squares on the parts AC and CB are equal to the rectangle contained twice by AC and CB, together with the square on the line DC.

For let the squares AE and CH be set up, and let DI be drawn parallel to CE, and let HG be produced to K. Now since AD is equal to CB, then, the common DC being added, the whole AC — that is, CE — will be equal to the whole DB. But CG is also equal to CB, since CH is a square. Therefore the remainder GE will also be equal to the remainder DC. And accordingly, since IE is also equal to DC, GE and IE will be equal; and therefore IG will be a square described on the excess DC. Now since the rectangles AI and DH are contained by the parts AC and CB (for AC is equal to each of the lines AF and DB, and CB to each of AD and BH), it is manifest that the squares AE and CH, on the parts AC and CB, are equal to the rectangles AI and DH — which are contained by the parts AC and CB — together with the square IG on the excess DC. Which is what was proposed.

Diagram. The figure for Commandino's theorem. A rectangle on the base A–D–C–B (read left to right), subdivided by verticals and a horizontal so as to display the two squares on the parts and the square on the excess. Labelled points:

- F (top-left corner)
- I (top edge, middle)
- E (top-right corner)
- K (middle horizontal, left)
- G (centre): meeting of the horizontal and the vertical through C
- H (middle horizontal, right)
- A (bottom-left corner)

- D (bottom edge, left division; AD equal to the smaller part CB)
- C (bottom edge, point of section)
- B (bottom-right corner)

SCHOLIUM.

[Scholium to Commandino's theorem.] In numbers. Let the number 10 be cut unequally into 4 and 6, so that the greater part exceeds the smaller by the number 2. You see, then, that the numbers 16 and 36, the squares of the parts — which make 52 — are equal to the number 24 (which is made from 4 into 6), taken twice, together with 4, the square of the excess 2, as the theorem required.

[Margin: viij.]

THEOR. 8. PROPOS. 8.

[Euclid, *Elements* II.8 — enunciation.] If a straight line is cut in any way, four times the rectangle contained by the whole and one of the segments, together with the square made on the remaining segment, is equal to the square described on the whole together with the said segment, as on a single line.

Book II — Proposition 8 (Theorem 8), demonstration

[Clavius's demonstration of the enunciation set out at the close of the preceding page.]

Let the straight line AB be divided at C in any way whatever. I say that the rectangle contained four times by AB and the segment CB — whether the larger or the smaller — together with the square on the remaining segment AC, is equal to the square on the line composed of the straight line AB and the said segment CB.

For let AB be produced toward the said segment CB, as far as D, and let BD be a straight line equal to the segment CB; and on the whole of AD let the square AE be described. Now, with the diagonal DF drawn, let BG and CI be drawn parallel to DE, cutting the diagonal at the points H and K; and through these points let LM and OP be drawn parallel to AD, cutting the earlier parallels at N and Q. Therefore, by the first corollary of Proposition 4 of this book, OI, NQ, BM, LG, and CP are squares about the diagonal DF.

And since OK is equal to the straight line AC [Margin (a): *Elements* I.34], OI will be the square on the segment AC. Again, since NH is equal to the straight line CB [Margin (b): *Elements* I.34], NQ will be the square on the segment CB, and

therefore equal to the square BM, since the straight lines CB and BD are equal. Hence the straight lines BH and HQ are equal to the segment CB; and so the two rectangles AH and LQ will be contained by AB and the segment CB, since LH is equal to the straight line AB [Margin (c): Elements I.34]. By the same reasoning the two rectangles NG and HE will be contained by AB and CB, since the straight lines NH and HM are equal to the straight lines CB and BD [Margin (d): Elements I.34], and the straight lines GH and EM are equal to FL — that is, to LH, that is, to AB.

And since the squares NQ and BM are equal, if the common square KG be added, BM and KG together will be equal to the rectangle NG. Therefore the five rectangles AH, LQ, HE, BM, and KG, which make up the gnomon RST, are equal to the rectangle contained four times by the straight line AB and the segment CB. Since, then, the gnomon RST together with the square OI is equal to the square AE, the rectangle contained four times by the given straight line AB and the segment CB, together with the square on the remaining segment AC, will be equal to the square on the line AD, which is composed of AB and the said segment CB. Therefore, if a straight line be divided in any way whatever, and so on. Which was to be demonstrated.

Diagram. A large square standing on the base AD, with the diagonal drawn from the top-left corner F to the bottom-right corner D, an inscribed circle, and an internal grid of parallels producing the squares and rectangles of the proof.

- A (bottom-left corner): endpoint of the divided line
- C (base, between A and B): the point of division of AB
- B (base, between C and D): the point where the smaller segment begins
- D (bottom-right corner): the endpoint to which AB is produced
- E (top-right corner): opposite corner of the square on AD
- F (top-left corner): corner from which the diagonal FD runs
- G (top edge, above B): where BG meets the top side
- O (left edge, upper): endpoint of parallel OP
- L (left edge, lower): endpoint of parallel LM
- P (right edge): endpoint of OP
- M (right edge, lower): endpoint of LM
- H, K (on the diagonal): intersections of BG, CI with the diagonal DF
- N, Q (interior): intersections of the horizontal parallels with the earlier verticals
- R, S, T (interior): the vertices marking the gnomon RST

- I (interior, right region): corner of square OI / CP [?]

Diagram. A second square on the base AD, drawn for the alternative case, again with a diagonal from the top-left corner F to the base, an inscribed circle, and the same lettering of internal parallels.

- A (bottom-left corner), C (base), B (base), D (bottom-right corner): the base as before
- F (top-left corner), I (top edge), G (top edge), E (top-right corner): the top side, left to right
- O (left edge), L (left edge): endpoints of the horizontal parallels
- P (right edge), M (right edge): the opposite endpoints
- R, T, K, Q (upper interior, along and about the diagonal): intersection points
- S (lower interior): vertex of the gnomon

Scholium

Alternatively: since the square on AD is equal to the squares on AB and BD together with twice the rectangle contained by AB and BD [Margin (e): Elements II.4] — that is, to the squares on AB and BC together with twice the rectangle contained by AB and BC — and since the squares on AB and BC are equal to twice the rectangle contained by AB and BC together with the square on AC [Margin (f): Elements II.7], the square on AD will be equal to the rectangle contained four times by AB and BC together with the square on AC. Which was to be demonstrated.

Now let the number 10 be divided in any way whatever, say into 6 and 4. Then the number 240, which is four times the product of the whole, 10, into the part, 6, together with 16 — the square of the other part, 4 — that is, the number 256, is equal to the square of the number 16, which is composed of the given number 10 and the said part 6, as is clear. In the same way, the number 160, which is four times the product of 10, the whole, into the part 4, together with 36 — the square of the other part, 6 — that is, the number 196, is equal to the square of the number 14, which is composed of 10 and 4, as is evident.

This proposition 8 can also be stated in the following way.

[Alternative enunciation:] If a straight line be cut in any way whatever, and to it there be added in a straight line another straight line equal to one of the segments, then the square on the whole composed line is equal to the rectangle contained four times by the given line and the added line — that is, the said segment — together with the square on the other segment.

For the straight line AB has been cut at C in any way whatever, and to it has been added BD equal to the segment CB; and it has been demonstrated that the square on the whole line AD is equal to the rectangle contained four times by the given line AB and the added line BD (that is, the said segment CB), together with the square on the other segment AC.

Or thus.

[A further enunciation:] If a straight line be bisected, and to it there be added in a straight line another straight line of any length whatever, then the square on the whole composed line is equal to the rectangle contained four times by the line composed of the half and the added part, and by the half, together with the square on the added part.

For the straight line DC has been bisected at B, and to it has been added CA; and it has been proved that the square on the whole AD is equal to the rectangle contained four times by AB (which is composed of BC, the half, and the added AC) and by the half CB, together with the square on the added part AC.

Diagram. A short vertical straight line marked with four points, illustrating the two alternative enunciations above.

- A (top): one end of the line
- C (below A): point of division / the half-point
- B (below C): the second point of division
- D (bottom): the far end

Moreover, from this Proposition 8 also we shall find, by another method, a square number such that any given number combined with it produces likewise a square number. For if from the fourth part of the given number 1 be subtracted, the remainder will be the side of the square sought. Thus, if the given number be 32, let 1 be taken from its fourth part, 8. The remaining number, 7, will give the square 49, with which the given number 32 makes the square 81, whose side, 9, is always greater by one unit than the fourth part of the given number. The reason for this is easy. For since the rectangle AH taken four times, together with the square OI, is equal to the square AE [Margin (g): Elements II.8], if the rectangle AH be set at 8 — namely the fourth part of the given number — while the square CH, and therefore CB its side, is 1, then the line AB will be 8, so that, multiplied into CB (=1), it makes 8. When 1 is therefore taken away, the remainder will be AC, the side of the square OI, equal to 7, which is what was sought.

But so that fractions may be avoided, it is necessary that the given number can be divided into four equal parts, so that it may be counted off by 4.

Conversely, we shall also find a square number from which the given number, subtracted, leaves a number that is likewise square. For if 1 be added to the fourth part of the given number, the side of the square sought will be produced. Thus, if the given number again be 32, and if 1 be added to its fourth part, 8, the side becomes 9; and if from the square of this, 81, the given number 32 be subtracted, there will remain the square number 49, whose side, 7, is always one unit less than the fourth part of the given number. The reason is that if the fourth part of the gnomon RST — which, taken from the square AE, leaves the square OI — that is, if the rectangle AH, which we demonstrated to be the fourth part of the gnomon RST, be set at 8, the fourth part of the given number 32, while the square BM, and therefore its side BD, is 1, then the line AB will be 8, as has been said, and so the whole side AD will be 9. From the square of this, AE, which is 81, if the gnomon RST be removed, which we assumed to be 32, the remainder will be the square OI, 49, whose side AC is 7 — inasmuch as AB was 8, and CB, that is BD, equal to it, is 1. And this side AC is perpetually one unit less than the fourth part of the given number 32, as has been said.

THEOR. 9. PROPOS. 9. [Margin: prop. viii.]

[Euclid's enunciation:] If a straight line be cut into equal and unequal parts, the squares on the unequal segments of the whole are together double both of the square on the half and of the square on the line lying between the points of section.

Book II — Proposition 9 (Theorem 9), demonstration

[Clavius's demonstration:] Let the straight line AB be bisected at C, and cut unequally at D. I say that the squares on the unequal segments AD and DB are together double of the squares that arise from the half AC and from CD, the line between the points of section. For from C let the perpendicular CE be erected to AB, equal to the half AC, or to CB, and let the straight lines EA and EB be joined. Then from D let the perpendicular DF likewise be drawn to AB, cutting EB at the point F; through F let FG be drawn parallel to AB, cutting CE at G; and finally let AF be joined.

Since, then, in the triangle ACE the sides CA and CE are equal, the angles CAE and CEA will be equal [Margin (a): Elements I.5]. But the angle ACE is a right angle; therefore the remaining angles [Margin (b): Elements I.32] will make up another

right angle, and so AEC will be half a right angle. By the same reasoning the angle BEC will be half a right angle; and on that account the whole angle AEB is a right angle. Again, since in the triangle FGE the angle EGF is equal to the right angle ECB — the exterior to the interior [Margin (c): Elements I.29] — the remaining two angles will be equal to one right angle [Margin (d): Elements I.32]. But it has been shown that the angle FEG is half a right angle. Therefore EFG too will be half a right angle, and consequently the angles EFG and FEG will be equal; and hence also the sides EG and GF are equal to one another [Margin (e): Elements I.6]. In the same way it will be shown that in the triangle BDF the sides BD and DF are equal. For the angle FDB is a right angle, and B half a right angle, and so on.

And so, since in the triangle ACE the angle C is a right angle, the square on the side AE will be equal to the two squares on the sides AC and CE [Margin (f): Elements I.47]. But these two squares are equal to one another, since the lines AC and CE are equal. Therefore the square on the side AE will be double the square on the side AC. Again, since in the triangle EGF the angle G is a right angle, the square on the side EF will be equal to the two squares on the sides EG and GF [Margin (g): Elements I.47]. But these two squares are equal to one another, because of the equality of the lines EG and GF. Therefore the square on the side EF will be double the square on the side FG — that is, the square on the line CD. For CD is a straight line equal to FG [Margin (h): Elements I.34].

Hence the two squares on the straight lines AE and EF are double the two squares on the straight lines AC and CD. But the two squares on AE and EF are equal to the square on AF [Margin (i): Elements I.47]; and the square on AF is equal to the two squares on AD and DF; therefore the two squares on AD and DF are double the two squares on AC and CD. But the square on DF is equal to the square on DB, for it has been shown that DF and DB are equal. Therefore the two squares on AD and DB, the unequal segments, are likewise double the squares on AC and CD — the half of the line and the line between the points of section. If, then, a straight line be cut into equal and unequal parts, and so on. Which was to be demonstrated.

Diagram. A right isosceles triangle standing on the base AB (extended to D), with apex E, the perpendicular CE, the perpendicular DF meeting EB at F, FG parallel to the base, and AF joined.

- A (bottom-left): endpoint of the line
- C (base, midpoint): point of bisection, foot of the perpendicular CE
- D (base, between C and B): point of unequal section, foot of the perpendicular DF

- B (base, right): the other endpoint
- E (apex, top): summit of the perpendicular CE
- F (interior, below and right of E): where DF meets EB
- G (interior, on CE): where FG meets the perpendicular CE

Scholium

Alternatively. Since the square described on the straight line AD is equal to the squares described on AC and CD, together with the rectangular parallelogram contained twice by the straight lines AC and CD [Margin (k): Elements II.4], if the common square on DB be added, the two squares on AD and DB will be equal to the three squares on AC, CD, DB, together with the rectangle taken twice under AC, CD (or under BC, CD). But the square on DB, together with twice the rectangle under BC, CD, is equal to the squares on BC (or AC) and on CD [Margin (l): Elements II.7]. Therefore the squares on AD and DB are equal to twice the squares on AC and CD; and consequently the squares on AD and DB are double the squares on AC and CD. Which was to be shown.

Alternatively, after Federico Commandino [Federico Commandino]. Since AC is equal to CB, and CB exceeds CD by the straight line DB, AC too will exceed CD by that same straight line DB [?]. Hence, as we showed at Proposition 7 of this book, the squares on the straight lines AC and CD are equal to twice the rectangle under AC, CD together with the square on the straight line DB; and consequently the squares on AC and CD, and the rectangle under AC, CD taken twice, together with the square on DB, are double the squares on AC and CD. But to the squares on AC and CD, together with the rectangle under AC, CD taken twice, the square on the straight line AD is equal [Margin (m): Elements II.4]. Therefore the squares on the straight lines AD and DB too are double the squares on AC and CD.

Now again let the number 10 be divided equally into 5 and 5, and also unequally into 7 and 3, so that the intermediate section is the number 2, as was said at Proposition 5. Then the squares of the numbers, 49 and 9, of the unequal parts 7 and 3, are double the squares 25 and 4 — of the half-number 5 and of the number 2 between the two sections — as is manifest.

And if it be pleasing, we shall also demonstrate this Proposition 9 from the construction itself, like the preceding ones, in the following way. Let the square AE be described on the whole line AB, and, with the diagonal BF drawn, let CG and DH be drawn through C and D parallel to the sides AF and BE, cutting the diagonal BF at Q and P. Since, then, by the first corollary of Proposition 4 of this book, all the rectangles about the diagonal are squares [Margin (n): Elements

I.34], and since LI is equal to AC, and QK to CD, and NK to AD, the figures NH and DO will be the squares on the unequal parts AD and DB, while LG and QP will be the squares on the bisected line AC and on CD, the intermediate section. I say that the former are double the latter.

For since the squares NH and DO exceed the squares LG and QP by the square DO and by the rectangles NI and IH — and since the square DO and the rectangles NI and IH are equal to the squares LG and QP, as will presently be demonstrated — it is clearly established that the squares NH and DO are double the squares LG and QP, since the latter are contained twice in the former. That the three rectangles DO, NI, and IH are equal to the squares LG and QP will be shown thus. The rectangle NI is equal to the rectangle QM [Margin (o): Elements I.36], because the straight lines NQ and QO are equal to the equal straight lines AC and CB [Margin (p): Elements I.34]. Therefore NI comprehends the square QP, and moreover KM. If, then, KM, DO, and IH be equal to the square LG, then DO, NI, and IH will necessarily be equal to the two squares LG and QP. That KM, DO, and IH are equal to the square LG we shall demonstrate thus. The rectangles KM and DO together are equal to PE, because the straight line BM [is equal to] CB, on account of the square CM [Margin (r): Elements I.34], and ME is equal to FL — that is, to LI, on account of the square LG, that is, to AC. When, therefore, the common IH is added, KM, DO, and IH will be equal to IE — that is, to the square LG [Margin (t): Elements I.36] — because IE and LG are equal, on account of the straight lines LI and IM being equal to the equal straight lines AC and CB [Margin (u): Elements I.34]. Which is what was proposed.

Diagram. The square AE on AB, with the diagonal from F to B, and the internal parallels CG, DH, LM, NO producing the squares LG, QP, NH, DO and the rectangles of the proof.

THEOR. 10. PROPOS. 10. [Margin: prop. x.]

[Euclid's enunciation:] If a straight line be bisected, and there be added to it in a straight line any straight line whatever, then the square on the whole with the added line, and the square on the added line, both together, are double both of the square on the half and of the square on the line composed of the half and the added line, described as on a single line.

Book II — Proposition 10 (Theorem 10), demonstration

[Clavius's demonstration:] Let the straight line AB be bisected at C, and let BD be added to it in a straight line. I say that the two squares on the straight lines AD and BD together are double of the squares described on the straight lines AC and CD. For on AB, from C, let the perpendicular CE be erected, equal to the half AC or CB, and let the straight lines AE and EB be joined. Then through D let DF be drawn parallel to CE, meeting the straight line EB, produced, at G; and through E let a line EF be drawn parallel to CD, cutting DF at F; and let the straight line AG be joined.

It will now be shown that the angle AEB is a right angle, as in the preceding proposition, and that CEB is half a right angle; and hence that its alternate angle EGF is likewise half a right angle [Margin (a): Elements I.29]. But the angle F is a right angle [Margin (b): Elements I.34], since in the parallelogram CF it is opposite the right angle C. Therefore the remaining angle FGE too [Margin (c): Elements I.32] will be half a right angle, and on that account equal to EGF. Hence the straight lines EF and FG, subtending the equal angles FEG and EGF, will likewise be equal [Margin (d): Elements I.6]. By the same technique you will show that the straight lines BD and DG are equal, because the angle BDG is a right angle and BGD half a right angle, and so on.

Since, then, the square on the straight line AE is equal to the equal squares on the equal straight lines AC and CE [Margin (e): Elements I.47], the square on the straight line AE will be double the square on the straight line AC. Again, since the square on the straight line EG is equal to the equal squares on the equal straight lines EF and FG [Margin (f): Elements I.47], the square on EG too will be double the square on EF — that is, on CD, since CD is a straight line equal to EF [Margin (g): Elements I.34]. Therefore the two squares on AE and EG are double the squares described on AC and CD. But to the two squares on AE and EG the square

on the straight line AG is equal [Margin (h): Elements I.47]; and to the square on AG are equal the two squares described on the two straight lines AD and DG. Therefore the squares on AD and DG are double the squares described on AC and CD. Since, then, the square on the straight line DG is equal to the square on the straight line BD, the squares on the straight lines AD and DB too will be double the squares described on AC and CD. And so, if a straight line be bisected, and so on. Which was to be shown.

Diagram. The bisected line AB extended to D, with the perpendicular CE, the parallel DF, the line EF, and AG joined, forming the figure of the proof.

- A (bottom-left): the far endpoint
- C (base, midpoint): the point of bisection, foot of the perpendicular CE
- B (base, right): the near endpoint
- D (base, right of B): the end of the added line BD
- E (upper-left): summit of the perpendicular CE
- F (upper-right): where EF meets DF
- G (lower-right, below D): where DF, produced, meets EB produced

Scholium

Alternatively. Since the square on AD is equal to the squares on AC and CD, together with twice the rectangle under AC, CD (or under BC, CD) [Margin (i): Elements II.4], if the common square on BD be added, the two squares on AD and BD will be equal to the three squares on AC, CD, BD, together with twice the rectangle under BC, CD. But the square on BD, together with twice the rectangle under BC, CD, is equal to the squares on CD and BC — that is, the squares on AC and CD [Margin (k): Elements II.7]. Therefore the squares on AD and BD are equal to twice the squares on AC and CD; and consequently the squares on AD and BD are double the squares on AC and CD. Which was to be demonstrated.

Alternatively, after Federico Commandino. Since AC is equal to CB, and [CB] exceeds CD [?], CD too will exceed AC by the same straight line BD. Hence, as we showed at Proposition 7 of this book, the squares on the straight lines AC and CD are equal to twice the rectangle under AC, CD together with the square on the straight line BD; and consequently the squares on AC and CD, and the rectangle under AC, CD taken twice, together with the square on BD, are double the squares on the straight lines AC and CD. But to the squares on the straight lines AC and CD, together with the rectangle under AC, CD taken twice, the square on the straight line AD is equal [Margin (l): Elements II.4]. Therefore the squares on AD and BD too are double the squares on AC and CD.

Let the number 10 be bisected into 5 and 5, and to it let any number, say 3, be added, so that the whole composed number is 13. Then the squares of the numbers 169 and 9, of these numbers 13 and 3, are double the square numbers 25 and 64, which are generated from the two numbers 5 and 8, as is evident.

Diagram. A short vertical straight line marked with four points, accompanying the alternative demonstrations above.

- A (top): one end
- C (below A): the point of bisection
- B (below C): the near endpoint
- D (bottom): the end of the added line

But this Proposition 10 too will easily be demonstrated from the preceding Proposition 9, just as above Proposition 6 was demonstrated from Proposition 5. For let the straight line AB be bisected at C, and let a straight line BD of any length be added to it. I say that the two squares on the straight lines AD and BD together are double of the two squares on the straight lines AC and CD together. For if to AB, on the side of A, there be added the straight line AE, which is equal to the added BD, then the whole ED will be cut at C into two equal parts, and at B into unequal parts, because EA and AC are equal to DB and BC. The straight line EB too will be equal to AD, and AB is common to both. Therefore the squares on the straight lines EB and BD — that is, on AD and BD — will be double the squares on the straight lines EC and CB [Margin (m): Elements II.9], that is, on CD and AC. Which is what was proposed.

Diagram. A horizontal straight line marked with five points, illustrating the reduction of Proposition 10 to Proposition 9.

- E (leftmost): the endpoint of the added segment
- A (next): the original left endpoint
- C (middle): the point of bisection
- B (next): the original right endpoint
- D (rightmost): the end of the added line BD

And if it be pleasing to demonstrate this same Proposition 10 from the construction itself, as we showed the preceding Proposition 9, it will be done in the following way. Let AD be produced to E, so that DE is equal to the added line BD; and, with the square AF described on the whole line AE, let CH, BI, DK be drawn through C, B, D parallel to the sides AG, EF, cutting the drawn diagonal EG at the points L, M, N; and through these let OP, QR, ST be drawn parallel to the

sides AE, GF, cutting the earlier lines at V, X, Y, Z, a, b. Since, then, by Proposition 4 of this book, all the rectangles about the diagonal EG are squares [Margin (n): Elements I.34], and since SN is equal to AD, and OL to AC, and aN to CD, then SK will be the square on the straight line AD, and DT the square on the straight line DE (or BD), and OH and aX the squares on the straight lines AC and CD. I say that the squares SK and DT together are double of the squares OH and aX together.

For since the squares SK and DT exceed the squares OH and aX by the square DT and by the rectangles SL and LK — and since the square DT and the rectangles SL and LK are equal to the squares OH and aX, as will presently be demonstrated — it clearly follows that the squares SK and DT are double of the squares OH and aX, since the latter are contained twice in the former. That the three rectangles DT, SL, and LK are equal to the squares OH and aX will be made plain thus. The rectangle QL is equal to the square OH [Margin (o): Elements I.36], because the lines QO and OG are equal — inasmuch as QO is equal to YL, and YL to OG, on account of the equal rectangles YV and OH, whose sides OL and LV are equal [Margin (p): Elements I.34]. Likewise SY is equal to aM, and LI to YV, and VK to VZ, and DT to bZ [Margin (q): Elements I.34]. Therefore the five rectangles QL, SY, LI, VK, DT — that is, the three rectangles DT, SL, LK — are equal to the five rectangles OH, aM, YV, VZ, bZ, that is, to the two squares OH and aX. Which is what was proposed.

PROBLEMA 1. PROPOSITIO 11. [Margin: prop. xj.]

[*Euclid's enunciation:*] To cut a given straight line so that the rectangle contained by the whole and one of the segments is equal to the square that is made from the remaining segment.

Euclid, *Elements*, Book II — Clavius's commentary (continued)

Proposition 11 (Problem 1) — demonstration concluded

Let AB be the given straight line, which we must cut into two parts in such a way that the rectangle contained by the whole AB and one of its segments — namely the smaller — is equal to the square on the remaining segment, that is, on the larger. On AB describe a square, and, having bisected at E the side AD (which makes a right angle with the given line AB), join the straight line EB. Along EA produced take EF equal to EB, and from the straight line AB cut off AG equal to AF.

For AB is greater than AF. [Margin: a — I.20] Since EB is equal to EF by construction, and the sides AE, AB are together greater than the side EB, the straight lines EA and AB will likewise be greater than the straight line EF; and so, when the common part AE is taken away, the remainder AB will be greater than the remainder AF.

I say that AB has been cut at G in such a way that the rectangle contained by AB and BG is equal to the square on the straight line AG — so that AG is the larger segment and BG the smaller. For through G draw the straight line HI parallel to DF, cutting CD at I; and through F draw FH parallel to AG, cutting HI at H. Then the parallelogram AH will be the square on the segment AG, since all four of its sides are equal — inasmuch as [Margin: b — I.34] FH and GH are equal to their opposites AG and AF, which are equal — and all its angles are right on account of the right angle at A, as we showed at Definition 1 of this book. The rectangle CG, moreover, will be contained by AB and the segment BG, since AB is equal to BC. It must therefore be proved that the rectangle CG and the square AH are equal.

Now since the straight line DA has been bisected at E and AF added to it in a straight line, [Margin: c — II.6] the rectangle DH (since FH is equal to FA), together with the square on the half AE, is equal to the square on the straight line EF — that is, to the square on the straight line EB, which is equal to EF. But the

square on EB is [Margin: d — I.47] equal to the squares on the straight lines AE and AB. Therefore the rectangle DH, together with the square on the straight line AE, is likewise equal to the squares on the straight lines AE and AB. When the common square on AE is removed, the rectangle DH will remain equal to the square on the straight line AB — that is, to the square AC. Therefore, when in turn the common rectangle AI is taken away, the rectangle CG and the square AH will remain equal to one another. This was what was proposed. We have therefore cut the given straight line AB, and so on. Which was to be done.

Diagram. The square described on AB, drawn with its interior division for the golden-section construction. All nine point-labels were read on the leaf.

- C (top-left corner of the square)
- B (top-right corner of the square)
- I (on the left side CD, at mid-height)
- G (interior, at the crossing of the horizontal line HI with the vertical rising from A; the point of section)
- H (on the right side BF, at mid-height)
- D (bottom-left corner)
- E (on the bottom side, left of centre; midpoint of the side DA)
- A (on the bottom side, right of centre)
- F (bottom-right corner)

A horizontal line I–G–H divides the square at mid-height; a vertical line rises from A to G; a diagonal runs from E up to B. Per the demonstration, the small square A–F–H–G (lower right) is the square on the greater segment AG, and the rectangle CG (upper region) is the rectangle contained by AB and the lesser segment BG.

Scholium **

This problem cannot in any way be fitted to numbers. For no number can be divided into two numbers such that the number produced from the whole into one of the parts is equal to the square of the other part — as we shall demonstrate at Proposition 14 of Book 9, where we shall also demonstrate in numbers the ten theorems that precede this one in the present book. And more clearly, at Proposition 29 of the same Book 9, we shall show that this Problem 11 can in no way be accommodated to numbers.

The practical execution of this problem, however, is not difficult. For at the extreme point A, where the greater segment must terminate, erect on the given line AB a perpendicular AD equal to the given line AB; bisect it at E; and if, at the

interval EB, EA be cut back and produced to F, then AF will be equal to the greater segment AG, as has been demonstrated.

Theorem 11. Proposition 12 **

[Margin: xij.]

Enunciation. In obtuse-angled triangles, the square on the side subtending the obtuse angle is greater than the squares on the sides containing the obtuse angle, by twice the rectangle contained by one of the sides about the obtuse angle — namely the one onto which, when produced, the perpendicular falls — and the line taken outside, cut off by the perpendicular near the obtuse angle.

Demonstration. Let the triangle ABC have the angle ABC obtuse, and from A let the perpendicular AD fall onto the side CB produced toward the part of the obtuse angle. I say that the square on the side AC, which is opposite the obtuse angle, is greater than the squares on the sides AB, BC by twice the rectangle contained by CB and BD — that is, that the square on the side AC is equal to the two squares on the sides AB, BC together with twice the rectangle contained by CB and BD.

For since the straight line CD has been divided at B in any manner whatever, [Margin: a — II.4] the square on the straight line CD will be equal to the two squares on the straight lines CB, BD together with twice the rectangle contained by CB, BD. Therefore, when the common square on the straight line AD is added, the two squares on the straight lines CD, DA will be equal to the three squares on the straight lines CB, BD, DA together with twice the rectangle contained by CB, BD. But [Margin: b — I.47] the square on the straight line AC is equal to the squares on the straight lines CD, DA. Therefore the square on the straight line AC will also be equal to the three squares on the straight lines CB, BD, DA together with twice the rectangle contained by CB, BD. And since [Margin: c — I.47] the square on the straight line AB is equal to the squares on the straight lines BD, DA, the square on the straight line AC will be equal to the squares on the straight lines CB, BA together with twice the rectangle contained by CB, BD. In obtuse-angled triangles, therefore, the square that is formed, and so on. Which was to be shown.

Diagram. The obtuse triangle for Proposition 12, with the perpendicular dropped onto the base produced. Four point-labels read on the leaf.

- A (apex, upper right)
- C (lower-left vertex)
- B (on the base, right of C; the obtuse angle ABC)

- D (foot of the perpendicular from A, on CB produced beyond B, at lower right)

The perpendicular AD is drawn from A to D; AC subtends the obtuse angle at B.

Scholium **

Here Euclid has demonstrated by how much, in an obtuse-angled triangle, the square on the side opposite the obtuse angle is greater than the squares on the other two sides. In the following Proposition 13 he will show by how much the square on the side opposite an acute angle is less than the squares on the two remaining sides — as we noted at the beginning of the scholium to Proposition 47 of Book 1.

Now since Euclid assumed that the perpendicular drawn from A falls onto the side CB produced toward the part of the obtuse angle, we shall demonstrate this point briefly. Let the angle ABC be obtuse in the triangle ABC, and let the side CB be produced toward B. I say that the perpendicular drawn down from A falls outside the triangle, onto the side CB produced — of which sort is the straight line AD. For if it were to fall inside the triangle — of which sort is the straight line AE — the two angles ABE and AEB would be greater than two right angles, since the former is obtuse and the latter right. And this is contrary to Proposition 17 of Book 1. But if it were to fall outside the triangle onto the side BC produced toward the part of C — of which sort is the straight line AF — then again, in the triangle ABF, the two angles ABF and AFB would be greater than two right angles, since the former is obtuse and the latter right. Which is absurd.

Diagram. The obtuse triangle illustrating that the perpendicular from A falls outside the triangle. Apex and five base-labels read on the leaf.

- A (apex, upper right)
- F (leftmost point of the base, beyond C)
- C (base vertex, left)
- E (on the base, between C and B; the hypothetical interior foot)
- B (base vertex; the obtuse angle)
- D (rightmost, on CB produced beyond B; the true foot of the perpendicular)

Lines are drawn from A to F, C, E, B, and D (variously dotted/dashed).

But this theorem too is true:

Enunciation (converse of Proposition 12). If in a triangle the square on one side is greater than the two squares on the two remaining sides, then the angle opposite that side will be obtuse.

Demonstration. In the triangle ABC let the square on the side AC be greater than the squares on the sides AB, BC. I say that the angle B, which the side AC subtends, is obtuse. For from B, to AB, draw the perpendicular BD equal to the line BC, and join the straight line AD. Since then the square on AD is [Margin: d — I.47] equal to the squares on AB, BD — that is, on AB, BC — while the square on AC is assumed greater than the squares on AB, BC, the square on AD will be less than the square on AC, and therefore the straight line AD is less than the straight line AC. And so, since the sides AB, BC of the triangle ABC are equal to the sides AB, BD of the triangle ABD, each to each, while the base AC is greater than the base AD, [Margin: e — I.25] the angle ABC will be greater than the angle ABD. But ABD is a right angle. Therefore ABC is greater than a right angle, and will be obtuse. This is what was proposed.

Diagram. The triangle for the converse of Proposition 12, with the auxiliary perpendicular BD.

- A (apex, upper right)
- C (lower-left vertex)
- B (on the base, between C and D — the obtuse angle; the printed glyph reads ambiguously as "E" [?], but the construction requires B here)
- D (lower right, foot of the perpendicular BD dropped from B; below A)

AD is joined; BD is the perpendicular to AB, set equal to BC.

Moreover, we shall demonstrate the converse of this Proposition 12 — namely:

Enunciation (second converse). If in a triangle the square on one side is greater than the squares on the two remaining sides by twice the rectangle contained by one of these sides and by the exterior line which the straight line dropped from the opposite angle cuts off from that side when produced: then this dropped line will be perpendicular to the produced side, and the angle of the given triangle opposite that former side will be obtuse.

Demonstration. In the triangle ABC let a straight line AD be dropped from the opposite angle A onto the side CB produced, and let the square on the side AC be greater than the squares on the sides AB, BC by twice the rectangle contained by CB, BD. I say that AD is perpendicular to CD, and that the angle ABC is obtuse. For

if AD is not the perpendicular, let a perpendicular be drawn from A to CB, which I say must of necessity fall onto CB produced toward the part of B.

First, let it fall, if it can, at B, so that AB is the perpendicular to CB. Then [Margin: f — I.47] the square on AC will be equal to the squares on AB, BC — which is absurd, since it is assumed greater. The perpendicular dropped from A onto CB therefore does not fall at the point B.

Second, let the perpendicular dropped from A fall, if it can, onto the side BC — of which sort is AF. Then [Margin: g — I.47] the square on AC will be equal to the squares on AF, FC. But the square on AC is assumed greater than the squares on AB, BC; therefore the squares on AF, FC will also be greater than the squares on AB, BC. Yet the squares on AB, BC are in fact greater than the squares on AF, FC, since the straight line AB, being opposite the right angle AFB, is [Margin: h — I.19] greater than AF, and BC as a whole is greater than its part FC. The perpendicular dropped from A therefore does not fall onto CB.

Third, let the perpendicular dropped from A onto the side BC fall, if it can, at C, so that AC is the perpendicular. Then [Margin: i — I.47] the square on AB will be equal to the squares on AC, CB, and so the square on AB will be less than the squares on AB, BC — which is absurd, since it is assumed greater. The perpendicular dropped from A onto BC therefore does not fall at C.

Fourth, let the perpendicular from A fall, if it can, onto BC produced toward the part of C — of which sort is AG. Since then [Margin: k — I.17] the two angles AGC, ACG are less than two right angles, and AGC is right, ACG will be less than a right angle, and consequently ACB obtuse. [Margin: l — I.19] The straight line AB will therefore be greater than AC, and on that account the square on AG will be less than the square on AB, and so very much less than the squares on AB, BC; yet it is assumed greater — which is absurd. Since therefore the perpendicular dropped from A onto CB falls neither at B, nor between C and B, nor at C, nor beyond C, it will fall beyond B — of which sort is AD, as will be demonstrated. [Margin: m — I.17] Hence the angle ABE will be acute and ABC obtuse. Which was the thing proposed in the second place, to be demonstrated.

That the angle ABC is obtuse, if the square on the straight line AC is greater than the squares on the straight lines AB, BC, we have demonstrated more easily in the preceding theorem of this scholium. From this it follows (as we showed at the beginning of this scholium) that the perpendicular dropped from A onto CB falls outside the triangle ABC, toward the part of the obtuse angle.

That AD is perpendicular to CB, we shall demonstrate thus. If it is not, let AE be drawn perpendicular to CB, falling beyond B, as we showed. Since then the angle ABC has been shown obtuse, the square on the straight line AC will be greater than the squares on the straight lines AB, BC by twice the rectangle contained by CB, BE. But the square on the same straight line AC is also assumed greater than the squares on the same straight lines AB, BC by twice the rectangle contained by CB, BD. Therefore the squares on AB, BC together with the rectangle contained by CB, BD will be equal to the squares on AB, BC together with twice the rectangle contained by CB, BE. And when the common squares on the straight lines AB, BC are taken away, twice the rectangle contained by CB, BE will be equal to twice the rectangle contained by CB, BD; and consequently the rectangle contained once by CB, BE will be equal to the rectangle contained once by CB, BD, and the straight line BE equal to the straight line BD — a part to the whole, or the whole to a part. Which is absurd. AD, therefore, is perpendicular to CD, and no other line is. This is what was proposed.

Diagram. The tall triangle enumerating the possible positions of the foot of the perpendicular from A. Apex and the crowded base-labels read on the leaf.

- A (apex, at top)
- G (leftmost of the base, on BC produced beyond C)
- C (base vertex, next to G)
- F (on the base, between C and B)
- B (base vertex; the obtuse angle)
- E (on CB produced beyond B)
- D (on CB produced beyond B; the true foot)
- (a further label at the extreme right of the base reads as "E" [?] — the base is very crowded at this resolution)

Lines run from A to each base-point (variously solid, dashed, and dotted).

Now, since neither this twelfth theorem nor the following thirteenth can, in every case, be explained through numbers — because, one side of a triangle being posited as any number of equal parts you please, the other sides, and the parts of them made by the perpendicular lines, for the most part cannot be expressed in numbers, but are lines incommensurable with that side (which did not happen in the preceding propositions, since, a divided straight line being posited as any number of equal parts, its parts can be set at will commensurable with it, as was done in the numerical examples employed) — we shall prescribe certain rules by which geometrical

obtuse-angled and acute-angled triangles (as many as one wishes) may be constructed of such a kind that all their sides, and the parts of them made by the perpendicular lines, are commensurable lines — so that the truth of each theorem may appear in numbers as well. Here, however, we shall treat of obtuse-angled triangles, and in the scholium to the following proposition, of acute-angled ones.

Now since an obtuse-angled triangle is either isosceles — in which the third side, which is opposite the obtuse angle, is always [Margin: m — I.9] the greater (for it cannot be equilateral, as we said at Definition 27 of Book 1) — or scalene; and since in the scalene case the perpendicular line falls either onto the smallest side produced, or onto the middle side: we shall set out three rules. In the first we shall exhibit an isosceles obtuse-angled triangle with commensurable sides, in which the segment of either of the equal sides produced, lying between the perpendicular and the obtuse angle, is also commensurable with those same sides. In the second we shall construct a scalene obtuse-angled triangle, likewise with commensurable sides, and in which the segment of the smallest side produced, lying between the perpendicular and the obtuse angle, is commensurable with those same sides. In the third, finally, we shall propose a scalene obtuse-angled triangle with commensurable sides, and in which the segment of the middle side produced, lying between the perpendicular line and the obtuse angle, is commensurable.

Rule I **

To construct an isosceles obtuse-angled triangle with commensurable sides, in which the exterior segment of one of the equal sides produced, lying between the perpendicular line and the obtuse angle, is likewise commensurable with those same sides: let the exterior segment be set as a number of equal parts such that their number is counted by 7 — as 7, or 14, or 21, or 28, and so on. Then let each of the equal sides be taken as two and four-sevenths ($2\frac{4}{7}$) of the said segment, and the greatest side, opposite the obtuse angle, as four and two-sevenths ($4\frac{2}{7}$) of the same segment — as, in the triangle ABC, let CD be drawn to BA, the side produced.

If, then, AD is set at 7 parts, and each of the sides AB, AC at 18 parts (which number you get if you double 7 and add four-sevenths of it), and the side BC at 30 parts (which number you will have if you quadruple 7 and add to it two-sevenths of it), the triangle ABC will be the one sought. For in this triangle the square on the side BC is 900, to which are equal the squares on the sides AB, AC — namely 324 and 324 — together with twice the rectangle contained by AB, AD, that is,

with 126 and 126. For these also make up the sum 900. Hence, as we have shown in this scholium, CD drawn to BD will be perpendicular, and the angle BAC obtuse.

And if you multiply each of the numbers of this triangle by any number, you will produce other lines of the triangle commensurable, yet proportional to the former ones. Thus if you double the numbers found, you will make AD 14, both AB and AC 36, and BC 60. You will also find the required triangle by setting the exterior segment AD at any number of parts, even if they are not counted from 7 — but then the sides will be whole numbers with fractions. Finally, you will hit upon the triangle by setting whatever side you wish to begin from at any number of parts, provided that the greatest is made four and two-sevenths of the segment AD, and each of the equal sides two and four-sevenths of the same segment.

Diagram. The isosceles obtuse triangle for Rule I, with numerical labels read on the leaf.

- D (apex region, top; BA produced meets the perpendicular from C at D)
- A (just below D; vertex of the obtuse angle BAC)
- B (bottom-left vertex)
- C (bottom-right vertex)
- Side AB (left): 18
- Side AC (right): 18
- Base BC: 30
- Exterior segment AD: 7

Rule II **

To produce a scalene obtuse-angled triangle with commensurable sides, in which the perpendicular falling onto the smallest side produced makes an exterior segment commensurable with the sides also: let the exterior segment be set as any number of equal parts you please, counted from 5 — as 5, or 10, or 15, or 20, and so on. To these if you add three-fifths, you will have the smallest side. But if you triple the same parts of the said segment and add one-fifth — or if you double the parts of the smallest side already found — you will make the middle side. And if, finally, you quadruple the same parts of the said segment, you will find the greatest side.

Thus, if in the triangle set before us the segment AD is set at 10, then AB will be 16, AC 32, and BC 40. Here too you see that to the square on the side BC, which is 1600, are equal the squares on the sides AB, AC — namely 256 and 1024 —

together with twice the rectangle contained by AB, AD, that is, with 160 and 160. From this it follows that CD is perpendicular to BD, and the angle BAC obtuse, as we showed above in this scholium.

Now if you multiply each of the numbers found by any number, other numbers proportional to them will be generated, which will do the same. Thus if you double them, the side AB will be 32, AC 64, and BC 80 — which numbers will indeed be found by the same art if you set the exterior segment AD at 20 parts, which have the double proportion to the former parts, 10. So too, if you triple the same numbers, you will make the exterior segment AD 30 parts, the side AB 48, AC 96, BC 120; and so on in succession.

Diagram. The scalene obtuse triangle for Rule II, with numerical labels read on the leaf.

- D (top; the smallest side produced meets the perpendicular at D)
- A (below D; vertex of the obtuse angle)
- B (bottom-left vertex)
- C (bottom-right vertex)
- Exterior segment AD: 10
- Side AB: 16
- Side AC: 32
- Base BC: 40

Rule III **

For a scalene obtuse-angled triangle with commensurable sides, in which the perpendicular line falling onto the middle side produced likewise makes a segment commensurable with the sides of the triangle: take again the exterior segment as any number of parts you please, counted from 5, as in the preceding rule. If you triple these and add one-fifth, you will produce the smallest side. But if you multiply the same by 6 and add two-fifths, you will have the middle side. And if, finally, you multiply the same by 8, you will produce the greatest side.

Thus, if in the triangle proposed the segment AD is made 5 parts, then AB will be 16, AC 32, and BC 40. And so, to the square on the side BC — namely 1600 — will be equal the squares on the sides AB, AC — namely 256 and 1024 — together with twice the rectangle contained by AC, AD, that is, with 160 and 160. And consequently BD will be perpendicular to CD, and the angle BAC obtuse, as we demonstrated above in this scholium.

And if you multiply the numbers found by any number, you will find other numbers of the sides proportional to them, in which this same Proposition 12 will be verified. Thus if you quadruple them, you will make the exterior segment AD 20 parts, the side AB 64, AC 128, and BC 160. And if you multiply those same former numbers by 10, the exterior segment AD will be 50, the side AB 160, AC 320, and BC 400. And so on to infinity.

Diagram. The elongated scalene obtuse triangle for Rule III, with numerical labels read on the leaf.

- D (upper left; the middle side produced meets the perpendicular at D)
- A (next to D; vertex of the obtuse angle)
- B (bottom-left vertex)
- C (bottom-right vertex, far to the right)
- Exterior segment AD: 5
- Side AB: 16
- Side AC: 32
- Base BC: 40

Beware, however, of supposing that, one side of an obtuse-angled triangle (or the exterior segment) being posited as any number of equal parts, the other sides must necessarily keep with it those proportions which we have set out in the foregoing rules: so that, one being known, the remaining

(Continuation of the scholium to Proposition 12, from the foot of the preceding page.)

may also be known. For this is false, since those [values] can be varied in a thousand ways and can bear one proportion after another. And so, from the three prescribed rules, the only thing to be gathered will be this: that from straight lines which preserve the said proportions an obtuse-angled triangle [triangulum amblygonium] can be constructed, together with the exterior segment, in which the truth of proposition 12 can be examined.

THEOR. 12. PROPOS. 13.

[Margin: xiiij.]

Enunciation (Euclid, Elements II.13).

In acute-angled triangles [oxygoniis triangulis], the square on the side subtending the acute angle is less than the squares on the sides containing the acute angle by twice the rectangle contained by one of the sides about the acute angle — namely the one on which the perpendicular falls — and the straight line cut off within by the perpendicular toward the acute angle.

Demonstration (Clavius).

Let all the angles of triangle ABC be acute, and from A let the perpendicular AD, when dropped, fall on the side BC. I say that the square on the side AB, which is opposite the acute angle ACB, is less than the squares on the sides AC, CB about the said acute angle by twice the rectangle contained by BC, CD — that is, that the square on the side AB, together with twice the rectangle contained by BC, CD, is equal to the two squares on the sides AC, CB.

For since the straight line BC has been divided at D, in whatever manner, the squares on BC, CD [Margin: a. Elem. II.7] are equal to twice the rectangle contained by BC, CD together with the square on BD. Adding, then, the common square on DA, the three squares on BC, CD, DA will be equal to twice the rectangle contained by BC, CD together with the two squares on BD, DA. But the two squares on CD, DA are equal to [Margin: b. Elem. I.47] the square on CA. Therefore the two squares on BC, CA are equal to twice the rectangle contained by BC, CD together with the two squares on BD, DA. Since, then, the two squares on BD, DA are equal to [Margin: c. Elem. I.47] the square on AB, the two squares on BC, CA will be equal to twice the rectangle contained by BC, CD together with the square on AB — which is what was proposed.

In the same way it will be shown that the squares on AB, BC are equal to twice the rectangle contained by CB, BD together with the square on AC — that is, that the square on the side AC is less than the squares on the sides AB, BC by twice the rectangle contained by CB, BD. Therefore, in acute-angled triangles, the square on the side [subtending the acute angle], and so on. Which was to be demonstrated.

Diagram. Three acute-angled triangles set side by side, illustrating the different positions the foot of the perpendicular may take. In each, A is the apex, BC the base, and AD the perpendicular dropped from A to the base (foot D).

- A (apex of each triangle): vertex from which the perpendicular is dropped
- B (left end of base): base vertex
- C (right end of base): base vertex (the acute angle in question, ACB)

- D (on the base, foot of the perpendicular AD): in the first triangle D lies close to C; in the second, roughly midway; in the third, close to B — showing the perpendicular meeting BC at varying points

SCHOLIUM.

And so, from three propositions — namely I.47, and II.12, and II.13 of this book — we know how great the square on any side of a triangle is, compared with the squares on the other two sides: whether, that is, it is equal to them, or greater, or less, and by how much it is greater or less, according as the angle opposite the assumed side is right, or obtuse, or acute.

Although Euclid proposes this theorem only for acute-angled triangles — those, namely, that have all their angles acute — the same is nevertheless true also for right-angled and obtuse-angled triangles [in the three triangles set out in the figure]. For in these triangles the two remaining angles are necessarily acute, as can be clearly gathered from I.17 or I.32. Only this must be observed: in right-angled and obtuse-angled triangles the perpendicular must be drawn from the right or obtuse angle, but in acute-angled triangles from any angle whatever; for in this way the perpendicular will always fall inside the triangle, as Euclid assumed in the demonstration. This is easily demonstrated as follows. Let there be in triangle ABC two acute angles ABC, ACB, while the angle BAC is right, or obtuse, or acute. I say that the perpendicular dropped from A falls inside the triangle. For if it fell outside, on CB produced toward B — such as the straight line AE — then in triangle ABE the exterior angle ABC, being acute, would be [Margin: d. Elem. I.16] greater than the interior and opposite right angle AEB, which is absurd. And if it fell outside BC, on the part produced toward C, such as the straight line AF, we should fall into the same absurdity, as is manifest.

Diagram. A single triangle with apex A and a base line carrying several marked points, showing that the perpendicular from A falls within the base.

- A (apex): vertex from which lines are drawn to the base
- E (leftmost point on the base): foot of the line AE, an assumed perpendicular falling outside toward B
- B (base, right of E): base vertex
- D (base, between B and C): foot of the true perpendicular AD, falling inside
- C (base, right of D): base vertex
- F (rightmost point on the base): foot of the line AF, an assumed perpendicular falling outside toward C

Federico Commandino [Federico Commandino] demonstrates this same theorem for right-angled and obtuse-angled triangles as well, even if the perpendicular AD does not fall on the side BC but is either the same as the side AB (as happens in right-angled triangles) or falls outside the triangle (as happens in obtuse-angled ones) — just as we demonstrated in the scholium of the preceding proposition. And that comes about precisely when the perpendicular is dropped not from the right or obtuse angle, but from one of the acute angles.

The right-angled case.

Let there be a right-angled triangle ABC whose angle B is right; and from the acute angle A let the perpendicular AD be drawn to BC — which will be the same as the side AB, because of the right angle B. I say that the square on the side AB, subtending the acute angle C, is less than the squares on the sides AC, CB by twice the rectangle contained by the side CB (on which the perpendicular falls) and by the line CD, which lies between the perpendicular AD and the acute angle C. For since the squares on AB, CB [Margin: e. Elem. I.47] are equal to the square on AC, then, adding the common square on CB, there will be three squares — namely that on AB and twice that on CB — equal to the two squares on AC, CB. But the square on CB is the same as the rectangle contained by CB, CD. Therefore the square on AB too, together with twice the rectangle contained by CB, CD, is equal to the squares on AC, CB. And accordingly the square on AB is less than the squares on AC, CB by twice the rectangle contained by CB, CD. Which is what was proposed.

The obtuse-angled case.

Again, let there be an obtuse-angled triangle ABC whose angle B is obtuse; and from the acute angle A let the perpendicular AD be drawn to BC, falling outside the triangle. I say that the square on the side AB, subtending the acute angle C, is less than the squares on the sides AC, CB by twice the rectangle contained by CB and CD. For since the squares on AD, CD

Diagram. An obtuse-angled triangle drawn with its apex A at upper right; the base runs C–B–D from left to right, and the perpendicular AD is shown as a dotted line dropping from A to D, which lies beyond B (the perpendicular falls outside the triangle).

- A (upper right, apex): vertex from which the perpendicular is dropped
- C (left end of base): base vertex, the acute angle ACB
- B (base, middle): the obtuse-angle vertex

- D (base, rightmost, directly below A): foot of the perpendicular AD, outside segment CB

(Continuation of the obtuse-angled case.)

are equal to [Margin: f. Elem. I.47] the square on AC, then, adding the common square on CB, the three squares on AD, CD, CB will be equal to the two squares on AC, CB. But the square on CD is equal to [Margin: g. Elem. II.4] the squares on CB, BD together with twice the rectangle contained by CB, BD. Therefore the two squares on AD, CB, together with the squares on CB, BD and twice the rectangle contained by CB, BD, are equal to the squares on AC, CB. But the squares on AD, BD are equal to [Margin: h. Elem. I.47] the square on AB. Therefore the square on AB too, and twice the square on GB [recte: CB], together with twice the rectangle contained by CB, BD, are equal to the squares on AC, CB. But the square on CB, together with the rectangle contained by CB, BD, is equal to [Margin: i. Elem. II.3] the rectangle contained by CD, CB. And therefore twice the square on CB, together with twice the rectangle contained by CB, BD, is equal to twice the rectangle contained by CD, CB. Therefore the square on AB too, together with twice the rectangle contained by CB, CD, is equal to the squares on AC, CB. And accordingly the square on AB is less than the squares on AC, CB by twice the rectangle contained by CB, CD.

Another proof, and shorter.

Since the square on AC is [Margin: k. Elem. II.12] greater than the squares on AB, BC by twice the rectangle contained by CB, BD — that is, the square on AC is equal to the squares on AB, BC together with twice the rectangle contained by CB, BD — the square on AB will be less than the square on AC by the square on BC and twice the rectangle contained by CB, BD. And accordingly, if to the square on AC the square on BC be added, the square on AB will be less than the squares on AC, BC by twice the square on BC and twice the rectangle contained by CB, BD. Since, then, the square on BC together with the rectangle contained by CB, BD is equal to [Margin: l. Elem. II.3] the rectangle contained by CB, CD, the square on AB too will be less than the squares on AC, CB by twice the rectangle contained by CB, CD. Which is what was proposed.

In a certain ancient scholium the following theorem is demonstrated, after the manner of the one that we demonstrated in the scholium of the preceding proposition in the second place. Namely:

Converse theorem.

If in a triangle the square on one side is less than the two squares on the two remaining sides, the angle opposite that side will be acute.

Demonstration.

In triangle ABC, let the square on the side AB be less than the squares on the sides AC, CB. I say that the angle C, which the said side subtends, is acute. For let there be drawn from C, perpendicular to AC, the line CD equal to the line CB, and let the straight line AD be joined. Since, then, the square on AD is equal to [Margin: m. Elem. I.47] the squares on AC, CD — that is, on AC, CB — while the square on AB is assumed less than the squares on AC, CB, the square on AD will be greater than the square on AB; and therefore the straight line AD is greater than the straight line AB. And so, since the two sides AC, CD of triangle ACD are equal to the two sides AC, CB of triangle ACB, each to each, and the base AD is greater than the base AB, the angle ACD will be [Margin: n. Elem. I.25] greater than the angle ACB. But ACD is right, by construction. Therefore ACB is less than a right angle, and will be acute.

Diagram. Three small triangles set side by side, each showing the construction for the converse theorem: triangle ACB (base C on the left, B on the right, apex A) with the right-angled construction line CD erected at C equal to CB.

- A (apex): vertex opposite the base CB
- B (right end of base): base vertex
- C (left end of base): the angle under test (ACB)
- D (near the apex region, top): endpoint of the perpendicular CD ($CD \perp CA$, and $CD = CB$); its position relative to A differs across the three copies

Converse theorem (second).

But we shall also demonstrate the converse of this proposition 13, namely:

If in a triangle the square on one side is less than the squares on the remaining two sides by twice the rectangle contained by one of these two sides and by the straight line lying between the angle opposite the former side and the straight line dropped from that angle onto the other of those sides — then this dropped line will be perpendicular to that other side, and the angle of the proposed triangle opposite the former side will be acute.

Demonstration.

In triangle ABC, onto the side BC let there be dropped, from the opposite angle A, the straight line AD; and let the square on the side AB be less than the squares on

the sides AC, CB by twice the rectangle contained by BC, CD. I say that AD is perpendicular to BC, and that the angle ACB is acute. For if AD is not perpendicular, let a perpendicular be drawn from A to BC — which, I say, must necessarily fall short of the point C, toward B; that is, either on the side BC, or at the point B, or on the side BC produced toward B. For let it fall, if it can, at C, so that AC is perpendicular to BC. Then [Margin: o. Elem. I.47] the square on AB will be equal to the squares on AC, CB. Which is absurd, since it is assumed less. Therefore the perpendicular dropped from A to BC does not fall at the point C.

Next, let the perpendicular from A fall, if it can, beyond C, at E — such as AE. Then [Margin: p. Elem. I.47] the square

Diagram. Three tall triangles stacked one above the other, each with apex A and a horizontal base crowded with marked points; solid and dotted lines run from A to these points, illustrating the successive cases of the reductio (the perpendicular assumed to fall at various feet). The base points are densely packed and their exact left-to-right order in each figure is hard to fix at this resolution.

- A (apex of each figure): vertex from which the lines descend
- D (on the base): foot of the true perpendicular AD
- E (on the base, toward the right end): foot of the assumed perpendicular AE falling beyond C
- F (repeated at several base positions): feet of the trial perpendiculars AF in the various cases
- B, C (base vertices of the triangle)
- Base-point sequence, first figure (crowded): F, B, F, D, F, C, E [?]; second figure: F, B, F, C, E [?]; third figure: F, D, F, B, F, C, E [?] — exact ordering uncertain

(Continuation of the second converse demonstration.)

on AB will be equal to the squares on AE, EB. But the square on AB is assumed less than the squares on AC, CB. Therefore the squares on AE, EB too will be less than the squares on AC, CB. Since, then, the square on AC is equal to [Margin: q. Elem. I.47] the squares on AE, EC, the squares on AE, EB will also be less than the squares on AE, EC, CB. And, the common square on AE being taken away, the remaining square on EB will be less than the squares on EC, CB. Which is absurd. For since the square on EB is equal to [Margin: r. Elem. II.4] the squares on EC, CB together with twice the rectangle contained by EC, CB, the square on EB will be greater than the squares on EC, CB. Therefore the perpendicular does not fall beyond C. But neither does it fall at C, as we have shown. Therefore it will fall

short of the point C — such as AD, as will be demonstrated; and on that account [Margin: s. Elem. I.17] the angle ACB will be acute. Which is what was proposed to be demonstrated in the second place.

For the rest — that the angle ACB is acute, if the square on AB is less than the squares on AC, CB — we demonstrated more easily in the immediately preceding theorem of this scholium. From which it follows (as was shown in Corollary 2 of I.17) that the perpendicular dropped from A to BC falls short of the acute angle ACB, toward B.

That AD, moreover, is perpendicular to BC, we shall show thus. If it is not, let AF be the perpendicular to BC, falling short of the point C (as has been proved), wherever this may happen — whether inside the triangle, or at the point B, or outside the triangle. (Only in the second triangle will the adversary not claim that the perpendicular falls at B, since it would then be the same as AD, which he denies.) Since, therefore, the angle ACB has been shown acute, [Margin: t. Elem. II.13] the square on AB will be less than the squares on AC, CB by twice the rectangle contained by BC, CF — that is, the square on AB, together with twice the rectangle contained by BC, CF, is equal to the squares on AC, CB. But the same square on AB is assumed to be less than the squares on AC, CB also by twice the rectangle contained by BC, CD — that is, the same square on AB, together with twice the rectangle contained by BC, CD, is assumed equal to the squares on AC, CB. Therefore the square on AB, together with twice the rectangle contained by BC, CD, will be equal to the same square on AB together with twice the rectangle contained by BC, CF. And, the common square on AB being taken away, twice the rectangle contained by BC, CD will be equal to twice the rectangle contained by BC, CF; and accordingly the rectangle contained once by BC, CD will be equal to the rectangle contained once by BC, CF, and therefore the lines CD, CF will be equal — the part and the whole. Which is absurd. Therefore AD is perpendicular to BC, and no other line. Which is what was proposed.

Now, just as in the scholium of the earlier proposition we constructed obtuse-angled triangles of commensurable sides and lines, in which the truth of proposition 12 could be examined by numbers, so in this place we shall set up acute-angled triangles of commensurable sides and lines, in which the truth of this proposition 13 may be explained. And since an acute-angled triangle is either equilateral, or isosceles, or scalene, we shall embrace this whole doctrine in seven rules. The first will treat of the acute-angled equilateral triangle. The second, of the isosceles in which the perpendicular falls on the unequal third side, whether that side be greater or less than either of the equal sides. The third,

of the isosceles whose third side is greater, and the perpendicular falls on one or other of the equal sides. The fourth, of the isosceles whose third side is less, and the perpendicular again falls on one or other of the equal sides. The fifth, of the scalene in which the perpendicular falls on the smallest side. The sixth, of the scalene in which the perpendicular is dropped on the middle side. The seventh, finally, of the scalene in which the perpendicular is drawn to the greatest side. I am speaking here also of those triangles in which the perpendicular line falls inside the triangle — and accordingly the two angles at the base are acute — whether the opposite angle is acute as well or not. For the proposition is to be understood of these too, as we have said. But how triangles in which the perpendicular line falls either outside them, or coincides with one of the sides, may likewise be fitted to numbers, we shall teach at the end of the rules.

REGVLA I.

If any side of an equilateral triangle be set at whatever number of equal parts — an even number, however, so that fractions be avoided — all the sides will be commensurable both with one another and with the segments made by the perpendicular. Thus in the equilateral triangle ABC the perpendicular AD divides the opposite side BC into two equal parts, as we demonstrated in the scholium of I.26. Wherefore, any side being set at 8, the segments BD, CD will be 4 and 4. Here you see that the square on the side AB, opposite the acute angle C (for all the angles in an equilateral triangle are acute, by Corollary 3 of I.17) — that is, 64 — together with twice the rectangle contained by BC, CD, that is, with 32 and 32, makes 128: which is precisely what the two squares on the sides AC, CB make, namely 64 and 64.

Diagram. An equilateral triangle ABC with apex A, base B–D–C, and the perpendicular AD dropped to the base, annotated with the numerical values used in the rule.

- A (apex): vertex from which the perpendicular AD is dropped
- B (left base vertex)
- D (foot of the perpendicular, midpoint of the base)
- C (right base vertex, the acute angle C)
- Numerical labels: "8" on side AB (left), "8" on side AC (right); "4" and "4" on the two base segments BD and DC; "8" beneath the base BC

REGVLA II.

If each of the equal sides of an isosceles triangle be set at any number of equal parts, and the third side at any even number of parts (so that fractions be avoided) — whether fewer parts be placed in this side than in either of the equal ones, or more, provided only they be not as many as in both together, or more; for so a triangle could not be made, since the two equal sides would not be greater than the third side, but either equal to it or less, which contradicts I.20 — if, I say, the sides be expressed in numbers in this way, all the lines of the triangle will be commensurable with one another. Thus, in the first of these isosceles triangles, let each of the sides AB, AC be set at 7, and BC at 4; in the second, let each of AB, AC be 5, and BC 6. Since, then, the perpendicular AD divides the base BC into two equal parts, by the scholium of I.26, the segments BD, CD will be, in the first triangle, 2 and 2, and in the second, 3 and 3. Here too it is clear that the square on the side AB, opposite the acute angle C (for each of the angles B, C is acute, by Corollary 3 of I.17), together with twice the rectangle contained by BC, CD, is equal to the squares on the sides AC, CB together, and so forth.

Diagram. Two isosceles triangles side by side, each with apex A, base B–D–C, and the perpendicular AD, annotated with numerical values.

- First (left) triangle: A (apex), B, D (foot of perpendicular), C; equal sides labelled "7" and "7"; base segments "2" and "2"; base BC labelled "4"
- Second (right) triangle: A (apex), B, D (foot of perpendicular), C; equal sides labelled "5" and "5"; base segments "3" and "3"; base BC labelled "6"

REGVLA III.

In an isosceles triangle in which the third side is greater, and the perpendicular falls on one of the equal sides, the segment near the greater third side will be the greater, as we demonstrated at I.47. If, therefore, you set the smaller segment at any number of parts and multiply them by 8, you will have the greater segment; but if you multiply the same by 12, you will produce the third side; and finally the two segments added together will make up each of the equal sides — which you will also produce from the multiplication of the smaller

Euclid's *Elements*, Book II — Clavius's commentary (continued)

Scholium to Proposition 13 — numeric rules (continued)

Rule III (conclusion)

the segment by 9.

For instance, if in the isosceles triangle ABC the smaller segment BD is set at 4, the larger segment CD will be 32, the side AC will be 48, and each of the two sides AB and BC will be 36. Now the square of side AB, opposite the acute angle C — namely 1296 — together with twice the product of BC and CD, that is 1152 and 1152, makes 3600; and this is exactly what the two squares on AC and CB produce, namely 2304 and 1296. In the same way the square on AC, namely 2304, together with twice the product of CB and BD, that is 144 and 144, makes 2592; and this number is likewise produced by the squares of the sides AB and BC, namely 1296 and 1296. In a triangle of this kind, therefore, the unequal segments stand in the ratio of eight to one; either of the equal sides to the smaller segment stands in the ratio of nine to one; and finally the third, greater side to that same smaller segment stands in the ratio of twelve to one.

Diagram. Isosceles triangle for Rule III, apex A above, base BC running left to right with D the foot of the perpendicular AD (drawn as a dashed line from A).

- A (apex): vertex
- B (base, left): vertex
- D (on BC): foot of the perpendicular from A
- C (base, right): vertex
- Segment BD: "4"
- Segment DC: "32"
- Side AC (right edge): "48"
- Side AB (left edge): "36" [reads as stacked "3 / 6"]
- Base BC: "36" [a second numeral near the base foot is faint — possibly a repeated "36"; the value 36 is confirmed by the text]

Rule IV

[Margin: (rule number IV)]

In an isosceles triangle whose third side is the smaller and onto which the perpendicular again falls on one of the equal sides, the segment nearer to the smaller side will be the third [part], smaller, as we have demonstrated at Prop. 47 of Book I. If you set this segment at any even number of parts, multiply them by 3 and add to the product half of the same (or multiply the same parts by 7), you will produce the greater segment. But if you multiply the same parts of the smaller segment by 3, you will make the third side, the smaller. Finally, each of the equal sides is composed of the two segments, which is also had by multiplying half of the smaller segment by 9. Thus, if in the isosceles triangle ABC the smaller segment CD is set at 6, the larger BD will be 21, and each side — both AB and BC — will be 27. The square of side AB, therefore, opposite the acute angle C, namely [729], together with twice the product of BC and CD, that is 162 and 162, makes 1053; and this number is also composed of the squares of the sides [AC and AB], namely 324 and 729.

Diagram. Isosceles triangle for Rule IV, apex A, base BC with D the foot of the perpendicular AD.

- A (apex): vertex
- B (base, left): vertex
- D (on BC): foot of the perpendicular
- C (base, right): vertex
- Segment BD: "21"
- Segment DC: "6"
- Side AB (left edge): "27"
- Base BC: "27"
- Side AC (right edge): "18" [glyph small; value confirmed by the arithmetic $324 = 18^2$]

Rule V

[Margin: (rule number V)]

In a scalene triangle in which the perpendicular is let fall onto the smallest side, the segment [nearer that side] will be the smaller, as was demonstrated at Prop. 47 of Book I. If this segment is set at some number of equal parts counted by 70 — that is, 70, or 140, or 210, and so on — and there are added to them $\frac{29}{70}$ of them, the greater segment will be produced; and from the addition of the parts of these segments the [smallest] side [is produced]. But if the parts of the smaller segment are doubled and there is added to the product $\frac{44}{70}$ of the parts, the middle side

will be generated. And finally, if $\frac{55}{70}$ — that is $\frac{11}{14}$ — of those same parts of the smaller segment are added, the greatest side will be put together. Thus in the scalene triangle ABC, if the smaller segment BD is set at 70, the greater CD will be 99, and the whole smallest side BC will be 169. The middle side AB will be 182, and the greatest AC 195. The square of side AB, therefore, opposite the acute angle C — that is, 33124 — together with the number produced by twice the product of BC and CD, that is 16731 and 16731, makes the number [66586], equal to the two squares taken together, 38025 and 28561, of the sides AC and CB, and so on.

Diagram. Scalene triangle for Rule V, apex A, base BC with D the foot of the perpendicular AD.

- A (apex): vertex
- B (base, left): vertex
- D (on BC): foot of the perpendicular
- C (base, right): vertex
- Side AB (left edge): "182"
- Side AC (right edge): "195"
- Segment BD: "70"
- Segment DC: "99"
- Base BC: "169"

Rule VI

[Margin: (rule number VI)]

In a scalene triangle, when the perpendicular falls onto the middle side, the smaller segment will be the one adjacent to the smallest side — as we showed from Prop. 47 of Book I. If this segment is set at some number of equal parts counted by 5 — as 5, or 10, or 15, and so on — and there are added $\frac{4}{5}$ [?], the greater segment will be made; and the parts of these segments, gathered into one sum, will compose the middle side. But if to the doubled parts of the smaller segment there are added $\frac{2}{5}$ [?] of the same, the smallest side will be produced. Finally, the triple of those same parts of the smaller segment will give the greatest side. Thus in the scalene triangle ABC, if the smaller segment BD is made 5, the greater segment CD will be 9, and the whole side BC — the middle — [14]. The smallest side AB will be 13, and the greatest AC 15, and so on.

Diagram. Scalene triangle for Rule VI, apex A, base BC with D the foot of the perpendicular AD (dashed vertical).

- A (apex): vertex
- B (base, left): vertex
- D (on BC): foot of the perpendicular
- C (base, right): vertex
- Side AB (left edge): "13"
- Perpendicular AD: "12"
- Side AC (right edge): "15"
- Segment BD: "5"
- Segment DC: "9" [glyph reads as "3" on the leaf; value 9 confirmed by the text]
- Base BC: "14"

Rule VII

[Margin: (rule number VII)]

In a scalene triangle, finally, where the perpendicular is drawn to the greatest side, the segment adjacent to the smallest side will be the one we wrote of at Prop. 47 of Book I. If, then, one takes for the smaller segment 33, or any other number counted by 33 — as 66 or 99 — and adds $\frac{2}{33}$, that is $\frac{3}{11}$, the greater segment will be made; and the two segments composed together will yield the greatest side. But if to the doubled number of the smaller segment there are added $\frac{4}{33}$, the middle side will be produced. And finally, if to the same smaller segment there are joined $\frac{32}{33}$, the smallest side will be exhibited. Thus, if in the scalene triangle ABC the smaller segment CD is 33, the greater segment BD will be 42, the whole greatest side BC 75, the middle side AB 70, and the smallest AC 65, and so on.

Diagram. Large scalene triangle for Rule VII, apex A, base BC with D the foot of the perpendicular AD (dashed).

- A (apex): vertex
- B (base, left): vertex
- D (on BC): foot of the perpendicular
- C (base, right): vertex
- Side AB (left edge): "70"
- Side AC (right edge): "65"
- Segment BD: "42"
- Segment DC: "33"

- A dimension mark below D reads "5" [?] — unclear; the base total $BC = 75$ is confirmed by the text

Concluding remarks of the scholium

If you multiply the several numbers of these rules by one and the same number, whatever it may be, you will generate other numbers to be assigned to the sides of triangles. The same numbers will also be found if the smaller segment, or the greater, or [any other] be [multiplied], provided the proportions are kept that we have set out in the rules given above.

Here, too, one must understand that the prescribed proportions are not to be found among the sides in every acute-angled triangle, since their proportions can be varied in a thousand ways. Nor indeed do those rules teach this; their use consists in this alone: that, keeping the proportions we have explained, acute-angled triangles can be formed in which Proposition 13 of this Book II is fitted to numbers.

Now if the perpendicular coincides with that side whose square is to be proved less than the two squares of the other two sides, and so on — so that the proposed triangle is right-angled — three numbers must be sought for the sides, from those we wrote of in the scholium to Prop. 47 of Book I. Thus, in the figure of Rule 6, if in the triangle ABD the smallest side BD is set at 5, AD will be 12 and AB 13. Here you see that the square of side AD, opposite the acute angle B, namely 144, together with twice the product of BD and

BD, that is 25 and 25, makes 194 — which is exactly what the two squares on AB and BD together produce, namely 169 and 25. By the same reasoning, if the smallest side BD is set at 6 parts, AD will be 8 and AB 10. Here too you see that the square of side AD, subtended by the acute angle B, namely 64, together with twice the product of BD and BD, that is 36 and 36, makes 136 — a number that the two square numbers of the sides AB and BD, namely 100 and 36, also produce. So likewise you see that the square number of side BD, opposite the acute angle A, that is 36, together with twice the product of AD and AD, that is 64 and 64, makes 164 — as much as the two square numbers of the sides AB and AD together produce, namely 100 and 64.

Finally, if in another triangle ACD the smallest side CD is set at 9, you will find from what we wrote at Prop. 47 of Book I that AD is 40 and AC is 41. Here it is manifest that the square number of side AD, opposite the acute angle [C], namely 1600, together with the number produced by twice the product of CD and CD, that is 81 and 81, makes 1762 — which number is equal to the square numbers of the

two sides AC and CD, that is, to the two numbers 1681 and 81; for these too make up the sum 1762. And if you make the smallest side CD 7, you will find AD to be 24 and AC 25, in which numbers you will experience the same thing. For the square number of side CD, subtended by the acute angle A, that is 49, together with the number twice produced by AD and AD, that is 576 and 576, makes 1201 — as much as the two square numbers of the sides AC and AD produce, that is, 625 and 576.

But if the perpendicular falls outside the triangle, so that the triangle is obtuse-angled, one must seek the exterior segment together with the sides, as we taught in the three rules of the scholium to the preceding proposition. For the exterior segment, together with the produced side, will give the whole segment lying between the assumed acute angle and the perpendicular. Thus in the figure of Rule 3 of the scholium to the preceding proposition, the whole segment CD, between the acute angle C and the perpendicular BD falling outside the triangle, will be 37. Here it is clear that the square of side AB, opposite the acute angle C — that is, 256 — together with twice the rectangle contained under AC and CD, that is 1184 and 1184, composes the number 2624; which is equal to the two [squares taken together], namely to the aggregate of the square numbers 1600 and 1024, and so on.

Diagram. Obtuse triangle ABC with the perpendicular BD dropped from B onto the side CA produced, its foot D lying beyond A (outside the triangle). B is at the lower left, C at the lower right, and D–A across the top left.

- Segment AD: "5"
- Side AB: "16"
- Side AC: "32"
- Base BC: "40"

Added theorem (from Pappus of Alexandria)

Nor did I think it out of place here to demonstrate the following theorem as well, taken from Pappus of Alexandria [Pappus]:

If in a triangle a straight line is drawn from any angle, bisecting the opposite side, then the two squares of the sides containing that angle together are

double of two squares taken together — one of which is described on the drawn line, the other on the half of the [bisected] side.

In the triangle ABC, let the straight line AD cut the side BC in half at D. I say that the squares on AB and AC are double the squares on AD and BD.

For let a perpendicular be dropped from A to BC. First let it coincide with the straight line AD, so that the triangle ABC is equilateral or isosceles, as we demonstrated at Prop. 26 of Book I. [Margin: (u) Elements I.47] Now since both the square on AB is equal to the squares on AD and DB, and the square on AC is equal to the squares on AD and DC, the two squares on AB and AC will be equal to the square on AD taken twice, together with the squares on DB and DC. And since the squares on DB and DC are equal, if the two squares on AD and DC are taken away, there will have been removed half of the four squares — namely, of the square on AD taken twice and the square on DC. Therefore the two squares on AB and AC are double the two squares on AD and DB. This is what was proposed.

The same is shown more clearly thus. [Margin: (x) Elements I.47] Since the square on AB is equal to the two squares on AD and DB, and since the two squares on AB and AC are double the square on AB (because of the equality of the lines AB and AC), the squares on AB and AC will also be double the squares on AD and DB. This is what had to be demonstrated.

Diagram. First case: isosceles (or equilateral) triangle in which the perpendicular from A coincides with the median AD. Apex A, base BC with D at its midpoint.

- A (apex): vertex
- B (base, left): vertex
- D (midpoint of BC): foot of the perpendicular = bisection point
- C (base, right): vertex

Next let the perpendicular AC coincide with the side AC [the right angle falling at C]. Since the square [on BC] is fourfold both the square on BD and the square on DC — as we showed in the scholium to Prop. 4 of this Book — the same square on BC will be double of the two squares on DB and DC. But the two squares on AC and CD, taken twice, are also double the square on AD, [Margin: (y) Elements I.47] because the squares on AC and CD taken once are equal to the square on AD. Therefore the square on BC, together with the squares on AC and CD taken twice, will be double the squares on DB and DC. And since the square on CD taken twice is double the square on CD, [Margin: (z) pronuntiatum 20] the remaining square on BC, together with the square on AC taken twice, will likewise be double of the remaining squares on DB and [AD]. But [Margin: (a) Elements I.47] the squares on

BC and AC are equal to the square on AB. Therefore the squares on AB and AC (which are equal to the square on BC together with the square on AC taken twice) are likewise double the squares on AD and DB. This is what was proposed.

Diagram. Second case: right triangle with the right angle at C, A above C. Base BC with D its midpoint; AD is the median.

- A (upper right, above C): vertex
- B (base, left): vertex
- D (midpoint of BC): bisection point
- C (base, right): vertex

Thirdly, let the perpendicular AE fall inside the triangle, between the points D and C. [Margin: (b) Elements II.9] Since the squares on BE and EC are double the squares on BD and DE, and likewise the squares on AE and DE [taken twice] are double the square on AD — [Margin: (c) Elements I.47] because the squares on AE and ED taken once are equal to the square on AD — the squares on BE and EC, together with the squares on AE and DE taken twice, will be double the squares on BD, DE, and AD. And since the square on DE taken twice is double the square on DE, [Margin: (d) pronuntiatum 20] the remaining squares on BE and EC, together with the square on AE taken twice, will likewise be double of the remaining squares on DB and AD. Therefore, since the square on AB is equal to the squares on BE and AE, [Margin: (e) Elements I.47] and the square on AC to the squares on EC and AE, the squares on AB and AC will also be double the squares on AD and DB. This is what was proposed.

Diagram. Third case: acute triangle with apex A, base marked B, D, E, C from left to right (D the midpoint of BC, E the foot of the perpendicular AE falling inside, between D and C).

- A (apex): vertex
- B (base, far left): vertex
- D (on base): midpoint of BC
- E (on base): foot of the perpendicular AE
- C (base, far right): vertex

Lastly, let the perpendicular AE fall onto the side BC produced. [Margin: (f) Elements II.10] Since the squares on BE and CE are double the squares on BD and DE, and likewise the squares on AE and DE, taken twice, are double the square on AD — [Margin: (g) Elements I.47] because the squares on AE and DE taken once [are equal] to the square on AD — the squares on BE and CE, together with the

squares on AE and DE taken twice, will also be double the squares on BD, DE, and AD. And since the square on DE taken twice is double the square on DE, [Margin: (h) pronuntiatum 20] the remaining squares on BE and CE, together with the square on AE taken twice, will likewise be double of the remaining squares on BD and AD. Therefore, since the square on AB is equal to the squares on BE and AE, [Margin: (i) Elements I.47] and the square on AC to the squares on CE and AE, the squares on AB and AC will also be double the squares on AD and DB. This is what had to be shown.

Diagram. Fourth case: triangle with apex A, base marked B, D, C, E from left to right (D the midpoint of BC, E the foot of the perpendicular AE falling on BC produced, beyond C).

- A (apex): vertex
- B (base, far left): vertex
- D (on base): midpoint of BC
- C (on base): vertex
- E (on base produced, beyond C): foot of the perpendicular AE

Do not be disturbed, however, that for the demonstration of this theorem we have employed the pronounce-

-ment 20, which is universally demonstrated by Euclid for every kind of multiples at Prop. 5 of Book V. For in the double ratio it can easily be granted without demonstration, as we said in the exposition of its principle; or else the theorem itself can be demonstrated after Book V, so that no circularity at all is committed in the demonstration, even if that principle is demonstrated in Book V — since Proposition 5 of Book V does not depend on this theorem.

Scholium (continued): finding the area of a triangle whose sides are known

From what has been demonstrated in the two preceding theorems and at Prop. 47 of Book I, we shall find the area of any triangle whose sides are known — as Campanus [Campanus of Novara] rightly advises in this place, and as Federico Commandino [Federico Commandino] demonstrates, by roughly this method.

Let there be, first, a right triangle ABC whose sides are known, namely AB 10, AC 8, BC 6. When the side BC is bisected at D, so that CD and BD are each 3 palms, let the rectangle ACDE be completed, which is equal to the triangle ABC, as we showed in the scholium to Prop. 41 of Book I. Since from drawing CD, 3 palms,

into CA, 8 palms, there is produced the area of the rectangle CE, 24 square palms — as we taught at the beginning of this Book — the triangle ABC, equal to the rectangle CE, will contain just as many square palms. This is what was proposed.

Diagram. Right triangle ABC with the completed rectangle ACDE. The right angle is at C; A above C, B at the lower left. D is the midpoint of the base BC; E the fourth corner of the rectangle above D.

- A (top right): vertex
- E (top, above D): corner of the rectangle
- B (lower left): vertex
- D (midpoint of BC): bisection point
- C (lower right): vertex; the right angle
- Hypotenuse AB: "10"
- Side AC: "8"
- Base BC: "6"
- Segments BD, DC: "3" and "3"
- Area of rectangle CE (inside): "24"

Let there be, next, an obtuse triangle ABC whose sides are known: AB 20 palms, AC 13, BC 11. First, the length of the perpendicular AD, dropped from A onto the side BC produced, must be found, in this way. Since the square of side AB [Margin: (k) Elements II.12] is greater than the squares of the sides AC and BC by twice the rectangle contained under BC and CD: if the squares of the sides AC and BC, namely 169 and 121, which make 290, are subtracted from 400, the square of side AB, there will remain 110 for twice the rectangle contained under BC and CD; and half of this number, 55, will give the rectangle under BC and CD. If, then, 55 — the rectangle under BC and CD — is divided by the known side BC, 11, the remaining side CD, 5 palms, will come out, as Johannes Regiomontanus [Regiomontanus] demonstrates at Prop. 17 of Book I of his *On Triangles*, and as we have demonstrated in our book *On the Measurement of All Magnitudes*. And since the squares of the sides AD and CD [Margin: (l) Elements I.47] are equal to the square of side AC: if the square 25 palms — namely of side CD, 5 palms, just found — is taken away from 169, the square of side AC, there will remain 144 for the square of side AD; and AD will be 12 palms, since the square root of this number 144 is 12. Now, the side BC being bisected at E, let there be drawn out from C and E, perpendicular to BD, the perpendiculars CF and EG, meeting the straight line AG (which is drawn through A parallel to BD) at the points F and G. This done, if EC, $5\frac{1}{2}$ palms, is drawn into CF, 12 palms — [Margin: (m) Elements

I.34] for CF is equal to AD — the area of the rectangle CG, 66 palms, will arise; and since this is equal to the triangle ABC by the scholium to Prop. 41 of Book I (for the rectangle CG and the triangle ABC are between the same parallels, and so on), the area of the triangle ABC will likewise be 66 square palms. This is what was proposed.

Diagram. Obtuse triangle ABC (obtuse at C), with the perpendicular AD dropped from A onto BC produced (D beyond C). E is the midpoint of BC; the perpendiculars CF and EG rise from C and E to the line AG drawn through A parallel to BD, meeting it at F and G. The rectangle CG (i.e. CEGF) is shaded and labelled with its area. Points G, F, A run across the top; B, E, C, D along the bottom.

- A (top): vertex
- G, F (top): corners of the rectangle on the line through A parallel to BD
- B (bottom left): vertex
- E (on BC): midpoint of BC
- C (bottom, before D): vertex
- D (bottom, beyond C): foot of the perpendicular AD
- Side AC: "13"
- Perpendicular AD (= CF): "12"
- Segment CD: "5"
- Segments BE, EC: "5½" each [a second fractional numeral reads "5¼" on the tile — likely "5½" repeated; flagged]
- Base produced BD: "16"
- Area of rectangle CG (inside): "66"
- An additional interior construction point/mark near the left of the rectangle is present but not clearly labelled [?]

Let there be, lastly, an acute triangle ABC having its sides known: AB 13 palms, AC 15, BC 14. Here too, first, the length of the perpendicular AD, dropped from A onto BC, must be found, by this reasoning. Since the square of side AB [Margin: (n) Elements II.13] is less than the squares of the sides AC and BC by the rectangle contained twice under BC and CD: if the square of side AB, namely 169, is subtracted from the squares of the sides AC and BC, that is from 225 and 196, which make 421, there will remain 252 for the rectangle contained twice under BC and CD; and half of this number, 126, will give the rectangle under BC and CD. If, then, 126 — the rectangle under BC and CD — is divided by the known side BC, that is by 14, the remaining side CD, 9 palms, will come out, as is established from Johannes Regiomontanus, *On Triangles*, Book I, Prop. 17, and as we have

demonstrated in the book *On the Measurement of All Magnitudes*. And since the squares on AD and CD [Margin: (o) Elements I.47] are equal to the square on AC: if the square 81 palms — namely of side CD, 9 palms, just found — is taken away from 225, the square of side AC, there will remain 144 palms for the square of side AD. Therefore, since the square root of this number 144 is 12, the side AD will be 12 palms. Now, the side BC being bisected at E, let there be drawn out from C and E, perpendicular to BC, the perpendiculars CF and EG, meeting the straight line AF (which is drawn through A parallel to BC) at the points G and F. This done, if CE, 7 palms, is drawn into EG, 12 palms — [Margin: (p) Elements I.34] for EG is equal to the straight line AD — the area of the rectangle EF, 84 palms, will arise. And since this is equal to the triangle ABC, by the scholium to Prop. 41 of Book I (for the rectangle EF and the triangle ABC are between the same parallels, and so on), the area of the triangle ABC will likewise be 84 palms. This is what was proposed.

Diagram. Acute triangle ABC with apex A, base marked B, D, E, C from left to right (D the foot of the perpendicular AD, E the midpoint of BC). The perpendiculars CF and EG rise to the line AF through A parallel to BC; the rectangle EF is shaded and labelled with its area. Points A, G, F run across the top.

- A (apex): vertex
- G (top, next to A): rectangle corner [lowercase "a" on the tile]
- F (top right): rectangle corner
- B (bottom left): vertex
- D (on base): foot of the perpendicular AD
- E (on base): midpoint of BC
- C (bottom right): vertex
- Side AB: "13"
- Perpendicular AD (= EG): "12"
- Side AC: "15"
- Segment BD: "5"
- Segment DC: "9"
- Segment EC: "7"
- Base BC: "14"
- Area of rectangle EF (inside): "84"

And so, universally, the area of any triangle is produced from half of the base into the perpendicular that is dropped from the vertex to the base, as is manifest in the examples given. But more about this matter in the book *On the Measurement*

of All Magnitudes, which — God willing — we shall shortly bring to light. As for how, when two sides together with one angle are known, or two angles with one side, the remaining angles and sides may be found — this we have demonstrated in our *Plane Triangles*.

Problem 2. Proposition 14

[Margin: *xiiij.*]

To construct a square equal to a given rectilineal figure.

Let A be the given rectilineal figure, to which a square is to be constructed equal. [Margin: (a) Elements I.45] Let a parallelogram BCDE be constructed, equal to the rectilineal figure A and having a right angle, one side of which — say DC — is produced to F, and let CF be a straight line equal to the straight line BC. Let DF also be bisected at the point G, which will fall either on the point C or not. If it falls on the point C, then BC (since it is set equal to CF) will be equal to CD. Therefore the rectangle BD will be a square, since the sides DE and EB [Margin: (b) Elements I.34] are equal to the opposite sides BC and CD; and so a square will have been constructed equal to the rectilineal figure A.

But if the point G does not fall on C, then with G as centre let a semicircle FHD be described with radius GD (or GF), and let BC be produced until it cuts the circumference at H. I say, then, that the square of the straight line CH is equal to the rectilineal figure A. For let GH be drawn. Since the straight line DF is bisected at G and not bisected at C, the rectangle contained under DC and CF — that is, the rectangle BD — together with the square of the straight line GC, [Margin: (c) Elements II.5] is equal to the square of the straight line GF, that is, to the square of GH (since GF and GH are equal). But the square of GH [Margin: (d) Elements I.47] is equal to the squares of the straight lines GC and CH. Therefore the rectangle BD, together with the square of GC, will also be equal to the squares of GC and CH. And so, the common square of GC being taken away, there will remain the rectangle BD — that is, the rectilineal figure A — equal to the square of CH. Therefore we have constructed a square equal to a given rectilineal figure. Which was to be done.

Diagram. Three figures side by side. At the left, the given rectilineal figure A (an irregular quadrilateral). In the middle, the right-angled parallelogram BCDE (a square, in the case where G falls on C): E and D across the top, B and C across the bottom, with G marked. At the right, the general construction: the rectangle BCDE

with DC produced to F below, the semicircle FHD drawn on centre G, and BC produced to H on the circumference.

- A: the given rectilineal figure (label inside the quadrilateral)
- B (lower left of rectangle): vertex
- C (lower, on the base line): vertex
- D (upper, above C): vertex
- E (upper left): vertex
- F (below C, on DC produced): endpoint, $CF = BC$
- G (bisection point of DF; centre of the semicircle): point
- H (on BC produced, on the circumference): point; CH is the side of the required square

Scholium [to Proposition 14]

(Clavius's scholium, continued.)

Constructing, on a given straight line, a rectangle equal to a given rectilineal figure of many angles is laborious — and this is something we often need to do. By Proposition 44 of Book I we can build a rectangle equal to a triangle; so it may be easier to describe a square equal to a given rectilineal figure by first resolving the given figure into triangles, then producing a square equal to each triangle — that is, by finding the side of a square equal to each single triangle. This is very easily done, as I shall show shortly. For if, by the method set out in the scholium to Proposition 47 of Book I, we then find the side of a further square equal to the squares on all the sides already found, we shall have accomplished what is proposed.

Thus, suppose the given rectilineal figure is ABCDEF. We resolve it into the triangles ABF, FBC, CFD, DEF, and we find the sides G, H, I, K whose squares are respectively equal to those triangles. Next we set up a right angle at M, and lines LM and MN equal to the sides G and H. Then, once NL has been drawn, we erect on it the perpendicular NO equal to the side I. Similarly, once OL has been drawn, we raise on it the perpendicular OP equal to the side K, and we join the straight line PL. We proceed in this way until a perpendicular equal to the last side has been taken — as here the perpendicular OP was equal to the last side K. For the square on the straight line PL, drawn last, will be equal to all the squares on the sides G, H, I, K, as we demonstrated at Proposition 47 of Book I, and therefore equal to all the triangles ABF, FBC, CFD, DEF together — that is, to the given rectilineal figure ABCDEF.

Diagram. The construction for resolving a rectilinear figure into triangles and combining their equal-squares. On the left, a six-sided figure ABCDEF triangulated from the common vertex F; to its right, four short vertical line-segments representing the sides G, H, I, K; below, the perpendicular "staircase" construction on points L, M, N, O, P.

- A (top of the polygon)
- B (upper-left vertex)
- C (left vertex)
- D (lower-left vertex)
- E (lower-right vertex)
- F (right vertex; apex to which all the diagonals FB, FC, FD run, forming triangles ABF, FBC, CFD, DEF)
- G, H, I, K (four vertical line-segments, the sides whose squares equal the several triangles)
- M (bottom-left; the initial right angle)
- N (left)
- O (top; foot of the perpendicular NO)
- P (right; foot of the perpendicular OP)
- L (bottom-centre; PL joined last)

Now the practical method [praxis] for finding a square equal to any triangle is straightforward. Suppose the square to be found is one equal to the fourth triangle, DEF, of the given rectilinear figure. Bisect any one side, say DE, at A, and extend it as far as you like. Then, through the opposite vertex F, draw FB parallel to the side DE; through E draw HEB perpendicular to DE, cutting FB at B; and let EH be equal to AE, that is, to half of DE. Finally, once the whole line BH has been bisected at G, describe with centre G and radius GH (or GB) an arc cutting the side DE, extended, at I. I say that the square on the side EI is equal to the triangle DEF. For if the rectangle AEC is completed and the semicircle on BH is drawn, and the straight line GI is joined, we shall show — as in this Proposition 14 — that the square on EI is equal to the rectangle AB. Since, then, the rectangle AB is equal to the triangle DEF (by the scholium to Proposition 41 of Book I, because the base DE is double the base AE), the proposition is established.

Diagram. The construction for a square equal to triangle DEF, using the semicircle on BH.

- C, B, F (top row: the parallel FB drawn through the vertex; C at left, B at centre, F at right)

- G (centre; midpoint of BH, centre of the semicircle)
- D (mid-left, an endpoint of the bisected side)
- A (bottom; midpoint of DE)
- E (bottom, beside A; foot of the perpendicular)
- H (bottom; the point with $EH = AE$)
- I (right; where the arc cuts DE extended)
- (a dotted semicircle is drawn on BH)

It is not, however, necessary to construct the rectangle AB. For if the right angle IEB is made, and on BH is taken EH equal to half the side DE, and the straight line EB is made equal to the perpendicular dropped from F onto the side DE, and BH is bisected at G, then the circumference described with centre G on BH will cut off the straight line EI, whose square is equal to the rectangle contained by BE and EH — that is, equal to the triangle DEF.

Now since, in this second book, Euclid has discussed many things about squares and about rectangular parallelograms, two problems concerning the square and the rectangular parallelogram may fitly be inserted here — neither unpleasant nor unprofitable. The second of them was solved most ingeniously by the learned and excellent mathematician Marino Ghetaldi [Marino Ghetaldi], a patrician of Ragusa and a close friend of mine, and solved in a way far different from, and much briefer than, the way in which it was once solved by someone else. To append that other solution would be superfluous, since I have set down here Ghetaldi's own, as the briefer and easier one.

I.

Problem. Given the excess of the diameter of some square over its side, to find the side of that square.

Demonstration. Let the diameter of some square exceed its side by the straight line AB, and let the side of that square be sought. On the straight line AB describe the square AC, and let its diameter BD be extended to E so that DE is equal to the straight line AD. I say that EB is the side of the square whose diameter exceeds that same side BE by the given excess AB. For draw EF perpendicular to BE, meeting BA extended at F. Now since, in the triangle BEF, the angle FEB is right and the angle EBF is half a right angle [semirectus], by Corollary 2 of Proposition 4 of this book [Margin: c) Bk. 1, Prop. 32], the angle BFE will also be half a right angle. [Margin: f) Bk. 1, Prop. 6] Therefore the straight lines BE and FE are equal. If, then, FG is drawn from F parallel to BE, and from B the straight line BG is drawn parallel to EF, meeting the first at G, the square on the line BE will have

been constructed. And if the straight line AE is drawn [Margin: g) Bk. 1, Prop. 5], the angles AED and EAD, opposite the equal lines DE and DA, will be equal. So if these are subtracted from the right angles DEF and DAF, the remaining angles AEF and EAF will be equal [Margin: h) Bk. 1, Prop. 6], and therefore the straight lines EF and AF will be equal. But since the diameter BF exceeds the straight line AF by the given straight line AB, that same diameter BF will exceed the side of the square EF by the same straight line AB — which is what was proposed.

Diagram. The figure for Problem I: the square AC on AB, its diameter BD extended to E, with EB the side sought and the auxiliary lines EF, AE, FG, BG.

- E (top; the extension of the diameter, $DE = AD$)
- D (upper-centre; corner of the square, on the diameter BE)
- C (upper-right; corner of the square AC)
- F (left; where EF meets BA extended)
- A (centre-lower)
- B (lower centre-right)
- G (bottom; the far corner of the constructed square on BE)

Corollary

Thus the straight line composed of the diameter of the square described on the given excess and of the side of that same square exhibits the side of the square that is sought. And the same diameter, together with twice the excess, constitutes the diameter of the square sought.

II.

Problem. Given the two excesses of the diameter of some rectangular parallelogram over each of its sides, to find the sides of that rectangle.

Demonstration. Let the diameter exceed the lesser side by the straight line AB, and the greater side by the straight line BC. Extend AC in both directions; take AD equal to AB; and, having described a semicircle on CD, erect BE perpendicular to AC, cutting the circumference at E, and take CF equal to BE. Now since, as is clear from the demonstration of Proposition 14 of this book, the square on the line BE is equal to the rectangle contained by DB and BC, BE will be greater than BC, the lesser side of the said rectangle. Therefore CF too will be greater than BC. So, taking FG equal to BC, the point G will fall between C and FE; and with GH — perpendicular to AF — made equal to BF, I say that AG is the greater side, and GH the lesser, so that the rectangle

Diagram. The figure for Problem II: the semicircle on CD, with BE perpendicular to the base and the auxiliary construction for the rectangle's sides.

- I (left; on the base line, extended)
- D, A, B, C (along the horizontal base line, left to right)
- F (right; on the base line)
- E (centre; where the perpendicular BE meets the circumference)
- K (upper-left arc of the semicircle)
- H (upper-right)
- G (right, below H)
- M (bottom of the figure)

(Problem II, demonstration continued.)

is that which was sought, GK. That AG is greater than GH will be proved thus. Since BC and FG are equal, and the common segment CG is added, BG and CF will also be equal. Adding, then, the unequal segments — AB to BG, and BC to CF — AG will be greater than BF, that is, than GH: since AB, once added, gives more than BC once added. That AG and GH are the sides sought will be demonstrated as follows. With centre A and radius AG describe a circle; draw through A and H a straight line cutting the circumference at L and M; and extend AD, cutting the circumference at I. Now since the rectangle contained by BC and BD [Margin: i) Bk. 2, Prop. 1] is equal to the rectangles contained by CB and BA, and by CB and AD — that is, to twice the rectangle on the excesses AB, BC — and since the square on BE is equal to the rectangle contained by BC and DB, as we showed, the square on BE will also be double the rectangle contained by AB and BC; that is, the square on BE will be equal to twice the rectangle contained by AB and BC.

Adding, then, the common square on BC, together with twice the rectangle contained by BG and BC — that is, by CF and BC — the squares on BE (or CF) and on BC, together with twice the rectangle contained by CF and BC, will be equal to twice the rectangle contained by AB and BC, together with the square on BC and twice the rectangle contained by CF and BC. But the squares on CF and BC, together with twice the rectangle contained by CF and BC [Margin: k) Bk. 2, Prop. 4], are equal to the square on BF. Therefore the square on BF too will be equal to twice the rectangle contained by AB and BC, together with the square on BC and twice the rectangle contained by CF and BC (or by BG and BC). Since, then, twice the rectangles contained by AB and BC and by BG and BC is equal to the rectangle contained by IG (because IG is double AB, BG taken together) and by BC (or FG), the square on BF will also be equal to the rectangle contained by IG and FG,

together with the square on BC (or FG). But the rectangle contained by IG and GE, together with the square on FG [Margin: l) Bk. 2, Prop. 3], is likewise equal to the rectangle contained by IF and FG. Adding, therefore, the common square on AG, the squares on GH and AG will be equal to the rectangle contained by IF and FG, together with the square on AG. But the square on AH is equal to the squares on GH and AG [Margin: m) Bk. 1, Prop. 47], and the square on AF is equal to the rectangle contained by IF and FG, together with the square on AG. [Margin: n) Bk. 2, Prop. 6] Therefore the square on AH is equal to the square on AF, and the straight line AH is equal to the straight line AF; and when the equals AL and AG are removed, the remainders LH and GF will be equal. The diameter AH of the rectangle GK — that is, the straight line AF — therefore exceeds the greater side AG, namely by GF, by the given excess BC; and it exceeds the lesser side GH itself, namely the straight line BF (equal to GH), by the given excess AB. Which is what was proposed.

Corollary

Thus the straight line BE (or CF), whose square is double the rectangle contained by the given excesses AB and BC, when added to the lesser excess BC, produces the lesser side sought, BF — that is, GH. And the same line BE — that is, BG — added to the greater excess AB, makes up the greater side sought, AG. And finally the same line BE (or CF), taken with both excesses AB and BC, constitutes the diameter AF (or AH).

FINIS ELEMENTI SECVNDI. (*End of the Second Element.*)

EUCLID'S THIRD ELEMENT

(*EVCLIDIS ELEMENTVM TERTIVM*)

DEFINITIONS

I.

Definition (Euclid). Circles are equal whose diameters are equal, or whose straight lines drawn from their centres are equal.

Commentary (Clavius). Since Euclid in this third book demonstrates various properties of the circle, he first explains certain terms that will be frequently used in it. He teaches first, then, that those circles are equal whose diameters, or whose semidiameters, are equal. For since a circle is described by the revolution of a semidiameter about one fixed and immovable extremity — as we said in

Book I — it is evident that those circles are equal whose semidiameters, that is, whose straight lines drawn from the centres, are equal; or likewise those whose whole diameters are equal. Thus if the diameters AB and BC, or the straight lines DF and EG drawn from the centres D and E, are equal, the circles AFB and BGC will be equal. So too, conversely, if the circles are equal, their diameters, or the straight lines drawn from their centres, will be equal. From this it is clear that circles whose diameters, or whose lines drawn from the centres, are unequal are themselves unequal — and indeed that the one whose diameter or semidiameter is greater is the greater. And conversely, that the diameters or semidiameters of unequal circles are unequal, the greater belonging to the greater circle and the lesser to the lesser.

Diagram. Four circles illustrating equal and unequal circles: the upper pair equal, the lower pair unequal (one large, one small). Each circle has a horizontal diameter and a vertical radius drawn to the circumference.

- Upper-left circle (AFB): A (left), D (centre), B (right); F (bottom, on the circumference)
- Upper-right circle (BGC): left endpoint [B?] (label not clearly legible [?]), E (centre), C (right); G (bottom, on the circumference)
- Lower-left circle (AFB, larger): A (left), D (centre), B (right); F (bottom)
- Lower-right circle (BGC, smaller): left endpoint [B?] (label not clearly legible [?]), E (centre), C (right); G (bottom)

II.

Definition (Euclid). A straight line is said to touch a circle when, on touching the circle, it does not — if produced — cut the circle.

Commentary (Clavius). Thus the straight line AB, if it touches the circle BFD at B in such a way that, when produced to C, it in no way cuts the circle but lies wholly outside it, will be said to touch the circle. But the straight line EF, because it so touches the same circle at F that, when produced to G, it cuts the circle and falls within it, will not be said to touch the circle, but to cut it.

Diagram. A circle BFD with a tangent line and a secant line, illustrating the distinction between touching and cutting.

- A, B, C (the tangent straight line across the top; B is the point of contact at the top of the circle)
- E, F, G (the secant line: E outside/upper-left, F where it meets the circumference, G where it passes within)

- D (bottom of the circle)

III.

Definition (Euclid). Circles are said to touch one another when, touching one another, they do not cut one another.

Book III — Definitions (continued)

Definition III (continued) — circles touching one another

Diagram. A group of illustrative figures at the head of the page, showing the ways in which two circles can meet. In the upper row are three small figures; in the lower row two larger pairs of circles.

- Upper-left figure: two circles touching, one lying within the other; labelled **C** (top of the inner circle), **B** (middle), **A** (at the bottom, near the point of contact) — internal tangency.
- Upper-middle figure: a single circle, labelled **A** (inside, upper part).
- Upper-right figure: a circle labelled **B** (top) and **C** (within, upper-left).
- Lower-left pair: two large circles overlapping and cutting one another (mutual intersection); no interior labels legible.
- Lower-right pair: a larger and a smaller circle in contact (external/internal tangency); no interior labels legible.

(Clavius's commentary on Definition III): In the same way, two circles AC and BC are said to touch one another at C, if they meet at C in such a way that neither cuts the other. This contact of circles is of two kinds. Either the circles touch one another externally — as when one is placed outside the other — or internally, when one is set inside the other. But if two circles touch one another in such a way that the one also cuts the other, then those circles are said to cut one another mutually, and not to touch.

IV.

(Euclid's definition): In a circle, straight lines are said to be equally distant from the centre when the perpendiculars drawn to them from the centre are equal. And a line is said to be farther off onto which the greater perpendicular falls.

(Clavius's commentary): Among all the straight lines drawn from any point to a given straight line, the shortest is the perpendicular, and it is always one and the

same, whereas the others can vary in infinitely many ways. The distance of a point from a straight line is therefore rightly reckoned by the perpendicular line.

Diagram. A triangle-like figure with apex above a horizontal base line, from which several lines descend.

- **A** (apex, above): the point from which the lines are drawn.
- Base line **BC** (horizontal), with the feet of the drawn lines marked, in order from the left: **B**, **F**, **E**, **D** (and the line runs on toward C).
- Lines **AD** (perpendicular, foot at D), **AE** and **AF** (oblique).

Thus the distance of the point A from the straight line BC is said to be the perpendicular AD, and not AE, or AF, or any other that is not perpendicular; for AD is shorter than all of them, by the corollary of Proposition 19 of Book 1 [Margin: a — *Elements* I.19]. Indeed, not only are AE and AF greater than AD, but they are also unequal among themselves. For AF is greater than AE, since the angle AEF is obtuse and AFE acute; and so with the other non-perpendicular lines. That AFE is acute is clear from this: in the triangle ADF the two angles ADF and AFD are less than two right angles [Margin: b — *Elements* I.17]; hence, since ADF is a right angle, the angle AFD must be less than a right angle. By the same reasoning the angle AED will be shown to be acute, because in the triangle ADE the two angles ADE and AED are less than two right angles [Margin: c — *Elements* I.17], and ADE is a right angle. Consequently, since AED and AEF together are equal to two right angles [Margin: d — *Elements* I.13], AEF will be obtuse.

This is why Euclid has defined the equal distance of straight lines in a circle from its centre by means of equal perpendiculars, and unequal distance by unequal ones. Thus two straight lines AB and CD in the circle ABCD are said to be equally distant from the centre E if the perpendiculars EF and EG are equal. But the line CD is said to be farther from the centre E than the line HI, if the perpendicular EG is greater than the perpendicular EK.

Diagram. A circle with centre E and several chords, with perpendiculars dropped from the centre.

- **A** (upper-left) and **B** (upper-right): endpoints of the chord AB.
- **C** (left) and **D** (lower-left): endpoints of the chord CD.
- **E** (centre).
- **F**: foot of the perpendicular EF on chord AB.
- **G**: foot of the perpendicular EG on chord CD.
- **H** (bottom) and **I** (right): endpoints of the chord HI.

- **K**: foot of the perpendicular EK on chord HI.

V.

(Euclid's definition): A segment of a circle is a figure contained by a straight line and a circumference of the circle.

(Clavius's commentary): Thus, if in the circle ABCD any straight line BD is drawn, then both the figure BAD — contained by the arc BAD and the straight line BD — and the figure BCD — contained by the straight line BD and the arc BCD — will be called a segment of the circle. From this it follows that there are three kinds of circular segment. There is the semicircle, when the straight line BD passes through the centre E; the segment greater than a semicircle, when the straight line BD does not pass through the centre, yet the centre lies within it, such as the segment BAD; and the segment less than a semicircle, outside of which the centre of the circle falls, such as the segment BCD. This we demonstrated in connection with Definition 18 of Book 1. By most geometers the straight line BD is called the *chord*, and the arc BAD, or BCD, the *arc*.

Diagram. A circle divided by a horizontal chord into an upper and a lower segment.

- **A** (top): a point on the upper arc.
- **E** (centre).
- **B** (lower-left) and **D** (lower-right): endpoints of the chord BD.
- **C** (bottom): a point on the lower arc.
- Upper segment BAD; lower segment BCD.

VI.

(Euclid's definition): An angle of a segment is one contained by a straight line and a circumference of the circle.

(Clavius's commentary): Euclid now defines the three kinds of angle that are considered in circles. In the first place, the angle of a segment: he says that the mixed angle BAC (or BCA), contained by the straight line AC and the arc ABC, is called the angle of a segment. If the segment of the circle is a semicircle, it will be called the angle of a semicircle. If the segment is greater than a semicircle, it will be called the angle of the greater segment; and finally, if the segment is less than a semicircle, it will be named the angle of the lesser segment.

VII.

(*Euclid's definition*): An angle in a segment is formed when some point is taken on the arc of the segment, and from it straight lines are joined to the ends of the straight line that is the base of the segment: that angle, I say, is the one contained by those joined lines.

(*Clavius's commentary*): Let ABC be any segment of a circle, whose base is the straight line AC. From any point B taken on the arc, let straight lines BA and BC be drawn to the points A and C, the ends of the base. The rectilineal angle ABC is then said to exist in the segment ABC.

Diagram. A segment of a circle with an inscribed angle.

- **B** (top, on the arc): the vertex of the inscribed angle.
- **A** (lower-left) and **C** (lower-right): the ends of the base AC.
- Lines BA and BC drawn; the angle ABC stands in the segment.

VIII.

(*Euclid's definition*): When the straight lines containing an angle cut off some arc, the angle is said to stand upon that arc.

(*Clavius's commentary*): From any point A taken on the circumference of the circle ABCD, let two straight lines AB and AD be drawn to the two ends B and D of the arc BCD, which those two straight lines AB and AD cut off. The rectilineal angle BAD is then said to stand upon the arc BCD. It is clear, however, that this angle does not differ from the preceding one except in name. For the very same rectilineal angle BAD is, by the preceding definition, said to be *in* the segment BAD, if the straight line BD is drawn as base; while by the present definition it is said to *stand upon* the arc BCD.

Diagram. A circle with an inscribed angle at A.

- **A** (top): the vertex of the angle.
- **D** (lower-left) and **B** (lower-right): the ends of the arc, to which the lines AD and AB are drawn.
- **C** (bottom): a point on the arc BCD.

Nevertheless, an angle in some segment must not be confused with an angle that stands upon the arc, even though it is one and the same angle; for they are referred to different things. An angle in a segment regards the segment in which it lies, whereas an angle standing upon an arc regards the arc that is the base of

the angle. Hence, if one takes some segment BCD of the circle in the circle ABCD, the angle lying in this segment and the angle standing upon its arc will not be the same. For the angle lying in it will be BCD; but the angle standing upon its arc BCD will be BAD, which differs greatly from it. On this point Orontius [Oronce Finé], Peletier [Jacques Peletier], and several other commentators have gone remarkably astray.

That the angle in a segment and the angle standing upon some arc are referred to different arcs will become clearer than daylight from the last proposition of Book 6, which can apply only to the arcs of circles upon which the angles stand, and not to those in which they lie — as we shall show in that place. The same is also readily established from the Greek word βεβηκέναι [Greek: bebēkenai, "to have stepped up," i.e. "to have ascended"], which means "to have ascended." For the angle DAB ascends above the arc BCD.

(*Clavius, further*): Besides the three angles just mentioned, geometers also consider the angle of contact [angulus contingentiae], which is contained by a straight line touching a circle and the arc of the circle; or else by two arcs touching one another, whether this happens externally or internally. For example: if the straight line AB touches the circle CDE at C, the mixed angle ACD (or BCE) will be called the angle of contact, or of tangency. Again, if the circle CED touches the circle EFG externally at E, and likewise the circle HFI touches the circle EFG internally at F, then the curvilinear angle CEF, as well as EFH (or GFI), will be called an angle of contact, or of tangency. And so, as you see, there are three angles of contact — one mixed, and the other two curvilinear.

Diagram. A circle with an inscribed triangle.

- A (top).
- B (left) and D (right).
- C (bottom).
- Chords drawn forming the inscribed triangle (ABD) and the diagonals, illustrating the angle standing on the arc.

Diagram. Two circles side by side, touching one another, with a straight line tangent above — illustrating the angle of contact.

- Along the top (tangent line): A, C, B, F (C and F marking points of contact).
- Left circle (CDE): D (far left), E (interior).
- Right circle (EFG / HFI): H (interior), G (far right).
- The point I is not legibly labelled on the tile [?].

IX.

(Euclid's definition): A sector of a circle is formed when an angle is constructed at the centre of the circle — the figure, namely, contained both by the straight lines containing the angle and by the arc cut off by them.

(Clavius's commentary): If in the circle ABCD, whose centre is E, the straight lines AE and CE form the angle AEC at the centre E, then the figure AECD — contained by the straight lines AE and EC and by the arc ADC, which those lines cut off — will be called a sector of the circle. From this it is also clearly gathered that the angle explained in Definition 8 is referred to the arc that is its base, and not to the one in which it lies, as many commentators have supposed. For just as in this definition Euclid understands the arc ADC — which is the base of the angle constructed at the centre — when he makes mention of the arc cut off by the straight lines AE and CE, so too in that other definition he must have understood, by the name "arc," the one that is the base of the angle constructed at the circumference and cut off by the straight lines; since in both definitions he used the same Greek word ἀπολαμβάνειν [Greek: apolambanein, "to cut off," i.e. to subtend an arc].

Diagram. A circle with two radii drawn from the centre, forming a sector.

- **B** (top) and **C** (right): points on the arc.
- **E** (centre).
- **A** (left) and **D** (bottom): further points on the circumference.
- Radii EA and EC drawn, cutting off the arc ADC (the sector AECD).

X.

(Euclid's definition): Similar segments of a circle are those that admit equal angles, or in which the angles are equal to one another.

(Clavius's commentary): That is to say, the segments ABDF and DCAE of the same circle ABCDEF, which admit these two equal angles ABF and DCE — or, what is the same thing, in which these same angles are equal — are, by Definition 7, called similar; and their arcs ABDF and DCAE are likewise called similar.

Diagram. A circle ABCDEF with inscribed chords forming two segments and their angles.

- **B** (top-left) and **C** (top-right).
- **A** (left) and **D** (right).

- F (lower-left) and E (lower-right).
- Chords drawn making the angles ABF and DCE, marking the similar segments ABDF and DCAE.

**

Definition X (commentary continued)

(Clavius's commentary): In the same way, segments of different circles — whether equal or unequal — are called similar by geometers when they either admit equal angles, or when equal angles exist in them. Thus, if in the circles ABCK, DEFL, GHIM the angles ABC, DEF, GHI are equal, then the segments (or arcs) ABC, DEF, GHI, which admit those angles — or in which the said angles exist — will be called similar.

Now this similarity of segments (or of arcs) consists in this: that whatever part one arc is of its own whole circumference, such a part also is the other arc, which is called similar to it, of its own whole circumference; so that, just as, and as great as, the part which the arc ABC is of the whole circumference ABCK, such and so great a part also is the arc DEF of the whole circumference DEFL; and likewise such and so great is the arc GHI of the whole circumference GHIM. Or rather, the similarity of the segments consists in this: that the similar segments (or arcs) have the same ratio to their whole circumferences. That segments which either admit equal angles, or in which equal angles exist, are indeed of this sort, we shall demonstrate in the last proposition of Book 6. For now let it suffice that such segments of circles — or also arcs, or circumferences — are called similar.

Diagram. Three circles side by side, each with an inscribed triangle, illustrating similar segments.

- First circle (ABCK): B (top), A (lower-left), C (lower-right), K (on the lower arc); inscribed triangle ABC.
- Second circle (DEFL): E (top), D (lower-left), F (lower-right), L (on the lower arc); inscribed triangle DEF.
- Third circle (GHIM): H (top), G (lower-left), I (lower-right), M (on the lower arc); inscribed triangle GHI.

(Clavius, further): By the same reasoning, arcs or circumferences are called similar when equal angles stand upon them, according to Definition 8. Thus, if in the same circles the angles ABC, DEF, GHI are equal, then the arcs (or circumferences) AKC, DLF, GMI upon which they stand will be called similar. Indeed, if the angles at the centres standing upon the arcs AKC, DLF, GMI are

equal, the arcs themselves will still be similar — which we shall demonstrate in the scholium to Proposition 22 of this Book.

PROBLEM 1. — PROPOSITION 1.

To find the centre of a given circle.

(*Clavius's demonstration*): Let ABCD be the given circle, whose centre is to be found. Draw in it any line AC, and let it be bisected at E [Margin: a — *Elements* I.10]; and through E let the perpendicular BD be drawn to AC, terminated on both sides at the circumference in the points B and D. Then, this line BD having been bisected at F, I say that F is the centre of the proposed circle.

For on the straight line BD no point other than F will be the centre, since every other point divides it unequally, whereas at F it was divided equally. If, then, F is not the centre, let some point G, off the straight line BD, be the centre, and from it let the lines GA, GE, GC be drawn. Now since the sides AE and EG of the triangle AEG are equal to the sides CE and EG of the triangle CEG, and the base AG to the base CG (for they are said to be drawn from the centre), the angles AEG and CEG will be equal [Margin: b — *Elements* I.8], and therefore right angles. But the angle AEF was also a right angle, by construction. Therefore the right angles AEF and AEG are equal — the part and the whole — which is absurd. Point G, therefore, is not the centre; and the same reasoning holds for every other point. Hence F will be the centre. And so we have found the centre of the given circle. Which was to be done.

Diagram. A circle with a horizontal chord AC and a vertical chord BD crossing it, with the false centre G marked above.

- **B** (top) and **D** (bottom): ends of the perpendicular chord BD.
- **A** (left) and **C** (right): ends of the chord AC.
- **E** (where BD meets AC; midpoint of AC).
- **F** (on BD; midpoint of BD — the true centre).
- **G** (above, off BD — the supposed false centre), with lines GA, GE, GC drawn.

COROLLARY.

(*Clavius*): From this it is manifest that, if in a circle some straight line cuts another straight line into two equal parts and at right angles, the centre of the circle lies on the cutting line. For from the fact that the straight line BD cuts the straight line AC into two equal parts at E and at right angles, it was shown that its midpoint F is necessarily the centre of the circle.

THEOREM 1. — PROPOSITION 2.

If two points whatever are taken on the circumference of a circle, the straight line joined to those points will fall within the circle.

(*Clavius's demonstration*): In the circle ABC let any two points A and C be taken on its circumference. I say that the straight line drawn from A to C falls within the circle, so that it cuts the circle. For if it does not fall within, let it fall outside, as does the line ADC, as the adversary would have it. Then, the centre E having been found [Margin: a — *Elements* III.1], let there be drawn from it, to the points A and C that were taken, and also to any point D on the line ADC, the straight lines EA, EC, ED; and let ED cut the circumference at B.

Now since the two sides EA and EC of the triangle whose base is the line ADC are equal (for they are drawn from the centre), the angles EAD and ECD will be equal [Margin: b — *Elements* I.5]. But the angle EDA is greater than the angle ECD [Margin: c — *Elements* I.16], being the exterior angle opposite the interior, since the side CD in the triangle ECD is produced to A. Therefore the same angle EDA will also be greater than the angle EAD. Hence the straight line EA, subtending the greater angle ADE — that is, the line EB, equal to it — will be greater than the line ED [Margin: d — *Elements* I.19], which subtends the lesser angle DAE: the part greater than the whole. Which is absurd. Therefore the straight line drawn from A to C will not fall outside the circle, but within.

For it will be demonstrated in the same way that the line drawn from A to C cannot fall upon the arc ABC, so as to coincide with the circumference ABC. For then the straight line EA would be greater than the straight line EB. This is also clear from the definition of a straight line, since ABC, being an arc, is a curved line and not a straight one. And so, if two points whatever are taken on the circumference of a circle, and so on. Which was to be proved.

Diagram. A circle with centre E; a supposed line ADC bulging outside above, with radii drawn to the centre.

- **D** (top): the point on the falsely-assumed exterior line ADC.
- **B** (just below D): where the radius ED cuts the circumference.
- **A** (left) and **C** (right): the two given points on the circumference.
- **E** (centre), with lines EA, EC, ED drawn.

SCHOLIUM

(*Clavius, continuing the scholium to Proposition 2*)

This same theorem can also be proved affirmatively, as follows. Let the straight line AB join two points A and B on the circumference of the circle AB whose centre is C. I claim that AB falls within the circle, so that all its intermediate points lie inside the circle. For take any one of its intermediate points, D, and draw from the centre the straight lines CA, CB, and CD. Since the two sides CA and CB of the triangle CAB are equal, the angles CAB and CBA are equal (d). But the angle CDA is greater than the angle CBA, being an exterior angle greater than the interior one (e). Therefore the same angle CDA is also greater than the angle CAD, and for that reason the side CA will be greater than the side CD (f). Hence, since CA is drawn from the centre all the way to the circumference, the line CD will not reach the circumference, and so the point D falls within the circle. The same can be shown for any other point taken. Therefore the whole straight line AB falls within the circle — which was to be proved.

[Margin: (d) Elements I.5] [Margin: (e) Elements I.16] [Margin: (f) Elements I.19]

Diagram. A circle with a chord across its upper portion and a triangle inscribed to the centre below.

- A (upper left, on circumference): endpoint of the chord
- B (upper right, on circumference): other endpoint of the chord
- D (on the chord AB, between A and B): the arbitrary intermediate point
- C (centre, lower middle): centre of the circle; radii CA, CB, CD are drawn from it

COROLLARIUM

From this it is clear that a straight line which is tangent to a circle, in such a way that it does not cut it, touches it at one point only. For if it were to touch it at two points, the part of the straight line lying between those two points would fall within the circle (g). It would therefore cut the circle — which is contrary to the hypothesis.

[Margin: (g) Elements III.2]

THEOR. 2. PROPOS. 3.

[Margin: iij.]

(Euclid's enunciation)

If in a circle a straight line drawn through the centre bisects another straight line not drawn through the centre, it will also cut it at right angles. And if it cuts it at right angles, it will also bisect it.

(Clavius's demonstration)

Let the straight line CE, extended through the centre A of the circle BCD, divide the straight line BD (which is not drawn through the centre) into two equal parts at F. I claim that AF is at right angles to BD. For, when the straight lines AB and AD are drawn, the two sides AF and FB of the triangle AFB will be equal to the two sides AF and FD of the triangle AFD, and the bases AB and AD will be equal. Therefore the angles AFB and AFD will be equal (a) — that is, right angles. This is what was proposed in the first place.

[Margin: (a) Elements I.8]

Now let AF be at right angles to BD. I claim that BD is bisected at F by the line CE. For when the straight lines AB and AD are again drawn, since the sides AB and AD of the triangle ABD are equal, the angles ABD and ADB will be equal (b). Since, then, the two angles AFB and ABF of the triangle ABF are equal to the two angles AFD and ADF of the triangle ADF, and the sides AB and AD, which lie opposite the equal right angles, are also equal, the sides FB and FD will be equal (c). This is what was proposed in the second place. Therefore, if in a circle a straight line drawn through the centre, and so on — which was to be demonstrated.

[Margin: (b) Elements I.5] [Margin: (c) Elements I.26]

This second part, which is indeed the converse of the first, could also easily be proved by the following reasoning. If AF is perpendicular to BD, then the square on AB will be equal to the squares on AF and FB (d), just as the square on AD will be equal to the squares on AF and FD. Since, then, the square on AB is equal to the square on AD, the squares on AF and FB will also be equal to the squares on AF and FD. Hence, when the common square on AF is taken away, the remaining squares on FB and FD will be equal, and therefore the lines FB and FD will also be equal.

[Margin: (d) Elements I.47]

Diagram. A circle with a vertical diameter and a horizontal chord crossing it, with an inscribed triangle.

- C (top, on circumference): upper endpoint of the diameter CE
- A (centre): centre of the circle

- F (on the chord BD, at its crossing with the diameter): point of bisection
- B (left, on circumference): left endpoint of the chord
- D (right, on circumference): right endpoint of the chord
- E (bottom, on circumference): lower endpoint of the diameter CE
- Straight lines AB and AD are drawn, forming the triangle ABD

COROLLARIUM

From this demonstration we shall easily infer that, in any triangle having two equal sides — whether it is equilateral or isosceles — the line that bisects the base is perpendicular to the base; and, conversely, that the line perpendicular to the base bisects the base. For in the triangle ABD, whose two sides AB and AD are equal (so that a circle can be described from the centre A through B and D): from the fact that the line AF bisects the base BD it has been shown that the angles at F are right angles; and from the fact that the angles at F are right angles it has been demonstrated that the base BD is bisected by the line AF. But we also demonstrated this at Proposition 26 of Book 1, and indeed more generally.

SCHOLIUM

We judge that this is also the place to prove the following theorem, which is not without use for what follows — namely:

(theorem)

If two circles are described from the same centre, and from some point of the outer circumference a straight line is drawn cutting the inner circumference, then the segments of it lying between the two circumferences will be equal to each other.

(demonstration)

Let two circles ABC and DEFG have the same centre H, and from the point A let there first be drawn, through the centre H, the straight line AC, cutting the inner circumference at D and G. I claim that the lines AD and CG are equal. For if from HA and HC, which are equal (e), we take away HD and HG, which are equal for the same reason, then the lines AD and CG will be equal (f).

[Margin: (e) Elements I, Definition 15] [Margin: (f) Common Notion 3]

Next, from the same point A let the straight line AB be drawn, not through the centre, cutting the inner circumference at E and F. I claim, again, that the lines AE and BF are equal. For when the perpendicular HI is drawn from the centre H to

AB (g), it will bisect both the line AB in the circle ABC and the line EF in the circle DEFG (h). Therefore, when the equal parts IE and IF are taken away from the equal parts IA and IB, the remainders AE and BF will be equal (i) — which is what was proposed.

[Margin: (g) Elements I.12] [Margin: (h) Elements III.3] [Margin: (i) Common Notion 3]

Diagram. Two concentric circles about a common centre H, with a diameter and an oblique secant drawn from the top point A.

- A (top, on outer circumference): the point from which the lines are drawn
- D (upper, on inner circumference): where the diameter meets the inner circle
- E (upper, on inner circumference): where the oblique line AB meets the inner circle
- I (interior, on line AB): foot of the perpendicular HI from the centre
- H (centre): the common centre of both circles
- F (lower left, on inner circumference): where the oblique line meets the inner circle again
- G (lower, on inner circumference): where the diameter meets the inner circle again
- B (lower left, on outer circumference): lower end of the oblique line
- C (bottom, on outer circumference): lower end of the diameter AC

[Margin: iv.]

THEOR. 3. PROPOS. 4.

(Euclid's enunciation)

If in a circle two straight lines cut each other, neither being drawn through the centre, they will not bisect each other.

(Clavius's demonstration)

Let two straight lines AB and CD cut each other at E in the circle ACBD, neither drawn through the centre. I claim that it is impossible for them to bisect each other. For if one of them passes through the centre, it is certain that it is not bisected by the other: only at the centre, through which the other is supposed not to pass, is it divided into two equal parts. But if neither is drawn through the centre, then although one of them may sometimes be bisected by the other, still

the other will by no means be bisected. So let both AB and CD, if it be possible, be bisected at E. Then, once the centre F of the circle has been found (a), let the straight line FE be drawn from it to E. Since, then, FE is supposed to cut the line AB into two equal parts at E, it will cut it at right angles (b). By the same reasoning CD will be cut at right angles, since it is supposed to be bisected at E. Hence the right angle FED is equal to the right angle FEB — a part equal to the whole, which is absurd. Therefore, if in a circle two straight lines cut each other, and so on — which was to be demonstrated.

[Margin: (a) Elements III.1] [Margin: (b) Elements III.3]

Diagram. A circle ACBD with two chords crossing inside it and a line drawn from the centre to their crossing point.

- F (centre, upper middle): centre of the circle
- A (left, on circumference): endpoint of the chord AB
- B (right, on circumference): other endpoint of the chord AB
- C (lower left, on circumference): endpoint of the chord CD
- D (right, on circumference): other endpoint of the chord CD
- E (interior): the point where AB and CD cross; the line FE is drawn to it

THEOR. 4. PROPOS. 5.

[Margin: vj.]

(Euclid's enunciation)

If two circles cut each other, they will not have the same centre.

(Clavius's demonstration)

Let two circles ABD and EBD cut each other at B and D. I claim that they do not have the same centre. For let there be, if it be possible, the same centre C for both, from which two straight lines are drawn: CB to the point of section B, and CA cutting both circumferences at A and E. Since, then, C is supposed to be the centre of the circle EBD, the line EC will be equal to the line CB. Again, since C is supposed to be also the centre of the circle ABD, the line AC will likewise be equal to the same line BC. Hence the lines EC and AC will be equal to each other (a) — a part and the whole, which is absurd. Therefore, if two circles cut each other, and so on — which was to be shown.

[Margin: (a) Common Notion 1]

Diagram. Two circles intersecting at two points, with a supposed common centre C and two lines drawn from it.

- B (top): one of the two points where the circles cut each other
- C (centre region): the assumed common centre
- A (left, on the outer circumference): where the line CA meets one circle
- E (between A and C, on the other circumference): where the line CA meets the other circle
- D (bottom): the other point where the circles cut each other

THEOR. 5. PROPOS. 6.

[Margin: vij.]

(Euclid's enunciation)

If two circles touch each other internally, they will not have the same centre.

(Clavius's demonstration)

Let two circles AB and BC touch each other internally at B. I claim that they do not have the same centre. For let them have, if it be possible, the same centre D, from which two straight lines are drawn: DB to the point of contact B, and DC cutting both circumferences at A and C. Since, then, D is supposed to be the centre of the circle AB, the line AD will be equal to the line BD. Again, since D is supposed to be the centre of the circle BC, the line CD will be equal to the same line BD. Hence the lines AD and CD will be equal to each other (a) — a part and the whole, which is absurd. Therefore, if two circles touch each other internally, and so on — which was to be demonstrated.

[Margin: (a) Common Notion 1]

Diagram. Two circles touching internally, with a supposed common centre D and two lines drawn from it.

- B (top): the point of internal contact of the two circles
- D (centre): the assumed common centre
- C (lower left, on the outer circumference): where the line DC meets the outer circle
- A (near C, on the inner circumference): where the line DC meets the inner circle

SCHOLIUM

Euclid proposed this theorem only for circles that touch each other internally, since for circles touching each other externally — one being outside the other — it is manifest that they cannot have the same centre.

THEOR. 6. PROPOS. 7.

(Euclid's enunciation)

If in the diameter of a circle some point is taken which is not the centre of the circle, and from that point certain straight lines fall onto the circle, then: the greatest will be the one on which the centre lies, and the least will be the remaining part [of the diameter]; and of the others, the one nearer to the line drawn through the centre is always greater than one more remote; and only two equal straight lines fall from the same point onto the circle, one on either side of the least or of the greatest.

(Clavius's demonstration)

In the diameter AB of the circle ACDEB, whose centre is F, let any point G be taken other than the centre, and from G let any number of lines GC, GD, GE fall onto the circle. I claim that, of all the lines drawn from G to the circumference, the greatest is GA, on which the centre lies, and the least is the remaining part GB, which completes the diameter. Next, that the line GC, which is nearer to the line GA drawn through the centre, is greater than the line GD, which is farther from that same GA; and by the same reasoning GD is greater than GE; and so on with the other lines, if they were to be drawn, to infinity. Finally, that from G, on either side of the least line GB or the greatest line GA, only two lines equal to each other can be drawn. Let the straight lines FC, FD, FE be drawn from the centre F to C, D, and E. Since, then, the two sides GF and FC of the triangle GFC are greater than the side GC (a); but the lines GF and FC are equal to the lines GF and FA, that is, to the whole line GA; GA will also be greater than GC. By the same reasoning the line GA will be greater than GD, and than GE. Hence GA is the greatest of all the lines that fall from G onto the circle.

[Margin: (a) Elements I.20]

Next, since in the triangle EFG the side EF is less than the two sides FG and GE (b), and EF is equal to FB, FB will also be less than the two lines FG and GE. Therefore, when the common line FG is taken away, GB will still remain less than GE. By the

same reasoning GB will be less than GD and than GC. Hence GB is the least of all the lines that fall from G onto the circumference of the circle.

[Margin: (b) Elements I.20]

Diagram. A circle with a vertical diameter AB, a centre F, an interior point G on the diameter, and several lines fanning out from G to the circumference.

- A (top, on circumference): upper end of the diameter; the greatest line GA runs to it
- C (upper left, on circumference): endpoint of line GC
- D (left, on circumference): endpoint of line GD
- F (centre): centre of the circle; lines FC, FD, FE drawn from it
- G (below F, on the diameter): the assumed point from which the lines fan out
- E (lower left, on circumference): endpoint of line GE
- B (bottom, on circumference): lower end of the diameter; the least line GB runs to it
- H (lower right, on circumference): endpoint of the line GH (introduced later in the demonstration on the facing page)

(continuation of the demonstration of Prop. 7)

Again, since the two sides GF and FC of the triangle GFC are equal to the two sides GF and FD of the triangle GFD, while the whole angle GFC is greater than the angle GFD, the base GC will be greater than the base GD (c). By the same reasoning GC will be greater than GE; likewise GD will be greater than GE. Hence the line nearer to the one drawn through the centre is greater than the one more remote.

[Margin: (c) Elements I.24]

Now let there be made, on the other side, an angle BFH equal to the angle BFE, and let the straight line GH be drawn. Since, then, the sides EF and FG of the triangle EFG are equal to the sides HF and FG of the triangle HFG, and the angles contained by these sides, EFG and HFG, are equal, the lines GE and GH — one on each side of the least line GB or the greatest line GA — will be equal to each other (d). And it is settled that no other line can be equal to these two. For if from G another is drawn which falls above the point H, it will, being nearer to the line drawn through the centre, be greater than GH; but if it falls below H, it will, being more remote from that same GA drawn through the centre, be less than GH, as was shown. Therefore only two equal straight lines fall on either side of the least

line GB or the greatest line GA. And so, if in the diameter of a circle some point is taken, and so on — which was to be demonstrated.

[Margin: (d) Elements I.4]

SCHOLIUM

[recte: SCHOLIUM]

Although Euclid demonstrated only that the line nearer to the line drawn through the centre is greater than the more remote one when both lines lie on the same side of the diameter AB, nevertheless the same is also true if they are drawn on different sides. For example, if someone says that the line GD is nearer to the line GA than the line GH is, I claim that GD is greater than GH. For if, on the other side, a line GE is drawn equal to GH, as was said — namely, if the angle GFE is made equal to the angle GFH, and so on — the point E will fall between D and B, because GH and GE are equally distant from GA on account of the equality of the angles GFH and GFE, whereas GD is supposed to be less distant than GH, and therefore less distant than GE. Since, then, GD is greater than GE (c), the same GD will also be greater than GH.

[Margin: (c) Elements III.7]

Diagram. A circle with a vertical diameter AB, centre F, an interior point G, and lines fanning out from G to points on the circumference (the same figure that serves Proposition 7).

- A (top, on circumference): upper end of the diameter
- C (upper left, on circumference): endpoint of line GC
- F (centre): centre of the circle
- D (left, on circumference): endpoint of line GD
- G (below F, interior on the diameter): the point from which the lines fan out
- E (lower left, on circumference): endpoint of line GE
- H (lower right, on circumference): endpoint of line GH
- B (bottom, on circumference): lower end of the diameter

Furthermore, some convert this proposition as follows.

(the converse, as stated by some)

If within a circle a point is taken, and of the straight lines falling from that point onto the circle one is the greatest and one the least, while of the rest some are

unequal and some equal, then: the greatest will pass through the centre; the least will be the remaining part of the diameter; and of the others, the greater ones will be nearer to the greatest, while the equal ones will be equally distant from that greatest (or from the least).

(demonstration)

In the circle ABC let a point D be taken, from which any number of lines DA, DC, DE, DF, DB fall onto the circumference, of all of which let DA be the greatest and DC the least; and of DE and DF let DE be the greater; and finally let DE and DB be equal. I claim that DA passes through the centre; that DC is the remaining part of the diameter — that is, that DC is in a straight line with DA; likewise that DE, which is supposed greater than DF, is nearer to the greatest line DA than DF is; and finally that DE and DB are equally distant from that same DA (or DC). For, first, if DA does not pass through the centre, then when some straight line is drawn from D through the centre, it will be the greatest of all the lines falling from D (f) — which is absurd, since DA is supposed to be the greatest. Therefore DA passes through the centre.

[Margin: (f) Elements III.7]

Next, if DC is not in a straight line with DA, then when AD is produced in a straight line, there will be another line, distinct from DC, falling from D — namely the produced part of AD — which is the least of all (g); which is absurd, since DC is supposed to be the least. Therefore DC is the remaining part of the diameter.

[Margin: (g) Elements III.7]

Again, if DE is not nearer to the greatest line DA than DF is, then either they will be equally distant from it, or DE will be farther from it. If they are said to be equally distant from DA on both sides, they will be equal (h) — which is absurd, for DE is supposed the greater. But if they are said to be equally distant from DA on the same side, then DE and DF will be one and the same line, and so DE will not be greater than DF, which is contrary to the hypothesis. And if DF is said to be nearer to the greatest line DA, then it will be greater than DE (i) — which is even more absurd.

[Margin: (h) Elements III.7] [Margin: (i) Elements III.7]

Finally, if DE and DB are not equally distant from DA (or DC), then the one that is farther from DA will be the smaller (k) — which is absurd, since DE and DB are supposed equal.

[Margin: (k) Elements III.7]

Diagram. A circle with an interior point D near the bottom, from which several lines are drawn to the circumference.

- A (top, on circumference): endpoint of the greatest line DA (through the centre)
- B (upper right, on circumference): endpoint of line DB
- E (upper left, on circumference): endpoint of line DE
- F (left, on circumference): endpoint of line DF
- D (interior, lower middle): the point from which the lines are drawn
- C (bottom, on circumference): endpoint of the least line DC (in a straight line with DA)

THEOR. 7. PROPOS. 8.

[Margin: viij.]

(Euclid's enunciation)

If some point is taken outside a circle, and from that point certain straight lines are drawn to the circle, of which one is extended through the centre while the rest are drawn as one pleases, then: of those falling on the concave arc, the greatest is the one drawn through the centre, while of the others the one nearer to the line drawn through the centre is always greater than the more remote. But of those falling on the convex arc, the least is the one that lies between the point and the diameter, while of the others the one nearer to the least is always less than the more remote. And only two equal straight lines fall from that point onto the circle itself, one on either side of the least or of the greatest.

(Clavius's demonstration)

From the point A, outside the circle BCDE whose centre is K, let lines cutting the circle be drawn, of which AI passes through the centre, while the others, AH, AG, AF, are drawn as one pleases. I claim that of all of them the greatest is AI, which runs through the centre. Next, that the line AH, which is nearer to the line AI drawn through the centre, is greater than the line AG, which is more remote from that same AI; and by the same reasoning that AG is greater than AF. On the contrary, that the line AB is the least of all those [parts] lying outside the circle. Next, that the line AC, which is nearer to the least line AB, ...

[The demonstration of Proposition 8 continues.]

Euclid's *Elements*, Book III — Clavius's Commentary (continued)

THEOR. 7. PROPOS. 8 (continued) — lines drawn from a point outside the circle

[Clavius's demonstration, continued from the previous page.]

that the least line AB is less than the more remote AD; and by the same reasoning that AD itself is less than AE. Finally, that from A, toward either side of the least line AB or of the greatest line AI, only two straight lines equal to one another can be drawn.

From the center K draw to the points C, D, E, F, G, H the straight lines KC, KD, KE, KF, KG, KH. Now the two sides AK, KH of triangle AKH are greater than the straight line AH [Margin: a — *Elements* I.20]; but the straight lines AK, KH together are equal to AK, KI, that is, to the whole line AI. Therefore AI too is greater than AH. By the same reasoning AI is greater than AG, and than AF. Hence AI is the greatest of all the lines that fall from A into the circle.

Next, since the sides AK, KH of triangle AKH are equal to the sides AK, KG of triangle AKG, and the whole angle AKH is greater than the angle AKG, the base AH will be greater than the base AG [Margin: b — *Elements* I.24]. By the same reasoning AH will be greater than AF, and AG greater than AF. Therefore the line nearer the one drawn through the center is greater than the line farther from it.

Again, since in triangle ACK the straight line AK is less than the two lines AC, CK [Margin: c — *Elements* I.20], if the equals BK, CK are subtracted, AB will still remain less than AC. By similar reasoning AB will be less than AD, and than AE. Therefore AB is the least of all the lines drawn from A outside the circle.

Again, since within triangle ADK the two straight lines AC, CK fall from the extremities of the side AK, the lines AC, CK will be less than AD, DK [Margin: d — *Elements* I.21]. When therefore the equals CK, DK are taken away, AC will still remain less than AD. By parity of reasoning AC is less than AE, and likewise AD is less than AE. Therefore the line nearer the least line AB is less than the line more remote from it.

Finally, let the angle AKL be made equal to the angle AKC, and let the straight line AL be drawn. Since the sides AK, KC of triangle AKC are equal to the sides AK, KL of triangle AKL, and the angles AKC, AKL contained by those sides are equal, the

straight lines AC, AL — one on either side of the least line AB or of the greatest AI — will be equal to one another [Margin: e — *Elements* I.4]. And it is evident that no other line can be equal to these. For if a line be drawn from A falling beyond L, it, being more remote from the least, will be greater than AL. But if it fall between B and L, it, being nearer the least, will be less than AL, as has been shown. Therefore only two equal straight lines fall on either side of the least, or of the greatest. If, then, a point be taken outside a circle, and from that point certain straight lines be drawn to the circle, of which one is extended through the center, and so on. Which was to be demonstrated.

SHOLIVM. [transcribed verbatim; the C is dropped — read "SCHOLIVM."]

[*Clavius's scholium.*]

By the same reasoning, from A only two equal lines will fall on the concave circumference, one on either side of the greatest line AI. For let the angle AKM be made equal to the angle AKH, and let the straight line AM be joined. Since then the sides of triangle AKH are equal to the sides AK, KM, and the angles AKH, AKM are also equal, the bases AH, AM will be equal [Margin: f — *Elements* I.4]. Nor indeed can any other line be shown equal to these two. For if from A a line be drawn toward the side of H, it will be either greater or less than AH, according as it is drawn short of AH or beyond it, as is manifest from the demonstration of the theorem.

This proposition is true also when one of the lines falling from A touches the circle. For since such a line lies farther from the line drawn through the center, it will be less than all the others falling on the concave circumference — as is the straight line AM in the earlier figure. For when the straight line KM is drawn from the center K, the two sides AK, KF of triangle AKF will be equal to the two sides AK, KM, while the angle AKF is greater than the angle AKM. Therefore the base AF will be greater than the base AM [Margin: g — *Elements* I.24]. By the same reasoning any other line falling on the concave circumference will be greater than the straight line AM. And by the same reasoning the tangent line AM will be greater than all the others falling on the convex circumference. For since the two sides AE, EK are less than the two sides AM, MK [Margin: h — *Elements* I.21], if the equals KE, KM be subtracted, the remainder AE will be less than the remainder AM. And the like reasoning holds for the rest.

Although Euclid demonstrated only that the line nearer the one drawn through the center is greater than the more remote, and likewise that the line nearer the

least is less than the more remote — provided both lines lie on the same side, that of the greatest or of the least — nevertheless the same is true also when the lines are drawn toward opposite sides. This will be demonstrated in no other way than the same was demonstrated in the scholium of the preceding proposition concerning two lines drawn toward opposite sides.

Diagram. The figure for Proposition 8: an external point A stands above a circle whose center is K, with straight lines drawn from A to the several points of the circle.

- A (apex, above the circle): the external point from which the lines are drawn
- L, B, C, D (in a row along the upper / near circumference, left to right): points where the drawn lines meet the near (convex) arc
- E (upper right, on the circumference)
- M (to the right, outside the circle)
- K (center of the circle)
- F (right, on the circumference)
- G (lower right, on the circumference)
- H (lower right, on the circumference)
- I (bottom, on the circumference — the far endpoint of the line through the center; AI is the greatest line)

Diagram. The figure accompanying the scholium: the external point A above a circle with center K, illustrating the equal lines falling on the concave circumference.

- A (apex, above the circle)
- K (center)
- H (lower left, on the circumference)
- M (lower right, on the circumference)
- I (bottom, on the circumference — far endpoint of the line AKI through the center)

THEOR. 8. PROPOS. 9 — a point from which more than two equal lines fall is the center [Margin: ix.]

[Euclid's enunciation.] If in a circle some point be taken, and from that point more than two equal straight lines fall to the circle, the point taken is the center of the circle.

[Clavius's demonstration.] Let there fall from the point A, taken in the circle BCD, more straight lines than two — AB, AC, AD — equal to one another. I say that A is the center of the circle. For let the points B, C, D be joined by the straight lines BC, CD; and these being bisected at E and F, let the straight lines AE, AF be drawn. Since then the sides AE, EB of triangle AEB are equal to the sides AE, EC of triangle AEC, and the bases AB, AC are also assumed equal, the angles AEB, AEC will be equal, and therefore right angles. In the same way we shall show that the angles at F are right angles. Therefore, since the straight lines AE, AF divide the straight lines BC, CD in half and at right angles, each of them, when produced, will pass through the center, by the corollary of Proposition 1 of this book. The point A, then, in which they mutually cut one another, will be the center of the circle. For if some other point were the center, both lines would not pass through the center. If, then, a point be taken in a circle, and so on. Which was to be demonstrated.

ALITER (another demonstration)

If the point A is not the center of the circle, let the center found be E [Margin: b — *Elements* III.1], and through E and A let the diameter FG be drawn. Since then in the diameter FG, besides the accepted center, lies the point A, from which the straight lines AD, AC fall to the circumference, the straight line AD — which is nearer to the line AG drawn through the center E — will be greater than the straight line AC, which is more remote from AG [Margin: c — *Elements* III.7]; which is absurd, for the lines AD, AC were assumed equal. The same absurdity will follow if any other point besides A be set as center.

But if it should happen that the straight line drawn through the center E and the point A coincides with one of the three given equal lines — as, for instance, if the three equals be called AB, AF, AC, where EA coincides with AF — then AF will be the least of all the lines falling from the point A [Margin: d — *Elements* III.7], and so less than AB and AC; which is absurd, for it is assumed equal to each of them.

THEOR. 9. PROPOS. 10 — a circle does not cut a circle in more than two points [Margin: x.]

[Euclid's enunciation.] A circle does not cut a circle in more than two points.

[Clavius's demonstration.] For let the circle ABCDEF cut the circle AGDBHE, if it be possible, in more than two points A, B, and D; let these be joined by the straight lines AB, BD; and these being bisected at I and K [Margin: a — *Elements* I.10], let the perpendiculars IL, KL be raised from I and K to AB and BD [Margin: b —

Elements I.11]. Since then the straight lines IL, KL cut the straight lines AB, BD in the circle AGBDHE in half and at right angles, each of them will pass through the center of that circle, by the corollary of Proposition 1 of this book. Therefore the point L, in which they divide one another, will be the center of the said circle. In the same way we shall demonstrate that the point L is the center of the circle ABCDEF. Two circles, then, cutting one another mutually, would possess the same center [Margin: c — *Elements* III.5]; which is absurd. Therefore a circle does not cut a circle in more than two points. Which was to be demonstrated.

ALITER (another demonstration)

Let the same two circles cut one another, if it be possible, in three points A, B, and D. Let I be the center found of the circle AGBDHE [Margin: d — *Elements* III.1], and from it let the straight lines IA, IB, ID be drawn to the three said points; these will be equal to one another by the definition of the circle. Since then within the circle ABCDEF the point I has been assumed, from which more than two equal straight lines fall to the circumference, I will be the center of the circle ABCDEF [Margin: e — *Elements* III.9]. But this same point I was the center of the circle AGBDHE. Therefore two circles cutting one another mutually would have the same center [Margin: f — *Elements* III.5]. Which is absurd.

THEOR. 10. PROPOS. 11 — internally tangent circles: the line of centers passes through the point of contact [Margin: xj.]

[*Euclid's enunciation.*] If two circles touch one another internally, and their centers be taken, then the straight line joined to their centers and produced will fall on the point of contact of the circles.

[*Clavius's demonstration.*] Let the circle ABC touch the circle ADE internally at A; let F be the center of the circle ABC, and G the center of the circle ADE — which will necessarily be distinct from F, since two circles touching internally cannot have the same center [Margin: a — *Elements* III.6]. I say that the straight line extended through G and F falls on the contact A. For if it does not so fall, let it cut each circle in the points D, B, C, E, and from the contact A let the straight lines AF, AG be drawn to the centers F, G. Since then in triangle AFG the two sides GF, FA are greater than the side GA [Margin: b — *Elements* I.20]; and GA is equal to the straight line GD (because G is set as the center of the circle ADE); the straight lines GF, FA together will be greater than GD. When therefore the common GF is subtracted, FA will remain greater than FD. And since FA is equal to FB (because F was set as the center of the circle ABC), FB too will be greater than FD — the part greater than the whole; which is absurd.

But if anyone should wish to maintain that F is the center of the circle ADE, and G the center of the circle ABC, the argument will be framed in this way. In triangle AFG the two sides FG, GA are greater than the side FA [Margin: c — *Elements* I.20]. But the straight line FA is equal to FE (since F is set as the center of the circle ADE). Therefore the straight lines FG, GA are greater than FE. When the common FG is subtracted, GA will remain greater than GE. And since GA is equal to GC (because G is set as the center of the circle ABC), GC too will be greater than GE — the part greater than the whole; which is absurd. The same absurdity will follow if the center of the greater circle be placed outside the smaller. Therefore the straight line FG, produced, will not cut both circles, but will fall on the contact A. Hence if two circles touch one another internally, and so on. Which was to be demonstrated.

THEOR. 11 PROPOS. 12 — externally tangent circles: the line of centers passes through the contact [Margin: xij.]

[*Euclid's enunciation.*] If two circles touch one another externally, the straight line joined to their centers will pass through the point of contact.

THEOR. 11. PROPOS. 12 (continued)

[*Clavius's demonstration.*] Let the two circles ABC, DBE touch one another externally at B; let the center of the circle ABC be F, and the center of the circle DBE be G. I say that the straight line extended through F and G passes through the contact B. For if it does not so pass, let it cut the circumferences in C and E, and from the centers F, G let the straight lines FB, GB be drawn to the contact B. Since then in triangle FBG the two sides BF, BG are greater than the side FG [Margin: a — *Elements* I.20]; and the straight line BF is equal to FC (because F is set as the center of the circle ABC), and the straight line GB is equal to GE (because G is set as the center of the circle DBE); the straight lines FC, GE together will be greater than the straight line FG — the part greater than the whole, since FG contains, besides FC and GE, the further straight line CE — which is absurd. If, then, two circles touch one another externally, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 12: two circles touching externally at B, with a dotted straight line running through the two centers and the point of contact.

- A (top of the left circle)
- D (top of the right circle)
- B (middle, the point of external contact)
- F (center of the left circle ABC)

- G (center of the right circle DBE)
- C (lower center, on the left circle near the contact)
- E (lower center, on the right circle near the contact)

THEOR. 12. PROPOS. 13 — a circle does not touch a circle in more than one point [Margin: xiiij.]

[*Euclid's enunciation.*] A circle does not touch a circle in more points than one, whether it touch internally or externally.

[*Clavius's demonstration.*] Let the circles ABCD, AECF touch one another internally, if it be possible, in more points than one, namely A and C. Let the centers of these circles, G and H, be taken; these will be distinct [Margin: a — *Elements* III.6]. Through them let the straight line GH be extended in both directions; and this must fall on the contacts A and C [Margin: b — *Elements* III.11]. Therefore, since G is the center and the straight line AGHC is a diameter, AGHC will be bisected at the point G. By similar reasoning the same line AC will be bisected at H; which is absurd. For one straight line is bisected at one point only. For if GC is the half of the whole AC, then HC will necessarily be less than the half, since it is a part of the half, GC.

But if anyone should say that the straight line GH, extended toward the side of G, falls indeed on the contact A, but toward the side of H does not reach the contact C, but rather cuts both circles at I and K, as is plain in the second figure — (for one might say that in the preceding proposition it was shown that a straight line drawn through the two centers of circles touching internally falls on only one contact, and not on the other; which, however, no one could rightly affirm, since the demonstration of the preceding proposition suits both contacts; but whatever anyone may say, we shall show that this is absurd) — then from the centers G, H there must be drawn to the contact C the straight lines GC, HC. Let G, then, first be set as the center of the circle ABCD, and H as the center of the circle AECF. And since in triangle GHC the two sides GH, HC are greater than the side GC [Margin: c — *Elements* I.20]; and the straight lines GH, HC are equal to GK (because HC, HK, drawn from the center H, are equal, and GH is common), and the straight line GC is equal to GI (since these are drawn from the center G); the straight line GK too will be greater than GI — the part greater than the whole; which is absurd.

Let G, secondly, be set as the center of the circle AECF, and H as the center of the circle ABCD. Since then the straight lines HG, GC are greater than the straight line HC [Margin: d — *Elements* I.20]; and HC is equal to HA (since both are drawn from the center H); the straight lines HG, GC together will be greater than GA.

When therefore the common HG is subtracted, GC will remain greater than GA; which is absurd, since both are drawn from the center G. Therefore the circles will not touch internally in more points than one.

[*The external case.*] Now let the circles AB, CB touch one another externally in more points than one, near F. From D, the center of the circle AB, let the straight line DE be drawn to E, the center of the circle CB; this will necessarily pass through the contact F [Margin: e — *Elements* III.12]. If, then, they also touch in some point other than F, let them touch at B. When the straight lines DB, EB are drawn, the straight lines DB, EB will be equal to the straight lines DF, EF, that is, to DE itself; but they are also greater [Margin: f — *Elements* I.20], which is absurd. Therefore the circles will not touch externally in more points than one.

ALITER (another demonstration)

If the circles AB, CB touch externally in two points B and F, then the straight line BF drawn will fall within one of the circles, by Proposition 2 of this third book, and therefore outside the other, which is contrary to the same proposition. Therefore a circle does not touch a circle in more than one point, and so on. Which was to be demonstrated.

SCHOLIVM.

[*Clavius's scholium.*]

If Euclid's demonstration be rightly considered — the one by which he proved that a circle cannot be touched internally by a circle in more points than one — it appears to conclude principally that a circle cannot be touched by a circle in two or more points that lie far apart, but not that one and the same contact cannot have more than one point; although this very thing could readily be demonstrated by the same argument. Therefore, so that the matter may be left confirmed on every side — that a circle cannot touch a circle in more points than one — we shall show briefly that in one and the same contact there cannot be more points than one.

For let the circle ABC touch the circle ABD near A, and through their centers E and F — which are distinct [Margin: g — *Elements* III.6] — let the straight line EF be drawn; this will necessarily reach the contact, namely the point A [Margin: h — *Elements* III.12]. I say, then, that these circles touch one another only at the point A. For if they touch also at some other point, say B, then, drawing the straight lines BE, BF from B to the centers E and F, the straight lines EF, FB will be greater than the straight line EB [Margin: i — *Elements* I.20]. But EB is equal to EA,

since both are drawn from the center E. Therefore the straight lines EF, FB together will be greater than EA. When the common EF is subtracted, FB will remain greater than FA; which is absurd, since FB, FA are drawn from the center F to the circumference, and so by the definition of the circle are equal. Therefore the circles ABC, ABD touch one another only at the point A, and at no other.

There seems, moreover, to be a further theorem that should not be omitted in this place, namely:

If in the produced semidiameter of a circle a point be taken beyond the center, the circle from that point,

Diagram. The figure for the alternative demonstration of Proposition 9: a circle with a horizontal diameter FG; near the center lie the assumed point A and the found center E (marked with a dot), with lines drawn from A to points on the circumference.

- F (left endpoint of the diameter, on the circumference)
- G (right endpoint of the diameter, on the circumference)
- A (near the center — the assumed point)
- E (near the center, marked with a dot — the found center)
- B (upper left, on the circumference)
- C (lower left, on the circumference)
- D (bottom, on the circumference)

[The demonstration of the preceding proposition concludes here. Its enunciation, whose final clause opens this page, states that a circle described with that point as its center, drawn through the endpoint of the semidiameter, will touch the earlier circle at the said endpoint of the semidiameter, and will fall entirely outside it.]

[Demonstration.] Let there be a circle ABC with center D, and on the semidiameter AD, produced, let any point E be taken. With E as center and EA as radius, let the circle AF be described. I say that it touches the circle ABC at the

single point A. For the point E is either inside the circle ABC or outside it. If it is inside: since AE is greater than AD — that is, than DC, and hence, all the more, than EC — then EF too, which is equal to AE, will be greater than EC. The point F therefore lies outside the circle ABC, and so the circle AF lies outside the same circle ABC near the point F. All the more will the point F fall outside the circle ABC if E lies outside that circle. Now suppose the circle AF does not fall entirely outside the circle ABC so as to touch it at the single point A; then, if it be possible, let the circle AF cut or touch the circle ABC at some other point B, and let the straight line DB be drawn. Since, then, the point D has been taken in the diameter of the circle AF, other than its center E, DA will be the least of all the straight lines falling from D [Margin k: Elements III.7]. Therefore DA is less than DB — which is absurd, since DA and DB are equal, being drawn from the center D to the circumference of the same circle ABC. The circle AF, therefore, does not cut or touch the circle ABC at any point other than A, but falls entirely outside it. This is what was proposed.

But if a point is taken in the semidiameter *not* produced, on the near side of the center, then the circle described from that point as center, through the endpoint of the semidiameter, will likewise touch the earlier circle at the said endpoint of the semidiameter, and will fall entirely inside it. Thus, if in the semidiameter AE of the circle AF the point D is taken, and with D as center and DA as radius the circle ABC is described, this circle will fall entirely inside the other and will touch it at the single point A. For since it has just been shown that the circle AF falls entirely outside the circle ABC, conversely this circle ABC will fall entirely inside AF, so that the two touch one another at the single point A.

Diagram. A large circle with a smaller circle internally tangent to it at the top point A; a vertical diameter runs down through the point of tangency.

- A (top): point of tangency of the two circles
- B (upper left): second intersection point assumed in the reductio
- D (upper middle, on the vertical line): center of circle ABC
- E (middle, below D): center of circle AF
- G (lower middle): point on the vertical line inside the inner circle
- F (bottom): endpoint of the diameter of circle AF

THEOR. 13. PROPOS. 14.

[Dual numbering: Theorem 13 = Proposition 14 (Euclid, Elements III.14).]

[Margin: xiiij.]

[Euclid's enunciation.] In a circle, equal straight lines are equally distant from the center; and those that are equally distant from the center are equal to one another.

[Demonstration.] Let there be, in a circle ABCD with center E, two equal straight lines AB and CD. I say that they are equally distant from the center E. From the center E let two perpendiculars EF, EG be drawn to the lines AB, CD, and let the straight lines EA, ED be joined. The lines EF, EG will bisect the lines AB, CD [Margin a: Elements III.3]. Therefore, since the whole lines AB, CD are assumed equal, their halves too — namely the lines AF, DG — will be equal. Now since the squares of the equal lines EA, ED are equal to one another; and the square of the line EA is equal to the squares of the lines AF, FE [Margin b: Elements I.47], while the square of the line ED is equal to the squares of the lines DG, GE; the squares of the lines AF, FE will also be equal to the squares of the lines DG, GE. Taking away, then, the equal squares of the equal lines AF, DG, the remaining squares of the lines FE, GE will be equal, and therefore the lines EF, EG will be equal as well. Hence the lines AB, CD are equally distant from the center E, by the 4th definition of this book.

Again, let the lines AB, CD be equally distant from the center E. I say that they are equal to one another. For let the perpendiculars EF, EG be drawn once more from the center E to AB, CD, which by the 4th definition of this book are equal; they will bisect the lines AB, CD [Margin c: Elements III.3]. When, then, the lines EA, ED have been drawn, their squares will be equal. But the square of the line EA is equal to the squares of the lines AF, FE, and the square of the line ED to the squares of the lines DG, GE [Margin d: Elements I.47]. Therefore the squares of the lines AF, FE are equal to the squares of the lines DG, GE. And since, of these, the equal squares of the equal lines EF, EG are taken away, the remaining squares of the lines AF, DG will be equal, and consequently their doubles AB, CD will be equal too. Thus in a circle equal straight lines are equally distant from the center, and so on. Which was to be demonstrated.

Diagram. A circle with center E containing two chords, AB and CD, each with a perpendicular dropped to it from the center and joined to the center by radii.

- A (top left) and B (bottom left): endpoints of one chord AB
- C (bottom right) and D (top right): endpoints of the other chord CD
- E (center): center of the circle

- G (middle right): foot of the perpendicular EG on CD

THEOR. 14. PROPOS. 15.

[Theorem 14 = Proposition 15 (Euclid, Elements III.15).]

[Margin: xv.]

[Euclid's enunciation.] In a circle the diameter is the greatest line; and of the others, the one nearer the center is always greater than the one farther off.

[Demonstration.] In a circle ABCDEF with center G, let the diameter be AF; let the line HI be nearer the center, and CD farther off. I say that AF is the greatest of all, and that HI is greater than CD. From the center G let the straight lines GK, GL be drawn perpendicular to CD, HI. And since CD is farther from the center than HI, GK will be greater than GL, by the 4th definition of this book. From GK cut off a line GM equal to GL, and through M draw BME perpendicular to GK, and join GB, GC, GD, GE. Since, then, the perpendicular lines GM, GL are equal, the lines BE, HI will be equally distant from the center, by the 4th definition of this book [Margin a: Elements III.14], and therefore they will be equal to one another. Again, since the lines GB, GE are indeed greater than BE [Margin b: Elements I.20], but are equal to the diameter AF, the diameter AF too will be greater than BE. By the same reasoning AF will be shown to be greater than all the other lines. Next, since the sides GB, GE of the triangle BGE are equal to the sides GC, GD of the triangle CGD, and the angle BGE is greater than the angle CGD, the line BE will be greater than CD [Margin c: Elements I.24]; and hence HI, which was shown equal to BE, will also be greater than CD. In a circle, therefore, the diameter is indeed the greatest line, and so on. Which was to be demonstrated.

Diagram. A circle with center G and horizontal diameter AF; three further chords are drawn parallel to one another, each met by a perpendicular from the center.

- A (far left) and F (far right): endpoints of the diameter AF
- G (center): center of the circle
- C (upper left) and D (upper right): endpoints of the chord CD (the farther chord)
- K (top): foot of the perpendicular GK on CD
- B (left) and E (right): endpoints of the constructed chord BE
- M (center, above G): foot of the perpendicular GM on BE
- H (lower left) and I (lower right): endpoints of the chord HI (the nearer chord)
- L (bottom): foot of the perpendicular GL on HI

SCHOLIUM.

The theorem will be demonstrated in nearly the same way if several lines fall from one and the same point of the circumference.

For let several lines AB, AC, AD fall from a point A, of which AD passes through the center E. I say that AD is the greatest of all, and that AC is greater than the more remote AB. For when the lines BE, CE have been drawn, then, since in the triangle AEC the sides AE, EC are greater than the side AC [Margin d: Elements I.20], and since the lines AE, EC are equal to the lines AE, ED — that is, to the line AD — AD will be greater than AC.

Next, since the two sides AE, EC of the triangle AEC are equal to the two sides AE, EB of the triangle AEB, and the angle AEC is wholly greater than the angle AEB [Margin e: Elements I.24], the base AC will be greater than the base AB. By the same argument, AC will be greater than any other line more remote from the center.

Moreover, here too only two equal lines can be drawn from the point A to either side of the greatest line AD. For if an angle AEF is made equal to the angle AEC, and the straight line AF is joined, then — since the sides AE, EC are equal to the sides AE, EF, and the contained angles AEC, AEF are also equal — the bases AC, AF will be equal [Margin f: Elements I.4]. And no other line equal to these two can be produced; for any line drawn from A above AC will be less than AC, while any drawn below AC will be greater, as has already been demonstrated.

But if AB, AF are drawn to opposite sides of the diameter AD, and AF is said to be nearer the center than AB, it will be shown, as in the scholium to Proposition 7 of this book, that AF is greater than AB [Margin g: Elements III.14]. For if, as was just shown, a line AC equal to AF is drawn on the other side — that is, if an angle AEC is made equal to the angle AEF, and so on — the point C will fall between B and D. This is because AF and AC are equally distant from AD, on account of their equality, or at any rate on account of the equal angles AEF, AEC. Hence it follows that, since AF is assumed nearer the center than AB, AC too, being equal to AF, is nearer the center than AB, and consequently the point C lies between B and D. Since, then, AC is greater than AB — as has been demonstrated in this scholium — AF too will be greater than AB.

THEOR. 15. PROPOS. 16.

[Theorem 15 = Proposition 16 (Euclid, Elements III.16) — the famous horn-angle proposition.]

[Margin: xvj.]

[Euclid's enunciation.] The line drawn at right angles to the diameter of any circle, from the extremity of the diameter, will fall outside that circle; and into the space enclosed between that straight line and the circumference no other straight line can fall; and the angle of the semicircle is greater than any acute rectilinear angle, while the remaining angle is less.

[Demonstration.] In a circle ABC with center D, let the diameter be AC, and to it, from A, its extreme point, let a perpendicular be drawn. I say that this perpendicular line necessarily falls outside the circle. For if it falls inside the circle — say, like AB — then, when DB has been drawn, the two angles DAB, DBA will be equal [Margin a: Elements I.5]; but DAB is a right angle by construction, so DBA too will be a right angle, which is absurd. For the two angles in a triangle are less than two right angles [Margin b: Elements I.17]. The perpendicular, therefore, does not fall inside the circle; nor, for the same reason, does it fall on the circumference itself, but outside — say, like EF.

I say further that no other straight line can fall from A into the space between the straight line AE and the circumference AB. For let one fall, if it be possible — the straight line AG — and from D let a perpendicular DH be drawn to it, cutting the circumference at I, which will necessarily lie toward the side of the acute angle DAG, by the 2nd corollary to Proposition 17 of Book I. Since, then, in the triangle DAH the two angles DHA, DAH are less than two right angles [Margin c: Elements I.17], and DHA is a right angle by construction, the angle DAH will be less than a right angle; and therefore the line DA — that is, the line DI, equal to it — will be greater than DH [Margin d: Elements I.19], the whole greater than the part, which is absurd. No straight line, therefore, will be intercepted between AE and the circumference AB; rather, whatever line is drawn from A below AE will cut the circle.

Finally, I say that the angle of the semicircle, contained by the diameter AC and the circumference AB, is greater than any acute rectilinear angle; while the remaining angle — the angle of contact, contained by the straight line AE and the circumference AB — is less than any acute rectilinear angle. For since it has been shown that every straight line drawn from A below the perpendicular AE falls inside the circle, such a line will necessarily make with AC a rectilinear acute angle less than the angle of the semicircle; but with AE it will make a rectilinear acute angle greater than the angle of contact, since the former is a part of the angle of the semicircle, whereas the latter is something whole in comparison with the angle of contact. This is plainly evident once the straight line AB has been

drawn in any way below AE. For since this line AB falls inside the circle, as has been demonstrated, the rectilinear acute angle CAB will be less than the angle of the semicircle contained by the diameter AC and the circumference ABC, since the former is a part of the latter; while the angle of contact contained by the tangent line AE and the circumference ABC will be less than the rectilinear acute angle BAE, since the former is a part of the latter. And the same reasoning holds for all the other acute rectilinear angles, since they are all contained by the diameter AC, or the tangent AE, and by lines drawn from A below AE, all of which fall inside the circle, as we have demonstrated. The angle of the semicircle, therefore, is greater than any acute rectilinear angle, while the remaining angle of contact is less. And so, the line drawn at right angles to the diameter of any circle from its extremity, and so on. Which was to be shown.

Diagram. A circle with center D and vertical diameter AC; at A the perpendicular is drawn (falling outside), with the various auxiliary lines of the reductio near the top.

- A (top): extremity of the diameter, from which the perpendicular is raised
- C (bottom): other extremity of the diameter
- D (center): center of the circle
- B (just below A, inside): endpoint of the line AB assumed (wrongly) to fall inside
- E (upper right): endpoint of the perpendicular line AE
- F (upper left): endpoint of the perpendicular line (EF) [?]
- G (upper right, near A): endpoint of the line AG assumed in the horn-space
- H (upper right): foot of the perpendicular DH on AG
- I (near A, inside): point where DH meets the circumference

COROLLARIUM.

From this it is manifest that the line drawn at right angles from the extremity of the diameter of a circle touches that circle. For it has been shown to fall outside the circle. Hence it meets the circle only at that extreme point of the diameter.

Therefore, if we are required to draw, through a given point A on the circumference of a circle AB, a straight line that touches the circle at A, we shall draw from A to the center C the straight line AC, and to it we shall raise the perpendicular DAE. For this line will touch the circle at A, as has been demonstrated.

Diagram. A circle with the tangent line drawn horizontally across its top through the point of contact.

- D (left) and E (right): endpoints of the tangent line DAE
- A (top center): point of contact
- C (center): center of the circle
- B (lower right): a point on the circumference

EX ORONTIO.

[From Oronce Finé — an alternative demonstration.]

This same theorem can be demonstrated by direct proof, in the following way. Let AC be the diameter in a circle ABC whose center is D. From A, at right angles to AC, let the perpendicular AE be drawn, which I say falls outside the circle. For let any point G be taken on it, and let the straight line GD be joined. Since, then, in the triangle ADG the two angles DAG, DGA are less than two right angles [Margin e: Elements I.17], and DAG has been made a right angle, DGA will be less than a right angle. Therefore the line DG will be greater than DA [Margin f: Elements I.19], and consequently the point G will lie outside the circle. And the same reasoning holds for all the other points of the line AE. The whole line AE will therefore fall outside the circle. Now from A, below AE, let the straight line AH be drawn, which I say necessarily cuts the circle. For let an angle ADI be made equal to the angle EAH. When, then, the common angle DAH is added, the two angles ADI, DAH will together be equal to the whole right angle DAE, and therefore less than two right angles. Hence the lines AH, DI will meet at some point, say at I [Margin g: Elements I.13 [?] — reference glyph uncertain]. I say, then, that the point I lies inside the circle. For since the three angles in the triangle DAI are equal to two right angles [Margin h: Elements I.32], and the two angles DAI, ADI have been shown equal to the right angle DAE, the remaining angle AID will be a right angle, and therefore greater than the acute angle DAI. Hence the line DA is greater than DI [Margin i: Elements I.19]. Therefore DI will not reach the circumference; and for that reason the point I will lie inside the circle; and consequently the line AH will cut the circle. The remaining parts of the theorem are shown as before.

Diagram. The figure for Oronce Finé's demonstration (the same construction, reprinted at the head of this page): a circle with center D and vertical diameter AC, the perpendicular AE across the top, and the auxiliary line AH cutting the circle.

- A (top center): extremity of the diameter, where the perpendicular is raised
- C (bottom): other extremity of the diameter
- D (center): center of the circle
- E (upper right): endpoint of the perpendicular AE
- F (upper left): endpoint of the perpendicular line on the left
- G (top, between A and E): point taken on the perpendicular AE
- H (right side, lower): endpoint of the line AH
- I (near center, above D): meeting point of AH and DI
- B (left): a point on the circumference

SCHOLIUM.

Peletier [Jacques Peletier] holds that the angle of contact, which Euclid here proved to be less than any acute rectilinear angle, is nothing at all — that indeed no angle whatever is produced by the contact of a straight line and a circumference. To make his view clearer, we shall set out the digression he undertakes at this point. He speaks thus:

When I considered rather attentively the last part of this theorem, it did indeed occur to me, at first sight, that geometry is not sufficiently consistent with itself — that it even admits a contradiction within itself.

For, in the first place, it is beyond understanding that among quantities there could be a smallest — such as the angle here, which they call the angle of contact, or more properly of contact, which we have set down as less than every acute angle. No more does it accord with reason that there should be a greatest quantity — such as this angle of the semicircle, which is set down as greater than every acute rectilinear angle. For a quantity is called a quantity precisely because it consists of parts, and because with respect to it a thing is said to be equal and unequal. And a continuous quantity is divisible to infinity. And so, when I had come upon the first proposition of Book X, I began all the more anxiously to weigh by what means so open a contradiction, as it appeared, could be reconciled. For the first proposition of Book X runs as follows:

[Euclid, Elements X.1:] If from the greater of two quantities there be taken away more than the half; and again from the remainder more than the half; and this be done continually; there will at last be left a magnitude less than the lesser magnitude set out.

For example, let there be two angles: A, a rectilinear one; and BCD, an angle of contact (if it is indeed an angle). The first proposition of Book X requires that, if more than the half be taken away from the angle A; and again more than the half from the remaining part; and thus continually more than the half from the residual parts; there be left at last an angle less than BCD. I do not here supply the demonstration, since it depends on what follows. Yet there is no proposition in all of geometry that is (so to speak) more naturally true. This becomes clearer than daylight from numbers, in which are the images of all things. For who does not see that, given the two numbers 8 and 2, when you take from the eight more than its half — say five — and then from the remaining three more than its half — say two — there is left a unit less than the two set out? Nor is it to the purpose that Campanus [Campanus of Novara] there makes an exception, holding that the sense of the proposition is to be understood of quantities of the same kind. For that reconciliation is worthless; indeed it is contrary to the mind of Euclid, as we shall make plain when we come to that place. Nay, Campanus even contradicts himself, since in demonstrating the second proposition of Book XII, and in several other propositions concerning solids, he takes a straight thing away from a curved one.

We, then, shall settle this difficulty in the following way: by saying that a straight line which touches a circle makes no angle with the circumference — that is to say, that BCD ought in no way to be called an angle. For every angle consists in a section, not in a contact. And where the section ceases, the form of the angle ceases too. And, to put it in a word, all the kinds of angles are completed in a crossing (I take "crossing" and "section" here without distinction). For let two lines AB and CD, cutting one another at right angles at the point E, be conceived to be moved around — namely, about the fixed point E — so that from CD there comes FG. From the right angle AEC there will then arise the obtuse angle AEF; and from the right angle BEC the acute angle BEF. And when HK has been made, on the one side the angle HEA will become more obtuse, and on the other the angle BEH more acute; and so on continually, until the moving line reaches AB and is confined within the same bounds together with it. For then, the line CD being (so to speak) merged into the line AB, the angle vanishes.

Nor is the case any different with a curved line. For let there be, in a circle ABCA with center D, a line DE passing beyond the circumference and cutting it at A, a fixed point, about which let DE itself be carried around, through the points F, G, H. Then angles will be made continually varying with the circumference, at the

very point A; until, the crossing ceasing, the line ED becomes EK and touches the circle. And then the line DE is understood to be no longer inclined, but merged into the line BAC, so far as the angle is concerned — no otherwise than if BAH were a straight line. Nor does it tell against this that lines are drawn out and make the space CAK. For this is done solely by the line AC, which shrinks from the straight line, yet embraces it at the point A. Since, then, every angle consists in no more than a single point, it comes about that the point A is as unfit for constituting an angle as, a moment ago, was the point of section E of the straight lines. Perhaps you will say that the point A of the straight line remains in its straightness, and the point A of the circumference in its roundness; that the two are not the same point; but that the lines only, as it were, graze one another, because the one shrinks from the other utterly and at every point — so that contraries, set side by side, may be made more manifest. But this the senses do not admit. For two circles touching one another externally would leave an intervening straight line untouched: that is, if we conceived a circle touching the circle ABC externally at the point A — which the nature of lines does not allow. But grant that it could be so, so that nothing falls into thought that geometry does not somewhere represent — even so it will not press the point in the least. On the contrary, all the less will the contact of lines be an angle. For their meeting will gape open on either side. But let us confirm these things by geometric reasonings, through theorems.

Diagram. Two figures side by side illustrating Peletier's example: at the left a narrow rectilinear angle; at the right a circle with a tangent line, showing the angle of contact.

- A (apex of the narrow wedge at left): the rectilinear angle A
- C (upper left of the circle): the point of contact
- B (upper right of the circle): endpoint of the tangent line
- D (right of the circle): point on the circumference marking the arc of the contact angle BCD

Diagram. A star-like figure of straight lines crossing at a common point, illustrating the "crossing" (decussation): two lines AB and CD cross at right angles at E, with further lines FG and HK shown in rotated positions.

- E (center): the point of crossing
- A (right) and B (left): endpoints of the line AB
- C (top) and D (bottom): endpoints of the line CD
- F (upper left) and G (lower right): endpoints of the rotated line FG

- H (left) and K (lower right): endpoints of the rotated line HK

Diagram. A circle with the line DE swept about the fixed point A on the circumference; the moving line is shown in several successive positions (its outer endpoint marked E in each), passing through F, G, H, until it becomes the tangent.

- A (top, on the circumference): the fixed point about which the line turns
- D (lower left, inside) and center of the circle
- E (several positions across the top): successive positions of the outer endpoint of the swept line
- F (lower center): one intermediate position
- G (lower right): a further position
- H (right): a further position, toward the tangent
- B (left) and C (lower right): points on the circumference

[This opening continues Clavius's scholium (digression) on the angle of contact, appended to Book III, Proposition 16. Clavius first lays out the demonstrations that Jacques Peletier had proposed, then refutes them. The display-capital lines below are Peletier's theorem-statements as Clavius quotes them.]

The interior contact of two circles is not a quantity.

Let there be a circle AFBA whose centre is C and whose diameter is AB; and through the endpoint A of that diameter let a line DE be drawn at right angles. From the corollary to this sixteenth proposition [III.16] it is established that the line DE touches the circle AFBA, and therefore that the angle DAF is less than any acute angle — this on Euclid's own authority, namely by the last part of this sixteenth proposition. Now between the points C and B let a centre G be taken on the diameter AB, and with the radius GA let a second, larger circle AHKA be described. I say that FAH is a quantity. For it is established that the circle AHKA passes between the straight line DA and the curve AF, since the radius GA is greater than the radius CA. It is likewise clear, from the same corollary to this sixteenth proposition, that the line DE touches the circle AHKA, and therefore that DAH is less than any acute angle. Let a third circle AMNA be described according to the still greater radius LA. By the same corollary DAM too will be less than any acute angle. In this way, on to infinity, all the contacts that the line DE makes with the circles drawn through the point A — whose centres lie on the line AB — will be less than any rectilinear [acute angle]; and thus all equal, if only equality can be predicated of things that are not quantities. Therefore the contact DAM will be equal to the contact DAF; and so it comes about that MAF, the

interior contact of the circles, neither increases nor diminishes the contact DAM. Therefore MAF is not a quantity. Which was to be demonstrated.

We shall also prove that the interior contact of the circles is not a quantity in the following way. Since all circles are similar, the semicircles too will be similar. Therefore the angles made by a diameter and the circumference are equal in all circles, by the converse of the definition of similar segments. (For the mixed angles are not excluded from this equality of angles.) Hence the angle BAF will be equal to each of the angles KAH and NAM; and therefore the contact FAM adds nothing to the angle BAF. So FAM is not a quantity. Which was to be demonstrated. From this the next result follows.

The contact of a straight line with a circle is not a quantity.

For, the same construction remaining, if DAF is a quantity, it will certainly be divisible either by a straight line or by an oblique one. Not by a straight line, since the last part of this sixteenth proposition forbids it; nor by an oblique line, such as the line AM. For then FAM would be a part of DAF; but FAM is not a quantity, as we have just proved. Therefore FAM is not a part of DAF. So DAF can be divided neither by a straight line nor by an oblique one. Therefore DAF is not a quantity. Which was to be proved. From this the third result arises.

The exterior contact of two circles is not a quantity.

In the same construction, let the diameter BA be extended to a point P. Then with centre P and radius PA let a circle AQRA be described, touching the circle ABFA externally at the point A. I say that the contact FAQ is not a quantity. This indeed is clear from the later demonstration. For it is not divided by an oblique line, since FAM is not a quantity, by the first of these; nor by a straight one, since DAF is not a quantity, by the second of them; nor is DAQ a quantity, by the same. Therefore, since FAQ has no parts, it will not be a quantity. Which was to be proved.

From these results this proposition emerges, which no one in geometry has hitherto thought admissible.

The angles made by a diameter and the circumference, whether inside or outside the circle, are right angles, and equal to rectilinear right angles.

As in the later figure, the angle BAF is equal to the angle BAD, since nothing accrues to it on account of the contact DAF, which is not a quantity; and for the same reason QAP too is a right angle, and equal to DAP, since DAQ adds nothing. Which was to be proved.

This is what Peletier says here. But in the letter he writes to Cardano [Girolamo Cardano] he brings forward another demonstration, which he himself says is fuller. I have therefore decided to append it here. First of all he sets out this theorem.

In circles, the angles made by a diameter and the circumference are equal.

Let there be, upon the centre A, two circles BCDB and EFGE, whose diameters are BD and EG; and let EG cut both circles at the points E, B, D, and G. I assert that the two angles CBD and FED are equal. For if FED were greater than CBD — the reverse cannot occur, that CBD should in any way be greater than FED — then let several circles be described upon the same centre A, of which one, HKLH, will suffice here. It will finally come about, through continual increase, that an angle made by a diameter and the circumference — for example the angle KHL — is greater than a right angle: which is contrary to Euclid's own view, for he holds all these angles to be less than a right angle. Therefore the interior angles at B and E are equal to one another. Which was to be shown. The same verdict holds for the exterior angles. Nor is there any paralogism in this manner of demonstrating. For although there is no comparison between the angles they call angles of contact and rectilinear angles, nevertheless there will be some comparison of the angles made by the cutting of a straight line and the circumference to those same rectilinear angles. For angles of this kind, which are called mixed, plainly become greater and less.

Diagram. A set of concentric circles about a common centre A, with a fourth circle set within them, illustrating Peletier's theorem that the angles a diameter makes with the circumference are equal across circles.

- A (centre): common centre of the three concentric circles
- M (just below A): centre of the inner circle BFNB
- H (top), K (left), L (bottom): points of the outermost circle HKLH (diameter HL)
- E (upper, on vertical), F (left), G (lower, on vertical): points of the middle circle EFGE (diameter EG)
- B (on vertical, below E), C (left), D (lower, on vertical): points of the circle BCDB (diameter BD)
- N (bottom): point of the inner circle BFNB (centre M)

Having demonstrated these things in this way, I assert that the interior contact of the circles is not a quantity. Upon a centre M placed on the same line HL, let a circle BFNB be described with a radius as great as the circle EFGE — that is, with

MB set equal to the radius AE — a circle that touches the circle BCDB at the point B. It is clear that the angle FBD is equal to the angle FED, on account of the equality of the circumferences and diameters. Therefore this same angle FBD will also be equal to the angle CBD. So the contact CBF adds nothing to the angle CBD. Hence CBF is not a quantity. Which was to be proved. And from this proceeds the demonstration of those theorems which we have adduced in Book III.

Diagram. The horn-angle construction: a straight line DE touching, at the point A, a family of circles whose centres lie along the diameter, together with an exterior tangent circle AQRA above the line.

- A (centre of the line DE): common point of tangency
- D (left end) and E (right end): the tangent line DE drawn through A at right angles to the diameter
- P (top), Q (upper left), R (upper right): the exterior tangent circle AQRA, centre on the extension of the diameter above A
- C, G, L (stacked below A on the diameter): the successive centres of the tangent circles
- B (below): point of the circle AFBA (centre C)
- K (below B): point of the circle AHKA (centre G)
- N (bottom): point of the circle AMNA (centre L)
- F, H, M (on the left, inner to outer): the points where the circumferences of the three circles lie against the line

This, then, is Peletier's view of the angle of contact, which is wholly contrary to Euclid. For if Euclid had held

that the angle of contact is nothing at all, and that the angle of the semicircle is equal to a rectilinear right angle, why, I ask, would he have laboured so hard to demonstrate that the angle of contact is less than every acute rectilinear angle, but the angle of the semicircle greater? For what could be clearer than that nothing — which is what the angle of contact is, on Peletier's view — is less than any angle whatever? And what more evident than that a right angle, which is what Peletier makes the angle of the semicircle to be, is greater than any acute angle? Therefore we affirm that the angle of contact is truly an angle and a quantity; and further, that the angle of the semicircle is less than a rectilinear right angle. Hence we must dissolve all the sophisms Peletier has brought forward in this digression to confirm that the angle of contact is nothing.

First, then, we admit that it is beyond understanding that there should be a least among quantities; but we deny that we assert the angle of contact to be a least

quantity. On the contrary, we maintain that any angle of contact, even though Euclid showed it to be less than every acute rectilinear angle, can be divided into infinitely many parts — not indeed by a straight line, as Euclid demonstrated, and excellently, but by a circular line. Thus, given the angle of contact CAB, if through A a circle AEH is described larger than the circle ABG, touching the straight line CD at A, the angle of contact CAE will be made less than the angle of contact CAB. And if a still larger circle AFI is described, the angle of contact CAF will be much less than the same angle of contact CAB. And so, without end, we shall always make a smaller angle of contact. Therefore an inequality is found among the angles of contact, even though each of them is less than any acute rectilinear angle whatever — just as any acute angle is less than a right angle, and yet a smaller one can be given than any acute angle assigned, since it can be divided infinitely. Thus the acute angle BAC is less than the right angle BAF; and yet, if a straight line AD is drawn between AC and AB, the acute angle BAD becomes smaller. And if another straight line AE is drawn between AB and AD, the acute angle BAE will be much smaller, and there will never be an end to this diminution.

Diagram. A straight tangent line CD meeting, at the point A, a nested family of circles ABG, AEH, AFI, illustrating that angles of contact can be made ever smaller.

- C (left) and D (right): the ends of the tangent line CD, drawn through A
- A (top): the point of tangency
- B, E, F (on the left, inner to outer): points where the three circles lie against the line
- G, H, I (on the vertical, inner to outer): the lower points of circles ABG, AEH, AFI respectively

By parallel reasoning we assert that the angle of contact can be increased infinitely, so that, given any angle of contact, others greater than it may be assigned without number. Thus in the upper circular figure the angle of contact CAF is less than the angle of contact CAE, and much less than the angle of contact CAB; and so on in turn: if smaller and smaller circles than ABG are described, touching the straight line CD at A, the angle of contact will be perpetually increased, yet it will always remain less than any rectilinear acute angle. In the same way, given any acute angle, other acute angles beyond number can be given that are greater. Thus in the next figure the acute angle BAE is less than the acute angle BAD, and this much less than the acute angle BAC. And if another straight line is drawn between the perpendicular AF and the straight line AC, a still

greater acute angle will be made, and there will never be an end to this increase. Therefore, just as in this kind of increase we never arrive at any acute angle equal to a right angle, or greater than a right angle, unless the acute angle is changed into a right or an obtuse angle — an acute angle always being less than a right or an obtuse one — so too, in the growth of the angle of contact, we never come to any angle of contact equal to a given acute rectilinear angle, or greater than an acute angle, unless the angle of contact is changed into another mixed angle (which is indeed made by two lines cutting one another, such as the angle of a segment). But the angle of contact is always less than an acute angle.

Diagram. A fan of straight lines from a single vertex A, illustrating that ever-greater acute angles can be formed short of a right angle.

- A (vertex, upper left): the common vertex
- B (bottom, below A): the endpoint of the base line AB
- E, D, C (on the right, in ascending order): endpoints of the intermediate rays AE, AD, AC
- F (upper right): the endpoint of the perpendicular AF

In the same way we deny that we posit the angle of the semicircle as a greatest quantity. On the contrary, we assert that, given any angle of the semicircle — even though Euclid showed it to be greater than every acute rectilinear angle — infinitely many greater ones can be given. Thus in the same upper circular figure the angle of the semicircle FAI is greater than the angle of the semicircle BAG; and so on in turn: if larger and larger circles than AFI are described, touching the straight line CD at A, the angle of the semicircle will be perpetually increased, yet it will always remain less than the right angle CAI. Conversely, the angle of the semicircle EAH is less than the angle of the semicircle FAI, and the angle of the semicircle BAG much less still; and there will never be an end to this diminution, and yet each remains greater than any acute rectilinear angle, however infinitely it is diminished, as Euclid demonstrated. Just so, given any acute angle, innumerable others are found that are greater, and others that are smaller.

That the angles of contact are unequal among themselves, and not all equal, as Peletier will have it — and likewise the angles of the semicircles — is clear from this: that every angle consists in a single point and in the inclination of the lines, which do not lie in a straight line, as is established from the definition of a plane angle. For hence it comes about that the equality of angles of the same kind requires the same inclination of the lines, so that the lines of the one coincide entirely with the lines of the other, if one is superimposed on the other; for those things are equal which mutually coincide, according to the eighth common

notion [postulate 8]. Since, then, in angles of contact, and likewise in angles of semicircles, the same inclination is by no means always found — for when one is superimposed on the other, their lines do not correspond but altogether diverge from one another, as is evident from the figures above — not all angles of this kind will be equal among themselves. On the contrary, any angle of contact can be increased and divided infinitely by a curved line, even though it cannot be cut by a straight one, as Euclid rightly shows. And for this fact the following cause too can be given. If a line touching a circle is conceived to be moved about the fixed point of contact, it will continuously cut the circle until it touches it again: for only then will it cease to cut the circle. Hence, if it is understood to be inclined even in the least degree about that fixed point of contact, it will cut the circle, since a straight line can touch a circle at one point only, as we gathered from Proposition 2 of this book.

Therefore only those angles of contact, and likewise only those angles of the semicircles, will be equal among themselves which are made by equal circumferences: for in these alone do the lines mutually coincide. But angles of contact made by smaller circumferences will be greater, and those made by larger circumferences smaller. And angles of the larger semicircles will finally be greater, of the smaller ones smaller, as can be understood without difficulty from the figures above. For the lines of such angles do not mutually coincide.

It is established, then, that any angle of contact has parts; and that one can be exhibited equal to another, and again unequal — namely greater or less — just as we see happen in all other angles. This can also be said of any angle of the semicircle. Peletier therefore did not correctly understand the angle of contact to be a least quantity, and the angle of the semicircle a greatest.

Next, there is no reason why the first proposition of the tenth book should trouble Peletier. For it is to be understood of quantities both of the same kind and of different kinds, provided that either of them, when multiplied, can exceed the other; and of such a kind are not the angle of contact

and the acute rectilinear angle. For any angle of contact, whether it be taken twice, or three times, or four times, or finally as many times as one pleases, is always less than an acute rectilinear angle. For if any number of angles of contact — say a hundred — equal to one another were to exceed an acute rectilinear angle, or to equal it, then one of them too would be greater than, or equal to, that rectilinear acute angle which is the hundredth part of the proposed acute rectilinear angle; which is absurd, since any angle of contact is less than any acute rectilinear angle whatever, as was demonstrated by Euclid. Hence it will in

no way be permissible to conclude from that proposition that if from an acute angle more than the half is taken away, and again from the remainder more than the half, and this is done continually, there is at last left an acute angle smaller than the proposed angle of contact; because the angle of contact, as has been said, however many times it is multiplied, or however much it is increased, always remains less than the acute angle, and can never exceed it — which nonetheless is necessarily required for the demonstration of that proposition. For to demonstrate it, the smaller proposed quantity must be multiplied so many times that it exceeds the greater, as may be seen in all the commentators on Euclid. Hence Campanus [Campanus of Novara] — or rather Euclid himself through Campanus — when in the stereometry he takes a straight quantity from a curved one, or the reverse, as the first proposition of Book X will have it, always assumes such magnitudes of which either, when multiplied, can exceed the other.

Now by no means shall we grant to Peletier that an angle is made only by two lines cutting one another. For it suffices, in order that an angle be made, that two lines in a plane be inclined toward one another, provided that they do not lie in a straight line, as is established from the description of a plane angle handed down by Euclid — even though they do not cut one another mutually if they are produced; of which kind are circumferences that touch one another. Therefore they truly make an angle, as we said before.

Furthermore, Peletier's demonstration by which he attempts to show that the interior contact is not a quantity is of no weight. For although all the angles of contact made by a tangent line and the circumference are less than any acute angle, it does not on that account follow that they must all be equal among themselves; rather one can be greater than another, and less, as we have said — just as all acute angles are less than a right angle, and yet they are not all equal among themselves. So too all ants (to take an example from natural things as well) are less than a man or a mountain, and yet they are quite unequal among themselves. Therefore Peletier does not rightly conclude that the interior contact is nothing.

Next, we deny that the angles of similar segments are equal, as he assumes in the following demonstration. For Euclid did not signify this in the last definition of this third book; rather he taught that those segments are similar in which the rectilinear angles are equal, or which admit equal rectilinear angles — not those whose angles are equal. On the contrary, there is a great difference between the angles in the segments and the angles of the segments, as will be clearly established from Proposition 31 of this book.

From these considerations the remaining demonstrations of Peletier will be easily rejected. For the angle of contact made by a tangent line and the circumference is divided by a circular line, so that the interior contact is truly a part of it, since he has by no means shown the contrary. In the same way the angle of contact which two circles touching one another externally constitute is divided both by a circular line and by the straight line that touches them both. By the same reasoning that theorem is refuted by which he asserted that the angle of the semicircle is equal to a rectilinear right angle. For the right angle exceeds the angle of the semicircle by that angle of contact which the tangent line and the circumference make. Finally, Peletier was also deceived in that demonstration which he sent to Cardano. For although the angle of the semicircle in a larger circle is greater than the angle of the semicircle in a smaller circle, it does not on that account follow that any angle of the semicircle is greater than a right angle. For a right angle will always surpass any angle of the semicircle by that angle of contact which the circumference and the tangent line make. Just as, given any acute angle, others greater than it can be given, yet no acute angle will ever exceed a right angle, as may be seen in the preceding figure. It is established, then, from these considerations, that the angle of contact truly is an angle, but that Peletier's demonstrations are sophistical, of no weight, and utterly unworthy of a man who is a geometer.

Moreover, this dispute of mine about the angle of contact so moved and disturbed Peletier that he supposed his reputation to have been altogether wounded and offended. And so, about five years after the publication of my commentary on Euclid — that is, in the year 1579 — in order to defend himself, he wrote an Apologia against me. In it, however, he neither dared to overthrow or attack the solutions I have adduced here, nor to confirm his own opinion — that novel and unheard-of one — with new arguments (for he had none), but attempts to defend himself only with words and abuse, as those who read it through will easily judge. To this Apologia I would long since have replied — not so much to clear myself as to defend the truth — had not the weighty authority of most learned men, who judged it altogether unworthy of a reply, called me back from that resolve. But now, since this place seems to demand of me that in this second edition I should again take up the defence of the truth, I have thought it not out of place to repel briefly, and with as much moderation as I can, what that Apologia charges me with. For although I already did this in the year 1586, in my *Spherical Triangles*, where mention necessarily had to be made of the matter itself and of his Apologia — yet, since perhaps not everyone has seen that book of mine, I judged it worth my while, if I insert that whole reply here, where its proper place is, so that the fair-minded reader may understand that Peletier, without cause,

blazed up against me with as much distress of mind and anger as he displays, and falsely imputed many things to me; whereas I, on the contrary, poured out no injurious word or abuse against him — which he complains of in vain in the dedicatory letter, where he openly testifies that I do not refrain from abuse. And in that *Apologia* nothing so offends me as that Peletier charges me with having acted not sincerely but with animosity, and even out of envy, in either censuring or praising him in my commentaries — faults which I have always held to belong to a petty mind, and utterly foreign to a man liberally and in a Christian manner educated. But how far these are from the discipline of our Society, and from my own habit, no one who knows us and our ways is ignorant. For those who do not know our ways, this very book will bear witness that everything is said sincerely, nothing out of envy, nothing out of animosity — plainly, so that it may appear that the truth was sought, and no one's authority was despised. Nor do I so far derogate from myself (though I claim nothing) as to think that I alone am forbidden, if something in another's writings should seem false and the occasion offers, to show why it is less approved by me — provided (as the custom of prudent and well-mannered men requires) I do this without abuse or mockery. And this very book, which... that though you should read the whole book through, you would not find even a single word that has any appearance of slander or abuse. For in this scholium on the angle of contact I could swear plainly that nothing was further from my thought than to attack Peletier in a spirit of disparagement; but that I had this one purpose (if only I could attain it): that the truth should have its place. And this I did the more freely because I judged that I should be doing it not only with Peletier himself unwilling, but even willing,

— even on his own authority. For he did not hesitate to dissent not only from Cardano [Gerolamo Cardano] and Campanus [Campanus of Novara], but also from Proclus [Proclus], Theon [Theon of Alexandria], Apollonius [Apollonius of Perga], Eratosthenes [Eratosthenes], Pappus [Pappus of Alexandria], Ptolemy [Ptolemy], and Hippocrates of Chios [Hippocrates of Chios] — the lights of Geometry — and finally from Euclid himself, the master of them all. No wonder: for, as he himself truly said in the *Apologia*, in every discipline, and especially in Geometry, it is not authority that must be regarded, but truth. And yet I do not see how a man can be a friend of truth in whose eyes truth breeds hatred — unless perhaps he either thinks himself incapable of being deceived (he who now and then proclaims that those pillars of Geometry have erred at times), or loves and seeks truth in other men's affairs rather than in his own. For my part, if anyone should show that I have erred in some matter — which, given the weakness of human intellect, I see can happen — truly I shall be most grateful to him who leads me, wandering, back into the way of truth.

But Peletier [Jacques Peletier] proves his zeal for truth: he cannot bear insults. What insults, pray? you ask. He calls my demonstrations sophisms. Now at last I understand what he means by insults; for I am quite certain there are no others in this book of mine, and from these — if they are insults — I confess I do not abstain. But I, a simple man and ignorant of words, never considered them insults, since they were spoken truly. I had no other word by which to call demonstrations that are plainly false and spurious; nor did the customary usage of philosophers and mathematicians supply me a more fitting one. Moreover, since I saw that Peletier — a man most careful in his speech — called the genuine demonstrations of Campanus and Cardano "paralogisms," I supposed that in refuting his false demonstrations I might with more impunity use a very similar word. But if "sophism" is a more insulting word than "paralogism" in France, let him pardon one ignorant of that custom, and let him suppose that I meant to say "paralogisms."

And so that Peletier may plainly understand that I wrote those things not out of a desire to contradict, let him consider with me how much material for refuting him he gave me, had it been my intention to refute the man rather than to explain the matter then in hand — although I often let slip an opportunity for reproaching him that had fallen into my lap, lest I should seem to have singled him out as the one I most wished to attack. For how splendid an opportunity there was in Props. 4 and 8 of Book 1, and in Prop. 24 of Book 3 (which he makes his 23rd)! In all these he rejects the most ancient demonstrations of Euclid as non-geometric, since in them one must conceive in the mind one figure being superimposed on another — which he thinks foreign to the dignity of Geometry, led solely by this reasoning: that he supposes such superposition [superpositio] to be something mechanical, and that nearly all propositions can, as he says, be demonstrated in this way, even problems, in which something is set forth to be constructed. And as an example of this he adduces Props. 2 and 3 of Book 1, which are problems. Here indeed I could rightly have censured Peletier, had it been my purpose (as he falsely charges) — especially in this, that he supposed superposition would be equally useful in demonstrating problems and theorems. For he seems not to have sufficiently understood in what way geometers employ superposition. They do not wish the superposition to be actually carried out in fact (that would be something mechanical), but only in thought and mind, which is the work of reason and intellect. And so in theorems this kind of argument will have its place, but not in problems. For in theorems, on account of the equality of the magnitudes, anyone's intellect grasps without any hesitation that the one is or is not superposed so as not to exceed the other, even though that superposition is not actually made — as was done in Prop. 4 of Book 1. But in problems, in which

one is bidden to construct a magnitude equal to another, even if in his mind he thinks of the given magnitude being transferred to another place, he will nonetheless accomplish nothing thereby, since in fact no transfer has been made. So it is astonishing that Peletier could persuade himself that Props. 2 and 3 of Book 1, and nearly all the others, could be demonstrated by superposition, or by the transfer of lines and figures, if this manner of arguing were permitted in Geometry.

And certainly in this matter Peletier calls into accusation not only Euclid, but also Archimedes [Archimedes], than whom, by everyone's judgment, no one was keener and subtler in demonstration, together with his most weighty commentator, that most learned Eutocius of Ascalon [Eutocius of Ascalon], who use the same kind of argument in the books *On Plane Equilibria* [*De aequaeponderantibus*] — indeed he thereby refutes all geometers, who not rarely employ this kind of argument. But let us see to what our excellent Geometer here at last descended, when he criticized all other geometers. Peletier had seen (for he could not fail to see a thing so obvious) that, if he removed this manner of arguing, he would utterly overturn the whole of Geometry, since very many — and those the chief — propositions in Geometry are demonstrated from Props. 4 and 8 of Book 1 and from Prop. 24 of Book 3, which indeed cannot be demonstrated in any other way than by that superposition of figures — not actually existing, but grasped only in thought, as I said. Where, then, was he to turn? What was he to do? He devised something even more foreign to Geometry than that superposition of figures. For he was forced to assert that Prop. 4 of Book 1 is a definition of equal angles (and who ever heard such a thing?), and hence must be conceded without demonstration; and that Prop. 8 of the same book is a principle known through itself. And to make this more credible, he writes thus on Prop. 4 of Book 1: ("For by no more evident mark is the equality of figures recognized than from the equality of their sides.") And he confirms and, as it were, repeats the same on Prop. 8 of the same book, when he speaks thus: ("For who would deny that two surfaces are equal, whose sides are equal in quantity and number?")

These things Peletier contrived so that the said propositions of Euclid might be admitted without demonstration — things which are entirely false, so that it is greatly to be wondered at that he could put forward propositions so foreign to Geometry so inconsiderately. Of course it is true, as the philosophers assert: given one absurdity, the rest follow. For Peletier had assumed Props. 4 and 8 of Book 1 as principles — which is indeed false and absurd. Hence he necessarily fell into those absurdities which even those who have barely yet touched the first

principles of Geometry could easily avoid. For who does not see that a rhombus and a square, even if they have sides equal in quantity and number, can nevertheless be very unequal to one another? The same can be seen in equilateral pentagons too, and in other figures of many equal sides — which it is not the place here to explain at greater length. Since, therefore, in all many-sided figures inequality is found even when the sides are equal in quantity and number, it was necessary for Euclid to demonstrate that the equality of triangles is gathered from the equality of their sides — seeing that in other figures it is not so gathered. Therefore neither will Prop. 4 be a definition, nor Prop. 8 a principle; and consequently all the propositions that rest on them — which are well-nigh innumerable — must necessarily collapse, unless Euclid's demonstrations are taken up again, since they cannot be demonstrated in any other way. For the new demonstration of Prop. 4 which Peletier contrived is nothing else than (to speak with the logicians) a begging of the question [*petitio principii*]. This will be evident to anyone who considers it carefully. For in it only one triangle is constructed equal to the latter from the two given — nay, the very same triangle — and this indeed most ineptly, since to accomplish it Peletier describes circles which, however, he does not use in the demonstration — a thing wholly faulty in Geometry. Then he infers that this constructed triangle, which does not differ from the latter set out from the two, is equal to the first, without any demonstration; yet it is certain that this was from the beginning what was set forth to be demonstrated. Hence he manifestly begs the question, since with the same ease he could have concluded straightway at the outset that the given triangles are equal, even without employing any construction — inasmuch as that construction does not bear on the matter. I say the same of the demonstration of Prop. 24 of Book 3, which he likewise newly contrived: what their judgment is, into whose hands his commentaries have come, I leave to them. I pass over countless other places in which he misuses Euclid's propositions in demonstrating, so that what he most often does —

— namely, clumsily takes the second proposition of Book 1 for the third, and so on. For it is not now my intention to examine his commentaries, but only to drive off from myself the slanders which he frequently employed in his *Apologia*. Since this is so, what he falsely said of me I could truly say of him: that (to use his own words) I blush that he fell to being an interpreter of Euclid who does not now emend Theon or Campanus, but faults Euclid himself without cause — whereas I, as is fitting, defend Euclid from his slanders, and uncover and refute all the snares and fallacies he had set against him. It is clear, then, that I was not of a mind to refute Peletier, since I passed over so many and such great errors in silence — errors which even now I would not have brought to light, did I not wish

everyone both to understand how much benefit Peletier received from me (of whom he complains so bitterly), and to gain some fruit and profit from this brief disputation.

Now, so that it may appear with how unequal a spirit he treated me, I will briefly set out his slanders, and so refute and dissolve them that all may see with their own eyes that they are slanders. Yet in this I will use such moderation that I in no way forget the modesty that befits a religious man. For I will not answer him as he provoked me.

First, then, Peletier objects that, in citing his demonstrations, I conducted myself in such a way as to show that, if I could in any way have suppressed his name, I would gladly have done so. How false this is, those who have read my commentaries will easily judge; since everywhere I name him honorably, and ascribe very many demonstrations to him as his own — which, however, I demonstrate otherwise than he does, and much more briefly, and sometimes even (what is more) more universally, as is clearly established from what I demonstrated after Peletier both at Prop. 38 and at Prop. 45 of Book 1, to say nothing meanwhile of others which I could not unjustly have claimed for myself. So that I marvel what came into his mind, to reckon that done by me insincerely, and even enviously, which I feared someone might rather judge to have been done too ambitiously in his favor. As for the fact that at Prop. 16 of Book 3, and at the first two definitions of Book 5, I set out — "boldly," as he objects; "freely," as I confess — what I thought of his demonstrations, this I did, as I said before, not for the sake of injuring anyone, but of seeking the truth. For such is the nature and condition of those who devote themselves to the liberal arts, that even if one now and then attacks another's opinion, they do not on that account seem to contend among themselves with hatreds rather than with intellects.

What others' feeling may be I do not know; for my part, as I said above, I am so disposed that, if anyone were to warn me of some error committed in demonstration, I would be most grateful to him. And so that they might do this more freely, I earnestly asked not a few, and now again I wish the same men, and others too, to be entreated as friends. For I know how easily anyone may be deceived in his own discoveries; I see (as Peletier himself also wisely asserted in the *Apologia*) that it is common to all men to err. Next, that in the additions to Prop. 47 of Book 1 I made no mention of him is nothing he should take ill, since those propositions were not discovered by him. For some of them were demonstrated long before him, either by Campanus, or by Proclus, or by Theon; and some indeed I myself demonstrated before I had seen his demonstrations.

They are so manifest and easy that they need no proof, but are, as it were, corollaries of Prop. 47. So that no praise or glory at all would seem to accrue to him, even if I had most emphatically proclaimed them to have been discovered by him (which, however, is not true); since anyone who has tasted mathematical studies even with the tip of his lips can gather them from Prop. 47 with no trouble. So that I do not see why he should, after all, call those propositions of such great weight, when they are, by everyone's judgment, most trifling — so much so that in most of them not even Peletier himself adduces any demonstration, on account of their evidentness, but confesses that they need no proof.

Finally, there is no reason for him to be so angry with me on the ground that I did not attribute to him the construction of an equilateral and equiangular pentagon upon a given finite straight line: for in that construction I borrowed nothing at all from him — which I leave to be judged by those who have compared my construction with his. For mine is entirely different, and he, in his own (to say nothing of other faults), makes wonderful misuse of Prop. 9 of Book 3, since from it he proves that a certain point is the center of a circle which has not yet been described. A true geometer, surely, would have said that that point is of such a kind that a circle described from it, at the interval of any one of those three straight lines which are there shown to be equal, passes through the extremities of the two remaining equal lines. For Prop. 9 of Book 3 does nothing to the purpose in that place, since the proposition in hand can be concluded from the construction itself and from what has already been demonstrated (as I just said), even if that proposition were not true, or had nowhere been demonstrated. Peletier commits the same fault in all the propositions of Book 4, in which a circle is to be described either within or about a rectilineal figure. But if I am to be blamed on the ground that I did not ascribe to him one proposition which I demonstrated in a very different and briefer way, I do not see how he himself does not fall into the same fault, since he claims for himself this problem ("given two unequal lines, to find the power of the greater over the lesser") which was demonstrated by Theon many centuries before him — for this reason only, as I judge: that he demonstrated it in another way, though a longer one.

I say nothing of this other problem ("given a rectilineal angle, to construct a curvilinear angle equal to it") which in the *Apologia* he calls his own, and boasts to have been wanting until now — although I myself demonstrated that very thing, taken from Proclus (who flourished many centuries before him), at Def. 5 of Book 5, much more briefly and clearly. For, as I showed in that place, if the straight lines containing a given rectilineal angle are made equal, and about them

two semicircles (which will be equal) are described toward the same parts, at once a curvilinear angle will be constructed equal to the given rectilinear angle; nor is there need to use as many roundabout steps as Peletier employs to demonstrate that thing — although the force of his demonstration is the same as that of mine. And what is more astonishing, Peletier admits that he saw my demonstration, and nonetheless dares to claim it for himself as his own. See, then, why Peletier cries out that I tried, not very honorably, to filch not a few demonstrations in order to claim them for myself! But who does not see that he blames in another what he counts glorious in himself? And so I can condemn him of that same charge much more truly and justly than he can condemn me, since I never called myself the discoverer of those propositions, as he does, but only kept his name silent, for the reasons I have set out.

Next, he tries with many words to show, against me, that the angle of contact and the acute rectilinear angle are of the same kind. But somehow he strays, as they say, from the mark. For he only proves that both angles are contained under the same kind of quantity — that is, that both are plane angles; and that an acute rectilinear angle, or even a right one, can be composed of an angle of contact and another mixed angle: which neither I, nor any geometer ever, denied. I denied that those angles are of the same kind for this reason alone: that an angle of contact, however much multiplied, cannot exceed an acute rectilinear angle, as I clearly showed in the scholium to this Prop. 16. For hence it comes about that the one has no ratio to the other, and so they are in a certain way of different kinds — just as, for the same reason, a finite and an infinite straight line are not reckoned to be of the same kind, since the one has no ratio to the other, although they are comprehended under the same kind of magnitude, namely under "straight line." This, then, he may strike so as to seem to have taken aim; but though he do everything, he will never hit the mark; so far is he from it that —

For that magnitudes of which the one, multiplied, cannot exceed the other, are not reckoned of the same kind (as far as ratio is concerned), even though they be placed under the same kind of quantity — that is, under length, or breadth, or depth, or number — is clearly established from Def. 5 of Book 5, where Euclid explains plainly enough what sort of magnitudes those of the same kind must be, among which a ratio is found. Therefore let others consider why Peletier, a thoughtful man, called me — thinking about this very thing — an unthinking man, as though I had not correctly understood which magnitudes are of the same kind and which are not. For I never said (a thing he fastened upon me in order to carp) that of two magnitudes placed under different kinds of quantity — such as line, surface, solid, and number — either one could be so multiplied as to exceed

the other: in which, with no one gainsaying it, he wearies himself in vain to teach that this cannot be done. But I spoke only of those magnitudes which, though they lie in the same kind of quantity, may nonetheless be reckoned of a different kind: such as a rectilineal surface and a curvilineal or mixed one; and likewise a straight line and a curved one. For these seem to differ among themselves in such a way —

— that Aristotle [Aristotle] plainly affirmed that the one cannot be equal to the other. This, however (with Aristotle's leave be it said), is not everywhere true, since Archimedes in his book *On Spiral Lines* [*De lineis spiralibus*] demonstrated what straight line can be equal to the circumference of any given circle, and we ourselves have shown the same in the quadrature of the circle. Therefore Peletier will not be able to deny that in Def. 5 of Book 5 Euclid excludes certain quantities from the definition of ratio, and that they are on that account in a certain way of a different kind, as far as ratio is concerned, even though they be placed in the same kind of magnitude: such as the angle of contact and the rectilineal angle, and likewise a finite and an infinite straight line. Nor will he be able to deny that many magnitudes which most people excluded are comprehended in that same definition of ratio — such as curvilineal and rectilineal surfaces, as also the circular and the straight line, as we said a little before and will explain more fully at Def. 5 of Book 5.

But Peletier, lest he be compelled to abandon that opinion of his about the angle of contact which he had once imbibed, was unwilling to accept this exposition of Def. 5 of Book 5; indeed, to attack it, he seems in the *Apologia* to have strained every nerve — forgetful of himself, who had formerly expounded that definition in Book 5 in almost the same way. Except that he does not rightly infer from it that the angle of contact is not a quantity, on the ground that, when multiplied, it cannot (as he says) exceed any magnitude. For this (with his leave I say it) is false. For although the angle of contact, multiplied, cannot exceed a rectilineal angle, it will nonetheless exceed another angle of contact. Hence from that definition only this is rightly gathered: that the angle of contact has no ratio at all to a rectilineal angle, but that it does have some ratio to any other angle of contact. But whether he understood that definition in this way (as can be gathered from his commentaries on Book 5), or otherwise (as he seems to indicate in the *Apologia*), I do not much labor over. Certainly, that it is to be understood as I have expounded, no one who weighs Euclid's words carefully will deny. But truly, if Peletier will not put faith in me, he will surely — unless he wishes to be thought arrogant — put faith either in Proclus, that most weighty writer, who in Book 2 of his commentary on Book 1 of Euclid, at the definition of a plane angle,

understood that definition in the same way; or in Pedro Nunes the Portuguese [Pedro Nunes], whom he esteems so highly (and rightly so, for he was a man of the keenest intellect, inferior to none in Mathematics in our age) that he cites him alone as a witness in place of many thousands, and as an approver of his demonstrations — who, in the plainest words, both in his book *On the Errors of Oronce Finé* [Oronce Finé] and in his *Algebra*, explains that definition just as it has been set forth by me. Indeed, in the same place he asserts that from that definition it follows that the angle of contact has no ratio to a rectilineal angle, and a finite line none to an infinite: so that Pedro Nunes, whom Peletier had produced as a witness for himself, now speaks testimony for me.

And from these two passages of Pedro Nunes anyone will easily understand how without reason, and with how great a zeal for contradiction, Peletier insults me, when once and again he odiously demands whence I could have carried off an infinite line to him. For into the same charge (if it is a crime to name an infinite line by way of example) he draws even Pedro Nunes, his own witness — indeed all the philosophers, whose saying is unheard by no one except Peletier: that a finite line has no ratio to an infinite. Let him therefore cease to inquire of me whence I carried off an infinite line: for I shall answer, "from where Pedro Nunes, from where all the philosophers carried it off." What of it? Is not that sophism of Peletier's — I always slip up here; I meant to say that demonstration, and indeed his crowning one — by which he tries to show that Prop. 1 of Book 10, together with Prop. 16 of Book 3, cannot stand if the angle of contact is granted to be a quantity, refuted by Pedro Nunes, Peletier's own authority, on exactly the same reasoning by which it is refuted by me myself?

And if it is a genuine demonstration, I wonder what the reason is that Nunes — most learned in Geometry, and Peletier's own approver — approved it the less; and why the demonstrations of the same Peletier, by which he makes plain (as he thinks) that the angle of contact is not a quantity, did not move that same Nunes in the least. For this (unless I am mistaken) is what those words of Nunes declare: ("If anyone should wish to embrace Peletier's opinion about the angle of contact.") For if he had considered them demonstrations, he would surely have said that Peletier's teaching must be retained on that point; for geometrical demonstrations are of such a kind that they wring out assent and exclude all doubt, and in no way allow anyone to be pulled apart by a wavering opinion, so as now to assent, if he wishes, and now, if he does not wish, to dissent. Behold why Peletier despises others' judgments on the strength of Nunes's testimony — behold the splendid testimony that Pedro Nunes gave to his demonstrations, so

that he may bear with a more even mind that they are held to be demonstrations no more by me than by that approver of his!

Thirdly, he cries out that it is false that I said he holds the angle of tangency [angulus contingentiae] to be nothing: for, he says, he nowhere said it is nothing, but that it is not a quantity. Is that so, indeed? But in the category of Quantity — a thing which is neither a point (for who would say that that inclination is a point?), nor a quantity — by what other name should it be called than Nothing? But however he put it, it is truly not only astonishing but monstrous, something like a portent in Geometry, to suppose that the angle of contact is not a quantity, when, afterward added to other angles, it makes a curvilinear angle equal to a rectilinear one. For what geometer ever joined to a magnitude that which is not a quantity, so as to make it equal to another? I pass over the fact that a three-sided curvilinear figure enclosed within three mutually tangent circles would, on Peletier's view, have no angle — because those three tangencies are not angles — even though it is contained by three distinct lines; which is altogether new and unheard-of among geometers. Likewise, if four or more circles were mutually tangent, so as to make a curvilinear quadrilateral, or a figure of more sides, it would have no angle. And again, if two straight lines containing an angle were tangent to one and the same circle, that three-sided figure, having its third side curved, would have but a single angle. If all these things are absurd, Peletier's opinion is not consistent with reason.

But perhaps I have said too much toward overturning that "Nothing" of Peletier's, for the defense of which he brings nothing. But since — lest he seem to do nothing on behalf of his "Nothing," when the matter itself cannot be defended — he carps at my words, I will defend those words, which indeed he distorts by I know not what sleights of hand, so that I seem to say that Nothing is less than any angle whatever; and (to entangle me, I suppose, as a simple man) he asks me what kind of speech that is. Let him see to it, from whose workshop it came. For I do not acknowledge any such statement; I nowhere said that Nothing is less than any angle whatever, except as following from Peletier's own view. But of course, being a vehement man, in order to avenge that "Nothing" of his, he fabricated another "Nothing" and attributed it to me, so that he might fight it with impunity. But how like a wrestler he fights! How pleased he is with himself here, while with marvelous elegance he turns against me the very argument by which he had been attacked! For he argues thus: ("The angle of contact is nothing; the angle of contact is greater than another angle of contact; therefore an angle is greater than nothing. But Clavius sets the same as less than nothing. Therefore the angle of contact is greater than nothing, and the same is less than nothing.") Then, as

though he had throttled that "Nothing" fashioned by himself, he exclaims: ("Behold Clavius's arguments — which, in the end, are they? Peletier's sophisms, or rather Clavius's figments, since it is he who says his angle of contact is nothing, not I?")

But so that this man of straw and shadow may not go on demanding anything to no purpose, I will point out a man with whom, if he wishes, he could contend with credit. In order to show that the angle of contact, on Euclid's view, is truly an angle, and that the angle of a semicircle [text uncertain at the center gutter of these two lines; here the reading joins with] is less than a right rectilineal angle of the circle [?], I argued as follows. If Euclid had held the angle of contact to be utterly nothing (that is, as Peletier understands it, that it is not an angle, or not a quantity) and had held the angle of a semicircle equal to a right rectilineal angle, why, I ask, would he have sweated so hard to demonstrate that the angle of contact is less than every acute rectilineal angle, but the angle of a semicircle greater? For what is clearer than nothing — of what sort the angle of contact is, on Peletier's view, that is, than —

[Printed p. 124 — running header: EVCLID. GEOM.]

than that what is not a quantity should be less than any angle whatever? And again, what is more evident than that a right angle — the very sort of angle that Peletier makes the angle of a semicircle to be — is greater than any acute angle? Let Peletier therefore acknowledge that we did not take that "Nothing" of his in a bad sense, and let him take his revenge in this way: by refuting this argument of mine. For if I said that the angle of contact is nothing — rather than asserting, following Peletier's own view, that it is nothing — I shall gladly give in. It seems that Peletier either did not understand my argument or was unwilling to understand it, unless one were to say that he deliberately chose to cavil at my words — which he also seems to do in a great many other places. For I never said that the angle of contact is less, or greater, than nothing. I affirmed only that any angle of contact whatever is less, or greater, than some other angle of contact; and it was not I who said this to be nothing, but Peletier, while Euclid duly demonstrated the same angle to be less than any acute rectilineal angle.

But so that Peletier may understand that I have learned dialectic — which he denies — let us examine for a moment that neat and subtle syllogism of his, by which he has so charmingly constructed that "Nothing" he fabricated for himself; so that it may appear with what right he calls others ignorant of dialectic. For to me at least that syllogism seems badly turned, and fit to be sent back to the anvil. Since it operates in the third figure, in it the major extreme (as the dialecticians

put it), which is "Nothing," ought to be predicated in the direct case of the minor extreme, which is "greater than the angle of contact," in this way:

The angle of contact is nothing. The angle of contact is greater than an angle of contact. Therefore something that is greater than an angle of contact is nothing.

This conclusion does indeed follow correctly from the premises — of which the first is Peletier's, not mine, while the latter is mine, and Proclus's, indeed Euclid's too. But that conclusion of Peletier's — "Therefore an angle is greater than nothing" — can in no way be inferred from the premises. For if, when he says "angle," Peletier means the angle of contact, then the middle term is taken up [into the conclusion] — the term that is the subject in both premises; and Aristotle in the *Prior Analytics* [*Analytica priora*], and all the dialecticians, cry out that this is illicit. But if he means some other angle, then a term is taken into the conclusion of which no mention at all was made in the premises; and there is no one so leaden in dialectic as not to know that this is no more permissible. Nor let Peletier contend that mention was made of the angle in the minor extreme, where it was said that the angle of contact is greater than an angle of contact. For the angle placed in the minor extreme stands in the oblique case, whereas in the conclusion it is made the subject in the direct case — which, as all the logicians teach on Aristotle's authority, cannot be done without fault.

To make this plain, let us use the very exercise-ground we learned from him. Suppose someone argued thus:

An angle in a semicircle is a right angle. An angle in a semicircle is greater than an acute angle. Therefore an acute angle is greater than a right angle.

Who, if he has any grounding in dialectic, would approve such reasoning, when the premises are true but the conclusion false? Such is that syllogism of Peletier's, who among the untrained crowd wished to seem a second Chrysippus. The conclusion that would correctly follow from the premises would be this: "Therefore some angle that is greater than an acute angle is a right angle." Yet I think he should be pardoned, since he professes to be a geometer by profession — and of geometry I frankly confess myself ignorant in the way I am ignorant of his dialectic, if it recoils from Aristotle's.

Next, Peletier admits that he does not understand how I can say both that no least rectilinear angle can be given, and yet that the angle of contact is less than any acute rectilinear angle — less than the least acute rectilinear angle — even though

that word "least" ... [Peletier claims] the angle of contact is less than every rectilinear acute angle, so that I may oblige the man without reluctance, although from the scholium on this proposition 16 he could [have seen] that I could say this, in the same way that we say an obtuse rectilinear angle is greater than every rectilinear obtuse angle, and that a rectilinear acute angle is less than every obtuse rectilinear angle. Likewise, just as it is one thing that a rectilinear acute angle is less than ... it is less than every obtuse rectilinear, than that a rectilinear acute angle is the least of obtuse rectilineals: because that acute angle is not obtuse, just as the angle of contact is not rectilinear, [as I noted] in book 2, on the definition of a right, obtuse, and acute angle. These matters belong rather to the grammarians than to the geometers.

Then, so as [not to make my book] too thick, he complains that I recited his own words; he reproaches me for the very thing in which I [wished readers] to see plainly that I reported his opinion sincerely and faithfully, [in a way] he himself would not have brought his mind to do in reciting others' words. For it was of much greater [importance] — what reason had I to make my labor, my book, thicker with Peletier's words? — that one who embraces in his volume neither rare nor empty commentaries on all the books of Euclid, [comprising the demonstrations only] of those books, has judged [it thick] enough. For in his *Apologia*, lest it should seem empty of matter, he inserts three demonstrations that have nothing whatever to do with the point, as I said above; the earlier of which he wrongly makes his own, as I noted above, [claiming] to have made it clearer, whereas I did so far more briefly and lucidly (unless love of my own things deceives me), as will most clearly appear from my *Practical Geometry* [*Geometria Practica*]. If it was permitted to him to attach companions and attendants in a new fashion, why should it not be permitted me [to weave others' opinions] into my writings? Either, then, let him reproach everyone — and above all [Oronce Finé, in exposing] Finé's paralogisms — or let him admit that he wrongly charged me with this as a fault. Peletier accuses me of having wrongly interpreted his opinion — [as if,] had I brought his view forward [in other words]. Indeed anyone will easily persuade himself...

Fourthly — to pass over these lighter matters — he thinks this his trump card: that he shows me laboring to prove that angles of contact are unequal to one another; because I wrote that equality of angles of the same kind requires the same inclination of the lines, so that the lines of the one coincide entirely with the lines of the other, if the one is superposed on the other, according to the eighth postulate. In this he says I err doubly. First, because I say that equality of angles of the same kind requires the same inclination of the lines — whereas a

rectilineal angle has been shown by me to be equal to a curvilinear one, and so of the same kind as it, even though the inclination of the lines is not the same in both. Secondly, because I hold that angles of contact are unequal to one another on the ground that they do not mutually coincide.

Now, if I understood that I had erred at all in this, and acknowledged the error — as befits a man of honorable and liberal upbringing — I would give thanks to Peletier as my corrector and emender (with whatever intent he did it). But as it is, since, having weighed the whole matter again and again, I see no fault at all in it, I shall so resolve the objections raised as still to be grateful to Peletier for giving me occasion to explain this passage more carefully. In that passage, then, I understood angles of the same kind to be those that have one straight line and one circular line — such as angles of contact and of semicircles, which we were then discussing. Therefore, since the straight line of the one coincides with the straight line of the other, but the circular line does not likewise coincide with the circular (unless the circles be assumed equal), it follows that those angles are unequal to one another, since the one exceeds the other. By the same reasoning, if two curvilinear angles of equal circles are given equal, the lines of the one must coincide with the lines of the other, if the one is superposed on the other. And if Peletier attacks this doctrine, let him know that he is now making war not on me but on Proclus, who in book 3 on the first book of Euclid, at [proposition 4, teaches exactly the same as I. For he says (Of angles,

[Printed p. 125 — running header: LIBER III.]

however, we shall take the equality according to the correspondence of the sides in rectilineal figures; but in all the rest that are of the same species — as in lunes, in systroids, and in figures convex on both sides, etc.) And further on: (Things given equal coincide with one another. This, however, is not true in all cases, but in those that are similar in species. By similar in species I mean, for example, a straight line to a straight line, and a circumference to a circumference of the same circle, and angles contained by similar lines similarly situated. Of these, I say, that whichever are given equal coincide with one another.)

Is it not clearer than daylight, from these words, that Proclus grants those angles alone to be equal whose straight line and whose curve mutually coincide? Rashly, then, does Peletier throw up against me the rectilineal and the curvilinear, the triangle and the square, and other such things, of which there was no talk in that passage — since they are not of the same species, and so maintain their equality even though the one does not coincide with the other. So that I now begin to fear that our Peletier is more eager for contention than for truth.

Lastly, so as to leave nothing untouched, he calls me ignorant not only of geometry but of logic too: because in book 5 I said that Proportion is not rightly divided by some into proportion of equality and of inequality, since many proportions of inequality are also irrational. Now I — though I am not one to claim anything for myself in any field — have nevertheless always maintained that in these studies, in which I am moderately versed, I am plainly no novice. How little I can do in either subject, let others judge, who are free from love and hatred; but I think I have thus far answered Peletier himself in such a way that I may now perhaps seem less ignorant of geometry and dialectic than he had supposed.

Now, so that he may see that I am neither obstinate nor at odds with the precepts of the dialecticians — which he stirs up — I gladly grant him that the division he charges me with censuring is sound, provided that in each member of the division the thing divided [*Divisum*] be understood. Nor indeed did I ever deny this, since elsewhere I use similar divisions. I contended only, in that passage, that Proportion is, in my judgment, more rightly divided universally by a twofold division: the first into rational and irrational proportion, the second into proportion of equality and of inequality — which I hold to be most true, and think no one will deny who weighs the matter more carefully — since both pairs of dividing members exhaust the whole thing divided, as the logicians say; whereas if the first member of the first division, that is, rational proportion, be cut into proportion of equality and of inequality, these dividing members extend more widely than the thing divided, unless the thing divided is understood in them.

And that twofold division commends itself to me the more because there are those who divide Proportion first into proportion of equality and of inequality, and then divide the latter into rational and irrational proportion — that is, in the opposite manner to the former group. So, in order to settle this controversy and to remove the doubt as to which do it more rightly, the former or the latter, I resolved that Proportion should be cut by two divisions, each of which is most absolute and most perfect. In no other way, I judge, will all be the more convinced, if a body be cut by a twofold division — first into living and non-living, and then into what is white, black, or of mixed color — than if a living body be divided into white, black, and mixed-colored, for the reason already given; even though this subdivision is sound, if the thing divided be always understood. I could adduce six hundred divisions of this kind; but it is enough that I have set out to the prudent reader my plan in dividing Proportion, and why I preferred that twofold division to the subdivision of others.

But if we were willing to be such sharp and severe judges of every single word or impropriety that now and then slips out through inadvertence, why, no writer would be free of some fault — not even Peletier himself, as is partly clear from what has been said, and as can partly appear from his other demonstrations too: which, if one cared to test against that fixed norm of the dialecticians, there would surely be no lack of material for censure. But it is no part of my plan to scrutinize others' faults out of a zeal for refutation; only, where occasion offers itself, to set out my own opinion — such as it is — about the views of others.

I ask only this of him (since he boasts himself so keen a dialectician that he seems to despise others — though from the syllogism above, which he turned against me, it is plainly evident how skilled he is in dialectic): from what logic did he draw this argument — "All angles of contact are less than any acute rectilineal angle: therefore they are all equal to one another"? And likewise this: "Angles of semicircles, the greater the circles from which they are made, are the greater: therefore we shall at last arrive at one that is greater than a right rectilineal angle"? — on which point he writes to Cardano [Cardanus] that there is no paralogism. I am utterly amazed that he could fall into hallucinations so open, and altogether unworthy of a geometer. But arguments of this kind have been more than sufficiently refuted by me in the scholium on this proposition 16, with the most evident counter-instances brought against them.

Then, that he presses me as if I understood too little what rational and what irrational proportion is, gives me little trouble. For it is plain that he said this out of a desire to disparage me — whereas, since I have everywhere defined these proportions after the view of the weightiest authors, he will not be able to show that I committed any fault in the matter. Certainly my commentary on Euclid's book 10 abundantly declares whether I understood them or not. Finally, his charge that in the definitions of book 5 I confound the name of "proportion" with the name of "ratio" is in no way true. For in plain words I taught, in definition 4 of book 5, that in my commentary I would, with many geometers, call the comparison of two quantities "Proportion," and the relation of proportions "Proportionality"; although in the text, following the translator, I call the former "Ratio" and the latter "Proportion." For I did not wish to change anything in the text of Euclid. And so there can be no ambiguity in my words.

From what we have said, it appears sufficiently, I think, that those most learned men whom I mentioned at the outset judged Peletier's *Apologia* empty, and unworthy of a reply, not without cause. Yet I, lest I should seem to scorn a man I have always thought worthy of praise, was moved by the occasion and thought it

best to reply in a friendly spirit. Let him hold that the angle of contact is not a quantity, and hence that the angle of a semicircle is equal to a right rectilineal angle: I for my part shall defend the contrary view, until something else is demonstrated to me by someone. For Peletier's reasonings are fallacious and contain nothing of probability in them, as I showed in the scholium on this proposition 16, where I dissolved them all; and to my own solutions he replied not so much as a single word (except for those points I brought forward above from book 10) — which yet was what most concerned the *Apologia*. So that not without cause have very many judged that he wrote that *Apologia* not out of zeal for truth, but so as not to appear to have yielded to the truth.

Nor let anyone suppose that I alone hold the angle of contact to be truly an angle, and the angle of a semicircle to be less than a right rectilineal angle. For I can cite many authors of that view, and those of great weight: Theon, Campanus [Campano], Pedro Nunes [Petrus Nonius], and (as Nunes reports) Archimedes, and Jordanus [Jordanus Nemorarius]; indeed also — what I value most — Euclid himself, and his most celebrated commentator Proclus; to say nothing of not a few most excellent and learned men from among the French, chief of whom is François de Foix-Candale [Franciscus Candalla], sprung from the most illustrious family of Foix, who published a notable volume on the geometric Elements of Euclid, where, on this very proposition 16, he teaches most openly that angles of contact are truly angles, from the definition of a plane angle, and that some are greater than, equal to, and less than others. Those who think otherwise (he doubtless means Peletier — for down to this day no one else has written on the matter) he says conclude many absurdities from false...

[Printed p. 126 — running header: EVCLID. GEOM.]

false suppositions. To this let there be added Henri de Monantheuil [Henricus Monantholius], royal professor of the mathematical arts, who, when he had seen Peletier's *Apologia* written against me, published a learned little work against Peletier on the angle of contact.

That the studious reader may see what Proclus thinks in this matter, I shall bring forward a few things from his commentaries on Euclid's book 1, which I noted in passing, and from which it will clearly stand established that his view is utterly contrary to Peletier's contrivance. First, then, he writes thus in book 2 on the first book of Euclid, on the definition of a plane angle:

(For two circumferences, by cutting one another or by touching one another, make angles. Moreover, an angle is contained by a straight line and a convex circumference, as the horn-like [Cornicular] angle.)

Now by the name "Cornicular angle" he understands the mixed angle of contact. For a little before he had said that the Cornicular angle is less than every rectilineal — which is the property of the angle of contact alone. Then, in the same book, on the definition of a right, obtuse, and acute angle, he has this:

(For the Cornicular angle is less than every right angle, since [it is less] than an acute angle too, yet is not itself acute: the semicircular angle likewise is less than every right angle, but is not acute.)

What is clearer than that Proclus here asserts the angle of a semicircle to be less than a right angle? Again, in book 3, on proposition 4 of Euclid's book 1, he writes thus:

(For we shall learn that the Cornicular angle is always unequal to an acute angle, and never equal; and the semicircular angle likewise, and that the passage from greater to less does not take place altogether through equality.)

See how openly he teaches that the angle of a semicircle cannot be equal to a rectilineal angle, and that the passage from greater to less therefore does not occur through equality — both of which Peletier denies, and he dares to call the latter a paralogism. Finally, in the same book 3, on proposition 23, these words are found:

(Since no mixed angle can be equal to a rectilineal, etc.)

And yet Peletier does not hesitate to make the angle of a semicircle, which is mixed, equal to a right rectilineal angle, against Proclus's view. From these things I judge it clear — to say nothing of the rest — that Proclus holds the same about the angle of contact and of the semicircle as I wrote against Peletier. And who would deny that Proclus's authority is greater, and his arguments better, than Peletier's?

In passing, I also think the reader should be warned here that what I taught about the angle of contact that occurs in a circle, following the view of Euclid and Proclus, is true likewise of the angle of contact that is produced in the conic sections — namely in the parabola, hyperbola, and ellipse. For, as Apollonius of Perga [Apollonius Pergaeus] demonstrates in book 1, proposition 32, into the space that lies between a conic section and the straight line tangent to it, no other

straight line falls; and so that angle of contact is less than every acute rectilineal angle, while the remaining angle out of the right angle (namely, if a perpendicular be raised from the point of contact to the tangent line) is greater than every acute rectilineal angle. If, therefore, as Peletier supposes, the angle of contact is not a quantity (for the reasoning here is the same as in the circle), then all angles of contact will be equal to one another — that is, as he would have it, not unequal — and each of the remaining angles will be equal to a right rectilineal angle. Here indeed a greater absurdity appears, to the senses, in an ellipse that has a very small breadth, and in a hyperbola that seems almost a straight line. For the angles set at the vertex of that ellipse and hyperbola are seen to be very unequal; so that it is altogether incredible — unless demonstrated by firm reasoning — that those angles of contact set at the vertices of the sections are equal to one another, and the remaining angles out of the right angles are also equal to one another; because in that ellipse the tangent line is seen to recede more from the circumference of the ellipse than in a circle, while in that hyperbola it recedes less. But let us leave these matters to be examined at another time: now let us return to the interrupted exposition of Euclid.

EX CARDANO. [From Cardano]

A certain quantity can be continually and infinitely increased, and another infinitely diminished; and yet the increase of the former, however great it be, will always be less than the decrease of the latter.

Diagram. A composite figure illustrating Cardano's claim, in two parts. On the left: a horizontal straight line **E–A–F** with **A** as the point of contact at its midpoint; below **A**, two nested circles are drawn tangent to the line at **A** (the larger with diameter toward **B** at the bottom, the smaller inner circle passing through the interior points), the angle of contact **BAE** being formed between line **EA** and the largest circle. On the right: a rectilineal acute angle with its vertex **G** at the top and rays descending to the base points, so that angle **HGI** is the outermost acute angle and the intermediate rays **GK**, **GL** fall within it.

- **E** (top left, on tangent line): left endpoint of the tangent
- **A** (top center): point of contact; vertex of the angle of contact
- **F** (top right, on tangent line): right endpoint of the tangent
- **B** (bottom of largest circle): marks the largest circle forming angle **BAE**
- **C** (interior, on middle circle): a smaller tangent circle
- **D** (interior, on innermost circle): the smallest tangent circle
- **G** (apex of right-hand figure): vertex of the acute rectilineal angle

- H (base, leftmost): outer ray endpoint (angle HGI)
- K (base): intermediate ray endpoint
- L (base): intermediate ray endpoint
- I (base, rightmost): outer ray endpoint (angle HGI)

The accompanying explanation reads: Let there be proposed the angle of contact **BAE** and the acute angle **HGI**. If, then, other smaller circles **AC**, **AD** be described, tangent to the straight line **EF** at **A**, the angle of contact will be continually increased, as was said. If again, between the straight lines **GH**, **GI**, other straight lines **GK**, **GL** fall, the acute angle will be continually diminished. And yet the angle of contact, however much it be increased, is always less than the acute angle, however much this be diminished.

EX CAMPANO. [From Campanus]

Moreover, from this proposition 16 it is evident that the argument is faulty which Brison [Bryson] used in squaring the circle, as Aristotle reports. Namely:

There is a passage from less to greater, or the reverse, and through all the means; therefore through the equal. Or: it happens that one finds this greater and that less than the same; therefore it happens that one finds an equal.

Diagram. A circle **ABC** with vertical diameter **AC** (**A** at top, **C** at bottom) and **B** on the circumference at the left. From the fixed point **A** at the top, three lines radiate to the right to the points **F** (uppermost), **E** (middle), and **D** (lower), representing successive positions of the far end of the rotating diameter as it turns about **A** until it becomes tangent at **A**.

- A (top): the fixed extremity of the diameter, about which it rotates
- B (left, on circumference): a point of the circle
- C (bottom): the other extremity of the diameter AC
- F (upper right): a swept position (through point F)
- E (middle right): a swept position (through point E)
- D (lower right): a swept position (through point D)

The accompanying explanation reads: Let a circle **ABC** be described, whose diameter **AC** is understood to be moved about the fixed extreme point **A**, through the points **D**, **E**, **F**, until it becomes tangent to the circle at **A**. This being granted, it is manifest that so long as the straight line **AC** cuts the circle, an acute angle is made less than the angle of a semicircle; but as soon as it ceases to cut it, a right

angle is made greater than the same angle of a semicircle. Since, therefore, the passage has been made through all the intermediate rectilineal angles, the flaw of the earlier argument is plain. Similarly, because no rectilineal angle is found equal to the angle of a semicircle — (for a right or an obtuse angle is greater; and an acute one, less) — it is established likewise that the latter consequence is faulty.

Book III

Problem 2. Proposition 17. [Euclid, *Elements* III.17]

[Margin: xvj.]

Proposition (Euclid). From a given point to draw a straight line that touches a given circle.

Demonstration (Clavius). From the point A a line is to be drawn that touches the circle BC, whose centre is D. Draw the straight line AD, cutting the circle BC at B. Then, with centre D and radius DA, describe the circle AE; and from B draw BE perpendicular to AD, cutting the circle AE at E. Finally, drawing the straight line ED — which cuts the circle BC at C — join the straight line AC; I say that this touches the circle BC at C. For the two sides DE, DB of the triangle BDE are equal to the two sides DA, DC of the triangle CDA, each to each, as is clear from the definition of a circle; and the angle D, contained by those sides, is common to both. Therefore [Margin: a — I.4] the bases BE, CA and the angles DBE, DCA standing upon them will be equal. But DBE is a right angle by construction; therefore DCA will also be a right angle. And so CA, being drawn perpendicular at C, the extremity of the radius CD, will touch the circle by the corollary of the preceding proposition. From the given point A, therefore, the straight line AC has been drawn touching the circle BC at C — which was to be done.

Diagram. Two concentric circles about the centre D: the outer circle AE and the inner circle BC. The straight line AD is drawn from A through B to the centre D; the radius DE reaches the top point E; BE is drawn perpendicular to AD; ED cuts the inner circle at C; and AC is the constructed tangent.

- A (upper left, on outer circle): the given external point
- E (top, on outer circle): foot of the perpendicular BE on the outer circle
- C (upper right, on inner circle): point of tangency
- B (left of centre, on inner circle): where AD meets the inner circle

- D (centre): centre of the given circle BC and of the auxiliary circle AE

Scholium

The practical construction of this problem is easily drawn from the demonstration itself. You will, however, find an easier construction at proposition 31 of this book.

But the following problem we shall solve together with Cardano [Gerolamo Cardano].

[Added problem: a common tangent to two circles]

Proposition. Given two circles, neither of which includes the other, to draw a straight line that touches both circles.

First case — equal circles. Let there first be two given equal circles AB and CD, whose centres E and F are joined by the straight line EF. To EF let the perpendiculars EA and FC be drawn, cutting the circumferences at the points A and C. I say that the straight line drawn through A and C touches both circles. For since EA and FC, the radii of equal circles, are equal, and [Margin: b — I.28] also parallel — because the angles E and F are right angles — [Margin: c — I.33] EF and AC will likewise be equal and parallel; and therefore [Margin: d — I.20 (?)] (printed "20"; sense requires I.29) the angles A and C are right angles. Hence, by the corollary of proposition 16 of this book, the straight line AC will touch both circles, since it makes right angles at the extremities of the radii.

Diagram. Two equal circles AB and CD standing side by side, their centres E and F joined by EF; the radii EA and FC are drawn perpendicular to EF up to the tangent line AC, so that AEFC forms a rectangle. The page prints this equal-circles construction in several near-identical variants (external and overlapping positions).

- A (top left, tangency point on circle AB)
- C (top right, tangency point on circle CD)
- E (centre of circle AB)
- F (centre of circle CD)
- B (bottom, on circle AB)
- D (bottom, on circle CD)

Second case — unequal circles. Next let two unequal circles AB and CD be given, whose centres E and F are again joined by the straight line EF. With centre E, the

centre of the larger circle, and with EF as radius, describe the circle FH (provided the larger circle does not pass through the centre of the smaller). Then, having drawn EA perpendicular to EF, cut off from it the portion AG equal to the radius of the smaller circle CD; and from G draw GH perpendicular to EA, as far as the circumference of the circle FH just described. Draw the straight line HE, and make the angle FEI equal to the angle HEA; and through F draw the straight line FC parallel to EI. I say that the straight line drawn through the points I and C touches both circles AB and CD. For let there be cut off from IE the straight line IK equal to AG, that is, to the radius FC of the smaller circle,

*(text continues *

Diagram. The construction for the unequal-circles common tangent, printed large at the foot of the page (and repeated at the head A large circle of centre E carries an inner auxiliary circle; a smaller circle of centre F stands to the right. The tangent line runs across the top through A (and the neighbouring point I) to C; the auxiliary radii and the equal triangles HEG, FEK are drawn to the interior.

- A (top left, on the large circle): tangency point on the larger circle
- I (top, just right of A): point through which the tangent IC passes
- C (upper right, on the smaller circle): tangency point on the smaller circle
- G (interior left): foot of the cut-off AG
- K (interior, right of G): where $IK = AG$ is cut off on IE
- H (interior right): endpoint of GH on the auxiliary circle
- E (centre): centre of the larger circle
- F (right of centre): centre of the smaller circle
- B (bottom): opposite point of the larger circle
- D (lower centre-right): opposite point of the smaller circle

equal to the radius of the smaller circle, so that the remainders EG and EK are also equal; and draw the straight line KF. Since, then, the sides HE, EG of the triangle HEG are equal to the sides FE, EK of the triangle FEK, and the angles contained by them are equal, by construction, [Margin: e — I.4] the angles HGE and FKE will be equal. And accordingly, since HGE is a right angle by construction, FKE will also be a right angle. Again, since CF and IK are equal and parallel by construction, [Margin: f — I.33] IC and KF will likewise be equal and parallel; and therefore the angle EIC, [Margin: g — I.29] being equal to the exterior angle FKE, will be a right angle; [Margin: h — I.29] and so ICF too will be a right angle. Wherefore, by the corollary of proposition 16 of this book, the

straight line IC will touch both circles, since it makes right angles at the extremities of the radii — which was proposed.

Diagram. The full unequal-circles construction: a large circle of centre E with an inner auxiliary circle, and a smaller circle of centre F overlapping it at the right. The tangent IC runs across the top; the equal right triangles HEG and FEK are drawn to the interior, together with KF.

- A (top): tangency point on the larger circle
- I (top, right of A): point through which the tangent passes
- C (upper right): tangency point on the smaller circle
- G (interior left) and K (interior centre): feet of the equal cut-offs
- H (interior right): endpoint of the perpendicular GH
- E (centre) and F (right of E): centres of the larger and smaller circles
- B (bottom): opposite point of the larger circle
- D (lower right): opposite point of the smaller circle

Diagram. A row of four small figures repeating the same two-circle construction in the successive positions (the "modes" in which the circles can stand). Each carries the same lettering — A, I, C at the top; G, K, H in the interior; E, F at the centres; B, D at the foot — but at this size several labels do not resolve. [Several labels illegible]

On the five and seven modes. It is sufficiently clear that, if the given circles are equal, this can happen in five ways: either one falls outside the other; or they touch each other; or they cut one another through their centres; or they do not, yet so that either the centres lie in their common segment, or else outside it.

Likewise, if the given circles are unequal, it can happen in seven ways. For either the smaller falls wholly outside the larger; or it touches it; or it cuts it, so that its centre lies on the circumference of the larger, or within the larger circle — yet on the condition that the circumference of the smaller passes short of the centre of the larger; or the centre of the smaller lies outside the larger circle; or it falls on the centre of the larger; or, finally, so far within that the circumference of the smaller includes the centre of the larger.

Diagram. Two circles, the smaller lying largely within the larger and overlapping it, illustrating the construction begun from the smaller circle. The interior carries the auxiliary lines and the points G, K, H.

- I (top left) and C (top right): the tangent passes through I and C

- A (below I): tangency point
- E (left of centre) and F (right): the two centres
- G (below E), K (centre), H (right of K): interior construction points
- D (bottom): opposite point
- [One further foot-point at lower left illegible — [?]]

A further problem: to describe circles tangent to given circles. Since, from what has been demonstrated, we can draw a straight line that touches a circle both through a point set on the circumference of the circle and through a point lying outside the circle — through a point on the circumference by the corollary of proposition 16, and through a point outside the circle by this proposition 17 — and since it has also been shown in this scholium that a straight line can be drawn to touch two circles, provided neither of them is wholly included in the other, it will not be out of place to demonstrate here how, through a given point, a circle is to be described touching a given circle, whether internally or externally; and likewise by what method a circle is to be described touching two other circles, one of which is not wholly within the other.

First. Let there be, in the circle AB whose centre is C, a given point A on the circumference, through which a circle is to be described touching the circle AB at A. Draw from A through the centre C the straight line AC, and take on it any point D; with radius DA describe the circle AE, which will touch the circle AB at A. And if the point D lies beyond the centre C, the circle AE will fall wholly outside the circle AB; but within it, if the point D lies on the radius AC — as we demonstrated in the scholium to proposition 13 of this book.

Then. Outside the same circle AB let a point G be given, through which a circle is to be described touching the circle AB. Draw from G through the centre C the straight line GCA, and, bisecting it at D, describe from D through A the circle AE, which will pass through the given point G and will touch the circle AB at A, by what we demonstrated in the scholium to proposition 13 of this book.

Otherwise. Let the point E again be given, outside the circle AB. Draw the straight line EA at random from the given point E, so that it cuts the circle and does not pass through the centre; then draw from A through the centre C the straight line AC. The angle EAC will be acute, since it is part of the angle of a semicircle, which is less than a right angle. At E let the angle AED be made equal to the angle EAC; then the straight line ED will meet AC at D, because the two angles DAE and DEA are less than two right angles. Since, then, the angles DAE and DEA are equal, [Margin: i — I.6] the sides DA and DE will also be equal.

Therefore the circle described from D through A will pass through the given point E and will touch the circle AB at A, by what we demonstrated in the aforesaid scholium to proposition 13 of this book.

Diagram. A single circle with an inscribed construction: from the top point A lines are drawn to points around and below the circle, the tangent circle being built on the diameter through the centre.

- A (top): the point of tangency / given point on the circumference
- B (right): a point on the circle
- C (centre) and D (just below C): centre of the circle and the taken point D
- E (lower left): the given external point
- F (bottom centre) and G (foot): further construction points

Third. Let a point F be given within the circle AE. Draw from F through the centre D the straight line FA, and, bisecting it at C, describe from C through A the circle AB, which will pass through the given point F and, by the said scholium, will touch the circle AE at A.

Otherwise. Let the point B again be given, within the circle AE whose centre is D. Draw any straight line AD through the centre D, not passing through the given point B; joined with the straight line AB, it will make the acute angle BAD — acute inasmuch as it is smaller than the angle of a semicircle, which is less than a right angle. At B, then, let the angle ABC be made equal to the angle BAD; the straight line BC will meet AD at C, because the two angles BAC and ABC are less than two right angles. Since, then, the angles BAC and ABC are equal, [Margin: k — I.6] the sides CA and CB will also be equal. Therefore the circle described from C through A will pass through the given point B and will touch the circle AE at A, by what we demonstrated in the scholium to proposition 13 of this book.

And if through a point N, given outside the circle QAR, a circle is to be described touching the circle QAR externally, so that neither falls within the other: draw from N, the given point, to the centre P of the circle QAR the straight line NP, cutting the circumference of the circle at A. Then, bisecting the straight line NA at L, describe from L through A a circle, which will pass through the given point N and will touch the circle QAR at A, because both circles touch, at A, the straight line DE drawn through A perpendicular to NP — by the corollary of proposition 16 of this book.

Diagram. A stacked figure: at the top a small circle QAR of centre P, with the horizontal line DAE drawn through A; below A, larger concentric circles share the

vertical diameter through C, G, L, B, K down to N, and the line from M through H and F sweeps to the left.

- Q (top left), P (top, centre of the upper circle), R (top right): the circle QAR
- A (junction of the circles): the point of tangency
- D (left) and E (right): the tangent DAE perpendicular to NP
- M (left), H, F (left of centre): points on the lower circles
- C, G, L (on the vertical diameter, descending): centres / division points
- B (lower), K (below B), N (bottom): the given external point N on the vertical

In the same way, if a point A is given on the circumference of the circle QAR, we shall describe a circle that touches the circle QAR externally at A. For, drawing from the centre P the straight line PAC through the given point A, if from any point of this line a circle be described through A — say AMN, with centre L — this will touch the circle QAR, as was said, at A.

Diagram. The same stacked construction repeated for the continuing text: the upper circle QAR of centre P with the horizontal DAE through A, and below it the larger circles on the vertical diameter through C, G, L, B, K, N, with M, H, F to the left.

- Q (top left), P (top centre), R (top right): the circle QAR
- A (junction): point of tangency
- D (left), E (right): the perpendicular tangent DAE
- M (left), H, F (left of centre): points on the lower circles
- C, G, L (descending on the vertical): division points
- B, K, N (lower vertical): with N the external point

[Margin: l — III.12]

From this it is clear that through the same given point several circles can be described touching a given circle — namely if, from the given points E and B in the earlier figure, other straight lines be drawn differing from the lines EA and BA; likewise if, from the given points F and G, other lines be sent out not passing through the centres C and D but cutting the circles; and at length, on the straight line AG of the same figure, or on PAC of the latter figure (when the point A is given on the circumference), other centres different from the centres C, D, L be assumed — whereas, through a given point outside the circle, only one single line toward the same side can be drawn touching the circle. But by what method a circle touching two circles is to be described, when one of them is not wholly

within the other, we shall demonstrate on this principle together with Giovanni Battista Benedetti [Ioan. Bapt. Benedicto].

First. Let there first be two unequal circles touching or cutting each other — AB the smaller and CDE the larger — whose centres are F and G; through these let the straight line FG be drawn, meeting the circumferences at A and C. If the circles touch at E, this line will pass through the point of contact E. Cut off the straight line EH from the radius of the larger circle, equal to the radius of the smaller; and from F, the centre of the smaller, with radius HC — which is greater than the radius of the smaller — describe an arc cutting the circumference of the larger at I; and from I draw through the centres F, G the straight lines IF, IG, meeting the circumferences at B, D. Since CH is equal to IF, and HE to FB, by construction, the wholes CE and IB will be equal. Since, then, the diameter ID is also equal to the diameter CE, IB too will be equal to ID. Therefore the circle described from I through B will pass through D; and since the same falls wholly outside both circles, by the scholium to proposition 13 of this book, it will touch both circles at B, D — which was proposed.

Diagram. Two overlapping circles — the smaller AB and the larger CDE — with their centres F, G on the horizontal line AC; the constructed touching circle passes through B and D, meeting at I below.

- B (top left, on the smaller circle) and D (top right, on the larger): the two points of contact
- A (far left), F (centre of smaller), E (contact), H (cut-off point), G (centre of larger), C (far right): points along the central line
- I (bottom): the centre of the touching circle

Then. Next let there be two circles touching or cutting each other, equal, AB and CD, through whose centres E, F the straight line AC is drawn. Then bisect the straight line EF, between the two centres, at G. (When the circles touch each other, the straight line EF is bisected at the point of contact, because of the equal radii of equal circles.) At G erect GH perpendicular to EF; and, taking any point H on it, draw from it through the centres E, F straight lines meeting the circumferences at B, D. Since, then, the two sides GE, GH are equal to the two sides GF, GH, and contain equal angles — namely right angles — [Margin: m — I.4] the bases HE, HF will also be equal; and, the equal radii EB, FD being added, the whole lines HB, HD will be equal. Therefore the circle described from H through B will pass through D, and will fall outside both circles, by the scholium to proposition 13 of this book. Hence it will touch both at B, D — which was proposed.

Diagram. Two equal overlapping circles AB and CD, centres E and F on the horizontal line AC, with the midpoint G, the perpendicular GH, and the touching circle through B, D meeting at H below.

- B (top left) and D (top right): the two points of contact
- A (left), E (centre), G (midpoint of EF), F (centre), C (right): points on the central line
- H (bottom): apex of the perpendicular and centre of the touching circle

Third. Third, let there be two circles, whether equal or unequal, AB and CD, one of which lies wholly outside the other. Through their centres E, F draw the straight line AC. And if the circles are unequal, describe from E, the centre of the smaller, with radius equal to the diameter of the larger CH, an arc; let it be cut at G by another arc described from F, the centre of the larger, with radius FI, compounded of the radius of the larger FH and of HI, equal to the radius of the smaller. Let us now suppose that these arcs intersect one another; when they do not cut, we shall say presently what is to be done. From G let straight lines be drawn through the centres E, F, cutting the circumferences at B, D. Since FG is equal to FI, the equals FK, FH being taken away, the remainders KG, HI will be equal. But HI was taken equal to the radius of the smaller, EB. Therefore KG too will be equal to EB. Since, then, EG is also equal to the diameter of the larger KD, the whole straight lines GB, GD will be equal. Wherefore the circle described from G through B will pass through D, and will fall outside both circles, by the scholium to proposition 13 of this book; and accordingly it will touch both at B, D — which was proposed.

Diagram. Two circles standing wholly apart, with the centres E, F on the horizontal line AC; the two auxiliary arcs meet below at G, and the touching circle is built through B, D.

- A (far left), E (centre of one circle), I, H (centre points), F (centre of the other), C (far right): points along the central line
- K (below the central line): where FK is cut off
- G (bottom): intersection of the two arcs and centre of the touching circle
- [The contact points B, D at the top of the two circles are not clearly resolved at this size — [?]]

But because those two arcs described from E and F do not always intersect — which happens on account of too great a distance of one circle from the other — we shall solve this problem in another way, which is general, whether the circles touch or not, even if they do not cut, and whether they are equal or unequal.

Draw the straight line AC through the centres of the circles, and take equal straight lines AG, CH, such that each exceeds the half of AC itself; and from centre E, through G, describe the arc GI; let another arc HI, described from centre F through H, cut it at I; and finally from I, through the centres E, F, let straight lines be sent out meeting the circumferences at B, D. And since EG, EI are equal, if the equals AE, BE be added, the wholes AG, BI will be made equal. By the same reasoning CH, DI will be equal. Since, then, AG, CH were laid down equal, BI, DI too will be equal. Therefore the circle described from I through B will pass through D, and, falling wholly outside both circles by the scholium to proposition 13 of this book, will accordingly touch both at B, D — which was proposed.

Diagram. The general construction: two circles on the horizontal line AC, with the auxiliary arcs from E and F meeting at I below, and the touching circle passing through B and D.

- B (top left) and D (top right): the two points of contact
- A (left), E (centre), H, G (centre points), F (centre), C (right): points along the central line
- I (bottom): intersection of the arcs and centre of the touching circle

(Continued from the preceding page.) By the same technique we shall now describe a circle of any given size that touches the two given circles, provided the radius of the circle to be described is greater than half the line AC drawn through the centres of the circles as far as their circumferences. For if from that line we cut off AG and CH equal to the radius of the given circle, we shall carry out the rest as was just explained.

Moreover it is also clear that, if from the midpoint of the line AC — drawn through the centres of the circles out to their circumferences — a circle is described through A and C, that circle touches both circles AB and CD, at A and at C, by the scholium to Proposition 13 of this book.

FROM PELETIER [Jacques Peletier du Mans]

Problem. *Parallel to a straight line that cuts a circle, to draw a line that touches the same circle.*

Diagram. A circle with centre D. A horizontal tangent line FAG runs across the top, touching the circle at A. A chord BC lies just below, parallel to FG; the line DA is perpendicular to BC, meeting it at E and extended up to A.

- F (top left): left end of the tangent line

- A (top, on circumference): point of tangency
- G (top right): right end of the tangent line
- B (left end of chord)
- E (on chord BC, foot of the perpendicular from the centre)
- C (right end of chord)
- D (centre of the circle)

Let the straight line BC cut the circle ABC, whose centre is D, and let a line parallel to BC be required, touching the circle ABC. From the centre D draw DE perpendicular to BC, and extend it to the point A on the circumference; and from A draw FG perpendicular to AD [Margin: n — El. I.28]. Then FG will be parallel to BC, and it will touch the circle at A, by the corollary to Proposition 16 of this book. Which was to be done.

THEOR. 16. PROPOS. 18.

[Margin: xvij.]

Enunciation (Euclid III.18). **If a straight line touches a circle, and from the centre a straight line is joined to the point of contact, the joining line will be perpendicular to the tangent.**

Diagram. A circle with centre E. A tangent line runs across the top through the points A, C, F, B (left to right), touching the circle at C. From the centre E two lines run up to C and to F, forming the narrow triangle CEF; D lies on the circumference at the left.

- A, C, F, B (top tangent line, left to right; C is the point of contact)
- E (centre)
- D (on the circumference, left)

Let the straight line AB touch the circle CD, whose centre is E, at C; and from E to C draw EC. I say that EC is perpendicular to AB. For if it is not, let EF be drawn perpendicular to AB, cutting the circumference at D. Now in the triangle CEF the two angles ECF, EFC are less than two right angles [Margin: a — El. I.17]; and EFC is a right angle by construction; therefore ECF is less than a right angle. Hence [Margin: b — El. I.19] the side EC — that is, ED — will be greater than EF, the part greater than the whole, which is absurd. Therefore EC is perpendicular to AB. And so, if a straight line touches a circle, etc. Which was to be demonstrated.

ANOTHER WAY. If EC is not perpendicular to AB, then one of the angles at C will be obtuse and the other acute. Let ECB be the acute one; and since it is greater

than the angle of the semicircle ECD, the angle of the semicircle would be less than some acute angle — which is absurd, since every angle of a semicircle is greater than every acute angle [Margin: c — El. III.16].

SCHOLIUM

Here it will be permissible to demonstrate the following theorem, which is not without use for what follows; namely:

When two circles are described from the same centre, all the straight lines that touch the inner circle and are extended as far as the circumference of the outer circle will be equal to one another, and will each be bisected at the points of contact.

Diagram. Two concentric circles with common centre G. The outer circle carries the points A and B (top), C (right) and D (bottom left); the chords AC and BD of the outer circle each touch the inner circle, AC at E and BD at F.

- A (top left), B (top right): on the outer circle
- E, F (inner circle): points where AC and BD touch the inner circle
- G (common centre)
- D (lower left), C (lower right): on the outer circle

Let two circles ABCD and EF be described from the same centre G, and let the straight lines AC, BD touch [the inner circle] at the points E, F. I say that the lines AC, BD are equal, and are bisected at E, F. For from the centre G to the points of contact E, F draw the straight lines GE, GF, which will be perpendicular to AC, BD [Margin: d — El. III.18]; and therefore, by Definition 4 of this book, the lines AC, BD are equally distant from the centre G in the circle ABCD, since the perpendiculars GE, GF are equal. Therefore the lines AC, BD are equal [Margin: e — El. III.14]. And they are also bisected at E, F by the perpendiculars GE, GF [Margin: f — El. III.3]. Which establishes what was proposed.

THEOR. 17 PROPOS. 19.

[Margin: xvii.]

Enunciation (Euclid III.19). If a straight line touches a circle, and from the point of contact a straight line is erected at right angles to the tangent, the centre of the circle will lie on the line so erected.

Diagram. A circle touched at its top by the tangent line ACB (A left, C the point of contact, B right). The perpendicular CE runs down from C through the interior to E at the bottom; F is an interior point (the falsely assumed centre), joined to C.

- A (top left), B (top right): ends of the tangent
- C (top, point of contact)
- F (interior, the assumed false centre)
- E (bottom, other end of the perpendicular CE)

Let the straight line AB touch the circle CDE at C; and from C draw CE perpendicular to AB. I say that the centre of the circle lies on CE. For if it lies outside CE, let F be the centre; and from F to C draw the straight line FC, which will be perpendicular to AB [Margin: a — El. III.18]. Then the right angle FCB will be equal to the right angle ECB, the part to the whole, which is absurd. Therefore the centre of the circle will not lie outside CE. And so, if a straight line touches a circle, etc. Which was to be demonstrated.

THEOR. 18. PROPOS. 20.

[Margin: xix.]

Enunciation (Euclid III.20). **In a circle, the angle at the centre is double the angle at the circumference, when the same arc is the base of both angles.**

Diagram. A circle with centre D. A is at the top, B at the lower left, C at the lower right. The lines DA, DB, DC run from the centre; the diameter AE is extended from A through the centre D down to E at the bottom, and AB, AC are the chords.

- A (top): vertex of the inscribed angle
- B (lower left), C (lower right): ends of the base
- D (centre)
- E (bottom, second end of the diameter AE)

In the circle ABC, whose centre is D, let the angle BDC be set up at the centre on the base BC, and on the same base the angle BAC at the circumference. I say that the angle BDC is double the angle BAC. First, let the two lines AB, AC enclose the two lines DB, DC; and through the centre D let the straight line AE be extended. Now since DA, DB are equal, the angles DAB, DBA will be equal [Margin: a — El. I.5]; and the exterior angle BDE is equal to the two interior angles DAB, DBA [Margin: b — El. I.32]; therefore BDE is double one of them, namely the angle DAB. In the same way the angle CDE will be shown to be double the angle DAC. Therefore the whole angle BDC is double the whole angle BAC. For when two

magnitudes are each the double of two others, one of each, then their sum is likewise double the sum of the others. Which establishes the proposition.

Diagram. A circle with centre D. A is at the top right, B at the lower left, C at the lower right; the line BA is a diameter passing through the centre D, and DC, AC are drawn.

- A (top right): vertex
- B (lower left): the diameter BA runs through D to A
- C (lower right): third point
- D (centre)

Next, let the lines AB, AC not enclose the lines DB, DC, but let AB be extended through the centre. Then since the exterior angle BDC is equal to the two interior angles DAC, DCA [Margin: c — El. I.32] — and these two are equal to one another, because the sides DA, DC are equal [Margin: d — El. I.5] — the angle BDC will be double one of them, namely the angle BAC. Which is the proposition.

Diagram. A circle with centre D. A is on the right, E on the left, B at the lower left, C at the lower right. The line AE passes through the centre D; DB, DC, AB and AC are drawn, so that the chord AB cuts DC.

- A (right): vertex
- E (left, second end of the diameter AE through the centre)
- B (lower left), C (lower right): ends of the base
- D (centre)

Thirdly, let the line AB cut the line DC, and through the centre D let the line AE be extended. Then since the angle EDC at the centre and the angle EAC at the circumference have the same base EC, and AE is drawn through the centre, the angle EDC will be double the angle EAC, as was shown in the second part. In the same way the angle EDB will be double the angle EAB, since these angles have the same base EB. Therefore the remaining angle BDC will be double the remaining angle BAC [Margin: e — Ax. 20]. For when the whole is double the whole, and the part taken away double the part taken away, the remainder too is double the remainder. Therefore, in a circle, the angle at the centre is double, etc. Which was to be demonstrated.

SCHOLIUM

To demonstrate the first part of this proposition, this principle was assumed: (*If two magnitudes are each the double of two magnitudes, one of each, then their sum*

is also double the sum of the others). And in the demonstration of the third part this other principle was used: (*If the whole is double the whole, and the part taken away double the part taken away, then the remainder too is double the remainder*). Both of these are demonstrated universally by Euclid, for every kind of multiple and for any number of magnitudes, in Book 5, Propositions 1 and 5. Yet the demonstration of this proposition is not on that account to be judged faulty, as though it assumed things not yet demonstrated: for those two principles are so evident by the natural light in the case of double magnitudes that anyone readily grants them without any demonstration; and both of those propositions of Book 5 can be demonstrated before this third book, since they do not depend on it — so that those two principles may with full right be used here as though demonstrated. Nor indeed does Euclid commit a circular argument in this matter, since the two principles by which Proposition 20 of this book is demonstrated do not rest on this same proposition, nor on any other propositions that depend on this twentieth.

But, if you please, we shall demonstrate the first part of this proposition without the former principle, and the third part without the latter (for the second part needs neither of them), in the following way. Let the first figure be repeated. Since [Margin: f — El. I.5] the angles DAB, DBA are equal to one another, and likewise the angles DAC, DCA, the whole angle BAC will be equal to the two angles B, C taken together; and therefore the three angles BAC, B, and C taken together will be double the angle BAC. But since the angle BDC is equal to those same three angles BAC, B, and C — for since [Margin: g — El. I.32] BDE equals the two interior angles B and DAB, and CDE equals the two interior angles C and DAC, the whole BDC will be equal to all four, that is, to the three BAC, B, and C — the angle BDC too will be double the angle BAC, which is the proposition.

ANOTHER WAY. Since [Margin: h — El. I.32] the six angles of the triangles ABD, ACD are equal to four right angles, and the three angles BDC, CDA, ADB are likewise equal to four right angles, by the second corollary of Proposition 15 of Book 1, these three will be equal to those six; and when the common angles ADB, ADC are removed, the remaining angle BDC will be equal to the remaining angles BAC, B, and C [Margin: i — Ax. 3]. Therefore, as before, BDC will be double BAC.

Let the third figure also be repeated, where the line DC cuts the line AB, as at E.

Diagram. A circle with centre D at the top. A is on the right, B at the lower left, C at the bottom; E is a central point where DC cuts AB, and F an interior point on AE. Lines DA, DB, DC, AB, AC and CF are drawn.

- D (centre, upper part)
- A (right): vertex
- F (interior point on AE, where CF cuts AE)
- E (central crossing point of DC and AB)
- B (lower left), C (bottom): ends of the base

Since, when the line AD has been drawn, the two angles DAC, DCA are equal [Margin: k — Ax. 5], and the angle DAC is greater than the angle EAC, the angle DCA too will be greater than the same angle EAC. If, then, the angle ACF is made equal to the angle EAC, CF will cut the line AE, as at the point F; and the angle EFC will be equal to the interior angles FAC, FCA [Margin: l — El. I.32], and therefore double the angle BAC. But since [Margin: m — El. I.5] the angles DAC, DCA are equal, and the angles FAC, FCA taken away are also equal, the remaining angles DAB, ECF will be equal. Then since [Margin: n — El. I.5] DAB is equal to DBA, ECF too will be equal to that same angle DBE; and the angles DEB, FEC at the vertex E are equal [Margin: o — El. I.15]. Therefore the remaining angles BDE, EFC will also be equal, by the first corollary of Proposition 32 of Book 1. And since the angle EFC has been shown to be double the angle BAC, the angle BDC too will be double the angle BAC, which is the proposition.

Diagram, left of the upper pair. A circle with centre D. B is at the top left, A at the top right, C on the right; E is at the bottom (label faint, matching its twin figure at right). Lines DB, DC and the chords AB, AC cross at the centre, illustrating the case where BD, CD do not form the angle on the base side.

- B (top left), A (top right), C (right)
- D (centre)
- E (bottom, second end of the diameter AE) [?]

Diagram, right of the upper pair. A circle with centre D. A is at the top, B on the left, C on the right, E at the bottom; the diameter AE passes through D, and the lines DB, DC and chords are drawn.

- A (top): vertex
- B (left), C (right)
- D (centre)
- E (bottom, second end of the diameter AE)

But if the lines BD, CD do not form the angle at the centre on the side of the base BC — which happens only when the segment BAC is either a semicircle or a smaller segment — nonetheless that space at the centre will be double the angle

at the circumference that has the same base as the space. For when the line AE is drawn through the centre, the angle BDE at the centre will be double the angle BAE at the circumference, and the angle CDE at the centre double the angle CAE at the circumference, as was shown. Therefore the space at the centre D, having the base BEC and made up of the two angles BDE, CDE, is double the whole angle BAC. Which is the proposition.

THEOR. 19 PROPOS. 21.

[Margin: xx.]

Enunciation (Euclid III.21). **In a circle, the angles that are in the same segment are equal to one another.**

Diagram. A circle with centre E. A is at the top left, B at the top right, D at the lower left, C at the lower right. The inscribed angles A and B both stand on the base DC (lines AD, AC, BD, BC), and DE, CE are drawn to the centre.

- A (top left), B (top right): the two inscribed angles in segment DABC
- D (lower left), C (lower right): ends of the common base
- E (centre)

In the circle ABCD, whose centre is E, let there be angles A and B in the segment DABC. I say that they are equal. First, let the segment DABC be greater than a semicircle; and let the straight lines DE, CE be drawn to the centre E. Then since the angle DEC at the centre is double both the angle DAC and the angle DBC at the circumference [Margin: a — El. III.20] — since all have the same base DC — the angles A and B will be halves of the angle E. Therefore they will be equal to one another [Margin: b — Ax. 7]. And by the same reasoning all the other angles in the segment DABC will be shown to be equal.

Next, let the segment DA, BC be either a semicircle or less than a semicircle.

Diagram, left of the middle pair. A circle with centre E. A is at the upper left, B at the upper right, D at the left, C at the right; G is at the lower left and F at the lower right, with the diameters AF, BG through the centre and lines DE, CE joined.

- A (upper left), B (upper right)
- D (left), C (right)
- E (centre)
- G (lower left, second end of diameter BG), F (lower right, second end of diameter AF)

Diagram, right of the middle pair. A companion circle with centre E, showing the same construction. A at the upper left, B at the upper right, D at the left, E the centre, G at the lower left, F at the lower right.

- A (upper left), B (upper right)
- D (left)
- E (centre)
- G (lower left), F (lower right)

Through the centre E let the straight lines AF, BG be drawn, and in the smaller segment let the lines DE, CE be joined. Then since the angle DEF at the centre is double the angle DAF at the circumference [Margin: c — El. III.20], and likewise the angle CEF double the angle CAF, the two angles DEF, CEF together are double the two angles DAF, CAF together — that is, of the whole angle DAC. But the angles DEG, GEF together are equal to the angle DEF; therefore the three angles DEG, GEF, FEC together are also double the angle DAC. By the same reasoning those same three angles are double the angle DBC. Therefore the angles DAC, DBC are equal [Margin: d — Ax. 7].

ANOTHER WAY. As we demonstrated in the scholium to the preceding proposition, the space at the centre E, whose base is DGFC, is double each of the angles DAC, DBC at the circumference; therefore the angles DAC, DBC themselves are equal to one another [Margin: e — Ax. 7].

Diagram, left of the lower-middle pair. A circle with centre E. A at the upper left, B at the upper right, D at the left, C at the right; the chords AC, BD cross at F, and AB is joined; E is the centre below F.

- A (upper left), B (upper right)
- D (left), C (right)
- F (crossing point of AC and BD)
- E (centre)

Diagram, right of the lower-middle pair. A companion circle with centre E showing the same crossing construction. A at the upper left, B at the upper right, D at the left, C at the right, F the interior crossing point, E the centre.

- A (upper left), B (upper right)
- D (left), C (right)
- F (interior crossing point)
- E (centre)

ANOTHER WAY. Let the lines AC, BD cut one another at F, and let the line AB be joined. Then since the three angles of the triangle AFD are equal to the three angles of the triangle BFC — for both sets are equal to two right angles [Margin: f — El. I.32] — if the equal angles AFD, BFC are taken away [Margin: g — El. I.15], the remaining angles ADF, DAF will be equal to the remaining angles BCF, CBF. But the angles ADF, BCF have been shown to be equal, being in the greater segment ADCB. Therefore the remaining angles DAC, DBC are also equal.

Diagram, left of the lowest pair. A circle with centre E. A at the left, B at the top, D toward the left, C at the right, F at the bottom; many chords are drawn (DF, CF, AF, BF and the sides of segment DABCF).

- A (left), B (top)
- D (left of centre), C (right)
- E (centre)
- F (bottom, the arbitrary point on the circumference)

Diagram, right of the lowest pair. A companion circle with centre E showing the same construction. A at the upper left, B at the top, D at the left, C at the right, F at the bottom.

- A (upper left), B (top)
- D (left), C (right)
- E (centre)
- F (bottom)

ANOTHER WAY. From any point F on the circumference, let the lines DF, CF be drawn enclosing the centre E, in such a way that both DABCF and FDABC are the greater segment; and let the lines AF, BF also be joined. Then since the angles DAF, DBF, being in the same greater segment DABCF, are equal, and likewise the angles FAC, FBC, being in the greater segment FDABC — if these are added to those, the whole angle DAC becomes equal to the whole angle DBC. And so, in a circle, the angles that are in the same segment, etc. Which was to be shown.

SCHOLIUM

We shall also easily convert this theorem, in this way: **If from two points four straight lines are drawn, two from each, which toward the same side contain two equal angles, then the circle described through those two points and through one of those angles will also pass through the other angle.**

Diagram. A small circle. B and C are at the base (B toward the right, C at the lower left), A and D above (A at the upper left, D at the upper right); E is the point on AB where the circle would cut it in the false case. Lines BA, CA, BD, CD and CE are drawn.

- A (upper left), D (upper right): the two equal angles
- B (base, right), C (base, lower left): the two points from which the lines issue
- E (on AB, where the displaced circle cuts it)

For from the two points B, C let four straight lines BA, CA, BD, CD be drawn, two from each, forming toward the same side two equal angles A, D. I say that the circle described through the points B, C and the angle D also passes through the angle A. For if it does not pass through A, it will pass either beyond A or short of it, cutting the line AB at E. Then when the line CE is drawn, the angles E and D will be equal [Margin: h — El. III.21]. But since the angle A is also supposed equal to the angle D, the angles CAB, CEB will be equal — an exterior and an interior angle — which is absurd; for the exterior angle is greater than the interior [Margin: i — El. I.16]. Therefore the circle passes through A, which is the proposition.

Clavius, *Opera Mathematica*, Tomus I — Commentary on Euclid, Book III

THEOR. 20. PROPOS. 22.

(Euclid's enunciation.)

The opposite angles of quadrilaterals inscribed in circles are equal to two right angles.

(Demonstration.) Let a quadrilateral ABCD be inscribed in a circle whose center is E. I say that the two opposite angles ABC and CDA — and likewise BCD and DAB — are equal to two right angles. Draw the two diagonals of the quadrilateral, AC and BD. [Margin: a — 21. tertij (*Elements* III.21; "tertij" = Book III)] Then the two angles ABD and ACD, being in the same segment ABCD, are equal. Similarly the two angles CBD and CAD, being in the same segment CBAD, are equal. Therefore the two angles ABD and CBD — that is, the whole angle ABC — are equal to the two angles ACD and CAD. Adding the common angle CDA, the two angles ABC and CDA are equal to the three angles ACD, CAD, and CDA. [Margin: b — 32. prim

(*Elements* I.32; "prim" = Book I)] But these three are equal to two right angles. Therefore the two angles ABC and CDA are also equal to two right angles.

In the same way we shall show that the angles BCD and DAB are equal to two right angles. For again the two angles ABD and ACD are equal; likewise the two BCA and BDA; and therefore the whole angle BCD is equal to the two angles ABD and BDA. Adding, then, the common angle BAD, the two angles BCD and BAD are equal to the three angles ABD, BDA, and DAB. [Margin: c — 32. prim (*Elements* I.32)] But these three are equal to two right angles. Therefore the two angles BCD and DAB will also be equal to two right angles. Therefore the opposite angles of quadrilaterals inscribed in circles, etc. Which was to be demonstrated.

Diagram. Two circles side by side, each carrying a cyclic quadrilateral for Proposition 22.

- Left circle — center E (marked by a dot at the middle); inscribed quadrilateral with vertices A (far left), B (upper left), C (upper right), D (right); both diagonals drawn.
- Right circle — center E (dot at middle); inscribed quadrilateral with vertices A (lower left), B (upper left), C (right), D (lower right); both diagonals AC and BD drawn.

SCHOLIVM.

The converse of this theorem can also be demonstrated, in this way.

If in a quadrilateral the opposite angles are equal to two right angles, then a circle described through any three of its angles will also pass through the remaining fourth angle; and so a circle can be described about the quadrilateral itself.

For in the quadrilateral ABCD let the opposite angles B and D be equal to two right angles, and let a circle be described through the angles A, B, C. (How this can be done will be shown at Proposition 25 of this book and at Proposition 5 of Book IV.) I say that it passes through D as well. For if not, it will pass either beyond D or short of D. So draw the straight lines CE and AE to the circumference, in such a way that they do not cut the lines CD and AD. This done, [Margin: d — 32. prim (*Elements* I.32)] the angles B and E will be equal to two right angles. But the angles B and D were also equal to two right angles. Therefore the two angles B and E are equal to the two angles B and D; and, removing the common angle B, the remaining angles D and E are equal — which is absurd. For, when the straight line AC has been drawn, [Margin: e — 21. primi (*Elements* I.21)] angle D will be

greater than angle E, or conversely angle E greater than angle D. Therefore the circle passes through the point D. Which is what was proposed.

It is enough, moreover, to take only two opposite angles equal to two right angles for this theorem to hold; because if two opposite angles are equal to two right angles, the remaining two opposite ones will necessarily also be equal to two right angles, since all four together are equal to four right angles, as we demonstrated at Proposition 32 of Book I.

From this proposition we shall also easily demonstrate the following theorem, which mathematicians frequently use as a principle, namely:

(Additional theorem.)

If similar segments are removed from semicircles or from circles, the remaining segments will also be similar.

First, let there be in the circles ABCDEF and GHIKLM the similar arcs CDE and IKL. I say that the remaining arcs EFABC and LMGHI are also similar. For, taking points D, B, K, H anywhere on the said arcs, join the straight lines DC, DE, BC, BE, KI, KL, HI, HL. Now since the arcs CDE and IKL are similar, the angles CDE and IKL will be equal, by the definition of similar segments. Since, then, the two angles CDE and CBE are equal to the two angles IKL and IHL, [Margin: f — 22. tertij (*Elements* III.22)] because both these and those are equal to two right angles, [Margin: g — 3. pron (Common Notion 3; "pron." = pronuntiatum, a common notion)] the remaining angles CBE and IHL will also be equal; and therefore, by definition 10 of this book, the arcs EBC and LHI will be similar.

Next, in the semicircles AEC and GLI let the arcs EC and LI be similar. I say that the remaining arcs AE and GL are also similar. For, taking points D, F, K, M anywhere on those arcs, join the straight lines CD, DE, CE, EF, FA, AE; IK, KL, IL, LM, MG, GL. Then, since the arcs EC and LI are similar, the angles CDE and IKL are equal, by the definition of the angle. Since, then, the two angles CDE and EAC are equal to the two angles IKL and LGI, [Margin: h — 22. tertij (*Elements* III.22)] because both these and those are equal to two right angles, the remaining angles EAC and LGI will also be equal. But the angles AEC and GLI — being in semicircles, that is, in the similar segments AEC and GLI — are also equal, by the definition of similar segments. Therefore in the triangles AEC and GLI the remaining angles ACE and GIL will also be equal, by the corollary of Proposition 32 of Book I. Since, then, the two angles ACE and EFA are equal to the two angles GIL and LMG, [Margin: i — 22. tertij (*Elements* III.22)] because both these and those are equal to two right angles, the remaining angles EFA and LMG will also

be equal; and accordingly, by the definition of similar segments, the remaining arcs AE and GL in the semicircles will be similar. Which was to be shown.

Diagram. A circle carrying the construction for the converse scholium: a circle drawn through three vertices of a quadrilateral, with the disputed fourth vertex.

- D (top): vertex drawn just outside the circle through A, B, C.
- E (upper arc, below D): the point constructed on the circumference where CE and AE meet it.
- A (right): vertex on the circle.
- C (lower left) and B (lower right): the other two vertices.
- A further D-like mark near the center [?] (possibly the true position of the vertex).

Diagram. Two circles for the theorem on removing similar segments, each with an inscribed polygonal construction (and the diameter marking off a semicircle).

- Left circle: A (top), B (right), C (bottom), D (lower left), E (left), F (upper left); diameter AC.
- Right circle: G (top), H (right), I (bottom — serified capital, reads I though close to a T [?]), K (lower left), L (left), M (upper left); diameter GI.

Since the discussion here has fallen upon similar segments, three theorems should not be omitted at this point — theorems highly necessary both for geometry and especially for astronomy. Let the first of them be this, which we undertook to demonstrate at definition 10 of this book, namely:

(Additional theorem — first of three.)

Angles standing on similar arcs of circles — whether at the centers or at the circumferences — are equal to one another. And conversely, arcs on which equal angles stand, whether at the centers or at the circumferences, are similar.

(Demonstration of the theorem just enunciated.) In the circles ABCD and EFGH, whose centers are I and K, let the arcs BCD and FGH first be similar, on which stand the angles I and K at the centers, and the angles A and E at the circumferences. I say that both the former and the latter are equal to one another. For let angles be constructed at C and G on those arcs, which by the definition of similar segments will be equal. [Margin: k — 22. tertij (*Elements* III.22)] Now the two angles C and A, and likewise the two G and E, are equal to two right angles. So, removing the equal angles C and G, the remaining angles A

and E will also be equal. And since the angles I and K [Margin: l — 20. tertij (*Elements* III.20)] are the doubles of these, [Margin: m — 6. pron (Common Notion 6)] they too will be equal. Which is what was proposed.

Next, let both the angles I and K, and the angles A and E, standing on the arcs BCD and FGH, be equal to one another. I say that the arcs BCD and FGH are similar. For if the two angles A and C, and the two E and G, are equal to two right angles, [Margin: n — 22. tertij (*Elements* III.22)] the remaining angles C and G will also be equal; and therefore, by the definition of similar segments, the arcs BCD and FGH — on which the equal angles A and E stand at the circumferences — are similar. But if the angles I and K at the centers are equal, [Margin: o — 7. pron (Common Notion 7)] their halves will also be equal, that is, the angles A and E. Hence, as before, the arcs BCD and FGH are similar. Which was to be shown.

Diagram. Two circles, each with an inscribed angle at the circumference and the corresponding central angle standing on the same arc.

- Left circle — center I (dot at middle); A (top), B (lower left), C (bottom), D (right); lines from A and from I to the arc BCD.
- Right circle — center K (dot at middle); E (top), F (lower left), G (bottom), H (right); lines from E and from K to the arc FGH.

The second theorem, which we also demonstrated in our work on the sphere at the end of the first chapter, let it be of this kind:

(Additional theorem — second of three.)

If two or more circles are described from the same center, and from the center two or more straight lines are drawn, then the arcs intercepted between any two of the lines will be similar.

Let two circles ABC and DEF be described from the same center G, and from the center G let two straight lines GB and GC be drawn. I say that the arcs EF and BC are similar. For, producing BG to A, join the straight lines AC and DF; likewise, taking points H and I anywhere, draw the straight lines BH, CH, EI, FI. Now since the angle G, standing at the center on the arcs EF and BC, [Margin: p — 20. tertij (*Elements* III.20)] is the double both of the angle EDF and of the angle BAC, [Margin: q — 7. pron (Common Notion 7)] the angles EDF and EIF will be equal to the two angles BAC and BHC, because [Margin: r — 22. tertij (*Elements* III.22)] both these and those are equal to two right angles. So, removing the equal angles EDF and BAC, [Margin: s — 3. pron (Common Notion 3)] the remaining angles EIF

and BHC will be equal; and accordingly the segments EF and BC, in which they lie, will be similar, by the definition of similar segments. Which was to be shown.

More briefly, thus. [Margin: t — 7. pron (Common Notion 7)] Since the angles A and D are equal — because the angle G at the center [Margin: u — 20. tertij (*Elements* III.20)] is the double of each — then by the preceding theorem the arcs BC and EF, on which they stand at the circumferences, are similar. Which is what was proposed.

Or still more briefly. Since equal angles at the center stand on the arcs EF and BC — indeed one and the same angle BGC — then by the preceding theorem the arcs EF and BC are similar. And in this demonstration no construction at all is needed, as is evident.

Diagram. Two concentric circles about a common center G.

- G (center).
- Outer circle: A (upper right), B (lower left), C (right).
- Inner circle: D (below A), E (inner left), F (inner right).
- I (bottom) and H (bottom, toward the right): points where the chords BH, CH, EI, FI meet the circumferences.

Finally, let the third — which we have also shown by another method in our *Astrolabe* — be this:

(Additional theorem — third of three.)

If two or more circles touch one another internally at a single point, from which two or more straight lines are drawn, then both the arcs intercepted between any two of the lines, and the arcs intercepted between any one line and the point of contact, will be similar.

Let two circles ABC and ADE touch one another internally at the point A, from which two straight lines AB and AC are drawn. I say that the arcs DE and BC, as well as AD and AB, and AED and ACB, are similar. For, taking two points F and G anywhere, join the straight lines BF, CF, DG, EG. Now since the two angles DAE and DGE are equal to the two angles BAC and BFC — because [Margin: x — 22. tertij (*Elements* III.22)] both these and those are equal to two right angles — then, removing the common angle BAC, [Margin: y — 3. pron (Common Notion 3)] the remaining angles DGE and BFC will be equal; and accordingly the arcs DE and BC will be similar, by the definition of similar segments.

More briefly, thus. Since the angle at A, common to both the arcs DE and BC, stands at the circumferences, then by what was demonstrated in the immediately preceding theorem the arcs DE and BC, on which it stands, are similar. Which is what was proposed.

And since, if a straight line AC is imagined drawn through the centers of the circles, [Margin: z — 11. tertij (*Elements* III.11)] this falls on the point of contact A, and in the same way the arcs DE and BC are similar, it follows that — these similar arcs being removed from similar semicircles — the remaining arcs AD and AB are also similar; and, these being removed from the whole similar circumferences, the remaining arcs AED and ACB are likewise similar, as we demonstrated a little earlier. Which is what was proposed.

Diagram. A larger circle and a smaller circle touching it internally at the top point A, with two lines from A.

- A (top): point of contact.
- B (left) and C (bottom): points on the larger circle, joined to A.
- D (upper, on the smaller circle) and E (center, on the smaller circle): where the lines meet the smaller circle.
- F (lower left) and G (interior): the points taken on the arcs, with chords BF, CF, DG, EG.

The following theorem can also be referred to this place.

If one side of a quadrilateral inscribed in a circle is produced, the exterior angle will be equal to the angle that stands opposite to the interior angle adjacent to it.

In the circle ABCD let any quadrilateral ABCD be inscribed, whose side AD is produced to E. I say that the angle EDC is equal to the angle B. For since the two angles at D [Margin: a — 13. prim (*Elements* I.13)] are equal to two right angles, and likewise [Margin: b — 22. tertij (*Elements* III.22)] the two angles B and D in the quadrilateral, the former two are equal to these latter two. Therefore, removing the common angle ADC, the remaining exterior angle EDC will be equal to the remaining angle B. Which is what was proposed.

Diagram. A circle with an inscribed quadrilateral, one side produced.

- A (upper left), B (lower left), C (lower right), D (top): the four vertices, inscribed in the circle.
- E (upper right, outside the circle): the point to which side AD is produced.

THEOR. 21. PROPOS. 23.

(Euclid's enunciation.)

Upon the same straight line, two similar and unequal segments of circles cannot be constructed on the same side.

(Demonstration.) For if it were possible, let two similar and unequal segments ACB and ADB be constructed on the same side of the straight line AB. Now it is clear that they intersect one another only at the points A and B, [Margin: a — 10. tertij (*Elements* III.10)] since a circle does not cut a circle in more than two points. Hence the whole circumference of one segment will lie outside the circumference of the other. So draw the straight line AD, cutting the circumferences at C and D, and join the straight lines CB and DB. Since the segments are supposed to be similar, then by definition 10 of this book the angle ACB will be equal to the angle ADB — the exterior to the interior — [Margin: b — 16. primi (*Elements* I.16)] which is absurd. Therefore the segments are not similar. And so, upon the same straight line, etc. Which was to be demonstrated.

Diagram. Two arcs raised on the same base AB, on the same side, one enclosing the other.

- A (lower left) and B (lower right): the endpoints of the base.
- C (on the inner arc) and D (top, on the outer arc): the points where the straight line AD cuts the two circumferences; chords CB and DB drawn.

SCHOLIVM.

By the same reasoning, neither will two similar and unequal segments of circles be constructed on opposite sides of the same straight line. For if one of them is imagined to be rotated about the line AB, so that both now lie on the same side, we shall fall into the same absurdity — as the figure shows — since the one will not coincide with the other, because of their inequality.

Diagram. A lens-shaped figure showing two unequal arcs on the base AB, brought to the same side.

- A (left) and B (right): endpoints of the base.
- C (upper) and D (top): points on the two arcs. A D-like label also appears at the foot of the figure [?].

THEOR. 22. PROPOS. 24.

(Euclid's enunciation.)

Upon equal straight lines, similar segments of circles are equal to one another.

(Demonstration.) Upon the equal straight lines AB and CD let similar segments AEB and CFD be constructed. I say that they are equal to one another. For since the lines AB and CD are equal, they will coincide with each other if one is placed upon the other. I say, then, that the segment AEB also coincides with the segment CFD. For if it does not coincide, it will fall either outside, or inside, or partly outside and partly inside. If it falls outside or inside, then upon the same straight line CD two similar and unequal segments AEB and AFB will be constructed, one of which falls wholly outside the other — which is absurd, [Margin: a — 23. tertij (*Elements* III.23)] for the contrary has been demonstrated. But if it falls partly outside and partly inside, they will cut each other in more than two points, namely at A, B, and G — which is absurd, [Margin: b — 10. tertij (*Elements* III.10)] since circles do not cut one another in more than two points. Therefore the segment AEB will coincide with the segment CFD, and so they will be equal to one another. And so, upon equal straight lines, etc. Which was to be demonstrated.

Diagram. Two similar segments raised on equal bases, together with several small nested figures illustrating the impossible cases.

- Main left segment: A (bottom left), E (top), B (bottom right).
- Main right segment: C (bottom left), F (top), D (bottom right).
- To the right, a row of small superposed figures (segments falling outside/inside one another and cutting at a third point), carrying the labels E, F, G over the base points A, B and A, C, D, B [some small labels indistinct].

SCHOLIVM.

Not only is it shown in this proposition that the similar segments AEB and CFD are equal upon the equal bases AB and CD, but also that their circumferences are equal, because, as has been demonstrated, they coincide with one another.

The converse of this proposition and of the preceding one will also easily be demonstrated: namely, that segments of circles which are equal — whether constructed upon equal lines or upon the same line — are similar. For on account of their equality, the one will coincide with the other; and so they will be similar, since by this reasoning all the angles constructed in them are equal. And if

anyone should say that the segments do not coincide with one another, then necessarily one circumference will cut the other; for that one does not fall outside the other is contrary to the hypothesis. So let the segments AFB and AGB be equal upon the same straight line AB, and let them cut each other at G. Then the circles AFB and AGB cut each other at the points A, G, B — more than two — which is absurd, [Margin: c — 10. tertij (*Elements* III.10)] since circles do not intersect one another in more than two points. The matter will be demonstrated in the same way if equal segments are constructed upon equal straight lines: namely, if the one is placed upon the other, etc.

PROBL. 3. PROPOS. 25.

(*Euclid's enunciation.*)

Given a segment of a circle, to describe the circle of which it is a segment.

(*Demonstration.*) Let ABC be the segment of a circle that must be completed. Subtend the straight line AC, bisect it at the point D, through D draw the perpendicular DB, and join AB. Then the angle DBA is either greater than the angle DAB, or equal to it, or less.

Let it first be greater — which will happen when the segment ABC is less than a semicircle. For then, since BD passes through the center (by the corollary of Proposition 1 of this book) — the part of it that lies outside the segment, since the segment is supposed to be less than a semicircle — DA will be greater than DB, because DB, which completes the diameter, [Margin: a — 7. tertij (*Elements* III.7)] is the least of all the lines that fall from the point D to the circumference.

Therefore the angle DBA [Margin: b — 18. prim (*Elements* I.18)] will be greater than the angle DAB. Then make the angle BAE equal to the angle DBA, and let the straight line AE cut the straight line BD, produced, at E. I say that E is the center of the circle of which ABC is a segment. For, when the straight line EC has been drawn, the sides AD and DE of the triangle ADE will be equal to the sides CD and DE of the triangle CDE, and the contained angles are right. [Margin: c — 4. prim (*Elements* I.4)] Therefore the bases EA and EC will be equal; [Margin: d — 6. primi (*Elements* I.6)] and EA is also equal to EB, since the angles EAB and EBA are equal. Therefore the three lines EA, EB, EC will be equal, [Margin: e — 9. tertij (*Elements* III.9)] and consequently E will be the center of the circle ABC, since from E more than two equal straight lines fall onto the circumference.

Next, let the angle DBA be equal to the angle DAB (which will finally happen when the segment ABC is a semicircle; for then AC will be the diameter, and D the

center, and so the lines DA and DB are equal, whence [Margin: f — 5. primi (*Elements* I.5)] the angles DAB and DBA are also equal). [Margin: g — 6. primi (*Elements* I.6)] Therefore the lines DA and DB will be equal; and DC was also equal to DA, since the line AC was bisected. Therefore, since the three lines DA, DB, DC fall from D onto the circumference, [Margin: h — 9. tertij (*Elements* III.9)] D will be the center.

(The third case — where the angle DBA is less than DAB, that is, where the segment is greater than a semicircle — continues on the following page.)

Diagram. The construction for the first case of Problem 25 (segment less than a semicircle).

- A (left), B (top), C (right): the three given points of the segment.
- D (on the chord AC, at its midpoint): foot of the perpendicular BD.
- E (below D, on BD produced): the constructed center; lines AE, EC, AB drawn.

Diagram. The construction for the second case (segment a semicircle).

- A (left), B (top), C (right): the three given points, forming a semicircle on the diameter AC.
- D (center, on AC): the center, with the perpendicular BD and the chord AB drawn. Faint additional construction lines appear within the figure [?].

[Euclid, *Elements* Book III — continuation of PROPOS. 25 / THEOR. 23: to complete a circle upon a given segment]

[Clavius's demonstration, continued — third case]

Let it be, thirdly, that the angle DBA is less than the angle DAB. (This indeed happens when the segment ABC turns out to be greater than a semicircle. For then, since BD passes through the center — by the corollary of Prop. 1 of this book [Margin: i — Elem. III.7] — and since BD lies within the segment, the segment being assumed the greater, DB will be the greatest of all the lines that fall from D to the circumference; it will therefore be greater than DA, and consequently the angle DAB greater than the angle DBA. [Margin: k — Elem. I.18]) Let the angle BAE be made equal to the angle DBA, and let the line AE cut the line BD at the point E, which will be shown to be the center in the same way we showed it when the angle DBA was greater than the angle DAB, as is evident if the line EC is drawn. Therefore upon the given segment of a circle we have described the circle of which it is the segment. Which was to be done.

Diagram. A circular segment (more than a semicircle) with its completed circle. The base AC is horizontal at the bottom; B is the apex above; the constructed center E lies inside, on the line BD.

- A (bottom left): left end of the base chord AC.
- B (top): apex of the segment; lines run from B to A, to C, and down through E to D.
- C (bottom right): right end of the base.
- D (bottom, on AC): foot of the perpendicular from B (midpoint of AC).
- E (center): the located center of the circle, where AE meets BD.

SCHOLIUM [Clavius]

But perhaps this demonstration of Euclid — which proceeds through all three kinds of segment of a circle — may be set up more easily as follows. Bisect the line AC at D, raise the perpendicular DB, and draw AB; then DB is either less than DA, or equal to it, or greater.

If it is less, the angle DBA will be greater than the angle BAD. [Margin: l — Elem. I.18] Therefore, having constructed the angle BAE equal to the angle ABD, we shall show, as before, that E is the center. And this happens when the segment is less than a semicircle.

But if DB is equal to DA, then all three lines DA, DB, DC will be equal, [Margin: m — Elem. III.9] and therefore D is the center. This case applies in the semicircle.

If, finally, DB is greater than DA, the angle DBA will be less than the angle DAB. [Margin: n — Elem. I.18] Therefore, having constructed the angle BAE equal to the angle ABE, E will be shown to be the center, as before. And this occurs with the greater segment.

Another way. The same problem will be solved in this manner. With the same things laid down as before, let the angle EAB be made equal to the angle DBA. And if the line AE falls below AC, the segment will be less than a semicircle, as in the first figure. But if AE falls above AC, the segment will be greater than a semicircle, as in the third figure; and in every case E will be the center, as has been demonstrated. And if, finally, the line making at A with AB an angle equal to the angle ABD coincides with AC, the segment will be a semicircle and the point D will be the center, as in the second figure.

A shorter way, however, will find the center of any given segment — whether it be less than a semicircle, or equal, or greater — by this method. Take on the arc

of the segment any three points whatever, A, B, and C; join them by the two straight lines AB and BC; and let these be bisected at D and at E. Then from D and E raise the perpendiculars DF, EF to AB and BC. Now since, by the corollary of Prop. 1 of this book, both DF and EF pass through the center of the circle of which ABC is the segment, the two will meet at the center, as at F. Therefore the center has been found. Which is what was proposed.

Diagram. A circle in which two chords AB and BC are drawn from B, with their perpendicular bisectors DF and EF meeting at the center F.

- A (lower left): one end of chord AB, on the circle.
- B (top): common endpoint of the two chords.
- C (right): end of chord BC, on the circle.
- D (left): midpoint of AB; foot of perpendicular DF.
- E (upper right): midpoint of BC; foot of perpendicular EF.
- F (center): intersection of the two perpendicular bisectors — the center of the circle.

Another way, as the practitioners [mechanics] do. Take on the circumference any two points, A and B; about them describe two arcs with any equal radius, which intersect one another at E and at F. Then from two other points, C and D, describe two more arcs cutting one another at G and H, with any radius — whether the same as before or different. If then the straight lines EF and GH are drawn, both will pass through the center. Therefore the point I, where they meet, will be the center.

That the lines EF, GH pass through the center is demonstrated thus. Draw the lines AE, AF, BE, BF, which will be equal to one another because of the equality of the circles [radii]. Since, then, the sides AE, EF of the triangle AEF are equal to the sides BE, EF of the triangle BEF, and the bases AF, BF are likewise equal, the angles AEF, BEF will be equal. [Margin: o — Elem. I.8] Again, draw the straight line AB cutting EF at K. Since the sides AE, EK of the triangle AEK are equal to the sides BE, EK of the triangle BEK, and the angles AEK, BEK have also been shown equal, the bases AK, BK and the angles AKE, BKE will be equal, [Margin: p — Elem. I.4] and therefore right angles. Thus, since EF divides the line AB within the circle into two equal parts and at right angles, it will pass through the center, by the corollary of Prop. 1 of this book. In the same way it will be shown that GH passes through the center. But the four points A, B, C, D must be so placed that the lines EF, GH do not meet in a straight line, but cut one another. For should it happen that EF, GH are set in a straight line, the line comprised within the

circumference must itself be bisected; for the point of division will then be the center of the circle, since that line is then a diameter of the circle, passing through the center, by the corollary of Prop. 1 of this book.

Diagram. The practitioners' construction: two pairs of intersecting arcs about the chords, with the lines EF and GH meeting at the center I.

- A (left): first base point.
- B (upper right): second base point (paired with A).
- C (upper right, further): third base point.
- D (lower right): fourth base point (paired with C).
- E (top left): intersection of the arcs about A and B (above).
- F (center left): the other intersection of the arcs about A and B (below).
- G (right): intersection of the arcs about C and D.
- H (middle right): the other intersection of the arcs about C and D.
- I (lower center): meeting point of EF and GH — the center.

THEOR. 23. — PROPOS. 26. [Euclid, *Elements* III.26] [Margin: xxv.]

[Enunciation] In equal circles, equal angles stand on equal arcs, whether they are constructed at the centers or at the circumferences.

[Clavius's demonstration] In equal circles ABC, DEF, whose centers are G, H, let there be constructed, first, at the centers, the equal angles AGC, DHF. I say that the arcs AC, DF on which they stand — that is, over which they were raised — are equal. For take on the arcs ABC, DEF two points B, E, to which draw the lines AB, CB, DE, FE, and join the lines AC, DF. Now since the angles G and H are equal, [Margin: a — Elem. III.20] they will themselves also be equal to one another. Therefore the segments ABC, DEF will be similar. And since the sides AG, GC of triangle

AGC are equal to the sides DH, HF of triangle DHF because of the equality of the circles, and the angles they contain, G and H, are equal by hypothesis, [Margin: b — Elem. I.4] the bases AC, DF will be equal. Since, then, the similar segments ABC, DEF stand upon the equal lines AC, DF, they will themselves be equal to one another. [Margin: c — Elem. III.24] Therefore the arcs AC, DF will also be equal. [Margin: continues — see below]

[Second part] Now let there be constructed, at the circumferences, two equal angles B and E; I say again that the arcs AC, DF over which they were raised are

equal. For, as before, the segments ABC, DEF will be similar. Since, then, they stand upon equal lines AC, DF — for since the angles G, H are equal, being double of the equal angles B and E, [Margin: d — Elem. III.20] the lines AC, DF will, as before, be equal — the segments will be equal to one another. [Margin: e — Elem. III.24] If then they are taken away from equal circles, the remaining arcs AC, DF will also be equal. And so, in equal circles, equal angles [stand on equal arcs], etc. Which was to be demonstrated.

SCHOLIUM [Clavius]

This second part will be demonstrated more briefly thus. Since the angles G, H are double of the equal angles B, E, they will be equal to one another. Therefore, as was shown before, the arcs AC, DF over which they were raised will be equal.

But now, if it should happen that the lines AG, CG; DH, FH do not form the angles at the centers upon the bases AC, DF, but upon the bases ABC, DEF — as the figures set below show — then the second part of this proposition must be demonstrated thus. Since the spaces [sectors] at the centers G, H, standing on the arcs AC, DF, are equal to one another — being, by the scholium of Prop. 20 of this book, double of the angles B, E at the circumferences — the angles AGC, DHF, which together with the space about G, and likewise the space about H, make up four right angles, will also be equal to one another, by the corollary 2 of Prop. 15 of Book 1. Therefore, as we shall show as before, the bases AC, DF of the triangles AGC, DHF are equal, and hence the similar segments ABC, DEF, on account of the equality of the angles B, E, standing upon the equal bases AC, DF, are equal, and so on.

Diagram. Two equal circles, centers G and H, with the angles taken at the circumference (apex B and E) rather than at the base chords.

- Left circle (center G): A (left) and C (right) on the circle, B (top) the apex; chords AB, CB and radii AG, GC drawn.
- A (lower left), B (top), C (lower right), G (center) — left circle.
- Right circle (center H): D (lower left) and F (lower right) on the circle, E (top) the apex; chords DE, FE and radii DH, HF drawn.
- D (lower left), E (top), F (lower right), H (center) — right circle.

Hence it also follows that equal spaces [sectors] at the centers stand on equal arcs. For if the spaces at the centers G, H, standing on the greater arcs AC, DF, are equal, the angles AGC, DHF will also, as we showed, be equal. Therefore, as was

demonstrated in the first part of the proposition, the arcs AC, DF — both the greater and the lesser, ABC, DEF — will be equal to one another.

But if the said angles are unequal, the greater will stand on the greater arc, and the lesser on the lesser. For in equal circles ABC, DEF, let the angle AGC at the center be greater than the angle DHF at the center, and likewise the angle ABC at the circumference greater than the angle DEF at the circumference. I say that the arc AC is greater than the arc DF. For if the angle CGI be made equal to the angle DHF, and the angle CBI equal to the angle DEF, then, as was shown, the arcs CI, DF will be equal. And on that account AC is greater than DF.

Diagram. Two equal circles for the case of unequal angles; the auxiliary point I is added in the left circle.

- Left circle (center G): A (lower left), B (top), C (lower right), G (center), I (bottom) — with the angle CGI cut off.
- Right circle (center H): D (lower left), E (top), F (lower right), H (center).

Moreover, this proposition and the three that immediately follow are to be understood also in one and the same circle. That is: in the same circle equal angles stand on equal arcs, and so on — as is plainly clear from the demonstration of this proposition and of the three following. For the same demonstration that is fitted to two or more circles holds also in one and the same circle.

THEOR. 24. — PROPOS. 27. [Euclid, *Elements* III.27] [Margin: xxvj.]

[Enunciation] In equal circles, the angles that stand on equal arcs are equal to one another, whether they are constructed at the centers or at the circumferences.

[Clavius's demonstration] In equal circles ABC, DEF, whose centers are G, H, let there stand, first, the angles at the centers, AGC and DHF, on the equal arcs AC, DF. I say that the angles AGC and DHF are equal. For if they are not equal, let the angle G be the greater, and let the angle AGI be made equal to the angle DHF. [Margin: a — Elem. III.26] The arcs AI, DF will then be equal. But since the arc AC is assumed equal to the arc DF, the arcs AI, AC will be equal to one another, the part to the whole; which is absurd. Therefore the angles AGC, DHF are equal.

Diagram. Two equal circles for Prop. 27; the auxiliary point I is added in the left circle, where the angle AGI is constructed.

- Left circle (center G): A (lower left), B (top), C (lower right), G (center), I (bottom).
- Right circle (center H): D (lower left), E (top), F (lower right), H (center).

Next let the angles B and E at the circumferences stand on the same equal arcs AC, DF; and these too I say are equal. For if one, say ABC, is the greater, let the angle ABI be made equal to the angle E. [Margin: b — Elem. III.26] Then the arcs AI, DF will be equal. Therefore, as before, the arcs AI, AC will be equal, the part to the whole; which is absurd. Therefore the angles ABC, DEF are equal. In equal circles, then, the angles that stand on equal arcs, and so on. Which was to be demonstrated.

SCHOLIUM [Clavius]

This second part will also be demonstrated thus, when the lines AG, CG; DH, FH form the angles at the centers upon the bases AC, DF. Since the angles ABC and E are halves of the angles AGC and H, [Margin: c — Elem. I.20 (recte III.20)] which we have already shown to be equal, they too will be equal to one another.

In the same way, the spaces [sectors] at the centers G, H, standing on the equal arcs ABC, DEF, will be equal. For when the equal arcs ABC, DEF are taken away from the equal circles, the remaining arcs AIC, DF are made equal; and hence, as we showed, the angles AGC, DHF will be equal. When these are taken away from the spaces about the centers GH — which are equal, since each is equal to four right angles, by corollary 2 of Prop. 15 of Book 1 — the remaining spaces at the centers G, H, standing on the arcs ABC, DEF, will also be equal.

But if the arcs are unequal, the greater angle will stand on the greater, whether at the center or at the circumference, than on the lesser. For in the figure of the preceding scholium, let the arc AC be greater than the arc DF. I say that the angle AGC is greater than the angle DHF, and the angle ABC greater than the angle DEF. For if the arc CI be made equal to the arc DF, and the lines IG, IB be drawn, then, as was shown, both the angles at the center, CGI, DHF, and the angles at the circumference, CBI, DEF, will be equal. Therefore both the angle AGC will be greater than the angle DHF, and the angle ABC greater than the angle DEF.

This is also to be understood of the spaces at the centers G, H, standing on the arcs ABC, DEF. For in the same way it will be demon-

strated that the space at H, standing on the arc DEF, is greater than the space at G, which stands on the arc ABC, if the arc DEF is assumed greater than the arc ABC.

[Corollary — parallel chords] Furthermore, from this proposition we shall infer that two straight lines which in the same circle cut off equal arcs, and do not cut one another, are parallel; and that if they are parallel, equal arcs are cut off by them. For in the circle ABCD let the lines AD, BC cut off the equal arcs AB, DC. I say that AD, BC are parallel. For when the line AC is drawn, since the arcs AB, DC are assumed equal, the angles ACB, CAD standing on them will be equal; [Margin: d — Elem. III.27] and since these are alternate angles, AD, BC will be parallel. [Margin: e — Elem. I.27]

Now let AD, BC be parallel. I say that the intercepted arcs AB, DC are equal. For since AD, BC are parallel, when the line AC is drawn the alternate angles ACB, CAD will be equal; [Margin: f — Elem. I.29] and hence the arcs AB, DC on which they stand will be equal. [Margin: g — Elem. III.26]

Diagram. A circle ABCD with the two parallel chords AD (upper) and BC (lower), and the diagonal AC drawn.

- A (upper left) and D (upper right): endpoints of the upper chord AD.
- B (lower left) and C (lower right): endpoints of the lower chord BC.
- The diagonal AC joins A to C.

It has also seemed not useless to add here the following theorem, bearing on what follows; namely:

[Clavius's added theorem — tangent parallel to chord] A straight line drawn tangent to a circle from the midpoint of some arc is parallel to the straight line that subtends that arc.

[Demonstration] In the circle ABC, whose center is D, from A, the midpoint of the arc BAC, let the line EF be drawn tangent to the circle. I say that EF is parallel to the line BC, which subtends the arc BAC. For draw from the center D to the point of contact A the line DA, cutting the line BC at G, and join the lines DB, DC. Then the angles standing on the equal arcs AB, AC will be equal; [Margin: h — Elem. III.27] and the sides BD, DG of triangle BDG are equal to the sides CD, DG of triangle CDG, each to each. Therefore the angles at G, upon the bases GB, GC, are equal, [Margin: i — Elem. I.4] and hence right angles. Consequently the adjacent angles AGB, AGC are also right. But the angles GAE, GAF are likewise right, [Margin: k — Elem. I.18 (recte III.18)] because DA is perpendicular to EF. Therefore EF, BC are parallel. [Margin: l — Elem. I.28] Which is what was proposed.

From what has been demonstrated in this proposition and the preceding one, there is also inferred this theorem, which we demonstrated at the very beginning of the [treatment of] rectilinear triangles.

Diagram. A circle ABC with center D; the tangent EF is drawn at the arc-midpoint A, and the radius DA cuts the chord BC at G.

- E (top left) — A (top center, point of contact) — F (top right): the tangent line EF touching the circle at A.
- B (left) and C (right): endpoints of the subtended chord BC.
- G (center, on BC): where DA meets BC.
- D (below G, center): center of the circle; radii DB, DC drawn.

[Clavius's added theorem — right angle and quadrant] A right angle at the center stands on a quadrant; an acute angle on an arc less than a quadrant; and an obtuse angle on an arc greater than a quadrant. And conversely, an angle at the center standing on a quadrant is a right angle; standing on an arc less than a quadrant, acute; and on an arc greater than a quadrant, obtuse.

[Demonstration] Let the right angle ABC stand on the arc AC, at the center B of the circle ACDE. I say that the arc AC is a quadrant, and so on. For when the lines AB, CB are produced to D, E, the angles ABE, CBD, adjacent to the right angle ABC, will also be right, by definition 10 of Book 1; and so too the angle DBE, since it is equal to the right angle ABC as vertical to it. [Margin: m — Elem. I.15] Therefore all four angles at the center B are equal, being right; and hence the arcs AC, CD, DE, EA, on which they stand, will be equal. [Margin: n — Elem. III.26] Each of them, then, is a quadrant. And since the line that makes an acute angle at B with AB falls within the arc AC, while the line that makes an obtuse angle at B with the same AB falls within the arc CD, it is plainly established that the acute angle stands on an arc less than a quadrant, and the obtuse on a greater.

Diagram. A circle ACDE with center B, divided into four quadrants by the two perpendicular diameters AD (vertical) and EC (horizontal).

- A (top): upper end of the vertical diameter.
- B (center): center of the circle.
- C (right): right end of the horizontal diameter.
- D (bottom): lower end of the vertical diameter.
- E (left): left end of the horizontal diameter.

But now let the angle ABC at the center B stand on the quadrant AC. I say that the angle ABC is a right angle, and so on. For when the lines AB, CB are again

produced to D, E: since both CAE and ACD, and AED, are semicircles, and AC is a quadrant, then both AE and CD will be quadrants also, and hence DE too, in the semicircle AED, will be a quadrant. Therefore the four arcs AC, CD, DE, EA are equal, and hence the angles at the center B that stand on them will be equal. [Margin: o — Elem. III.27] Since, then, all four together are equal to four right angles, each of them will be a right angle. And because the line drawn with AB that cuts off an arc less than the quadrant AC makes at the center B, with AB, an angle less than the right angle ABC; while the line drawn with the same AB that cuts off an arc greater than the quadrant AC forms at the center B an angle greater than the right angle ABC — it is evident that the angle standing on an arc less than a quadrant is acute, and that standing on a greater, obtuse. Which is what was proposed.

By like reasoning this theorem too is drawn out from what has been demonstrated — the theorem which we also demonstrated in [the doctrine of] sines.

[Clavius's added theorem — a line from the center bisecting a chord] A straight line drawn from the center of a circle and bisecting another straight line not drawn through the center will also bisect the arc that this line subtends. And conversely, if it bisects the arc, it will also bisect the line subtending it.

[Demonstration] From the center A of the circle BCDE, let the line AE, going out, cut the line BD in two equal parts at F. I say that the arc BED is also bisected at E, and so on. For when the lines AB, AD are drawn: since the two sides AB, AF are equal to the two sides AD, AF, each to each, and the base BF is assumed equal to the base DF, the angle BAF will be equal to the angle DAF. [Margin: p — Elem. I.8] Therefore the arc BE will be equal to the arc DE. [Margin: q — Elem. III.26] So the arc BD has been bisected at E.

Diagram. A circle BCDE with center A; the vertical diameter runs C (top) — A — E (bottom), and the chord BD is cut at F.

- A (center): center of the circle.
- B (left) and D (right): endpoints of the chord BD, on the circle.
- C (top): upper end of the vertical line through the center.
- E (bottom): lower end of the vertical line, on the circle.
- F (on BD, below A): point where AE meets and bisects the chord BD.

Now let the line AE bisect the arc BD at E. I say that the line BD is likewise bisected at F, and so on. For when the lines AB, AD are again drawn: since the

arcs BE, DE are assumed equal, the angles BAE, DAE at the center will also be equal. [Margin: r — Elem. III.27] And so, since the two sides AB, AF are equal to the two sides AD, AF, each to each, and they contain equal angles, as we showed, the bases BF, DF will also be equal; [Margin: s — Elem. I.4] and hence the line BD is bisected at F. Which was to be demonstrated.

Nor does it seem right to omit in this place a certain outstanding property of the circle, which Giovanni Battista Benedetti [Giovanni Battista Benedetti], drawing on Cardano [Gerolamo Cardano], *De subtilitate* Book 16, ch. 1, demonstrates; namely:

[Benedetti / Cardano theorem] If in a circle two diameters are drawn cutting one another at right angles, and one of them is produced; and if on one side any number of parallels are drawn dividing each quadrant into equal parts; and finally, if from the endpoint of the other diameter, through the endpoint of the nearest parallel, a straight line is drawn to meet the produced diameter: then the whole line, taken between the point of meeting and the concave circumference of the circle, will be equal to all the parallels together with the diameter that was produced, all taken together.

(continued from the previous page — the demonstration of the corollary theorem appended to Proposition 27)

In the circle ABCD let the diameters AC and BD cut one another at right angles, and let AC be produced beyond C as far as you please. Now divide the quadrant BC into any number of equal parts CF, FG, GB, and the quadrant BA into the same number of parts, and join the straight lines FH and GI. By the scholium of Proposition 27 of this book these will be parallel to AC, since they intercept equal arcs. Finally, from B through G draw the straight line BG extended until it meets AC produced at K. I say that the straight line AK is equal to all the parallels AC, HF, IG taken together.

For draw the straight lines HC and IF and produce them until they meet AK. Since the angles CHF and HFI, standing on the equal arcs CF and HI, are equal, [Margin: (t) *Elem.* III.27] the straight lines HC and IL will be parallel; [Margin: (u) *Elem.* I.27] and FH is also parallel to CL. Therefore CHFL is a parallelogram, [Margin: (x) *Elem.* I.34] and consequently the straight line CL is equal to the straight line FH. By the same reasoning KL will be equal to GI, and so on in turn, if there are more of them. When, therefore, the common segment AC is added, the whole line AK becomes equal to AC, HF, and IG taken together. Which was what was proposed.

Diagram. A circle ABCD with two perpendicular diameters — AC drawn vertically (A at the top, C at the bottom) and BD drawn horizontally (B at the left, D at the right) — crossing at the center E. The upper-left quadrant BA and the lower-left quadrant BC are each subdivided; the chords FH and GI (parallel to the vertical diameter) are drawn. The line BG is produced downward past C to K and L, the whole construction tapering to a point P far below the circle.

- A (top of circle): upper end of the vertical diameter
- B (left of circle): left end of the horizontal diameter
- D (right of circle): right end of the horizontal diameter
- C (bottom of circle): lower end of the vertical diameter
- E (center): intersection of the two diameters
- H (upper-left arc): division point on quadrant BA
- I [?] (upper-left arc, near H): division point on quadrant BA
- G (lower-left arc): division point on quadrant BC
- F (lower-left arc, below E): division point on quadrant BC
- L (below C, on the produced line): point where the construction meets the extended diameter
- P (far bottom): terminal point of the produced line

THEOR. 25. PROPOS. 28.

[Margin: (right) xxvij.]

Enunciation (Euclid). In equal circles, equal straight lines cut off equal arcs, the greater equal to the greater and the lesser equal to the lesser.

Demonstration. In equal circles ABC and DEF, whose centers are G and H, let the straight lines AC and DF be equal. I say that the greater arc ABC is equal to the greater arc DEF, and the lesser arc AC equal to the lesser arc DF. For draw the straight lines AG, GC, DH, HF. Then the sides AG, GC of triangle AGC are equal to the sides DH, HF of triangle DHF; and the bases AC, DF are assumed equal.

Therefore the angles at G and H will be equal, [Margin: (a) *Elem.* I.8] and consequently the arcs AC, DF on which they stand will be equal. [Margin: (b) *Elem.* III.26] These, being taken away from the equal wholes, leave the remainders ABC and DEF equal as well. Therefore in equal circles equal straight lines, and so on. Which was to be demonstrated.

Diagram. Two equal circles side by side, each with an inscribed isosceles triangle whose apex is the center.

- Left circle: B (top of circle), G (center, apex of the triangle), A (lower-left) and C (lower-right), the base AC being a chord.
- Right circle: E (top of circle), H (center, apex), D (lower-left) and F (lower-right), the base DF being a chord.

Scholium. But if the straight lines in equal circles are unequal, the greater line will cut off the greater arc, provided we are speaking of arcs of the circle that are less than a semicircle. For if the discussion concerns arcs greater than a semicircle, the greater line will cut off the lesser arc. For in equal circles ABC, DEF, whose centers are G and H, let the straight line AC be greater than DF. I say that the arc AC, less than a semicircle, is greater than the arc DF, but that the arc ABC is less than the arc DEF. For draw the straight lines AG, GC, DH, HF; then the sides AG, GC of triangle AGC are equal to the sides DH, HF of triangle DHF, while the base AC is assumed greater than the base DF. Therefore the angle AGC will be greater than the angle DHF. [Margin: (c) *Elem.* I.25] Make the angle CGI equal to the angle DHF; then the arc CI will be equal to the arc DF, [Margin: (d) *Elem.* III.26] and consequently the arc AIC will be greater than the arc DF; and therefore the remainder ABC will be less than the remainder DEF.

Diagram. Two equal circles. In the left circle the chord AC (the greater line) is drawn well above the center, and a radius GI is dropped from the center G to the point I on the far arc, marking off the arc CI.

- Left circle: B (top), G (center), A (left) and C (right) on the chord AC, and I (bottom of circle) where the radius GI meets the circumference.
- Right circle: E (top), H (center), D (left) and F (right), with the inscribed triangle DHF.

THEOR. 26. PROPOS. 29.

[Margin: (right) xxvii.]

Enunciation (Euclid). In equal circles, equal arcs are subtended by equal straight lines.

Demonstration. In the same equal circles let equal arcs ABC, DEF be laid down, and likewise AC and DF. I say that the straight lines AC, DF which subtend them are equal. For, the lines being drawn as before, the sides AG, GC of triangle AGC will be equal to the sides DH, HF of triangle DHF; and the angles at G and H are also equal, [Margin: (a) *Elem.* III.27] since they stand on the equal arcs AC, DF. Therefore the bases AC, DF will be equal. [Margin: (b) *Elem.* I.4] Therefore in equal circles equal arcs, and so on. Which was to be shown.

Diagram. Two equal circles, each with an inscribed isosceles triangle apexed at the center.

- Left circle: B (top), G (center, apex), A (lower-left), C (lower-right), base AC.
- Right circle: E (top), H (center, apex), D (lower-left), F (lower-right), base DF.

Scholium. But if the arcs are unequal, the greater line will subtend the greater arc rather than the lesser, provided the discussion concerns arcs less than a semicircle. For if we speak of arcs greater than a semicircle, the lesser line will subtend the greater arc rather than the lesser. For in equal circles ABC, DEF, whose centers are G and H, let the arcs AC, DF be less than a semicircle, and let AC be greater than DF, so that ABC is less than DEF. I say that the line AC is greater than DF. For, drawing the straight lines AG, GC, DH, HF, the angle AGC will be greater than the angle DHF, by the scholium of Proposition 27 of this book. Since, then, the sides AG, GC of triangle AGC are equal to the sides DH, HF of triangle DHF, the base AC will be greater than the base DF, [Margin: (c) *Elem.* I.24] and so on.

Diagram. Two equal circles. In the left circle the chord AC lies high, near the center, giving a shallow (obtuse-apexed) triangle AGC; the right circle has the triangle DHF.

- Left circle: B (top), G (center), A (left), C (right) on the chord AC.
- Right circle: E (top), H (center), D (left), F (right), base DF.

Now the four immediately preceding propositions — 26, 27, 28, and 29 — are to be understood as holding also within one and the same circle, as we noted in the scholium of Proposition 26, and as is clear from the demonstrations given; for those same demonstrations hold good in one and the same circle.

And so these same four propositions will be made more universal if they are stated as follows:

In equal circles, or in the same circle, equal angles stand on equal arcs, whether they are set up at the centers or at the circumferences.

In equal circles, or in the same circle, angles that stand on equal arcs are equal to one another, whether they are set up at the centers or at the circumferences.

In equal circles, or in the same circle, equal straight lines cut off equal arcs, the greater equal to the greater and the lesser to the lesser.

In equal circles, or in the same circle, equal arcs are subtended by equal straight lines.

Scholium. But it will not be without use to demonstrate the following propositions as well.

I. Circles from which equal straight lines cut off similar circumferences are equal.

Demonstration. From the circles ABC, DEF let the equal straight lines AC, DF cut off similar circumferences ABC, DEF. I say that the circles themselves are equal. For if the segments ABC, DEF are similar, then the remaining segments AC, DF will also be similar, as we demonstrated at Proposition 22. Again, since upon the equal straight lines AC, DF similar segments ABC, DEF are set up, these will be equal to one another. [Margin: (d) *Elem.* III.24] By the same reasoning the segments AC, DF, which have been shown to be similar, will be equal. Therefore the whole circles will be equal. In like manner, if the equal straight lines AC, DF are said to cut off similar circumferences AC, DF, then, by what we demonstrated at Proposition 22, the segments ABC, DEF will also be similar. [Margin: (e) *Elem.* III.24] Therefore both the one set and the other will be equal to one another; and consequently the whole circles too will be equal to one another. Which was what was proposed.

Diagram. Two circles side by side, each with an inscribed triangle from the center to a chord (the figure shared by Theorems I–IV).

- Left circle: B (top), G (center), A (lower-left), C (lower-right), base AC.
- Right circle: E (top), H (center), D (lower-left), F (lower-right), base DF.

II. From unequal circles, equal straight lines cut off dissimilar circumferences.

Demonstration. In the same figure let the straight lines AC, DF be equal, but the circles ABC, DEF unequal. I say that the circumferences ABC, DEF are dissimilar. For if the circles themselves were similar, then — as we demonstrated just now — they would be equal; and this conflicts with the hypothesis. Therefore the circumferences ABC, DEF are dissimilar. By the same reasoning the circumferences AC, DF will be dissimilar. Which was to be shown.

III. From unequal circles, the straight lines that cut off similar circumferences are unequal.

Demonstration. In the same figure let the circles be unequal, but the circumferences ABC, DEF similar. I say that the straight lines AC, DF are unequal. For if they were said to be equal, then, by the first theorem, the circles would be

equal — which is absurd, since they are assumed unequal. Therefore the straight lines AC, DF are unequal. In the same way, if the circumferences AC, DF are said to be similar, it will be demonstrated that the straight lines AC, DF are unequal.

IV. Straight lines that cut off similar unequal circumferences from any circles whatever are unequal.

Demonstration. In the same figure let the circumferences ABC, DEF be similar and unequal. I say that the straight lines AC, DF are unequal. For either the circles are equal or they are unequal. Let them first be equal. If, then, the straight lines AC, DE [recte DF] are said to be equal, the circumferences ABC, DEF cut off will be equal, [Margin: (f) *Elem.* III.28] which is contrary to the hypothesis. Therefore the straight lines AC, DF are not equal. Let the circles next be unequal. Then the straight lines AC, DF cutting off the similar circumferences ABC, DEF are unequal, as was demonstrated in the third theorem. We shall show in no other way that the straight lines AC, DF are unequal if the circumferences AC, DF are assumed similar and unequal.

Diagram. A second pair of circles, each with an inscribed triangle from the center to a chord, serving Theorem IV.

- Left circle: B (top), G (center), A (lower-left), C (lower-right), base AC.
- Right circle: E (top), H (center), D (lower-left), F (lower-right), base DF.

V. If in the diameter of a circle a point is taken other than the center, and from it two straight lines falling on the circumference on opposite sides make equal angles with the diameter, then those straight lines will be equal and will cut off equal arcs. And if the lines are equal, they will make equal angles with the diameter and cut off equal arcs. And finally, if they cut off equal arcs, those straight lines will be equal and will make equal angles with the diameter.

(demonstration of Theorem V)

In the circle ABCDE, whose center is F, let a point G be taken on the diameter AD, other than the center, and let first two equal angles CGD, EGD be set up. I say that both the straight lines GC, GE and the arcs CD, ED are equal. For since the two angles CGD, CGF, and likewise the two angles EGD, EGF, are together equal to two right angles, [Margin: (g) *Elem.* I.13] then if the equal angles CGD, EGD are taken away, the remainders CGF, EGF will also be equal. So, drawing the straight lines CF, EF to the center, the two sides FC, FG will be equal to the two sides FE, FG, and the sides opposite the equal angles FGC, FGE will be equal. And each of the remaining angles FCG, FEG is less than a right angle — for if the straight line CD is

drawn, the angle FCD in the isosceles triangle FCD is acute, by the third corollary of Proposition 17 of Book I, and therefore FCG is a fortiori acute; and in the same way, drawing the straight line DE, the angle FEG is acute. Hence, by what we have demonstrated, the base GC will be equal to the base GE, and the angle CFG equal to the angle EFG; [Margin: (h) *Elem.* III.26] and consequently the arcs CD, ED will be equal. The proposition is therefore established.

Diagram. A circle with five points A, B, C, D, E on the circumference, center F, and a point G on the diameter AD below the center. Straight lines run from F and from G to the circumference, forming a star of triangles; the auxiliary point H lies on GB (used in the following theorem).

- A (top): upper end of the diameter AD
- D (bottom): lower end of the diameter AD
- F (center): center of the circle
- G (on the diameter, between F and D): the point taken other than the center
- B (upper-left, on the circle)
- C (left, on the circle)
- E (right, on the circle)
- H (inside, on GB): the point marked off so that GH equals GD (belonging to the following theorem)

Next, let the lines GC, GE be equal. I say that the angles CGD, EGD are also equal, and likewise the arcs CD, ED. For if the lines GC, GE are equal, the two sides GC, GF will be equal to the two sides GE, GF; and the base FC is also equal to the base FE. Therefore the angles FGC, FGE will be equal, [Margin: (i) *Elem.* I.8] and consequently the remainders CGD, EGD, taken from two right angles, will be equal. Again, since the two sides FC, FG are equal to the two sides FE, FG, and the bases GC, GE [recte; printed "GC, CE"] are assumed equal, the angles CFD, EFD will also be equal, [Margin: (k) *Elem.* I.8] and therefore the arcs CD, ED will be equal. [Margin: (l) *Elem.* III.26] Which was what was proposed.

Thirdly, let the arcs CD, ED be equal. I say that the lines GC, GE and the angles CGD, EGD are equal. For if the arcs CD, ED are equal, the angles CFD, EFD will also be equal. [Margin: (m) *Elem.* III.27] Therefore, since the two sides FC, FG are equal to the two sides FE, FG and contain equal angles, the bases GC, GE will be equal, [Margin: (n) *Elem.* I.4] and the angles FGC, FGE; and consequently the remainders CGD, EGD, taken from two right angles. All of which was to be demonstrated.

This theorem, however, is far more universally covered by Lemma 21 of Book I of our *Astrolabe*.

V. [recte VI]

Enunciation. If in the diameter of a circle a point is taken other than the center, and at it two equal angles are set up on the same side, then these equal angles will stand on unequal arcs, and the greater will be that which is farther from the smaller portion of the diameter.

Demonstration. In the same figure just drawn, let there be two equal angles CGD, CGB. I say that the arc BC is greater than the arc CD. For, drawing the straight lines BC, CD: since the straight line GB is greater than the straight line GD, [Margin: (o) *Elem.* III.7] mark off GH equal to GD and join the straight line CH. Since the two sides GH, GC are equal to the two sides GD, GC and contain equal angles, the bases CH, CD will be equal, and the angle GHC equal to the angle GDC. [Margin: (p) *Elem.* I.4] But GDC is acute, being in the isosceles triangle FCD, by the third corollary of Proposition 17 of Book I. Therefore GHC too will be acute; and consequently the remaining angle CHB, taken from two right angles, will be obtuse. Since, then, the two angles CHB, CBH are less than two right angles, [Margin: (q) *Elem.* I.17] the angle CBH will be acute. Therefore the side BC will be greater than the side CH. [Margin: (r) *Elem.* I.19] But CH has been shown equal to CD. Therefore the straight line BC will also be greater than CD; and consequently, by the scholium of Proposition 28 of this book, the arc BC will be greater than the arc CD. Which was to be shown.

PROBL. 4. PROPOS. 30.

[Margin: (right) xxix.]

Enunciation (Euclid). To bisect a given arc.

Demonstration. Let ABC be the arc to be bisected. Draw the straight line AC subtending it, and, this being bisected at D, erect the perpendicular DB, which will bisect the arc ABC at B. For, drawing the straight lines AB, CB, the sides AD, DB of triangle ADB will be equal to the sides CD, DB of triangle CDB; and the angles at D are also equal, namely right angles. Therefore the bases AB, CB will be equal, [Margin: (a) *Elem.* I.4] and consequently the arcs AB, CB will be equal. [Margin: (b) *Elem.* III.28] We have therefore bisected the given arc. Which was to be done.

Diagram. An arc ABC standing on its chord AC; B is the top of the arc, and the perpendicular BD is dropped to the midpoint D of the chord, with the lines BA and BC drawn. A faint full circle is sketched below as construction.

- B (top): the point where the perpendicular meets the arc
- A (lower-left): one end of the chord
- C (lower-right): the other end of the chord
- D (lower-center): the midpoint of the chord AC

Praxis. The practical procedure for dividing a given arc in two does not differ from the procedure for dividing a straight line in two which we set out at Proposition 10 of Book I. For whenever any arc is proposed, such as ABC, one must always understand the straight line AC that subtends it, even if it has not been drawn; and from the points A and C one describes arcs with the same interval, cutting one another above and below the points A and C, and so on, exactly as if the said straight line AC were to be bisected. For the straight line that bisects the line AC will also bisect the given arc in two.

THEOR. 27. PROPOS. 31.

[Margin: (right) xxx.]

Enunciation (Euclid). In a circle, the angle in a semicircle is a right angle; the angle in the greater segment is less than a right angle; and the angle in the lesser segment is greater than a right angle. Moreover, the angle of the greater segment is greater than a right angle, while the angle of the lesser segment is less than a right angle.

Demonstration (begins). For let AC be the diameter of the circle ABC, whose center is D, and let the angle ABC be set up in the semicircle, and let the angle BAC exist in the greater segment CAB. Let the angle BEC also be set up in the lesser segment CEB. I say that the angle ABC in the semicircle is a right angle; that the angle BAC in the greater segment is less than a right angle; and that the angle BEC in the lesser segment is greater than a right angle. Likewise, that the angle of the greater segment, contained by the straight line BC and the arc BAC, is greater than a right angle; but that the angle of the lesser segment, contained by the straight line BC and the arc BEC, is less than a right angle. For draw the straight line BD to the center, and produce AB to F. Since, therefore, the straight lines DA, DB...

Diagram. A circle with horizontal diameter AC and center D. B lies on the upper-left arc and E on the upper-right arc; the lines BA, BC, BD, and BE are drawn, EC is drawn, and AB is produced beyond B to the external point F.

- A (left end of diameter)
- C (right end of diameter)

- D (center)
- B (upper-left, on the circle)
- E (upper-right, on the circle)
- F (outside the circle, upper-left): the point to which AB is produced

Euclid, *Elements*, Book III — Clavius's Commentary

Proposition 31 (continued) — demonstration concluded

[DA and] DB are equal, and so [Margin: a — Elem. I.5] angle DBA is equal to angle DAB. By the same reasoning angle DBC will be equal to angle DCB, [Margin: b — Elem. I.32] and therefore the whole angle ABC will be equal to the two angles BAC and BCA together. But the exterior angle FBC is also equal to those same two interior angles BAC and BCA in triangle ABC. Therefore angles ABC and FBC are equal to one another, and hence each is a right angle. So angle ABC is a right angle — which was the first point.

Now since in triangle ABC [Margin: c — Elem. I.17] the two angles ABC and BAC are together less than two right angles, and angle ABC has been shown to be right, angle BAC (in the greater segment) will be less than a right angle — which was the second point.

Again, since in the quadrilateral ABEC inscribed in the circle [Margin: d — Elem. III.22] the two opposite angles BAC and BEC are equal to two right angles, and angle BAC has been shown to be less than a right angle, angle BEC (the angle in the lesser segment) will be greater than a right angle — which was the third point.

It is enough, however, to have demonstrated that one angle in the semicircle — namely ABC — is right; that one in the greater segment — such as BAC — is less than a right angle; and finally that one in the lesser segment — such as BEC — is greater than a right angle. For since all angles in the same segment are equal to one another, it is clear that if one angle in the semicircle is right, all the angles in the same semicircle are right; if one in the greater segment is less than a right angle, all in the same segment are less than a right angle; and finally, if one in the lesser segment is greater than a right angle, all in the same segment are greater than a right angle. I say this because Euclid does not prove absolutely that any angle whatever in the greater segment BAC is less than a right angle — as is

evident if some other angle were set up in that segment which was not subtended by the diameter, as angle BAC is. Hence any other such angle will likewise be shown to be less than a right angle, because [Margin: e — Elem. III.21] it is equal to angle BAC in the same greater segment, which Euclid has shown to be less than a right angle.

Diagram. A circle with horizontal diameter AC, center D. On the upper-left circumference is B; at the upper right is E. Point F lies outside the circle above and to the left, where the line AB is produced. Chords are drawn from B to E, to C, and to A; the line through F meets B; AC is the diameter; EC is joined.

- A (left end of diameter): terminus of diameter
- C (right end of diameter): terminus of diameter
- D (center): center of the circle
- B (upper-left circumference): vertex of the semicircle angle ABC
- E (upper-right circumference): vertex of the angle BEC in the lesser segment
- F (outside, upper left): point on AB produced

Furthermore, since the right angle ABC is part of the angle of the greater segment BAC (the angle contained by the straight line BC and the arc BAC), the angle of the greater segment will be greater than a right angle — which is the fourth point.

Finally, since the angle of the lesser segment (contained by the straight line BC and the arc BEC) is likewise part of the right angle FBC, the angle of the lesser segment will be less than a right angle — which is the fifth point. Therefore in a circle the angle in the semicircle is right, etc. Which was to be demonstrated.

Another demonstration of this proposition

Diagram. A semicircle on diameter AC with center D; B is the apex on the arc. Straight lines are drawn from B to A, to D, and to C.

- A (left end of base): terminus of the diameter
- D (center of base): center of the semicircle
- C (right end of base): terminus of the diameter
- B (apex on the arc): vertex of the right angle

In the semicircle whose diameter is AC and whose center is D, let ABC be the angle, which I say is right. For when the straight line BD has been drawn, [Margin: f — Elem. I.5] the angles DBA and DAB will be equal, because the straight lines DA and DB are equal. Since, then, the exterior angle BDC [Margin: g

— Elem. I.32] is equal to the two interior angles DBA and DAB in triangle ABD, angle BDC will be double angle DBA. In the same way angle ADB will be double angle DBC; and thus the two angles at D together will be double the whole angle ABC. Since, then, [Margin: h — Elem. I.13] the angles at D are equal to two right angles, angle ABC will be half of them — that is, a right angle. Which was the first point.

Or thus: Since [Margin: i — Elem. I.5] angle DAB equals angle DBA, and angle DCB equals angle DBC, the two angles A and C together will equal angle ABC in triangle ABC. And accordingly angle ABC is half of the three angles A, C, and ABC of that same triangle. Therefore, [Margin: k — Elem. I.32] since the three angles of triangle ABC are equal to two right angles, ABC will be half of two right angles, and hence a right angle.

Diagram. A circle with B at the top; the diameter AE runs from A (left) through the center D to E (upper right on the circumference); C is at the lower right. Chords AB, BC, and BE are drawn, together with AC.

- A (left): one end of diameter AE
- E (upper right circumference): other end of diameter AE
- D (center): center of the circle
- B (top): vertex of the angle in the greater segment
- C (lower right): further point on the circumference

Again, let there be, in the greater segment whose center is D, the angle ABC, which I say is less than a right angle. For when the diameter AE has been drawn and the straight line BE joined, angle ABE will be right, being in a semicircle, as has been demonstrated. Therefore angle ABC, being part of a right angle, will be less than a right angle — which is the second point. And this demonstration fits every angle in the lesser segment [recte "greater segment"? —] — something that could not be said of the earlier demonstration, as we noted there.

Diagram. A figure with B at the top; A at the left, D at the center, C at the lower right, and E below and to the right, outside the original arc, where the diameter AE (produced) meets the circumference. Straight lines AB, BC, and BE are drawn.

- A (left): one end of the diameter
- E (lower right, outside): end of the produced diameter
- D (center): center
- B (top): vertex of the angle in the lesser segment
- C (lower right): point on the circumference

Again, let there be, in the lesser segment whose center is D, the angle ABC, which I say is greater than a right angle. For when the diameter AE has been drawn, meeting the produced circumference at E, and the straight line BE joined, angle ABE will be right, being in a semicircle, as has been demonstrated; and since it is part of angle ABC, angle ABC will be greater than a right angle — which is the third point.

Diagram. A circle with center E. B lies on the upper-left circumference and C at the right, with BC a diameter through the center E. A lies on the lower-left circumference; the line BAF is drawn through A and produced to F outside the circle at the lower left. D lies on the lower circumference; AC is joined.

- B (upper left): one end of diameter BC
- C (right): other end of diameter BC
- E (center): center of the circle
- A (lower left): point where BAF crosses the circumference
- F (outside, lower left): point on BA produced
- D (lower circumference): point in the lesser segment ADC

Now let there be proposed a greater segment ABC and a lesser segment ADC, whose center is E. I say that the angle CAB of the greater segment — namely the one formed by the straight line CA and the arc ABC — is greater than a right angle; but that the angle CAD of the lesser segment, formed by the same straight line CA and the arc ADC, is less than a right angle. For when the diameter CB and the straight line BAF have been drawn, its part BA — joining the two points B and A — will fall [Margin: 1 — Elem. III.2] inside the circle, while the remaining part AF falls outside it; and angle BAC will be right, being in a semicircle, and consequently the adjacent angle FAC will also be right. Since, then, the rectilineal right angle BAC is part of the angle CAB of the greater segment — namely the one contained by the straight line CA and the arc ABC —

— and the angle CAD of the lesser segment, contained namely by the straight line CA and the arc ADC, is likewise part of the right angle FAC, both points are established.

Corollary

Hence it is clear that the angle of a triangle which is equal to the remaining two is a right angle — because the angle adjacent to it (formed when a side is produced beyond the triangle) is equal to those same two, which is evident from the earlier

demonstration; or because it is half of the three angles of the triangle, which are equivalent to two right angles, which is evident from the later demonstration.

From Campanus [Campanus of Novara]

From this proposition it is also clear that those two arguments have no force which we attacked at Proposition 16 of this book. One of them is: "One passes from the greater to the lesser through all intermediate values; therefore through the equal." The other is of this kind: "It is possible to find something greater and something lesser than the same thing; therefore it is possible to find something equal."

Diagram. A circle with center D. A is at the left; the diameter AE runs to E at the right. B lies on the upper-right circumference; from A the line AB is drawn and produced upward beyond the circle. C lies at the lower part of the circumference, and F below and to the left, where AC is produced. Straight lines are drawn from A to B, to E (the diameter), and to C (produced to F).

- A (left): fixed point from which the moving line turns
- D (center): center
- E (right): far end of diameter AE
- B (upper right): point on the circumference; angle ABE in the greater segment
- C (lower circumference): point reached as the line turns to AC
- F (lower left, outside): point on AC produced; angle ACF of the lesser segment

For in the circle ABC, whose center is D and whose diameter is AE, let the straight line AB be drawn. [Margin: m — Elem. III.31] Angle ABE, of the greater segment, will be greater than a right angle. Hence if AB is turned toward AE about the fixed point A, it will always make with the circumference an angle greater than a right angle, until it reaches the diameter AE, [Margin: n — Elem. III.16] where it will make the angle of a semicircle, which is less than a right angle. And if it is turned further, to AC, [Margin: o — Elem. III.31] it will a fortiori make the angle ACF of the lesser segment, which is less than a right angle. Therefore one passes from the angle of the greater segment, which is greater than a right angle, to the angle of the semicircle — or even to that of the lesser segment, each of which is less than a right angle — yet not through an angle equal to a right angle. Since, then, the passage is made through all the intermediate angles, it is clear that the aforesaid inferences are faulty.

Scholium

It is also evident that the converse of this theorem holds — namely: The segment of a circle in which the angle set up is right is a semicircle; the one in which the angle is acute is a greater segment; and the one in which the angle is obtuse is a lesser segment. And the segment whose angle is greater than a right angle is greater than a semicircle; while the one whose angle is less than a right angle is either a semicircle or less than a semicircle.

For, the angle being right, if the segment is not a semicircle it will be either greater — and so the angle will be acute — or lesser — and so the angle in it will be obtuse; both of which conflict with the hypothesis. Again, the angle being acute, if the segment is not greater than a semicircle it will be either a semicircle — and so the angle in it will be right — or less — and so the angle in it will be obtuse; both of which likewise conflict with the hypothesis. Finally, the angle being obtuse, if the segment is not less than a semicircle it will be either a semicircle — and so the angle in it will be right — or greater — and so the angle in it will be acute; which is similarly contrary to the hypothesis. Moreover, when the angle of the segment is greater than a right angle, if the segment is not greater than a semicircle it will be either a semicircle or less than a semicircle, and so its angle will be less than a right angle — which is not what is assumed. But when the angle of the segment is less than a right angle, if the segment is not a semicircle or less than a semicircle it will be greater, and so its angle will in turn be greater than a right angle. Which contradicts the hypothesis.

Indeed, this theorem too is true, namely:

If a straight line is subtended to a right angle — that is, if in a right triangle the side opposite the right angle is bisected, and about that straight line (the side), from the point of division, a circle is described — that circle will necessarily pass through the right angle.

Diagram. The right-angle vertex B stands at the top; below it, on the described circle, is the point E. The base runs A (left) — D (center) — C (right), with the circle AEC drawn on AC and center D. Straight lines join B to A and to C, and E to A and to C. [A second B-like mark appears near the apex — [?].]

- B (top): vertex of the right angle of triangle ABC
- E (below B, on the described circle): point at which the circle would meet, if it did not pass through B
- A (left of base): end of the hypotenuse

- D (center of base): midpoint of the hypotenuse AC
- C (right of base): end of the hypotenuse

For let the straight line AC be subtended to the right angle ABC — or, in the right triangle ABC, let the side AC opposite the right angle B — be bisected at the point D, and from D, with radius DA or DC, let the circle AEC be described, which I say passes through B. For if it were to pass on the near side of B, or beyond it, then when the straight lines AE and CE are drawn so as not to cut AB and AC but to fall either inside or outside them, [Margin: p — Elem. III.31] angle AEC would also be right. Then the right angles B and E would be equal — which is absurd, since angle E must necessarily [Margin: q — Elem. I.21] be either greater or less than angle B. Therefore the circle passes through the point B — which was proposed.

From what has been demonstrated in the earlier part of this proposition, we shall without difficulty draw, from a given point outside a circle, two straight lines — one on each side of the straight line drawn from that same point through the center of the circle — which touch the circle. This is what we promised at Proposition 17 of this book.

Diagram. Two overlapping circles. D is the external point at the left. The line DC runs to C, the center of the given circle, passing through E [printed here as F on the figure — see below], the midpoint of DC. The described circle passes through A (at the top) and B (at the bottom), the points of contact. Straight lines DA and DB are drawn, together with AC and BC.

- D (left, external): the given point outside the circle
- F (on DC, center): midpoint of DC, center of the described circle (*labelled F on the figure; the text calls this point E*)
- C (center-right): center of the given circle
- A (top): point of contact of tangent DA
- B (bottom): point of contact of tangent DB

For let there be a circle AB whose center is C, and a point D outside it. Let the straight line DC be drawn from the given point to the center, and bisected at E; and from E, with radius EC or ED, let the circle ACBD be described, cutting the given circle at the points A and B; and let the straight lines DA and DB be joined. I say that each touches the circle at A and at B. For when the straight lines AC and BC are drawn, [Margin: r — Elem. III.31] each angle A and B will be right, being in a semicircle. Therefore, by the corollary to Proposition 16 of this book, the straight line DA will touch the circle AB at A, and the straight line DB will touch

the same circle at B — since the former is perpendicular to the extremity of the radius AC just as the latter is to the extremity of the radius CB.

But we shall also demonstrate here this not-unwelcome theorem drawn from Pappus of Alexandria [Pappus]:

If through the center of a circle another circle is described, and a straight line is projected through the centers of both circles, and from the point where this line is cut by the latter circle a straight line is drawn in any way whatever, then the portion of it that lies inside the former circle will be bisected by the circumference of the latter.

Diagram — first figure. The larger semicircular arc ABC stands on the base line, with A at the left, D at the center, C toward the right, and F at the right end. A smaller circle DEF sits within it, passing through D, E, and G. The line AF is the base (through both centers); the line FB rises from F and cuts the circumferences at B, E, and G.

- A (left): one end of line AF
- F (right): point where circle DEF meets line AF
- D (center of large circle): also on the small circle
- C (between D and F): point on the base
- B (top left, on large arc): point where FB meets the large circumference
- E (middle, on small circle): point where FB meets the small circumference
- G (right, on large arc): further intersection of FB

Let there be a circle ABC, through whose center D another circle DEF is described, and through the centers of these circles let the straight line AF be drawn; and finally, from the point F, where the circle DEF cuts the straight line AF, let the straight line FB be drawn, cutting the circumferences at B, E, G. I say that BE and GE are equal. For when the straight line DE has been drawn, [Margin: r — Elem. III.31] angle DEF will be right, being in the semicircle DEF. Therefore [Margin: s — Elem. III.3] the straight line DE bisects the straight line BG.

Diagram — second figure. The larger arc AB...C with base A (left) — D (center) — C (right); the inner circle now passes through D, E, and C. The line from B descends through E to C.

- A (left): end of the base
- D (center): center of the large circle
- C (right): point through which the inner circle passes

- B (top): point on the large arc
- E (middle): intersection on the inner circle

But if the latter circle passes through the point C, as in the second figure, then again [Margin: t — Elem. III.31] angle DEC will be right, being in the semicircle DEC; and [Margin: u — Elem. III.3] therefore BC is bisected at E.

Diagram — third figure. The large arc with base A (left) — D (center) — C and G together at the right; the inner circle DEF lies wholly within. The line from B descends through E toward G.

- A (left): end of the base
- D (center): center of the large circle
- C (right): point on the base
- G (right, on arc): intersection of the descending line
- B (top): point on the large arc
- E (middle): intersection on the inner circle

And finally, if the latter circle lies wholly within the former, as in the third figure, then again [Margin: x — Elem. III.31] angle DEF will be right, being in the semicircle DEF. Therefore [Margin: y — Elem. III.3] the straight line DE will bisect the straight line BG. Which was to be shown.

This theorem too can easily be demonstrated in another way.

Additional theorem — the inscribed quadrilateral

A quadrilateral inscribed in a circle, two of whose opposite sides are parallel and equal, is a rectangular parallelogram — that is, either a square or an oblong ["longer on one side"].

Diagram. A circle with an inscribed quadrilateral. A is at the upper left, D at the upper right, B at the lower left, C at the lower right; the diagonals AC and BD cross at the center E.

- A (upper left): vertex
- D (upper right): vertex
- B (lower left): vertex
- C (lower right): vertex
- E (center): intersection of the diagonals AC and BD

In the circle ABCD let a quadrilateral ABCD be inscribed, two of whose opposite sides AD and BC are parallel and equal. I say that it is a parallelogram and a rectangle. For since the straight lines AD and BC are parallel and equal, [Margin: z — Elem. I.33] AB and DC will also be parallel and equal. Therefore ABCD is a parallelogram. And since [Margin: a — Elem. III.28] arc AD equals arc BC (because the straight lines AD and BC are equal), and arc AB equals arc DC (because the straight lines AB and DC are equal), the whole arc BAD will equal the whole arc BCD, and the whole arc ADC will equal the whole arc ABC; and accordingly, when the straight lines BD and AC are drawn, BAD, BCD, ADC, and ABC will be semicircles. Therefore [Margin: b — Elem. III.31] the angles of the quadrilateral will be right. Which was proposed.

Theorem 28. Proposition 32.

[Margin: xxxj — Elem. III.31;]

[*Euclid, Elements III.32 — enunciation.*] If a straight line touches a circle, and from the point of contact a straight line is drawn cutting the circle, then the angles which it makes with the tangent are equal to the angles standing in the alternate segments of the circle.

Diagram — first (upper) figure. The straight tangent line runs A — C — B horizontally across the top, touching the circle at C. Within the circle, D is on the left circumference and G on the right; E is at the bottom, diametrically opposite C, so that CE is a diameter. Straight lines CD, CG, DE, and GE are drawn.

- A (left of tangent): one end of the tangent
- C (tangent point): point of contact
- B (right of tangent): other end of the tangent
- E (bottom): far end of the diameter CE
- D (left circumference): vertex of angle CDE
- G (right circumference): vertex of angle CGE

Diagram — second (lower) figure. Again the tangent A — C — B runs across the top, touching at C. D is on the left circumference, G on the right, E at the lower left, and F at the bottom. Here CE does not pass through the center; CF is the diameter (drawn through the center to F), and EF is joined. Straight lines CD, CG, CE, EF, DE, and GE are drawn.

- A (left of tangent): one end of the tangent
- C (tangent point): point of contact

- B (right of tangent): other end of the tangent
- F (bottom): far end of the diameter CF, drawn through the center
- E (lower left circumference): point on the chord CE
- D (left circumference): vertex of angle CDE
- G (right circumference): vertex of angle CGE

Let the straight line AB touch the circle CDE at the point C, and from C let the straight line CE be drawn, dividing the circle into two segments in which the angles CGE and CDE are formed. I say that angle ACE is equal to angle CGE in the alternate segment, and that angle BCE is equal to angle CDE in the other alternate segment.

First let the straight line CE pass through the center, as in the first figure. [Margin: a — Elem. III.18] Then each angle ACE and BCE will be right; [Margin: b — Elem. III.31] and the angles CGE and CDE, being in semicircles, are also right. Therefore angle ACE is equal to angle CGE, and angle BCE to angle CDE.

Now let CE not pass through the center, as in the latter figure. Then let the straight line CF be drawn through the center, and let the straight line EF be joined. [Margin: c — Elem. III.18] Then CF will be perpendicular to AB, [Margin: d — Elem. III.31] and angle CEF will be right; and therefore the remaining angles ECF and EFC will together equal one right angle — equal to the right angle ACF. So when the common angle ECF is taken away, the remaining angle ACE will equal the remaining angle CFE. [Margin: e — Elem. III.21] But angle CGE is also equal to angle CFE, since both are in the segment CGE. Therefore angle ACE will equal angle CGE. And since in the quadrilateral CDEG [Margin: f — Elem. III.22] the two angles CDE and CGE are equal to two right angles, [Margin: g — Elem. I.13] and the two angles ACE and BCE are also equal to two right angles, then if the equal angles ACE and CGE are taken away, the remaining angle BCE will equal angle CDE. Therefore, if a straight line touches a circle, and from the point of contact, etc. Which was to be shown.

Book III (continued)

Scholium [to Proposition 32]

[Clavius's scholium, giving the converse of the tangent-chord theorem.]

This theorem can be converted, as follows.

[Converse — enunciation.] If a straight line drawn to the extremity of a line that cuts the circle makes with it angles equal to those which stand in the alternate segments of the circle, then the drawn line will be tangent to the circle.

[Demonstration.] In the same figure as before, let the straight line CE first pass through the center, cutting the circle CDE, and let the straight line AB be drawn through C, making the angle ACE equal to the angle CGE. I say that AB touches the circle. Since [Margin: (h) III.31] the angle CGE is a right angle, the angle ACE, being equal to it, will also be a right angle. Therefore, by the corollary to Proposition 16 of this book, AB touches the circle.

Now let CE not pass through the center, and let the latter figure be constructed, as above. Since, then, the angle ACE is assumed equal to the angle CGE in the alternate greater segment, and [Margin: (i) III.21] this in turn is equal to the angle CFE, the angle ACE will also be equal to the angle CFE. Adding therefore the common angle ECF, the angle ACF will equal the two angles EFC and ECF taken together. But the angles EFC and ECF are equal to one right angle, because [Margin: (k) III.31] the angle CEF, being in a semicircle, is a right angle, and [Margin: (l) I.32] the three angles of the triangle CEF are equal to two right angles. The angle ACF is therefore also a right angle; and so, by the corollary to Proposition 16 of this book, AB touches the circle.

In the same way, if the angle BCE is equal to the angle CDE in the alternate lesser segment, the straight line AB will be shown to touch the circle. For since [Margin: (m) I.13] the angles BCE and ACE are equal to two right angles, and likewise [Margin: (n) III.22] the two angles CDE and CGE are equal to two right angles, then if the equal angles BCE and CDE are subtracted, the remaining angles ACE and CGE will be equal. Therefore, as has now been demonstrated, the straight line AB touches the circle.

PROBL. 5. PROPOSITIO 33.

[Margin: xxxij]

[Euclid — enunciation.] On a given straight line to describe a segment of a circle admitting an angle equal to a given rectilineal angle.

[Demonstration.]

First case (the given angle is a right angle). Let the given straight line be AB, and let the given angle first be the right angle C. It is required, then, to describe on AB a segment in which the angle standing will be equal to the given right angle C.

Bisect AB at D, and with center D and radius DA (or DB) describe the semicircle AEB; and what was proposed will be done. For [Margin: (a) III.31] the angle AEB in the semicircle so described is a right angle, and therefore equal to the right angle C.

Diagram. The construction for the right-angle case of Proposition 33. At the far left stands the given right angle, marked C, drawn as two perpendicular arms. To its right, a semicircle is erected on the diameter AB; its apex on the arc is E.

- C (far left): vertex of the given right angle.
- A (left end of the diameter): endpoint of the given line.
- D (midpoint of AB): center of the semicircle.
- B (right end of the diameter): other endpoint of the given line.
- E (apex on the arc): vertex of the inscribed right angle AEB.

Second case (the given angle is acute). Next let the given angle C be acute. At the point A make the angle DAB equal to the acute angle C; and draw AE perpendicular to DA, which will fall above AB. Then make the angle FBA equal to the angle FAB, and let BF cut the straight line AE at F. [Margin: (b) I.6] The straight lines FA and FB will then be equal. Hence, if with center F and radius FA a circle AGB is described, it will pass through B. I say, then, that the angle in the segment AGB, which has been described on AB, is equal to the angle C. For let an angle be made in the said segment AGB. Since AE passes through the center F, and DA is perpendicular to it, the straight line DA touches the circle at A, by the corollary to Proposition 16 of this book. Therefore [Margin: (c) III.32] the angle DAB — that is, the given angle C — will be equal to the angle G in the alternate segment AGB.

Third case (the given angle is obtuse). Third, let the given angle H be obtuse. Again make the angle IAB equal to the angle H, and draw AE perpendicular to IA, which will fall above AB. Let everything else be done as before; and there will be described on AB the segment AKB, in which the angle K is equal to the given obtuse angle H. For the angle IAB — that is, the given angle H — is [Margin: (d) III.32] equal to the angle K in the alternate segment AKB. The demonstration is the same. Thus on the given straight line we have described the segment, and so forth. Which was to be accomplished.

Diagram. The construction for the acute and obtuse cases of Proposition 33, combined in one circle with center F. The chord AB is drawn, with the tangent line passing through A (the point D lies on it below-left, the point I on its extension above-left, for the obtuse case). The major arc carries the point G (segment AGB), the minor arc the point K (segment AKB). At the far left the given

angles are set out (the acute angle and the obtuse angle H). Several small peripheral labels are hard to resolve even at high magnification.

- G (top, major arc): vertex of the inscribed angle for the acute case, segment AGB.
- E (interior, on the perpendicular AE): point where BF meets AE.
- F (center): center of the constructed circle.
- A (left end of chord): tangent point / endpoint of AB.
- B (right end of chord): other endpoint of AB.
- D (lower-left, on the tangent line): point of the tangent DA.
- I [?] (upper-left, on the tangent extended): point of the line IA for the obtuse case.
- K [?] (bottom, minor arc): vertex of the inscribed angle for the obtuse case, segment AKB.
- H [?] (far left): vertex of the given obtuse angle.

[— 3 peripheral labels flagged.]

PROBL. 6. PROPOS. 34.

[Margin: xxxiij]

[Euclid — enunciation.] From a given circle to cut off a segment admitting an angle equal to a given rectilineal angle.

[Demonstration.] Let the given circle be ABC, from which a segment must be cut off in which the angle standing is equal to the given angle D. [Margin: (a) III.17] Draw the straight line EF touching the circle at A. Then make the angle FAB equal to the given angle D. I say, then, that the angle ACB in the cut-off segment ACB is equal to the given angle D. For [Margin: (b) III.32] the angle FAB is equal to the angle C in the alternate segment ACB. Since, then, the angle FAB has been made equal to the given angle D, the angle C will also be equal to the angle D. From the given circle, therefore, we have cut off the segment ACB, and so forth. Which was to be done.

Diagram. To the left stands the given rectilineal angle D (an open V-shape). To the right is the circle carrying the cut-off segment: the tangent line EF touches it at A (top), the chord AB is drawn, and C lies on the arc of the segment ACB.

- D (left): vertex of the given angle.
- A (top, tangent point): where EF touches the circle.

- C (left of circle, on the arc): vertex of the inscribed angle ACB.
- B (lower right, on the circle): other end of the chord.

(The tangent's endpoints E and F, named in the text, are not separately lettered near the point of contact on this small cut; only A, B, C, D are legible.)

THEOR. 29. PROPOS. 35.

[Margin: xxxiv]

[Euclid — enunciation.] If in a circle two straight lines cut one another, the rectangle contained by the segments of the one is equal to the rectangle contained by the segments of the other.

[Demonstration.] In the circle ACBD let the straight lines AB and CD cut one another at E. I say that the rectangle contained by the segments AE and EB is equal to the rectangle contained by the segments CE and ED. For either both lines pass through the center, or one only, or neither.

First case (both pass through the center). Let both first pass through the center. Since, then, all four segments are equal to one another, it is plain that the rectangle contained by the two segments of one line is equal to the rectangle contained by the two of the other line, from what we wrote at the beginning of Book II.

Diagram. A circle in which two diameters AB and CD cross at the center E.

- A (top left): end of one diameter.
- D (top right): end of the other diameter.
- E (center): intersection of the diameters.
- C (bottom left): other end of CD.
- B (bottom right): other end of AB.

Second case (only CD passes through the center, bisecting AB). Next let CD alone pass through the center F, and let it first bisect the straight line AB — [Margin: (a) III.3] and therefore at right angles — and let the straight line BF be joined. Since, then, CD is divided into equal parts at F and into unequal parts at E, [Margin: (b) II.5] the rectangle contained by CE and ED, together with the square on EF, will be equal to the square on FD, and therefore to the square on FB, since FD and FB are equal. But the square on FB is [Margin: (c) I.47] equal to the squares on FE and EB. Therefore the rectangle contained by CE and ED, together with the square on EF, will also be equal to the squares on FE and EB. So, when the common square

on FE is taken away, the rectangle contained by CE and ED will remain equal to the square on EB — that is, to the rectangle contained by AE and EB, since AE and EB are equal; and consequently the rectangle contained by them is a square, from what we wrote regarding Definition 1 of Book II.

Diagram. A circle with the diameter CD (vertical) through the center F, and the chord AB (horizontal) which it bisects at E; the triangle FEB is drawn.

- C (top): upper end of the diameter.
- F (center): center of the circle.
- A (left, on the chord): left end of AB.
- E (on AB, at the crossing): foot where CD meets AB.
- B (right, on the chord): right end of AB.
- D (bottom): lower end of the diameter.

Third case, part a (CD passes through the center but does not bisect AB). Now let CD, passing through the center, divide the straight line AB, but not into two equal parts. Let AB therefore be bisected at G, and let the straight lines FG and FB be drawn; [Margin: (d) III.3] and FG will be perpendicular to AB. Now since the rectangle contained by CE and ED, together with the square on FE, [Margin: (e) II.5] is equal to the square on FD — that is, to the square on FB — and the square on FE is [Margin: (f) I.47] equal to the squares on FG and GE, while the square on FB is equal to the squares on FG and GB: the rectangle contained by CE and ED, together with the squares on FG and GE, will also be equal to the squares on FG and GB. So, when the common square on FG is removed, the rectangle contained by CE and ED, together with the square on GE, will remain equal to the square on GB. But the rectangle contained by AE and EB, together with the square on GE, [Margin: (g) II.5] is also equal to the same square on GB, because the straight line AB is bisected at G and cut unequally at E. Therefore the rectangle contained by CE and ED, together with the square on GE, is equal to the rectangle contained by AE and EB, together with the square on the same line GE. Hence, when the common square on GE is taken away, the rectangle contained by CE and ED will remain equal to the rectangle contained by AE and EB. Which was proposed.

Diagram. Two circles side by side (mirror-image variants of the same construction). In each: the diameter CD (C at top, D at bottom) passes through the center F; the chord AB is cut by CD at E and bisected at G, with radii FG and FB drawn.

- C (top of each): upper end of the diameter.
- D (bottom of each): lower end of the diameter.

- F (center of each): center of the circle.
- A (left/right end of the chord): one end of AB.
- B (opposite end of the chord): other end of AB.
- G (on the chord): midpoint of AB.
- E (on the chord): where CD crosses AB.

Third case, part b (neither passes through the center). Third, let neither pass through the center — whether one of them is bisected [by a diameter] or neither. Let the straight line GH be drawn through the center F and the point of section E. Since, then, it has been shown that the rectangle contained by AE and EB is equal to the rectangle contained by GE and EH, whether AB is bisected or not; and likewise that the rectangle contained by CE and ED is also equal to the same rectangle contained by GE and EH, whether CD is bisected or not: the rectangle contained by AE and EB will be equal to the rectangle contained by CE and ED. Which was proposed. If, then, in a circle two straight lines cut one another, and so forth. Which was to be demonstrated.

Diagram. Two small circles (variant configurations) for the case in which neither chord passes through the center. In each, the auxiliary diameter GH is drawn through the center F and the crossing-point E; the two given chords are AB and CD. The labels are very small even at high magnification.

- G (top): one end of the auxiliary diameter.
- H (bottom): other end of the auxiliary diameter.
- F (center): center of the circle.
- E (interior, crossing point): intersection of the two chords.
- A [?], B [?] (on the circle): ends of one chord.
- C [?], D [?] (on the circle): ends of the other chord.

[— small clustered labels, several flagged.]

Scholium

[Clavius's scholium, giving the converse of Proposition 35.]

This theorem can be converted, as follows.

[Converse — enunciation.] If two straight lines cut one another in such a way that the rectangle contained by the segments of the one is equal to the rectangle contained by the segments of the other, then a circle can be described through

the four extreme points of those lines — that is, a circle described through any three of their extreme points will also pass through the fourth.

[Proof.] Let the straight lines AB and CD cut one another at E, and let the rectangle contained by AE and EB be equal to the rectangle contained by CE and ED. I say that the four points A, D, B, C fall on the circumference of a circle — that is, a circle can be described through them — so that a circle described through the three points A, D, B necessarily passes through the point C as well. For let some circle be described through the three points A, D, and B (how this is done we shall show at Proposition 5 of Book IV); and if it does not pass through C, it will pass either beyond C or short of it, as through F. Since, then, the rectangle contained by FE and ED [Margin: (h) III.35] is equal to the rectangle contained by AE and EB, and the rectangle contained by CE and ED is also assumed equal to the same rectangle contained by AE and EB, the rectangles contained by CE, ED and by FE, ED will be equal — a part and a whole; which is absurd. Therefore the circle will pass through the point C. Which was proposed.

Diagram. A circle with two chords AB and CD crossing at E; the point F (the alternative intersection of the described circle with CD) is marked near C.

- C (upper left, on the circle): end of one chord.
- F (on CD, near C): the point where an incorrectly-placed circle would meet CD.
- A (left): end of chord AB.
- E (interior): crossing point of the chords.
- B (right): other end of AB.
- D (bottom): other end of CD.

THEOR. 30. PROPOS. 36.

[Margin: xxxv]

[Euclid — enunciation.] If some point is taken outside a circle, and from it two straight lines fall on the circle, of which one cuts the circle and the other touches it: the rectangle contained by the whole secant and the part of it taken outside, between the point and the convex circumference, will be equal to the square described on the tangent.

[Demonstration.]

First case (the secant passes through the center). Outside the circle ABC let the point D be taken, from which the line DA is drawn cutting the circle at C, [Margin:

(a) III.17] and the line DB touching the circle at B. I say that the rectangle contained by DA and DC is equal to the square on DB. For let the straight line DA first pass through the center E, and let EB be joined, [Margin: (b) III.18] which will be perpendicular to DB. Since, then, CA is bisected at E, and CD is added to it in a straight line and continuously, [Margin: (c) II.6] the rectangle contained by DA and DC, together with the square on EC — that is, with the square on EB — will be equal to the square on DE. But the square on DE is [Margin: (d) I.47] equal to the squares on EB and BD. Therefore the rectangle contained by DA and DC, together with the square on EB, will be equal to the squares on DB and BE. So, when the common square on EB is taken away, the rectangle contained by DA and DC will remain equal to the square on DB. Which was proposed.

Second case (the secant does not pass through the center). Now let DA, the secant, not pass through the center E. Let AC therefore be bisected at F, and let the straight lines EB, EC, ED, EF be drawn; [Margin: (e) III.18] and EB will be perpendicular to BD, [Margin: (f) III.3] and EF to AC. Since, then, CA is bisected at F, and the straight line CD is added to it, [Margin: (g) II.6] the rectangle contained by DA and DC, together with the square on CF, will be equal to the square on DF. Adding, then, the common square on FE, the rectangle contained by DA and DC, together with the squares on CF and FE, will be equal to the squares on DF and FE. But the squares on CF and FE are [Margin: (h) I.47] equal to the square on EC, and therefore also to the square on EB; and [Margin: (i) I.47] the squares on DF and FE are equal to the square on DE. Therefore the rectangle contained by DA and DC, together with the square on EB, will be equal to the square on DE. Since, then, the square on DE [Margin: (k) I.47] is equal to the squares on DB and BE, the rectangle contained by DA and DC, together with the square on EB, will also be equal to the squares on DB and BE. So, when the common square on BE is taken away, the rectangle contained by DA and DC will remain equal to the square on DB. Which was proposed. If, then, some point is taken outside a circle, and so forth. Which was to be demonstrated.

Diagram. The first case of Proposition 36: the secant passes through the center. From the external point D (upper right) the secant runs through C and the center E to A (bottom); the tangent DB touches the circle at B (upper left), with the radius EB drawn.

- D (upper right, external): the point taken outside the circle.
- B (upper left, tangent point): where DB touches the circle.
- C (on the circle, near the secant's entry): nearer intersection of the secant.
- E (center): center of the circle.

- A (bottom): farther intersection of the secant.

Diagram. The second case (secant not through the center), shown in two side-by-side circles. From the external point D the secant cuts the circle at C and A; the tangent DB touches at B; the center is E, with F the midpoint of AC and the radii EB, EC, ED, EF drawn.

- D (top, external): the external point.
- B (upper left, tangent point): where the tangent touches.
- C (on the circle): nearer intersection of the secant.
- A (left, on the circle): farther intersection of the secant.
- E (center): center of the circle.
- F (on AC): midpoint of AC.

First case (secant through center) and second case (secant not through center) are both illustrated; F appears in the right-hand figure.

COROLLARIUM I

It is clear from this that, if from any point taken outside a circle very many straight lines are drawn cutting the circle, the rectangles contained by the whole lines and their outer parts are equal to one another. For example, if from A the straight lines AC, AD, AE are drawn cutting the circle at F, G, H, the rectangles contained by AC, AF; likewise by AD, AG; and by AE, AH, will be equal to one another. For, when AB is drawn touching the circle, [Margin: (l) III.36] each of those rectangles will be equal to the square on AB; and therefore they will all be equal to one another as well.

Diagram. From the external point A (top) a tangent AB and three secants AC, AD, AE are drawn to the circle. The secants cut the near arc at F, G, H and reach the far points C, D, E; B is the tangent point.

- A (top, external): the external point.
- B (upper left, tangent point): where AB touches the circle.
- F [?], G [?], H [?] (clustered on the near/upper arc): the nearer intersections of the three secants.
- C (left, on the circle): far intersection of one secant.
- D (bottom, on the circle): far intersection of another secant.
- E (lower right, on the circle): far intersection of the third secant.

[— the cluster F, G, H is hard to resolve.]

COROLLARIUM II

It is also established that two straight lines drawn from the same point and touching a circle are equal to one another. For let AB and AC be drawn from A, touching the circle; I say that these are equal to one another. For when the straight line AD is drawn cutting the circle at E, both the square on AB and the square on AC will be [Margin: (m) III.36] equal to the rectangle contained by AD and AE. Therefore the squares on AB and AC will be equal to one another, and consequently the straight lines AB and AC will also be equal.

Diagram. From the external point A (top) two tangents AB and AC touch the circle, and the secant AD cuts it at E.

- A (top, external): the external point.
- B (left, tangent point): where AB touches.
- E (interior, on the secant): nearer intersection of AD.
- C (right, tangent point): where AC touches.
- D (bottom, on the circle): farther intersection of AD.

COROLLARIUM III

It is likewise evident that from the same point taken outside a circle only two lines can be drawn touching the circle. For if, besides the two AB and AC, a third AD could be drawn touching the same circle, then, when the straight lines EB and ED are drawn from the center E, [Margin: (n) III.18] the angles ABE and ADE would be right angles, and therefore equal; which is absurd. For if the straight line AE is drawn, [Margin: (o) I.21] the angle ADE will be greater than the angle ABE.

Otherwise: if a third line AD also touches the circle, then the two tangents AB and AD will be equal, as was shown; which is absurd. For when the straight line AE is drawn to the center E, cutting the circle at F, [Margin: (p) III.8] AD, being nearer to the least line AF, will be less than AB, which is farther from the least line AF. Or thus: if AB and AD are equal, then, adding the equals EB and ED, AB and BE will also be equal to AD and DE; which is absurd, [Margin: (q) I.21] for AB and BE are greater. Therefore only two straight lines can be drawn from the point A touching the circle. Which was proposed.

Diagram. From the external point A (top) the tangents AB and AC touch the circle, and the line AE runs to the center E, cutting the circle at F; D marks the assumed third point of contact. The radii EB and ED are drawn.

- A (top, external): the external point.
- F (interior, on AE): where AE cuts the circle.
- D (interior, left): the assumed third tangent point.
- B (left, tangent point): where AB touches.
- C (right, tangent point): where AC touches.
- E (center): center of the circle.

Euclid's *Elements*, Book III — conclusion (Prop. 36 scholia; Prop. 37) → Book IV (Definitions)

[Printed p. 148 — running header: EVCLID. GEOM.]

COROLLARIUM IV. [Corollary IV — continuing the corollaries of Prop. 36]

Finally, this too is established: if two equal straight lines fall from some point onto the convex circumference, and one of them is tangent to the circle, then the other is tangent to the circle as well. For example, if the two straight lines AB and AC in the preceding figure are equal, and AC is tangent to the circle at C, then AB will likewise be tangent to the same circle at B. For if it is not tangent, let AD be drawn tangent — since two tangents can always be drawn from the same point, as is clear from the scholium of Prop. 31 of this book — and then, by the second corollary, AC and AD will be equal. Since, therefore, AB too is assumed equal to AC, three equal straight lines AB, AC, AD would be drawn, which is absurd. For only two can be drawn.

[Margin: reference letter *r*, marginal citation partly illegible [?]]

ALITER. [An alternative demonstration]

In the figure of the following proposition, let there be two equal straight lines DB and DF, and let DB be tangent to the circle at B. I say that DF too is tangent to the same circle at F. For when the straight lines EB and EF have been drawn from the center, the two sides DB, BE will be equal to the two sides DF, FE, and the base DE is common. [Margin: I.8 (ref. s)] Therefore the angles B and F will be equal.

[Margin: III.18 (ref. t)] But B is a right angle. Therefore F too will be a right angle, and for that reason DF will be tangent to the circle at F, by the corollary of Prop. 16 of this book.

SCHOLIUM. [Scholium to Prop. 36]

We shall demonstrate this proposition with the greatest ease by means of the preceding proposition, in this way.

Diagram. A figure showing an external point A with two concentric-drawn circles (an inner circle BCD and an outer circle AKL sharing the region), a tangent AB, and two secants (AE through the center, and AN not through the center), used for the demonstration below. Points read off the scan under magnification, with position and role where the text makes it plain:

- A (top): the external point from which the tangent and secants are drawn
- K (upper left): on the outer circle AKL
- M (upper right, small): on the tangent/chord near L
- L (right): on the outer circle AKL
- O (left): on the outer circle AKL
- C (center-left): point where the second secant AN meets the inner circle
- D (center): point where the first secant AE meets the inner circle
- B (center-right): point of tangency of AB on the inner circle
- F (center, below C–D): the center of the circle(s)
- N (lower left, inside): on secant AN
- I (right): endpoint on the outer circle after producing AB
- G (lower left, on outer circle): endpoint after producing AN
- E (lower center): endpoint of the first secant on the inner circle
- H (bottom): endpoint of AE produced on the outer circle

From the point A, outside the circle BCD, let the tangent AB and the secant AE be drawn, the secant first passing through the center F and cutting the circumference at D. I say that the rectangle contained by AE, AD is equal to the square on AB. For when a circle AKL has been described from F through A, let AE and AB be produced as far as H and I, and through D let the perpendicular KL be drawn to AH, which will be tangent to the same circle BCD at D, by the corollary of Prop. 16 of this book. And from what has been demonstrated in the scholium of Prop. 3 [?] of this book, AD and HE will be equal; and therefore, with the common DE added, AE and HD will also be equal. Likewise, from the scholium of Prop. 18 of this book, AI and KL will be equal, and they will be bisected at B and D; and therefore the rectangles contained by AB, BI and by KD, DL will be equal to each other — indeed they will be squares, because of the equality of the lines AB, BI, KD, DL. And so, since the rectangle contained by HD, DA — that is, the rectangle

contained by AE (which was shown equal to HD) and AD — [Margin: III.35 (ref. *u/a* [?])] is equal to the rectangle contained by KD, DL, that is, to the rectangle contained by AB, BI, or the square on AB, the proposition is established.

But now let the secant line AN not pass through the center F, and let it cut the circumference at C. I say again that the rectangle contained by AN, AC is equal to the square on AB. For, again, when a circle AKL has been described from F through A, let AN and AB be produced as far as G and I, and through C let OM be drawn tangent to the circle BCD. Then, from the scholium of Prop. 3 [?] of this book, AC and GN will be equal; and therefore, with the common CN added, AN and GC will be equal. Likewise, from the scholium of Prop. 18 of this book, AI and OM will be equal, and they will be bisected at B and C; and therefore the rectangles contained by AB, BI and by OC, CM will be equal to each other — indeed squares — because of the equality of the lines AB, BI, OC, CM. And so, since the rectangle contained by GC, CA — that is, the rectangle contained by AN (which was shown equal to GC) and AC — [Margin: III.35 (ref. *x*)] is equal to the rectangle contained by OC, CM, that is, to the rectangle contained by AB, BI, or the square on AB, once again what was proposed is established.

We shall also convert the first corollary of this proposition in roughly the following way.

[Converse theorem] If two finite straight lines go out from some point, and are cut into two parts in such a way that the rectangles contained by the wholes and the segments near the point are equal, then a circle can be described through the extreme points of the other segments — that is, a circle described through three of the extreme points of the other segments will also pass through the fourth extreme point.

Diagram. A circle with an apex point A above it, from which two lines descend to B and C on the circle; the segments are cut at interior points, with F marked as the alternative (false) intersection.

- A (top): the external point from which AB and AC go out
- D (upper, on AB): a cut point; note that **two "D" labels appear printed near the top of chord AB** [?] (apparently D the cut point and a second D near the circle)
- F (between the two D's): the alternative point (short of D) used for the *reductio*
- E (right, on AC): the other cut point
- B (bottom-left, on circle): extreme point

- C (right, on circle): extreme point

For let two straight lines AB, AC go out from the point A, cut at the points D, E in such a way that the rectangles contained by AB, AD and by AC, AE are equal. I say that the four points B, C, E, D fall on the circumference of a circle — that is, a circle can be described through them — so that a circle described through the three points B, C, E necessarily passes through the remaining point D as well. For let a circle BCE be described through the three points B, C, E (as we shall teach at Prop. 5 of Book 4); and if it be said not to pass through the fourth point D, it will pass either short of D or beyond, as through F. Since, then, the rectangle contained by AB, AF is equal, by the first corollary of this proposition, to the rectangle contained by AC, AE, and the rectangle contained by AB, AD is assumed equal to the same rectangle contained by AC, AE, the rectangles contained by AB, AF and by AB, AD will be equal to each other — a part and the whole — which is absurd. Therefore the circle passes through the point D. Which was to be demonstrated.

It will also be permissible to gather from what has been demonstrated in this proposition a problem of the following kind.

[Problem] Given two straight lines, whether equal or unequal, to adjoin a straight line to one of them, so that the rectangle contained by the whole composite line and the adjoined line is equal to the square of the other.

Diagram. On the left, a vertical line marked (top to bottom) G, B, D, A, with a short separate segment C beside A; on the right, a circle with center A through which the construction is carried out.

- G (top of the line / on the circle, upper right): the extreme point of the adjoined part
- E (top, apex, outside the circle): endpoint of the perpendicular DE
- B (on the line AB): the point to which BG is adjoined
- D (midpoint of AB / on the circle at left): the bisection point
- A (bottom of the line / center of the circle): the center
- C (short segment near A): the given line C
- F (bottom of the circle): endpoint of the secant EF through the center

Let two straight lines AB and C be given, and let a line be adjoined to AB, the smaller, so that the rectangle contained by the whole composite line and the adjoined line is equal to the square of the line C, the larger. Let AB be bisected at D, and with center A [reading of the qualifier "from any center" uncertain [?]] and

radius AD, the half, let a circle DFG be described; and at D let a perpendicular DE be erected to AD, equal to C; and finally, from E through the center A, let the straight line EF be extended, cutting the circumference at G. I say that, if to the line AB there is added BG equal to EG, the rectangle contained by the whole AG and GB is equal to the square of the line C. For since the rectangle contained by FE, EG [Margin: III.36 (ref. y [?])] is equal to the square of the line ED (because ED is tangent to the circle at D, by the corollary of Prop. 16 of this book); and the rectangle contained by FE, EG is equal to the rectangle contained by AG, GB (because the lines FE, EG are equal to the lines AG, GB — for GB was taken equal to EG, and AB was assumed equal to FG); and the square on ED is equal to the square on C (because of the equality of the lines ED and C by construction): therefore the rectangle contained by AG, GB too will be equal to the square on C. Which is what was proposed.

The proposition will be demonstrated in no different way if a line is to be adjoined to C, the larger, so that the rectangle contained by the whole composite line and the adjoined line is equal to the square of the line AB, the smaller.

[Printed p. 149 — running header: LIBER III.]

THEOR. 31. PROPOS. 37.

[Outer-margin numeral: xxxvj (= 36; probably a slip for xxxvij / Euclid III.37 — see report)]

[Enunciation] If some point is taken outside a circle, and from that point two straight lines fall onto the circle, one of which cuts the circle while the other meets it; and if the rectangle contained by the whole secant together with the part assumed outside — between the point and the convex circumference — is equal to the square described on the line that meets the circle: then the line that meets it will be tangent to the circle.

Diagram. Two side-by-side figures for the two cases of the proof (the secant through the center, and the secant not through the center). In each, an external point D lies above a circle, with a tangent DF, a secant DA cutting the circle at C, and radii drawn to the center E.

- D (top): the external point
- B (upper left, on the circle): the point of tangency of DB (the line "meeting" the circle)
- C (upper middle, on the circle): where the secant DA cuts the circle
- F (right, on the circle): the point of tangency of the auxiliary tangent DF

- E (center): the center of the circle
- A (bottom left, on the circle): the far intersection of the secant

Outside the circle ABC, whose center is E, let a point D be taken, from which let the straight line DA be drawn cutting the circle at C, and the straight line DB meeting the circle at the point B; and let the rectangle contained by DA, DC be equal to the square on the line DB. I say that DB is tangent to the circle at B. [Margin: III.17 (ref. *a*)] For let DF be drawn tangent to the circle, and let the straight lines EB, EF be joined. And if the secant DA does not pass through the center E, let the straight line DE also be joined. Since, then, the square on the tangent DF [Margin: III.36 (ref. *b*)] is equal to the rectangle contained by DA, DC, and the square on the line DB is assumed equal to the same rectangle contained by DA, DC, the squares on the lines DF, DB will be equal to each other, and therefore the lines DF, DB will also be equal to each other. And so, since the sides DF, FE of the triangle DFE are equal to the sides DB, BE of the triangle DBE, and the base DE is common, [Margin: I.8 (ref. *c*)] the angles DFE, DBE will be equal. [Margin: III.18 (ref. *d*)] But the angle DFE is a right angle, because DF is tangent to the circle. Therefore the angle DBE too will be a right angle. And for that reason, by the corollary of Prop. 16 of this book, DB will be tangent to the circle — which is what was proposed. If, therefore, some point is taken outside a circle, and so on. Which was to be demonstrated.

SCHOLIUM. [Scholium to Prop. 37]

This theorem is, as is plain, the converse of the preceding theorem. It is worthwhile to demonstrate here the following theorem as well.

[Theorem] If from a given point outside a circle two straight lines are drawn tangent to the circle — or two lines drawn as far as the convex circumference and equal to each other — then the straight line projected from that same point through the center of the circle bisects the angle contained by them. And conversely, the straight line that bisects the angle contained by them will pass through the center of the circle.

In the first figure of this proposition, let the two lines DB, DF be tangent to the circle ABCF at the points B, F — points which, by the second corollary of the preceding proposition, will be equal [in their tangent lengths] — or else let any two equal lines DB, DF be drawn. And through the center E let the straight line DEA be drawn. I say that the angle BDF is bisected by the line DA. For, when the straight lines EB, EF have been joined, since the two sides BD, DE are equal to the

two sides FD, DE, and the base EB is equal to the base EF, [Margin: I.8 (ref. *e*)] the two angles at D will be equal to each other. Which is what was proposed.

Now let the straight line DA bisect the angle BDF. I say that the line DA passes through the center. For if the center is not on DA, let the center E be outside it, and let the straight line ED be joined, as in the later figure of this proposition. Then, as has been demonstrated, the line ED will bisect the angle BDF; and consequently the angles BDA, BDE, being the halves of the angle BDF, will be equal to each other — a part and the whole — which is absurd. Therefore the line DA passes through the center. Which was to be demonstrated.

[Printed p. 150 — chapter opening; no running header]

EVCLIDIS ELEMENTVM QVARTVM. [Euclid's Fourth Book of the Elements]

DEFINITIONES. [Definitions]

I.

A rectilinear figure is said to be inscribed in a rectilinear figure when the individual angles of the figure that is inscribed touch the individual sides of the figure in which it is inscribed.

[Commentary] In treating, in this fourth book, of the various inscriptions of rectilinear figures within a circle and of their circumscriptions about a circle — likewise of the inscriptions of a circle within those same figures and of the descriptions of a circle about them — Euclid sets out in a few definitions what it is for a figure to be inscribed in a figure, or to be described about a figure, beginning with rectilinear figures. Thus, if the angles D, E, F of the inner triangle DEF touch the sides AB, AC, BC of the outer triangle ABC, the triangle DEF will be said to be inscribed in the triangle ABC. But since the angle M of the triangle KLM does not touch the side HI of the triangle GHI, the triangle KLM will not be said to be inscribed in the triangle GHI — even though it lies wholly within it and its two angles K, L touch the two sides GH, GI.

Diagram. Two triangle figures illustrating inscription. Left: an outer triangle ABC with an inner triangle DEF whose vertices touch the sides. Right: an outer triangle GHI with an inner triangle KLM whose vertex M does not reach the side HI.

- A (top), B (bottom-left), C (bottom-right): vertices of the outer triangle (left figure)
- D (left, on AB), E (right, on AC), F (bottom, on BC): vertices of the inscribed triangle
- G (top), H (bottom-left), I (bottom-right): vertices of the outer triangle (right figure)
- K (left), L (right), M (bottom-center, not touching HI): vertices of the interior triangle

II.

Similarly, a figure is said to be described about a figure when the individual sides of the figure that is circumscribed touch the individual angles of the figure about which it is described.

[Commentary] Conversely, the triangle ABC will be said to be described about the triangle DEF, since its individual sides touch the individual angles of the latter. But the triangle GHI will not be said to be described about the triangle KLM, because its side HI does not touch the angle M of the latter. The same is to be understood of the inscriptions and circumscriptions of other rectilinear figures. Moreover, rectilinear figures are, properly speaking, said to be described within rectilinear figures, and to be described about them, when the inscribed and circumscribed figures have their sides equal in number and their angles equal in number — although this is not altogether necessary, since a square can also be described within a triangle, as we shall teach toward the end of Book 6.

III.

A rectilinear figure is said to be inscribed in a circle when the individual angles of the figure that is inscribed touch the circumference of the circle.

[Commentary] Thus, if the angles A, B, C of the triangle ABC touch the circumference of the circle ABC, the triangle will be said to be inscribed in the circle. But if even one only of the angles did not touch the circumference, the triangle would not be said to be inscribed in the circle.

Diagram. A circle with an inscribed triangle ABC, its three vertices touching the circumference.

- A (top): vertex on the circumference
- B (lower left): vertex on the circumference
- C (lower right): vertex on the circumference

IV.

A rectilinear figure, on the other hand, is said to be described about a circle when the individual sides of the figure that is circumscribed touch the circumference of the circle.

Euclid's *Elements*, Book IV (continued)

Definitions (continued)

Definition IV (conclusion). But if the sides of triangle ABC each touch the circumference of circle DEF, the triangle will be said to be described about the circle.

V.

Similarly, a circle too is said to be inscribed in a rectilinear figure when the circle's circumference touches each of the sides of the figure in which it is inscribed.

VI.

A circle, moreover, is said to be circumscribed about a figure when the circle's circumference touches each of the angles of the figure about which it is described.

Clavius's note. Conversely, in the figure of Definition 4 the circle DEF will be said to be inscribed in the triangle ABC; whereas in the figure of Definition 3 the circle ABC will be said to be circumscribed about the triangle ABC. Make the same judgment about the other rectilinear figures that are said to be inscribed in a circle or circumscribed about one, or in which a circle is said to be inscribed, or about which a circle is said to be described.

Diagram. A triangle with an inscribed circle, illustrating Definitions 4–6.

- A (top vertex): apex of the triangle
- B (bottom-left vertex)
- C (bottom-right vertex)
- D (on side AB, upper-left): tangent point of the circle
- E (on base BC, bottom): tangent point
- F (on side AC, upper-right): tangent point

VII.

A straight line is said to be *fitted* [accommodari] or *adapted* [coaptari] in a circle when its extremities lie on the circumference of the circle.

Clavius's note. For example, the straight line AB, since its extremities A and B lie on the circumference of circle ABC, will be said to be adapted or fitted in the said circle; but not the line E, nor CD, because the latter [CD] has only one of its extremities — namely C — on the circumference of the circle, while the former [E] has neither.

Diagram. A small circle illustrating Definition 7, with several chords/segments.

- A (lower-left, on the circle): one extremity of chord AB
- B (lower-right, on the circle): other extremity of chord AB
- C (upper-left, on the circle): extremity of line CD lying on the circumference
- D (upper-right, on/just inside the circumference): the other extremity of line CD
- E (interior, center): a short segment lying wholly within the circle (neither extremity on the circumference)

PROBL. 1. PROPOS. 1.

Enunciation (Euclid). In a given circle, to fit a straight line equal to a given straight line that is not greater than the diameter of the circle.

Demonstration (Clavius). In circle ABC let a straight line be fitted equal to the given straight line D, which however is not greater than the diameter of the given circle. For since the diameter [Margin: a — Elem. III.15] is the greatest of all the straight lines in a circle, if the given line were greater than the diameter, no line equal to it could be fitted in the circle. So draw the diameter BC. Then, if the given line D is equal to the diameter, BC has been fitted, equal to it. But if D is less than the diameter, [Margin: b — Elem. I.3] cut off BE equal to D; and with center B and radius BE describe a circle EA, cutting circle ABC at A. Then, when the straight line BA has been drawn, it will be the line fitted in circle ABC, equal to the given line D. [Margin: c — Def. I.15] For BA is equal to BE, and D is equal to the same BE, by construction. Therefore AB and D will also be equal to one another. So in the given circle we have fitted a straight line, and so on. Which was to be done.

Diagram. Circle ABC with a diameter BC and a second (auxiliary) arc; the given line D stands separately at the left.

- D (left, a short vertical segment): the given straight line
- A (top): the point where the auxiliary arc cuts circle ABC; BA is the fitted chord
- B (center-left): center of the circle / endpoint of the diameter and center of arc EA
- C (right): the other endpoint of the diameter BC
- E (on the diameter, between B and the center): point with BE cut off equal to D

EX FEDERICO COMMANDINO.

(An additional treatment from [Federico Commandino].)

Enunciation. In a given circle, to fit a straight line equal to a given straight line — not greater than the diameter of the circle — and parallel to another given line.

Demonstration. In a given circle ABC, whose center is D, let a straight line be fitted equal to the line EF (not greater than the diameter) and parallel to the line G. [Margin: d — Elem. I.31] Through the center D draw the diameter AC parallel to G. Now if EF is equal to the diameter, what was proposed is already done. But if it is less than the diameter, [Margin: e — Elem. I.11] bisect it at H, and cut off DI equal to HE and DK equal to HF, so that the whole IK is equal to the whole EF. Through I and K draw LM and NO at right angles to AC, and join LN. I say that LN is the line fitted, equal to EF and parallel to G. For since LM and NO are equally distant from the center, [Margin: f — Elem. III.14] they will be equal to one another; and since they are bisected at I and K — because they are cut at right angles by AC, which passes through the center D — [Margin: g — Elem. III.3] their halves LI and NK will also be equal. And since LI and NK are also parallel, [Margin: h — Elem. I.28] [Margin: i — Elem. I.33] LN and IK will likewise be equal and parallel. Therefore, since IK is equal to EF and parallel to G, LN too will be equal to EF [Margin: k — Elem. I.30] and parallel to G. By the same reasoning, if the line MO is drawn, it will be equal to EF and parallel to G. Which is what was proposed.

Diagram. Circle with center D and diameter AC; a rectangle LMNO is inscribed, its vertical sides LM and NO cutting AC at I and K. At the right stand the given line EF (with midpoint H) and the given direction-line G.

- A (left end of diameter AC)
- C (right end of diameter AC)
- D (center of the circle)

- B (top of the circle)
- L (top-left corner of the inscribed rectangle [?])
- M (bottom-left corner)
- N (top-right corner)
- O (bottom-right corner)
- I (on AC, foot of side LM)
- K (on AC, foot of side NO)
- E, H, F (the given line EF, drawn vertically at the right, with midpoint H)
- G (the given direction-line, a separate segment)

THEOR. 2. PROPOS. 2.

Enunciation (Euclid). In a given circle, to inscribe a triangle equiangular to a given triangle.

Demonstration (Clavius). Let there be inscribed in the given circle ABC a triangle equiangular to any given triangle DEF. Draw the line GH tangent to the circle at A, and make the angle GAB equal to the angle F and the angle HAC equal to the angle E; extend the lines AB, AC to the circumference at the points B and C, and join the line BC. The line AC will not fall on the line AB, nor between the lines AB and AG, because the angles GAB and HAC — that is, the angles F and E — [Margin: a — Elem. I.17] are less than two right angles. [Margin: b — Elem. I.13] For they would be equal to two right angles if AC fell on AB, or greater than two right angles if it fell between AB and AG. I say that the triangle ABC inscribed in the given circle is equiangular to the given triangle DEF. For the angle C [Margin: c — Elem. III.32] is equal to the angle GAB, and the angle F is equal to the same angle GAB by construction. Therefore the angles C and F will also be equal to one another. Similarly, since the angle B [Margin: d — Elem. III.32] is equal to the angle HAC, and the angle E is equal to the same angle HAC by construction, the angles B and E will also be equal to one another. Since, then, the two angles B and C of triangle ABC are equal to the two angles E and F of triangle DEF, [Margin: e — Elem. I.32] the remaining angles A and D will also be equal. Therefore the triangle ABC is equiangular to the triangle DEF. So in the given circle we have inscribed a triangle, and so on. Which was to be done.

Diagram. The given triangle DEF at the left (shown twice), and at the right a circle with the inscribed triangle ABC and the tangent line HAG at the top.

- D, E, F: the given triangle

- H (upper-left), A (top), G (upper-right): the tangent line GH touching the circle at A
- A (top vertex of the inscribed triangle, the point of tangency)
- B (lower-right vertex on the circle)
- C (left-center vertex on the circle)

PROBL. 3. PROPOS. 3.

Enunciation (Euclid). About a given circle, to circumscribe a triangle equiangular to a given triangle.

Demonstration (Clavius). About the given circle ABC let a triangle be circumscribed equiangular to the given triangle DEF. Produce the side EF in both directions to G and H; take the center of the circle, I; draw any line AI; and make the angle AIB equal to the angle DEG and the angle BIC equal to the angle DFH. Then from A, B, C draw KL, LM, MK perpendicular to AI, BI, CI; these will touch the circle at the points A, B, C (by the corollary to III.16) and will meet at the points K, L, M. For if the line AC were drawn, the two angles KAC and KCA would be less than two right angles, and therefore AK and CK will meet, and so on. For this line AC, when drawn, would fall outside the lines AI, CI, because these make an angle at I. Since the space about I is equal to four right angles (by the 2nd corollary to I.15) — that is, to the four angles at E and F — and since the two angles AIB, CIB are equal to the two angles DEG, DFH, the remaining space AIC will be equal to the remaining two angles DEF, DFE. But [Margin: a — Elem. I.17] these are less than two right angles. Therefore the space AIC too will be less than two right angles, and so AIC will be a proper angle. Otherwise that space would be either equal to two right angles — namely if AI and CI formed a single straight line — or greater than two right angles, if AI produced fell beyond IC. So of necessity AI produced falls below CI, and therefore the angle AIC is formed toward the side of K; and the line AC, when drawn, will make with AK, CK two angles less than two right angles, and so the lines AK, CK will meet at K. In just the same way we shall show that AL, BL meet at L, and CM, BM at M, because the lines AB, BC, when drawn, will make with AL, BL, CM, BM angles less than two right angles. Therefore there has been circumscribed about the circle the triangle KLM, which I say is equiangular to the triangle DEF. For since all the angles in the quadrilateral AIBL are equal to four right angles — as was shown at I.32 — and the angles IAL, IBL are two right angles, the remaining angles AIB and L will be equal to two right angles. And since [Margin: b — Elem. I.13] the angles DEG, DEF are also equal to two right angles, if the equal angles AIB, DEG are taken away, there will remain the angle L equal to the angle DEF. By like reasoning we shall

show that the angle M is equal to the angle DFE. [Margin: c — Elem. I.32]
 Therefore the remaining angle K will be equal to the remaining angle D, and so the triangle KLM is equiangular to the triangle DEF. Therefore about the given circle we have circumscribed a triangle, and so on. Which was to be accomplished.

Diagram. At the left, the given triangle DEF with its base EF produced to G (beyond E) and H (beyond F). At the right, the circle (center I) with the circumscribed triangle KLM touching it at A, B, C.

- D (apex of the given triangle); E, F (its base); G (extension of the base beyond E); H (extension beyond F)
- I (center of the circle)
- A (upper tangent point on the circle)
- B (lower tangent point)
- C (right-hand tangent point)
- K (top vertex of the circumscribed triangle — the woodcut engraves "V" at the apex)
- L (lower-left vertex)
- M (lower-right vertex)

PROBL. 4. PROPOS. 4.

Enunciation (Euclid). In a given triangle, to inscribe a circle.

Demonstration (Clavius). Let a circle be inscribed in the given triangle ABC. Bisect the two angles ABC, ACB by the straight lines BD, CD, which meet within the triangle at D; and from D draw the perpendiculars DE, DF, DG to the three sides. Now since the two angles DBE, DEB of triangle DBE are equal to the two angles DBF, DFB of triangle DBF, each to each, and the side BD is common, [Margin: a — Elem. I.26] the sides DE, DF will also be equal. By the same reasoning the sides DF, DG in the triangles DCF, DCG will be equal. Since, then, the three lines DE, DF, DG are equal, a circle described with center D and radius DE will pass through the remaining points F and G, and will touch the sides of the triangle at E, F, G (by the corollary to III.16), because the sides are perpendicular to the radii DE, DF, DG. So in the given triangle we have inscribed a circle. Which was to be accomplished.

Diagram. Triangle ABC with an inscribed circle, center D; lines run from D to the vertices and to the three points of tangency.

- A (top vertex)

- B (bottom-left vertex)
- C (bottom-right vertex)
- D (center of the inscribed circle)
- E (tangent point on side AB)
- F (tangent point on base BC)
- G (tangent point on side AC)

SCHOLIVM.

Introduction (Clavius). But since Euclid demonstrated in Book 1 [Margin: b — Elem. I.20] that in every triangle any two sides taken together are greater than the remaining one, it will not be out of place to demonstrate here, with [Giovanni Battista Benedetti], by how much they are greater, by means of this theorem.

Theorem. In every triangle, if a circle is inscribed, any two sides exceed the remaining one by a straight line whose square is four times the rectangle contained by the straight line drawn from the angle contained by those two sides to the concave circumference, together with its outer segment. And if the contained angle is a right angle, those two sides will exceed the side opposite the right angle by the diameter of the circle inscribed in the triangle.

Demonstration. Let there be a triangle ABC, [Margin: c — Elem. IV.4] in which a circle DEF is inscribed, touching the sides of the triangle at the points D, E, F; and from any angle B — whether it be right, obtuse, or acute — let the line BH be drawn, cutting the circle at I. I say that the two sides BA, BC exceed the side AC by a straight line whose square is four times the rectangle contained by BH, BI. For since, by corollary 2 to III.36, the line CF is equal to the line CE, and the line AD to the line AE, the two lines FC, DA will be equal to the side AC. Therefore the sides BA, BC exceed the side AC by the segments BD, BF; and since these are equal (by the same corollary), the same sides BA, BC will exceed the side AC by a line double the segment BD. But the square of the line double the segment BD is four times the square of the line BD, by the scholium to II.4. And [Margin: d — Elem. III.36] the square of the line BD is equal to the rectangle under BH, BI. Therefore the sides BA, BC exceed the side AC by a line whose square is four times the rectangle under BH, BI. Which is what was proposed.

But if the angle A is a right angle, I say that not only do the two sides AB, AC exceed the side BC by a line whose square is four times (*the sentence continues on the next page*)

Diagram. Triangle ABC with an inscribed circle (center G), touching the sides at D, E, F; the line BH is drawn from B, cutting the circle at I. Tick-marks on the sides indicate equal tangent segments.

- A (top vertex)
- B (bottom-left vertex)
- C (bottom-right vertex)
- D (tangent point on side AB)
- E (tangent point on side AC)
- F (tangent point on base BC)
- G (center of the inscribed circle)
- H (upper-right, where line BH meets the far side)
- I (point where BH cuts the near arc of the circle)

Book IV (continued)

Scholium demonstration, continued (Clavius). ... four times the rectangle contained by the line drawn from A into the concave circumference, together with its outer segment, as was shown; but also that this excess is equal to the diameter of the circle DEF. For if from the center G the lines GD, GE are drawn to the points of contact D, E, [Margin: e — Elem. III.18] the angles at D and E will be right. Since, then, the angle A too is assumed to be a right angle, [Margin: f — Elem. I.28] the line AE will be parallel to DG, and AD to EG; and therefore AG will be a parallelogram. [Margin: g — Elem. I.34] Hence AD will be equal to the radius EG, and AE to the radius DG — that is, the two lines AD, AE together will be equal to the whole diameter of the circle. But the two sides AB, AC exceed the side BC by the two lines AD, AE, as was shown. For EC is equal to FC, and DB to FB, by corollary 2 to III.36. Therefore the same sides AB, AC exceed the side BC by the diameter of the inscribed circle. Which is what was proposed.

Corollary within the scholium. And so any two sides exceed the remaining one by the two lines that touch the circle inscribed in the triangle and lie between the angle contained by those two sides and the circle. For it was shown that the sides AB, AC exceed the side BC by the tangent lines AD, AE, and so on.

Application (Clavius). Now that these things have been demonstrated, if the three sides of a triangle are known, we shall find without difficulty the three points at which the circle to be inscribed in the triangle must touch the sides. For since the sides, for example AB, AC, must exceed the side BC by two tangents drawn from A — which are indeed equal — if the side BC is subtracted (known from the known

sides AB, AC), there will remain the two tangents AD, AE, known. So half of this excess will give each of the points D and E. Then the remaining segment EC will give the segment CF, up to the third point F; or the remaining segment DB will give the segment BF, to the same point F. If, then, from the two points D, E perpendiculars DG, EG are erected, they will meet at G, the center of the circle to be inscribed.

For example: let side AB be 6, side AC be 8, and side BC be 10 palms. Subtracting the side BC, 10 palms, from the two sides AB, AC — that is, from 14 palms — there remain 4 palms. So AD, as well as AE, will contain two palms. The segment DB, then, will contain 4 palms, and the segment BF will have as many. But the segment EC, and therefore also CF, will be 6 palms. Likewise, subtracting the side AB, 6 palms, from the sides AC, BC — that is, from 18 palms — the remainder is 12 palms. So each segment CE, CF will be 6 palms, and each of BD, BF, 4 palms. Finally, subtracting the side AC, 8 palms, from the sides AB, CB — that is, from 16 palms — there remain 8 palms. So each segment BD, BF will have 4 palms; but each of CF, CE, 6 palms; and each of AD, AE, 2 palms.

Diagram. The scholium figure, repeated: triangle ABC with an inscribed circle (center G), touching the sides at D, E, F; the line BH is drawn from B, cutting the circle at I. Tick-marks along the sides mark the equal segments used in the numerical example.

- A (top vertex)
- B (bottom-left vertex)
- C (bottom-right vertex)
- D (tangent point on side AB)
- E (tangent point on side AC)
- F (tangent point on base BC)
- G (center of the inscribed circle)
- H (upper-right, where line BH meets the far side)
- I (point where BH cuts the near arc of the circle)

PROBL. 5. PROPOS. 5.

Enunciation (Euclid). About a given triangle, to circumscribe a circle.

Demonstration (Clavius). Let a circle be circumscribed about the given triangle ABC. Bisect two sides AC, AB (which, in a right-angled or obtuse-angled triangle, are for convenience taken about the right or obtuse angle — though this is not strictly necessary, since any two sides can be bisected) at the points D and E; from

these draw DF, EF perpendicular to the said sides, meeting at F. (That they meet is clear: for if the line DE were drawn, the angles FDE, FED would be less than two right angles.) And F will be either within the triangle, or on the side BC, or outside the triangle. Draw the lines FA, FB, FC. Now since the sides AD, DF of triangle ADF are equal to the sides BD, DF of triangle BDF, and the angles at D are right, [Margin: a — Elem. I.4] the bases FA, FB will be equal. In the same way FA, FC will be equal. Since, then, the three lines FA, FB, FC are equal, the circle described with center F and radius FA will pass also through the points B and C. Therefore about the given triangle we have circumscribed a circle. Which was to be done.

Diagram. Three cases of the circumscribing circle are shown side by side, illustrating the three positions of the center F: within the triangle (acute), on the side BC (right), and outside the triangle (obtuse). In each, triangle ABC is inscribed in a circle.

- A (top vertex of the triangle in each case)
- B (left vertex)
- C (right vertex)
- D (midpoint of side AC)
- E (midpoint of side AB)
- F (circumcenter — inside in the first figure, on BC in the second, outside in the third)

COROLLARIUM.

From this it is clear that, if the center falls within the triangle, [Margin: b — Elem. III.31] all the angles are acute, since they all stand in a segment greater than a semicircle; but if it lies on the side BC, [Margin: c — Elem. III.31] the angle BAC opposite that side is a right angle, because it stands in a semicircle; and finally, if it falls outside the triangle, [Margin: d — Elem. III.31] the opposite angle BAC is obtuse, because it stands in a segment less than a semicircle.

Conversely, it is evident that, if the triangle is acute-angled, the center falls within the triangle; if right-angled, on the side opposite the right angle; and finally, if obtuse-angled, outside the triangle. This is easily shown by reducing to some inconsistency or absurdity. For if in an acute-angled triangle the center fell on one side, the angle opposite it would be right; but if outside, that same angle would be obtuse. Likewise, if in a right-angled triangle it fell within, all the angles would be acute; but if outside, the opposite angle would be obtuse. Finally, if in an obtuse-angled triangle it fell on one side, the angle opposite it would be right;

but if within, all the angles would be acute. All of which follow from the earlier part of this corollary, and conflict with the hypothesis.

SCHOLIVM.

It is also gathered from this problem by what art a circle is to be described that passes through three given points not lying on one straight line. For if the given points are joined by three straight lines so as to form a triangle, a circle will easily be described about it, as was taught in this proposition. This, however, will be done more easily by that practical method we handed down at III.25. For let the three given points be A, B, C. From A and B, with any one and the same radius, describe two arcs cutting each other at the points D and E, through which draw the straight line DH. Likewise from A and C, with any equal radius — or, if you like, that former one — draw two other arcs cutting each other at the points F and G, through which draw the line FH, cutting the line DH at H. I say that H is the center of the circle passing through the given points A, B, and C. For if the lines AB, AC, BC were drawn, the sides AB, AC of triangle ABC would be bisected by the lines DH, FH, as was demonstrated in that practical method of proposition III.25. Therefore, as Euclid shows in this fifth problem, H will be the center of the circle described about the triangle ABC. Which is what was proposed.

Diagram. The three-point construction: three given points A, B, C, with pairs of intersecting arcs used to locate the center. The figure is small and schematic (arcs drawn as dotted curves); several labels are faint.

- A (top): a given point
- B (left): a given point
- C (right): a given point
- D (upper-left [?]): intersection of the first pair of arcs
- E (near D [?]): second intersection of the first pair of arcs
- F (upper-right [?]): intersection of the second pair of arcs
- G (right [?]): second intersection of the second pair of arcs
- H (center [?]): meeting point of lines DH and FH — the sought center

PROBL. 6. PROPOS. 6.

Enunciation (Euclid). In a given circle, to inscribe a square.

(The demonstration begins on the following page.)

(Continuation of Proposition 6 — to inscribe a square in a given circle; the enunciation was given at the close of the previous pages.)

Demonstration. Let a square be inscribed in the given circle ABCD, whose centre is E. Draw the two diameters AC and BD, cutting one another at right angles at the centre E, and join the straight lines AB, BC, CD, DA. I say that ABCD is a square inscribed in the given circle. For the sides EA, EB of triangle AEB are equal to the sides EC, ED of triangle CED — since all are radii from the centre — and the contained angles are right angles; therefore the bases AB and CD will be equal [Margin: a — *Elements* I.4]. By the same reasoning the straight lines BC and DA will be equal, likewise CD and DA, and DA and AB. All the sides of the quadrilateral ABCD are therefore equal to one another. We may reach this more briefly as follows. Since the four angles at E are equal — being right angles — the four arcs on which they stand will be equal [Margin: b — *Elements* III.26], and consequently the four chords subtending them will also be equal [Margin: c — *Elements* III.29]. Every side of the quadrilateral ABCD is therefore equal. Moreover its angles are right angles [Margin: d — *Elements* III.31], since they all stand in semicircles. ABCD will therefore be a square, and so we have described a square in the given circle. Which was to be done.

Diagram. A circle with an inscribed square, its diagonals drawn as the two perpendicular diameters through the centre.

- A (top of circle): upper vertex of the square
- B (left of circle): left vertex
- D (right of circle): right vertex
- C (bottom of circle): lower vertex
- E (centre): intersection of the diameters AC and BD

PROBL. 7. PROPOS. 7. [Margin: vij.]

About a given circle to describe a square.

Demonstration. Let a square be described about the given circle ABCD, whose centre is E. Draw the two diameters AC and BD, cutting one another at right angles at the centre E; and through A, B, C, and D draw lines perpendicular to the diameters — FG, FH, HI, IG — meeting at the points F, H, I, G. That AF and BF do in fact meet is clear from this: the straight line AB, when drawn, makes with AF and BF two angles less than two right angles; and the same holds for the others. I say that FHIG is a square described about the given circle. For since the angles AEB and FEB are right angles, FH and AC will be parallel [Margin: a — *Elements*

I.28]; and in the same way GI and AC will be parallel [Margin: b — *Elements* I.28]. Hence FH and GI are also parallel. In the same manner FG and HI are parallel. Since, then, ACHF is a parallelogram, its opposite sides AC and FH will be equal, and its opposite angles ACH and AFH equal [Margin: c — *Elements* I.38]. But ACH is a right angle; therefore AFH will be a right angle. By the same reasoning we shall show that the angles at H, I, and G are right angles, and that the sides HI, IG, GF are equal to the diameters BD and AC. Therefore, since the diameters are equal, the four sides FG, FH, HI, IG will also be equal, and so FGIH will be a square — whose sides indeed touch the circle, by the corollary to Proposition 16 of Book 3. We have therefore described a square about the given circle. Which was to be accomplished.

Diagram. A circle with an inscribed square rotated 45° (vertices at A, B, C, D, the points where the diameters meet the circle) and a larger square FGIH circumscribed about the circle, its sides tangent at A, B, C, D.

- F (top-left corner of the outer square): corner of the circumscribed square
- A (top, tangent point): where the outer side FG touches the circle / top of the inner diameter
- G (top-right corner): corner of the circumscribed square
- B (left, tangent point): where side FH touches the circle
- E (centre): centre of the circle, intersection of diameters AC, BD
- D (right, tangent point): where side GI touches the circle
- H (bottom-left corner): corner of the circumscribed square
- C (bottom, tangent point): where side HI touches the circle
- I (bottom-right corner): corner of the circumscribed square

PROBL. 8. PROPOS. 8. [Margin: viij.]

In a given square to inscribe a circle.

Demonstration. Let a circle be inscribed in the given square ABCD. Bisect the sides at E, F, G, H, and draw the straight lines EG and FH, cutting one another at I. Now since AD and BC are equal and parallel straight lines, their halves AH and BF will also be equal and parallel [Margin: a — *Elements* I.33]. Consequently AB too is parallel and equal to FH. By the same reasoning DC will be parallel and equal to that same FH; and likewise the straight lines AD, BC will be parallel and equal to EG. Therefore AI, IB, CI, ID are parallelograms, and so the straight lines IE, IF, IG, IH will be equal to the straight lines AH, EB, DH, AE. But these last are equal to one another, being halves of the equal lines AD, AB, and so on. Therefore the

straight lines IE, IF, IG, IH will be equal, and so a circle described from I with radius IE will also pass through the points F, G, H. Since it touches the sides AB, BC, CD, DA — by the corollary to Proposition 16 of Book 3, seeing that the angles at E, F, G, H are right angles [Margin: b — *Elements* I.29] — it will be inscribed in the square AC [i.e. square ABCD]. We have therefore described a circle in the given square. Which was to be accomplished.

Diagram. A square with an inscribed circle; the two midlines EG (horizontal) and FH (vertical) are drawn, crossing at the centre I.

- A (top-left corner): vertex of the square
- H (top, midpoint of side AD): tangent point
- D (top-right corner): vertex
- E (left, midpoint of side AB): tangent point
- I (centre): intersection of the midlines EG and FH; centre of the inscribed circle
- G (right, midpoint of side CD): tangent point
- B (bottom-left corner): vertex
- F (bottom, midpoint of side BC): tangent point
- C (bottom-right corner): vertex

PROBL. 9. PROPOS. 9. [Margin: ix.]

About a given square to describe a circle.

Demonstration. Let a circle be described about the square ABCD. Draw the diameters AC and BD, cutting one another at E. Now since the sides AB and AD of triangle ABD are equal, the angles ABD and ADB will be equal [Margin: a — *Elements* I.5]; but the angle BAD is a right angle. Therefore ABD and ADB will be half right angles [Margin: b — *Elements* I.32]. In the same way we shall show that all the remaining angles at A, B, C, D are half right angles, and hence equal to one another. Since, then, the angles [B]DA are equal, the straight lines EA and ED will be equal [Margin: c — *Elements* I.6]. By the same reasoning EA and EB will be equal; and likewise EB and EC, and again EC and ED. Therefore a circle described from E with radius EA will pass through the remaining points B, C, D. We have thus described a circle about the given square. Which was to be done.

Diagram. A square inscribed in a circle, with both diagonals (the diameters AC and BD) drawn to the centre.

- A (top-left): vertex of the square, on the circle

- D (top-right): vertex, on the circle
- E (centre): intersection of the diagonals AC and BD; centre of the circle
- B (bottom-left): vertex, on the circle
- C (bottom-right): vertex, on the circle

SCHOLIUM.

If about a given circle a square be described, and in the same circle another square be inscribed, the circumscribed square will be double the inscribed square. For the side of the circumscribed square is equal to the diameter of the circle, as is established from Proposition 7 of this book — that is, equal to the diagonal of the inscribed square. But the square on the diagonal is double the square of which it is the diagonal, as we showed at Proposition 47 of Book 1. The proposition is thus established.

Diagram. An unlabelled figure illustrating the scholium: an outer square, a circle inscribed in it, and a smaller square inscribed in the circle (rotated 45°, its vertices at the circle's points of tangency), with the inscribed square's diagonals drawn. No point-letters are printed.

PROBL. 10. PROPOS. 10. [Margin: x.]

To construct an isosceles triangle having each of the angles at its base double of the remaining angle.

Demonstration. Take any straight line AB, and let it be divided at C so that the rectangle contained by AB, BC is equal to the square on AC [Margin: a — *Elements* II.11]. Then with centre A and radius AB let a circle be described, and in it let there be fitted a straight line BD equal to AC [Margin: b — *Elements* IV.1], and let AD be joined. Since the straight lines AB and AD are equal, the triangle ABD will be isosceles. I say that each of the angles ABD, ADB is double of the remaining angle A. For let CD be joined, and let a circle DCA be described about the triangle ACD [Margin: c — *Elements* IV.5]. Now since the rectangle contained by AB, BC is equal to the square on the straight line BD, and the straight line AB cuts the circle DCA, the straight line BD will touch that same circle DCA at D [Margin: d — *Elements* III.37]. Therefore the angle BDC is equal to the angle A, in the alternate segment CAD [Margin: e — *Elements* III.32]. Adding the common angle CDA, the whole angle ADB will be equal to the two angles CAD and CDA together; but the external angle BCD is also equal to these same two [Margin: f — *Elements* I.32]. The angle BCD will therefore be equal to the angle ADB — that is, to the angle ABD, since ABD and ADB are equal [Margin: g — *Elements* I.5]; and hence the

straight lines CD and BD will be equal [Margin: h — *Elements* I.6]. But BD was made equal to the straight line AC. Therefore CD too will be equal to CA, and hence the angles CAD and CDA are equal [Margin: i — *Elements* I.5]. The angle ADB, then, which was shown equal to the two angles CAD and CDA, will be double of one of them — namely of the angle A. Therefore the angle ABD too will be double of that same angle A. We have thus constructed an isosceles triangle having, and so on. Which was to be accomplished.

Diagram. A large circle (centre A, radius AB) and a smaller circle DCA circumscribed about the triangle ACD; the isosceles triangle ABD is drawn with its sub-triangle ACD.

- A (top of the inner circle): apex of the isosceles triangle; centre of the large circle
- C (left, on the inner circle): the point dividing AB
- D (lower, on the large circle): base vertex; point of tangency of BD
- B [?] (bottom-left, on the large circle): base vertex of triangle ABD (*glyph abraded, resembles "J"; identified as B from the construction*)

COROLLARIUM.

Since the three angles of triangle ABD are equal to two right angles [Margin: k — *Elements* I.32] — that is, to five fifths of two right angles — it is clear that the angle A is a fifth part of two right angles, while each of B and D is two fifths. Likewise A is two fifths of one right angle, and each of B and D is four fifths, seeing that all three together are equal to two right angles [Margin: l — *Elements* I.32] — that is, to ten fifths of one right angle.

SCHOLIUM.

This problem could have been proposed in the manner of a theorem, thus:

If a straight line be cut as taught in Proposition 11 of Book 2, then an isosceles triangle whose base is equal to the greater segment, and each of whose equal sides is equal to the given line itself, has each of the equal angles at the base double of the remaining angle.

There is no reason for Campanus [Campanus of Novara] and Peletarius [Jacques Peletier] to torment themselves in proving that the straight line BD is so applied to the circle DCA that it in no way cuts it. For, because the square on the straight line BD is equal to the rectangle contained by AB, BC, it was shown in the last proposition of Book 3 that the straight line BD is perpendicular to the semidiameter

of the circle drawn from D. It will therefore touch the circle and will in no way cut it.

As for the art by which an isosceles triangle is to be constructed such that each of its base angles has to the remaining angle any given ratio — not merely the double, as Euclid has done here — this we shall set forth, together with Pappus [Pappus of Alexandria], at the end of Book 6. It is a matter that has hitherto been wanting.

PROBL. 11. PROPOS. 11. [Margin: xj.]

In a given circle to inscribe an equilateral and equiangular pentagon.

Demonstration. Let an equilateral and equiangular pentagon be inscribed in the given circle ABCDE. Construct an isosceles triangle FGH such that each of the angles G, H is double of the remaining angle F [Margin: a — *Elements* IV.10]; and in the circle inscribe a triangle ACD equiangular with the triangle FGH [Margin: b — *Elements* IV.2], and let each of the angles ACD, ADC be bisected by the straight lines CE, DB [Margin: c — *Elements* I.9], and let the straight lines AB, BC, CD, EA be joined. I say that the pentagon ABCDE, inscribed in the given circle, is equilateral and equiangular. For since each of the angles ACD, ADC is double of the angle CAD and is bisected, the five angles ADB, BDC, CAD, DCE, ECA will be equal. Hence the arcs AB, BC, CD, DE, EA, on which they stand, will be equal [Margin: d — *Elements* III.26], and therefore the straight lines AB, BC, CD, DE, EA will be equal as well [Margin: e — *Elements* III.29]. The pentagon ABCDE is therefore equilateral. Again, since the arcs AB and ED are equal, adding the common arc BCD they become the equal arcs ABCD and EDCB. The angles AED and BAE, standing on the said arcs, will therefore be equal [Margin: f — *Elements* III.27]. In the same way the remaining angles will be equal to each of these; for they stand on equal arcs, each of which is composed of three equal arcs. The pentagon ABCDE is therefore equiangular. And since it has also been shown to be equilateral, an equilateral and equiangular pentagon will have been inscribed in the given circle. Which was to be done.

Diagram. A circle with an inscribed equilateral pentagon ABCDE, its five diagonals drawn to form the inscribed pentagram (five-pointed star).

- A (top): pentagon vertex
- B (upper-left): pentagon vertex
- E (upper-right): pentagon vertex
- C (lower-left): pentagon vertex
- D (lower-right): pentagon vertex

Diagram. The auxiliary isosceles triangle FGH, with apex F above and base GH.

- F (apex, top): the vertex whose angle is single
- G (base, left): base angle (double of F)
- H (base, right): base angle (double of F)

COROLLARIUM.

It follows from this that the angle of an equilateral and equiangular pentagon comprises three fifths of two right angles, or six fifths of one right angle [Margin: g — *Elements* III.27]. For since the three angles BAC, CAD, DAE are equal — inasmuch as they stand on the equal arcs BC, CD, DE — and CAD is, by the corollary to the preceding proposition, a fifth part of two right angles (or two fifths of one right angle), the whole angle BAE will be three fifths of two right angles, or six fifths of one right angle.

SCHOLIUM.

If a straight line CD, of given length, be set out, we shall construct upon it an equilateral and equiangular pentagon in this way [Margin: h — Elements IV.10]. Let an isosceles triangle FGH be made, having each of the angles G, H double of the remaining angle F. Then let angles ACD, ADC be constructed equal to the angles G, H, and let the straight lines CA, DA meet at A [Margin: i — Elements I.32]; these will make the angle CAD equal to the angle F, and hence in the triangle ACD each of the angles ACD, ADC will be double of the remaining angle CAD. Now let a circle ABCDE be described about the triangle ACD [Margin: k — Elements IV.5]. Since the triangle ACD is inscribed in it, if the angles ACD, ADC are bisected, there will be inscribed — as before — an equilateral and equiangular pentagon whose side is the straight line CD. Which was the thing proposed.

We shall accomplish the same more easily by this method. Let the given straight line AB, on which the equilateral and equiangular pentagon is to be constructed, be cut at C as taught in Proposition 11 of Book 2, and let it be produced in both directions, and let AD, BE be made equal to the greater segment AC. Then with radius equal to the given line AB, from A and D let two arcs be described cutting one another at F. Likewise from B and E, with the same radius, let two others cut one another at G. Finally from F and G, with the same radius, let two others divide one another at H, and let the straight lines AF, FH, HG, GB be joined. I say that the pentagon ABGHF, described upon the given straight line AB, is equilateral and equiangular. That it is equilateral is clear from the construction, since all the lines taken are equal to AB — that is, all the arcs were described with radius AB. That it is also equiangular is shown thus. Let the straight line DF be drawn; then ADF will

be isosceles, of the kind constructed by Euclid in Proposition 10 — as is clear from the scholium to that same proposition — because its base AD is equal to the greater segment AC, which is equal to the line AB. Hence, by the corollary to that same Proposition 10, the angle DAF will comprise two fifths of two right angles, so that the remaining angle BAF comprises the other three fifths of two right angles. And since, by the corollary to this present proposition, the angle of an equilateral and equiangular pentagon comprises three fifths of two right angles, BAF will be the angle of an equilateral and equiangular pentagon. By the same reasoning ABG will be the angle of an equilateral and equiangular pentagon. From which it follows that the whole pentagon is equiangular. For if it be completed, or conceived to be completed — that is, if upon F and G two other sides be conceived described [Margin: l — Elements I.21] — these will of necessity fall upon the point H. Otherwise, if they were to meet above or below H, they would be either greater or less than the straight lines FH, GH — as is evident, if the base FG were subtended to the angle H — and therefore they would not be equal to the other sides FA, AB, BG, which is absurd. The pentagon ABGHF is therefore both equilateral and equiangular. Which was to be demonstrated.

Diagram. A circle with an inscribed equilateral pentagon and its inscribed pentagram (for the first construction of the scholium), with the auxiliary isosceles triangle FGH drawn to its right.

- A (top of the circle): pentagon apex
- B (upper-left): pentagon vertex
- E (upper-right): pentagon vertex
- C (lower-left): pentagon vertex
- D (lower-right): pentagon vertex
- F (apex of the triangle at right): single-angle vertex
- H (base of the triangle, lower right): base vertex (*the second base vertex G is not separately legible on the leaf [?]*)

Diagram. The pentagon ABGHF constructed on the base line (second construction of the scholium): a collinear base carries the points D, A, C, B, E; F and G stand above, and the apex H is at the top; construction arcs are shown as dotted lines.

- H (apex, top): pentagon apex
- F (upper-left): pentagon vertex
- G (upper-right): pentagon vertex
- D (base, far left): endpoint (AD = greater segment AC)
- A (base): pentagon vertex on the base line

- C (base, centre): the point of section
- B (base): pentagon vertex on the base line
- E (base, far right): endpoint (BE = greater segment AC)

PROBL. 12. PROPOS. 12. [Margin: xij.]

About a given circle to describe an equilateral and equiangular pentagon.

Demonstration. Let an equilateral and equiangular pentagon be described about the given circle ABCDE. In it inscribe an equilateral and equiangular pentagon ABCDE [Margin: a — *Elements* IV.11], and from the centre F draw the straight lines FA, FB, FC, FD, FE; to these draw perpendiculars GH, HI, IK, KL, LG, meeting at G, H, I, K, L. For since the angles GAE, GEA are less than two right angles — being parts, that is, of the right angles FAG, FEG — the straight lines AG, EG will meet toward the parts of G [Margin: b — I.13 [?]], and so with the rest. And since they touch the circle, by the corollary to Proposition 16 of Book 3, an equilateral and equiangular pentagon GHIKL will be described about the circle; which I say to be equilateral and equiangular. For when the straight lines FG, FH, FI, FK, FL are drawn, the squares on both FA, AH and on FB, BH will be equal to the square on the straight line FH [Margin: c — *Elements* I.47]. Therefore the squares on FA, AH will be equal to the squares on FB, BH. Taking away the equal squares on the equal lines FA, FB, there will remain the squares on AH, BH equal; and hence the straight lines AH, BH will be equal. This is also established from the second corollary to Proposition 36 of Book 3, since AH, BH are drawn from the same point H to touch the circle at A and B. Since, then, the sides AF, FH of triangle AFH are equal to the sides BF, FH of triangle BFH, and the base AH is equal to the base BH, as was shown, the angles AFH, BFH will be equal [Margin: d — *Elements* I.8]; and therefore so will the angles AHF, BHF [Margin: e — *Elements* I.4]. The angle AFB is therefore double of the angle BFH, and the angle AHB double of the angle BHF. In the same way we shall show that the angle BFC is double of the angle BFI, and the angle BIC double of the angle BIF. Since, then, the angles AFB, BFC are equal — because they stand on the circumferences AB, BC [Margin: f — *Elements* III.27], which are equal, being subtended by the equal straight lines AB, BC [Margin: g — *Elements* III.28] — their halves BFH, BFI will also be equal. Wherefore, since the two angles BFH, HBF of triangle BFH are equal to the two angles BFI, IBF of triangle IFB, and the side belonging to them adjacent...

Diagram. A circle with an inscribed equilateral pentagon ABCDE (touching the circle at its vertices) and a larger equilateral pentagon GHIKL circumscribed about the circle, its sides tangent to the circle; radii from the centre F to the tangent points are drawn, with many internal lines.

- G (top): apex of the outer (circumscribed) pentagon
- A (upper-left, tangent point): vertex of the inner pentagon
- E (upper-right, tangent point): vertex of the inner pentagon
- H (left): vertex of the outer pentagon
- F (centre): centre of the circle
- L (right): vertex of the outer pentagon
- B (lower-left, tangent point): vertex of the inner pentagon
- D (lower-right, tangent point): vertex of the inner pentagon
- I (bottom-left): vertex of the outer pentagon
- C (bottom, tangent point): vertex of the inner pentagon
- K (bottom-right): vertex of the outer pentagon

Euclid, *Elements*, Book IV — Clavius's Commentary (continued)

Proposition 12 (continued) — to circumscribe an equilateral and equiangular pentagon about a given circle

being adjacent [to it], and with BF common [to both], the sides BH, BI will also be equal, and the angles BHF, BIF equal. Therefore the straight line HI is double the line HB. [Margin: h. Elements I.26] By the same reasoning we shall show that GH is double the line HA. But the lines HB, HA have been shown equal; therefore their doubles HI, HG will also be equal. Similarly we shall demonstrate that the straight lines IK, KL, LG are each equal to any of the lines HI, HG. Therefore the pentagon GHIKL is equilateral.

Again, since it has been shown that the angles BHF, BIF are equal, and are halves of the angles BHA, BIC, their doubles BHA, BIC will also be equal. And by the same reasoning the angles IKL, KLG, LGH will each be equal to any of the angles BHA, BIC. Therefore the pentagon GHIKL is equiangular. And since it has been shown to be equilateral as well, an equilateral and equiangular pentagon will have been circumscribed about the given circle. Which was to be accomplished.

Corollary

[Body heading, p. 157: COROLLARIVM.]

It follows from the demonstration of this problem that, if any equilateral and equiangular figure is described in a circle, and at the ends of the radii drawn

from the center to the angles perpendicular lines are raised, these perpendiculars form another figure, of just as many sides, circumscribed about the circle. For it will always be demonstrated, by the very same reasoning, that these perpendiculars meet, and that they make equal angles — provided that straight lines are drawn from them to the center, as was done in the pentagon — lines which will bisect those same angles, just as was here proved in the pentagon, and so on.

To this belongs the following theorem, bearing on equilateral and equiangular figures, which will be very useful for finding the centers of the circles to be described about those figures, or inscribed within them, as will appear from what follows.

In an equilateral and equiangular figure: if indeed the number of angles is odd, a straight line dropped from any angle and bisecting the opposite side also bisects that angle; and conversely, a straight line bisecting the angle also bisects the opposite side. But if the number of angles is even, a straight line drawn from any angle to the opposite angle bisects both angles; and conversely, a straight line bisecting any angle falls on the opposite angle and bisects it as well.

[Odd-sided figure.] Let there first be an equilateral and equiangular figure of an odd number of sides, ABCDEFG, and from angle A let the straight line AH be dropped, bisecting the opposite side DE. I say that the angle BAG too is bisected. For, drawing from A straight lines to all the non-adjacent angles: since the two sides BA, BC are equal to the two sides GA, GF, and contain equal angles, by hypothesis, [Margin: i. Elements I.4] the lines AC, AF will be equal, and so will the angles BAC, GAF, as well as BCA, GFA. And accordingly, since the whole angles BCD, GFE are assumed equal, the remaining angles ACD, AFE will also be equal. Then again, since the two sides CA, CD are equal to the two sides FA, FE and contain equal angles, as was shown, [Margin: k. Elements I.4] the bases AD, AE will be equal, and so will the angles CAD, FAE, as well as CDA, FEA. And so one must proceed until the opposite side is reached. There, since again the whole angles CDE, FED are equal, the remaining angles ADH, AEH will also be equal. Therefore, since the two sides DA, DH are equal to the two sides EA, EH and contain equal angles, [Margin: l. Elements I.4] the angles DAH, EAH will also be equal. Consequently, since as many angles GAF, FAE, EAH are equal, each to each, the whole angle BAH will also be equal to the whole angle GAH; and therefore the angle BAG is bisected. Which was proposed.

But now let the straight line AH bisect the angle BAG. I say that it also bisects the opposite side DE. For suppose it does not bisect DE: if from A another straight line

be drawn bisecting DE, then — as we have just shown — that line would also bisect the angle BAG. Thus two straight lines would bisect the same angle BAG, which is absurd. Therefore the straight line AH, bisecting the angle BAG, also bisects the side DE.

Diagram. A regular heptagon inscribed in a circle, illustrating the odd-sided case. Straight lines are drawn from the top vertex A to all the non-adjacent vertices, and the line AH descends to H, the midpoint of the base DE.

- A (top vertex): apex from which the lines are drawn
- B (upper left vertex)
- G (upper right vertex)
- C (middle left vertex)
- F (middle right vertex)
- D (lower left vertex)
- H (foot on base, midpoint of side DE)
- E (lower right vertex)

[Even-sided figure.] Next let there be an equilateral and equiangular figure of an even number of sides, ABCDEFGH, and from angle A to the opposite angle E let the straight line AE be drawn. I say that the line AE bisects both the angle BAH and the angle DEF. For, drawing straight lines from A to all the non-adjacent angles, we shall demonstrate, as in the preceding figure, that any angles BAC, CAD, DAE are equal to just as many angles HAG, GAF, FAE, each to each; and therefore that the whole angle BAE is equal to the whole angle HAE, and likewise that the angle DEA is equal to FEA. Therefore each of the angles BAH, DEF is bisected. Which was proposed.

But now let the straight line EA bisect the angle BAH. I say that it falls on the opposite angle E and divides it in half. For if it be denied to fall on E: if from A another straight line be drawn, it will bisect the angle BAH, as we have just shown. Thus two straight lines would bisect the same angle BAH — which is absurd. Therefore the straight line AE, bisecting the angle BAH, falls on E, and consequently, as was just demonstrated, also bisects the angle DEF. Which was proposed.

Diagram. A regular octagon inscribed in a circle, illustrating the even-sided case. Straight lines are drawn from the top vertex A to all the non-adjacent vertices, with the diagonal AE reaching the opposite vertex E.

- A (top vertex): apex from which the lines are drawn

- B (upper left vertex)
- H (upper right vertex)
- C (middle left vertex)
- G (middle right vertex)
- D (lower left vertex)
- E (bottom vertex, opposite A)
- F (lower right vertex)

PROBL. 13. PROPOS. 13.

[Margin: xij.]

To inscribe a circle in a given equilateral and equiangular pentagon.

Let a circle be inscribed in the given pentagon ABCDE. [Margin: a. Elements I.9] Let two of its adjacent angles, BAE and ABC, be bisected by the straight lines AF, BF, which meet at F. Since (by the scholium of the preceding proposition) the straight lines AF, BF bisect the opposite sides CD, DE, the two straight lines AF, BF must necessarily cut one another within the pentagon before they meet the sides CD, DE. Then let the straight lines FC, FD, FE be joined. Now since the sides AB, BF of triangle ABF are equal to the sides CB, BF of triangle CBF — and by construction the angles contained by them, ABF and CBF, are equal — [Margin: b. Elements I.4] the bases AF, CF and the angles BAF, BCF will be equal. Since therefore the angles BAE, BCD are assumed equal, and BAF is half of angle BAE, by construction, BCF too will be half of angle BCD. Thus the angle BCD is bisected. In like manner we shall show that the remaining two angles, CDE and DEA, are bisected. Now let perpendiculars FG, FH, FI, FK, FL be drawn from F to the several sides of the pentagon. Since the two angles FGA, FAG of triangle FAG are equal to the two angles FLA, FAL of triangle FAL, and the side AF, subtending one of the equal angles, is common, [Margin: e. Elements I.26] the straight lines FG, FL will be equal. And similarly the remaining perpendiculars FH, FI, FK will be shown equal to each of these. Therefore a circle described with center F and radius FG will pass through the points H, I, K, L as well. And since the sides of the pentagon touch this circle (by the corollary of *Elements* III.16), because they make right angles with the radii FG, FH, and the rest, the circle will be inscribed in the given pentagon. Which was to be done.

Diagram. An equilateral pentagon ABCDE with an inscribed circle centered at F. The angle-bisectors from the vertices meet at F, from which perpendiculars run

to the five sides; the inscribed circle touches each side at the foot of its perpendicular.

- A (top vertex)
- B (upper left vertex)
- C (lower left vertex)
- D (lower right vertex)
- E (upper right vertex)
- F (center; meeting point of the bisectors, center of the inscribed circle)
- G (foot of perpendicular on side AB, upper left)
- H (foot of perpendicular on side BC, lower left)
- I (foot of perpendicular on side CD, at the bottom) [?]
- K (foot of perpendicular on side DE, lower right)
- L (foot of perpendicular on side EA, upper right)

Scholium

[Body heading, p. 158: SCHOLIVM.]

By this very same art we shall describe a circle in any equilateral and equiangular figure whatever. For we shall always show that, when two adjacent angles have been bisected, if from the point of concurrence of the angle-bisecting lines perpendiculars are drawn to the sides, these are equal to one another; and therefore that that point of concurrence is the center of the circle to be inscribed. Now the two straight lines which bisect the two adjacent angles necessarily meet within the figure — because in a figure of an odd number of sides they bisect the opposite sides, while in a figure of an even number of sides they bisect the opposite angles, as was shown in the scholium of the preceding proposition.

THEOR. 14. PROPOS. 14.

[Margin: xiiij.]

To describe a circle about a given equilateral and equiangular pentagon.

Let a circle be described about the equilateral and equiangular pentagon ABCDE. Let the two angles BAE, ABC be bisected by the straight lines AF, BF, which meet at F within the pentagon, as was demonstrated in the preceding proposition; and joining the straight lines FC, FD, FE, we shall show, as in the preceding problem, that the remaining angles BCD, CDE, DEA are also bisected. Therefore all the half-angles will be equal to one another, since the whole angles are assumed equal.

Now since in triangle AFB the two angles FAB, FBA are equal, [Margin: a. Elements I.6] the straight lines FA, FB will be equal. And by the same reasoning the remaining lines FC, FD, FE will each be equal to these. Therefore a circle described with center F and radius FA will pass through the points B, C, D, E as well. So about the given pentagon [a circle will have been described], and so on. Which was to be done.

Diagram. An equilateral pentagon ABCDE inscribed in its circumscribed circle, centered at F. Straight lines from F run to the five vertices, and the diagonals of the pentagon are drawn, forming a pentagram.

- A (top vertex)
- B (left vertex)
- E (right vertex)
- C (lower left vertex)
- D (lower right vertex)
- F (center of the circumscribed circle)

Scholium

[Body heading, p. 158: SCHOLIVM.]

By the very same device we shall describe a circle about any equilateral and equiangular figure whatever. For we shall always show that, when two adjacent angles have been bisected, the straight lines drawn from the point of concurrence of the angle-bisecting lines to the angles of the figure are equal to one another; and therefore that that point of concurrence is the center of the circle to be circumscribed.

PROBL. 15. PROPOS. 15.

[Margin: xv.]

To inscribe in a given circle a hexagon that is both equilateral and equiangular.

Let there be a given circle ABCDEF, whose center is G, in which an equilateral and equiangular hexagon is to be inscribed. Drawing the diameter AD, let a circle be described with center D and radius DG, which cuts the given circle at the points C and E; and from these, through the center G, let the straight lines CF, EB be extended. Then if the straight lines AB, BC, CD, DE, EF, FA be joined, a hexagon ABCDEF will be inscribed in the given circle; and I say that it is both equilateral

and equiangular. For since the straight line GC is equal to the straight line GD, and the straight line DC is equal to the same straight line DG, by the definition of the circle, the straight lines GC, DC will also be equal to one another; and therefore the triangle CDG will be equilateral. [Margin: a. Elements I.5] Hence its three angles CGD, GDC, DCG will be equal to one another; and since [Margin: b. Elements I.32] they are equal to two right angles, each of them — namely CGD — will be a third part of two right angles. In the same way the angle DGE will be a third part of two right angles. But [Margin: c. Elements I.13] the three angles CGD, DGE, EGF are equal to two right angles. Therefore the remaining angle EGF will also be a third part of two right angles. So the three angles CGD, DGE, EGF are equal to one another; and since [Margin: d. Elements I.15] the vertical angles FGA, AGB, BGC are also equal to them, the six angles at the center G will be equal. [Margin: e. Elements III.26] Therefore the arcs on which they stand, [Margin: f. Elements III.29] and consequently the straight lines AB, BC, CD, DE, EF, FA, will be equal. Wherefore the hexagon ABCDEF is equilateral. Again, since the arc BC is equal to the arc AF, if the common arc CDEF be added, the arcs BCDEF, AFEDC will be equal. Therefore the angles standing on them, BAF and ABC, [Margin: g. Elements III.27] will be equal. And similarly we shall show that the remaining angles BCD, CDE, DEF, EFA are equal to each of these, since each of them stands on an arc composed of four equal arcs — namely, of as many as the inscribed figure has sides, less two. From which it follows that all the angles stand on equal arcs. Therefore the hexagon ABCDEF is also equiangular. So in the given circle we have described an equilateral and equiangular hexagon. Which was to be done.

Diagram. A regular hexagon ABCDEF inscribed in a circle with center G, drawn along the diameter AD. A second circle, with center D and radius DG, cuts the given circle at C and E; the diagonals CF and EB pass through the center G, together with the radii to the vertices.

- A (top vertex; endpoint of the diameter AD)
- B (upper left vertex)
- F (upper right vertex)
- G (center of the given circle)
- C (lower left vertex; intersection of the second circle with the given circle)
- E (lower right vertex; intersection of the second circle with the given circle)
- D (bottom vertex; endpoint of the diameter AD and center of the second circle)

Corollary

[Body heading, p. 158: COROLLARIVM.]

From this it is manifest that the side of a hexagon is equal to the radius of the circle. For DC, the side of the hexagon, is equal to the radius DG, by the definition of the circle.

**

Scholium (continued)

[Body heading, p. 159: SCHOLIVM.]

Moreover, by what has been said about the pentagon in Propositions 12, 13, and 14, we shall describe an equilateral and equiangular hexagon about a given circle. Likewise, in a given equilateral and equiangular hexagon we shall inscribe a circle; and finally, about the same hexagon we shall describe a circle. For, in order that a hexagon be circumscribed about a circle, a hexagon must first be inscribed within the circle, as Euclid has taught in this Proposition 15. But if a circle is to be described either in a hexagon or about a hexagon, the two adjacent angles must be bisected; and the rest is then to be completed, as is delivered in Propositions 12, 13, 14.

Furthermore, from these results we shall also easily demonstrate that there can be given an isosceles acute-angled triangle [triangulum isosceles oxygonium — from Greek ὀξυγώνιον, "acute-angled"] whose third side is greater than either of the equal sides; or, equivalently, in which either of the equal sides is less than the third — a point we noted at Definition 28 of Book I. For let A be the center of the circle BCDE, in which the arc DE is a sixth part and BE a quarter. [Margin: h. Elements IV.15] Then the chord subtending DE will be equal to the radius. And if from any point C, between B and D, a straight line CE be drawn to E, this will be greater than DE (by the scholium of *Elements* III.29) — that is, greater than the radius. Therefore, joining the two radii AC, AE, the triangle ACE will be isosceles, whose third side CE is greater than either of the equal sides AC, AE. I say that the same triangle is also acute-angled. For since [Margin: i. Elements I.5] the angles ACE, AEC are equal, and [Margin: k. Elements I.17] together are less than two right angles, each of them will be acute. And drawing the straight line AB, the angle BAE — standing at the center on the quadrant BE — will be a right angle (by the scholium of *Elements* III.27); and therefore CAE will be acute. Therefore the isosceles triangle ACE, having its third side CE greater than either of the equal sides, is acute-angled. Which was proposed.

Diagram. An arc of a circle centered at A, carrying the points B, C, D, E. The radii AC and AE, together with the chord CE, form the isosceles acute-angled triangle ACE; the radius AB and the short chord DE are also drawn.

- A (apex; center of the circle)
- B (leftmost point on the arc)
- C (point on the arc between B and D)
- D (point on the arc, adjacent to E)
- E (rightmost point on the arc)

PROBL. 16. PROPOS. 16.

[Margin: xvj.]

To describe in a given circle a quindecagon [quintidecagonum — a fifteen-sided figure] that is both equilateral and equiangular.

Let a quindecagon, equilateral and equiangular, be inscribed in the given circle ABC. An equilateral triangle D having been constructed — which, by the corollary of *Elements* I.5, will also be equiangular — [Margin: a. *Elements* IV.2] let an equiangular triangle ABC be inscribed in the given circle, which will also be equilateral, by the corollary of *Elements* I.6. [Margin: b. *Elements* III.26 or 28] And the three arcs AB, BC, CA will be equal — either because the three straight lines AB, BC, CA are equal, or because the three angles A, B, C of triangle ABC are equal. Therefore, of whatever equal parts the whole circumference ABC is fifteen, the arc AB — which is a third part of the whole circumference — will be five such parts. [Margin: c. *Elements* IV.11] Again, let an equilateral and equiangular pentagon AEFGH be inscribed in the given circle, applying one of its angles at the point A; [Margin: d. *Elements* III.28] and the five arcs AE, EF, FG, GH, HA will be equal.

Therefore, of whatever equal parts the whole circumference ABC is fifteen, the arc AE — being a fifth part of the whole circumference — will be three such parts. And so, since the arc AB contains five such parts, and the arc AE three, the remaining arc EB will contain two. [Margin: e. *Elements* III.30] Therefore, the arc EB being bisected at I, the arc BI will be a fifteenth part of the whole circumference. Hence the straight line BI, when drawn, will subtend a fifteenth part of the whole circumference; and if [Margin: f. *Elements* IV.1] fourteen other equal chords be fitted into the circle, an equilateral quindecagon will be inscribed in the circle, [Margin: g. *Elements* III.27] which is also equiangular, since its angles subtend equal arcs — all of them composed, namely, of 13 equal arcs, as is

evident. Therefore in the given circle [we have inscribed] a quindecagon, and so on. Which was to be done.

Similarly, by what has been said about the pentagon above, in Propositions 12, 13, and 14, we shall describe an equilateral and equiangular quindecagon about a given circle. Likewise, in a given equilateral and equiangular quindecagon we shall inscribe a circle; and finally, about the given quindecagon we shall describe a circle.

Diagram. The construction of a regular quindecagon in a circle. An equilateral triangle ABC and a regular pentagon AEFGH are inscribed in the same circle, sharing the vertex A; the arc EB (the difference between the triangle's and the pentagon's arcs) is bisected at I, so that the chord BI subtends one fifteenth of the circumference. A separate small equilateral triangle, labeled D, is the auxiliary figure used to construct the inscribed triangle. The heavy foxing on this page makes several of the lower vertices hard to resolve.

- A (top vertex; shared vertex of the triangle and the pentagon)
- E (upper left vertex, pentagon)
- I (left; midpoint of arc EB)
- B (lower left vertex, triangle)
- F (lower left vertex, pentagon; near the auxiliary triangle D) [?]
- G (lower right vertex, pentagon)
- H (right vertex, pentagon)
- C (lower right vertex, triangle) — not clearly legible under the staining [?]
- D (separate small equilateral triangle serving as the auxiliary construction)

Scholium

[Body heading, p. 159: SCHOLIVM.]

From the structure and demonstration of this problem a method, and a certain art, can be gathered, by which almost infinitely many figures may be inscribed in a given circle. For since the straight line AB is named from the ternary — three — because it is the side of the equilateral triangle, and the straight line AE from the quinary — five — because it is the side of the pentagon; if 3 be multiplied by 5, there result 15. Therefore, from those two sides...

[This opening continues Clavius's scholium to Book IV, Proposition 16 (the quindecagon). Everything in these three pages is Clavius's own added material — a

general theorem on inscribed-polygon sides, followed by two paired "Observations" on the relation between equilateral and equiangular figures inscribed in, or circumscribed about, a circle, each with its demonstrations. Euclid's Book IV has already ended at Prop. 16; Book V does not begin within these pages.]

Book IV — Clavius's scholia to Proposition 16 (continued)

[End of the quindecagon scholium:]

described in the circle, there will be inscribed in the same circle a figure of 15 sides and equal angles, by this reasoning. The denominator of side AB — that is, 3 — is exceeded by the denominator of side AE — that is, by 5 — by the binary [i.e. by 2]. Therefore the arc BE will contain two sides of the aforesaid figure; and so, once the arc BE has been bisected at I, the chord BI will be a side of the figure of 15 sides and equal angles, as was demonstrated. It was by roughly this technique that Euclid proceeded in describing the quindecagon within a circle. From it we may infer a theorem of the following kind.

[Theorem.] If two sides of two equilateral and equiangular figures are inscribed in a circle from the same point, the arc enclosed between those sides will contain as many sides of another figure — to be inscribed in the same circle — as there are units by which the denominators of those two sides differ from one another. And the figure to be inscribed will have as many sides, and equal angles, as there are units in the number produced by multiplying the two denominators together.

Diagram. A circle with point A at the top of the circumference and points B, C, D, E marked in succession down the left-hand arc. From A four chords are drawn — AB, AC, AD, AE — so that the arcs BC, BD, BE, CD, CE, DE between the endpoints can be compared. It illustrates the theorem on the sides of successive inscribed regular figures.

- A (top of circle): common starting point of all the chords
- B, C, D, E (descending the left arc): endpoints of the sides of the hexagon, pentagon, square, and equilateral triangle respectively

[Demonstration by example.] Let there be inscribed in the circle ABCDE — always starting from point A — several sides: namely, of the hexagon the side AB, of the pentagon AC, of the square AD, and finally of the equilateral triangle AE. Since, then, the denominator of side AB — namely 6 — exceeds the denominator of side AC — namely 5 — by a unit, the arc BC enclosed between those sides will contain one side of a figure of 30 sides and equal angles; for from multiplying 5 by 6 there is produced 30. That this is so will be demonstrated as follows. Of such equal

parts as the whole circumference is 30, the arc AB — a sixth part of the circumference — is 5, and the arc AC — a fifth part of the circumference — is 6. Therefore the arc BC will contain one such part.

By like reasoning the arc BD will contain two sides of a figure of 24 sides and equal angles. For the denominator of side AB, namely 6, exceeds the denominator of side AD, namely 4, by the binary [by 2]; and from multiplying 4 into 6 there come 24.

In the same way too the arc BE will comprise three sides of a figure of 18 sides. [For the denominators 6 and 3 differ by 3, and $3 \times 6 = 18$.]

The arc CD, for its part, will embrace one side of a figure of 20 sides. [Denominators 5 and 4 differ by 1; $5 \times 4 = 20$.]

The arc CE, again, two sides of a figure of 15 sides. [Denominators 5 and 3 differ by 2; $5 \times 3 = 15$.]

And finally the arc DE will contain one side of a figure of 12 sides and equal angles. [Denominators 4 and 3 differ by 1; $4 \times 3 = 12$.] By this art and method, then, the sides of almost infinitely many figures are found out.

[First Observation.] It must not be passed over in this place that every equilateral figure **inscribed** in a circle is also equiangular; but that not every equilateral figure **circumscribed** about a circle is necessarily equiangular as well — except when the number of its angles is odd, or, if it is even, when two adjacent angles are equal, or two non-adjacent ones (provided that, one of them being set first, the other occupies any even place whatever, such as the fourth — for if it occupied the second it would be adjacent to the first, which is contrary to the hypothesis — or the sixth, eighth, tenth, and so on). In this matter several have been deceived, thinking that every equilateral figure circumscribed about a circle is necessarily equiangular too; among them is Campanus [Campanus of Novara], no obscure interpreter of Euclid.

Diagram. An equilateral pentagon ABCDE inscribed in a circle, with A at the top, B at the upper left, E at the upper right, C at the lower left, and D at the lower right. It serves the demonstration that an equilateral inscribed figure is equiangular.

- A (top): first vertex
- B (upper left), E (upper right): adjacent vertices
- C (lower left), D (lower right): the remaining vertices

Demonstration. Let there be an equilateral figure ABCDE, of any number of angles, inscribed in a circle. I say that it is necessarily equiangular as well. For since the sides AB, BC, CD are equal, the arcs AB, BC, CD will also be equal [Margin: h — *Elements* III.28]; and therefore the whole arc ABC will be equal to the whole arc BCD. Hence the remaining arcs ADC, BED in the same circle will be equal. Consequently the angles ABC, BCD standing upon them will be equal [Margin: i — *Elements* III.27]. In the same way all the angles, however many there be, will be shown to be equal; and therefore the figure ABCDE is equiangular, whether the number of its angles be even or odd. Which was to be demonstrated.

Diagram. An equilateral pentagon ABCDE circumscribed about a circle whose centre is F. The vertices are A (top), B (upper left), E (upper right), C (lower left), D (lower right). From the centre F radii run to every vertex and to the points of contact G, L, H, K, I on the sides. It serves the demonstration for a circumscribed figure with an odd number of angles.

- A (top), B (upper left), E (upper right), C (lower left), D (lower right): vertices of the pentagon
- F (centre): centre of the inscribed circle
- G (on side AB), L (on side AE), H (on side BC), K (on side DE), I (on side CD): points of contact / feet of the perpendiculars from F

Demonstration. Let there be, again, an equilateral figure ABCDE, of any odd number of angles, circumscribed about a circle whose centre is F. I say that it is necessarily equiangular too. For when straight lines are drawn from the centre F to all the vertices and to the points of contact, these last will be perpendicular to the sides [Margin: k — *Elements* III.18]. And since the tangents AG, AL are equal (from the second corollary of *Elements* III.36), the two sides AG, AF will be equal to the two sides AL, AF. Then, since the bases FG, FL from the centre are also equal, the angles at A will be equal [Margin: l — *Elements* I.8]; and so the angle BAE will be bisected. In just the same way we shall show that all the remaining angles of the figure are bisected. Again, since the two sides AB, BF are equal to the two sides CB, BF, and contain equal angles (shown to be equal), the bases AF, CF and the angles BAF, BCF will also be equal [Margin: m — *Elements* I.4]. Since, then, these angles are the halves of the angles BAE, BCD, as was shown, the whole angles BAE, BCD will likewise be equal. By the same reasoning the line CF will equal the line EF, and the angle BCD will equal the angle DEA. And so on in succession: if the figure has more angles, every third angle will always be equal to the one from which it is third, one being left between them in the middle — that is, the first (and any angle whatever may be set up as the first) will be equal

to the third, the third to the fifth, the fifth to the seventh, the seventh to the ninth, and so on. Thus all the angles set in odd places will be equal to one another; and by the same reasoning all the angles of even places, such as the second, fourth, sixth, eighth, tenth, and so on, will be equal to one another —

Book IV (continued) — printed running header: LIBER IV. (p. 161)

— since the fourth is third from the second, and the sixth also occupies the place third from the fourth, and so on. Therefore, since the proposed figure has an odd number of angles, the first angle — which has been shown equal to all the angles in odd places — will be equal to the last angle, which is odd and adjacent to the first. And this last angle will, by the same reasoning, be equal to the second angle, being the third from the last (the first being left in the middle), and equal to all the others that occupy the place third from the second, such as the fourth, sixth, eighth, tenth, and so on up to the last but one. Wherefore all the angles of the proposed figure will be equal to one another. Which was to be demonstrated.

[Scholium on the even case.] This demonstration does not hold for equilateral figures circumscribed about a circle that have an even number of angles. For from it one may conclude only that the first angle is equal to the third, fifth, seventh, ninth, and the rest occupying odd places; but it will never be proved that the first is equal to the last, because the last occupies an even place — as in a quadrilateral the fourth, in a hexagon the sixth, in an octagon the eighth, and so on. Likewise, from the same demonstration it will only be gathered that the second angle is equal to the fourth, sixth, eighth, tenth, and the rest occupying even places; but it will never be shown that the second angle equals the first, because the first occupies an odd place. And so only the angles of odd places will be proved equal to one another, and only the angles of even places equal to one another.

But if two adjacent angles — or even two non-adjacent ones, provided that one of them is placed in an odd position and the other in an even position — are equal to one another, then at last the equality of all the angles will be concluded by the demonstration above. For if the first angle is equal to the second (since, when two adjacent angles are equal, we may call one of them the first and the other the second), then, since the first has been shown equal to all the angles occupying odd places, and the second to all those in even places, they will all be equal to one another. But if the first angle is equal to some angle occupying an even place (since, when two non-adjacent angles are equal, one lying in an odd place and the

other in an even place, we may call one of them the first and the other the fourth, or sixth, or eighth, and so on, according to how far it stands from the first — but not the second, since the second is adjacent to the first), then, since the first has been shown equal to all the others in odd places, and the other equal to all those in even places — and therefore also to the second angle — the first will also be equal to the second: that is, the two adjacent angles will be equal to one another. Wherefore, as we have just demonstrated, all the angles are equal to one another.

[Objection and counter-example.] But suppose someone should say that, although it cannot be gathered from that demonstration that every equilateral figure whose number of angles is even, circumscribed about a circle, is also equiangular, nevertheless the contrary is not gathered from it either; and that consequently such a figure may indeed be equiangular — not, to be sure, on account of that demonstration, but on account of some other — so that no equilateral figure circumscribed about a circle can be given which is not at the same time equiangular, as Campanus, with some others, asserted. If, I say, anyone should speak so, we reply that infinitely many equilateral figures of an even number of angles, circumscribed about a circle, are **not** equiangular.

Diagram. A hexagon BCDEFG circumscribed about a circle whose centre is A. The circle's circumference is divided by the three diameters BE, CF, DG into six equal parts at the points O, P, Q, R, S, T; six further points H, I, K, L, M, N are the points where the sides of the hexagon touch the circle. The tangent lines drawn at these points meet to form the (equilateral but non-equiangular) hexagon. This is a small-type, densely labelled figure; several peripheral labels could not be resolved with confidence.**

- A (centre): centre of the circle [label not clearly visible in the engraving — [?]]
- B (top vertex), C (left vertex), D (lower-left vertex), F (lower-right / right vertex), G (upper-right vertex): hexagon vertices; the sixth vertex E [?] (right side) could not be confirmed
- O (top), P (left), Q (lower left), R (bottom), S (lower right), T (right): the six equal division points of the circumference
- H (upper left), I (upper right), K (left), N (right), L (lower left), M (lower right / bottom): points of contact of the sides

Demonstration of the counter-example. Let a circle be described about the centre A, and let its circumference be divided by the three diameters BE, CF, DG into six equal parts OP, PQ, QR, RS, ST, TO, in the manner set out in the description of the hexagon. Next let the arc OP be cut unequally at H, so that OH is the greater

segment and PH the lesser. Let arcs OI, QK, QL, SM, SN be taken equal to the arc OH, in such a way that six equal arcs are laid off on both sides of the three non-adjacent semidiameters, one being left in the middle between each pair. There will then be, on both sides of the semidiameters left over, the six remaining arcs PH, PK, RL, RM, TN, TI, all equal. When straight lines have likewise been drawn from the centre A to the points H, K, L, M, N, I, let a perpendicular BC be drawn through H at right angles to HA, cutting the semidiameters AO, AP produced at B and C; this line will touch the circle at H, by the corollary of *Elements* III.16. The lines HB and AB must necessarily meet, because the two angles BHA, BAH are less than two right angles. For BHA is a right angle, and BAH — standing on the arc OH, which is less than a quadrant — is less than a right angle, by the scholium of *Elements* III.27. Let the straight line BI also be joined. And since the two sides AH, AB are equal to the two sides AI, AB, and contain equal angles standing on the equal arcs OH, OI [Margin: n — *Elements* III.27], the bases BH, BI and the angles H, I will also be equal [Margin: o — *Elements* I.4]. Since, then, BHA is a right angle by construction, BIA will be a right angle too; and therefore the line BI will touch the circle at I, and will meet the semidiameter AI produced at G, because the angles AIG, GAI are less than two right angles. For AIG has been shown to be a right angle, while GAI is less than a right angle (by the scholium of *Elements* III.27), on account of the arc TI, which is less than a quadrant. And since the two angles I, A of triangle GAI are equal to the two angles H, A of triangle CAH — for I and H are right angles, and GAI, CAH are equal, standing on the equal arcs TI, PH [Margin: p — *Elements* III.27] — and the sides AI, AH adjacent to them are equal, the sides GI, GA will also be equal to the sides HC, CA [Margin: q — *Elements* I.26]. Since, then, BI has been shown equal to BH, the whole BG will be equal to the whole BC. By the same reasoning, the line GN drawn will touch the circle at N and will meet the semidiameter AF produced at F, and will be equal to GB. Likewise the line FM joined will touch the circle at M, and will meet the semidiameter AR produced at E, and will be equal to FG. Similarly the line EL drawn will touch the circle at L, and, the semidiameter AQ being drawn out, will meet it at D, and will become equal to EF. Finally the line DK joined will touch the same circle at K, and will meet the semidiameter AP produced at C, and will become equal to DE. That DK meets the semidiameter AP at the same point C at which the line BH meets it, is manifest. For if it cut it at another point, then — since the line CK drawn touches the circle at K, as has been demonstrated — two straight lines would touch the circle at the same point K, and thus between the circumference and the tangent a single straight line would be intercepted up to the point of contact, which Euclid demonstrated cannot happen [Margin: r — *Elements* III.16]. Therefore the hexagon BCDEFG circumscribed about the circle is equilateral. But

that this same figure is **not** equiangular we shall demonstrate as follows. Since the figure BCDEFG is equilateral, then, by what we showed a little earlier, the angles of odd places — namely B, D, F — will be equal to one another, and the angles of even places — namely C, E, G — will be equal to one another; and all will be bisected by the semidiameters. But since the three angles of triangle ABH are equal to the three angles of triangle ACH [Margin: s — *Elements* I.32], the right angles at H being taken away, the remaining two will be equal to the remaining two. Now BAH is greater than CAH (by the scholium of *Elements* III.27), because the arc OH is greater than the arc PH. Therefore the remaining angle ABH will be less than the remaining angle ACH; and since these are the halves of the whole angles B and C, as was shown, the whole angle CBG will also be less than the whole angle BCD. In the same way the whole angles D, F will be shown to be less than the whole angles E, G. Therefore the hexagon BCDEFG is not equiangular. Which was to be demonstrated.

The very same construction and demonstration can be carried out in the octagon (the circle being cut by four diameters into 8 parts), in the decagon (by five diameters into 10 parts), and so on.

[*Corollary.*] But if an equilateral figure of any number of angles be circumscribed about a circle by the method of Proposition 12 — a similar figure having first been described within the circle, and lines drawn touching the circle at the angles of the inscribed figure, as was done in the pentagon of Proposition 12 — then that figure will necessarily be equiangular as well, as is clearly established from the demonstration of that same proposition.

Book IV (continued) — printed running header: EVCLID. GEOM. (p. 162)

[*Second Observation — the converse.*] It is also worth observing that every equiangular figure **circumscribed** about a circle is also equilateral; but that not every equiangular figure **inscribed** in a circle is necessarily equilateral as well — except when the number of its sides is odd, or, if it is even, when two adjacent sides are equal, or two non-adjacent ones (provided that, one of them being placed first, the other occupies any even place whatever, such as the fourth — for if it occupied the second it would be adjacent to the first, which is contrary to the hypothesis — or the sixth, eighth, tenth, and so on). In this matter, too, one might easily be deceived.

Diagram. An equiangular pentagon ABCDE circumscribed about a circle whose centre is F, with A at the top, B upper left, E upper right, C lower left, D lower

right; radii run from F to the vertices and to the points of contact G, L, H, K, I on the sides. It serves the demonstration that an equiangular circumscribed figure is equilateral.

- A (top), B (upper left), E (upper right), C (lower left), D (lower right): vertices of the pentagon
- F (centre): centre of the inscribed circle
- G (on AB), L (on AE), H (on BC), K (on DE), I (on CD): points of contact / feet of the perpendiculars from F

Demonstration. Let there be an equiangular figure ABCDE circumscribed about a circle whose centre is F. I say that it too is necessarily equilateral. For when straight lines FG, FH, FI, FK, FL are drawn from the centre F to the points of contact — which are perpendicular to the sides of the figure [Margin: t — *Elements* III.18] — and likewise straight lines FA, FB, FC, FD, FE are drawn from the centre F to the vertices of the figure: since the tangents AG, AL are equal (from the second corollary of *Elements* III.36), the two sides AG, AF of triangle AGF will be equal to the two sides AL, AF of triangle ALF; and the bases FG, FL from the centre are also equal. Therefore the angles at A, contained by those sides, are equal [Margin: u — *Elements* I.8]; and so the angle BAE is bisected. In just the same way we shall show that the remaining angles of the figure are bisected; and therefore, since the whole angles are supposed equal, their halves will be equal too. Hence the two angles A, G of triangle AFG will be equal to the two angles B, G of triangle BFG; and the side FG, opposite to one of the equal angles, is common. Therefore the sides AG, BG will also be equal [Margin: x — *Elements* I.26]; and so the side AB is bisected at G. In the same way you will prove that the remaining sides of the figure are bisected. Since, then, AG, AL are equal to their halves, the whole lines AB, AE will also be equal. And by the same reasoning AB, BC, and BC, CD, and CD, DE, and DE, EA will be equal. Wherefore the figure ABCDE is equilateral, whether the number of its sides be even or odd. Which was to be demonstrated.

Diagram. An equiangular pentagon ABCDE inscribed in a circle, with A at the top, B upper left, E upper right, C lower left, D lower right, and a small point marked i near the interior. It serves the demonstration for an inscribed equiangular figure with an odd number of sides.

- A (top), B (upper left), E (upper right), C (lower left), D (lower right): vertices of the inscribed pentagon
- i (interior): auxiliary point

Demonstration. Let there be, again, an equiangular figure ABCDE, of any odd number of sides, inscribed in a circle. I say that it too is necessarily equilateral. For since the angles BAE, ABC are supposed equal, the arcs BCE, ADC on which they stand will be equal [Margin: y — *Elements* III.26]; and when the common arc is taken away from these, the remaining arcs BAE, ABC will likewise be equal. Therefore, the common arc AB being subtracted, the remaining arcs will also be equal. By the same reasoning the arc BG will be equal to the arc DE; and consequently the side AE will be equal to the side BC [Margin: z — *Elements* III.29], and the side BC to the side DE. And so on in succession: if the figure has more sides, every third side will always be equal to the one from which it is third, one being left in the middle — that is, the first (and any side whatever may be set up as the first) will be equal to the third, the third to the fifth, the fifth to the seventh, the seventh to the ninth, and so on. And in this way all the sides set in odd places will be equal to one another. By the same reasoning all the sides of even places, such as the second, fourth, sixth, eighth, tenth, and so on, will be equal to one another — since the fourth is third from the second, and the sixth also occupies the place third from the fourth, and so on. Therefore, since the proposed figure has an odd number of sides, the last side will be equal to the first, to which it is next; and this last side will, by the same reasoning, be equal to the second, being the third from the last, the first being left in the middle; and to all the others that occupy from the second the place third, and so on up to the last but one. Wherefore all the sides of the proposed figure will be equal to one another. Which was to be demonstrated.

[*Scholium on the even case.*] This demonstration, however, does not fit equiangular figures of an even number of sides inscribed in a circle. For from it one may conclude only that the first side is equal to the third, fifth, seventh, and the others occupying odd places; but it will never be demonstrated through it that the first is equal to the last, because the last occupies an even place — as in a quadrilateral the fourth, in a hexagon the sixth, and so on. By like reasoning the same demonstration proves only that the second side is equal to the fourth, sixth, eighth, and the others in even places; but it will never be gathered from it that the second side is equal to the first, because the first lies in an odd place. And so only the sides of odd places will be proved equal to one another, and only the sides placed in even places equal to one another.

But if two adjacent sides, or even two non-adjacent ones — provided one of them is set in an odd place and the other in an even place — are equal to one another, then at last the demonstration above will conclude the equality of all the sides. For if the first side is equal to the second (since, when two adjacent sides are

equal, we may call one of them the first and the other the second), then, since it has been shown that the first is equal to all the sides of odd places, and the second to all those of even places, it is clear that all are equal to one another. And if the first side is equal to some side occupying an even place (since, when two non-adjacent sides are equal, one lying in an odd place and the other in an even place, we may call one of them the first and the other the fourth, or sixth, and so on, according to how far it stands from the first — but not the second, since the second is adjacent to the first), then, since the first has been shown equal to all the others of odd places, and the other to all those of even places, and therefore also to the second side, the first will also be equal to the second: and thus the two adjacent sides will be equal to one another. As, therefore, we have just demonstrated, all the sides will be equal to one another.

[Objection and geometrical proof.] But if anyone should doubt whether an equiangular figure of an even number of sides can be given, inscribed in a circle, which is not equilateral (for although the demonstration above does not prove that all its sides are equal when all its angles are equal, yet the contrary cannot be inferred from it either), we shall demonstrate it geometrically in this way. In the first place, it is agreed that this holds in quadrilateral figures. For a rectangle longer on one side [an oblong] is equiangular — since all its angles are right — but not equilateral. And who would doubt that it can be inscribed in a circle? Next, then, let there be an equilateral and equiangular hexagon ABCDEF described in a circle; and in the arc BC let any point G be taken; and in the third arc from it let an arc DH be taken equal to the arc BG; likewise in the fifth arc from it, an arc FI equal to it; and let the straight lines AG, GC, CH, HE, EI, IA be joined. I say that the hexagon AGCHEI is equiangular, but not equilateral.

Diagram. A circle carrying a regular hexagon ABCDEF (solid), with B upper left, A upper right, C left, F right, D lower left, E lower right; and an inscribed irregular hexagon AGCHEI (dotted), where G lies on the arc BC (left), I on the arc FA (right), and H on the arc DE (bottom). It shows an equiangular but non-equilateral inscribed hexagon.

- B (upper left), A (upper right): adjacent vertices of the regular hexagon
- C (left), F (right): vertices of the regular hexagon
- D (lower left), E (lower right): remaining vertices of the regular hexagon
- G (on arc BC, left), I (on arc FA, right), H (on arc DE, bottom): the added points forming the dotted hexagon AGCHEI

Demonstration (begins). That it is equiangular we shall show thus. The angles B and G are equal, being in the same segment ABC [Margin: a — *Elements* III.21]. By

the same reasoning the angles D, H and F, I are equal. Moreover, since the arcs BG, DH are equal by construction, the common arc GD being added, the whole arcs BCD, GCH will be equal. Therefore the remaining arcs BFD, GFH left in the circle will be equal; and consequently the angles BCD, GCH standing upon them will likewise be equal [Margin: b — *Elements* III.27]. In just the same way we shall show that the angles

(Continuation of the scholium to Book IV, Proposition 16 — Clavius's commentary on inscribing regular polygons.)

that DEF, HEI and FAB, IAG are equal to one another. Therefore the six angles of the hexagon AGCHEI are equal to the six angles of the hexagon ABCDEF, each to each. And so, since this latter is assumed to be equiangular, the former will be equiangular too. That it is not, however, equilateral, we will prove as follows. Side AG is greater than side AB, and side GC is less than side BC, by the scholium to Proposition 29 of Book III. By the same reasoning, sides CH and EI are greater than sides CD and EF, while sides HE and IA are less than sides DE and FA. Since, then, the sides AB, BC, CD, DE, EF, FA are assumed equal, the sides AG, GC, CH, HE, EI, IA will be unequal — although AG, CH, EI are equal to one another, and GC, HE, IA to one another (leaving always one in the middle), as we showed above.

The very same thing will be demonstrated in the same way to be possible in the octagon, the decagon, and the other figures of an even number of sides, provided that first an octagon, decagon, and the other equilateral and equiangular figures are inscribed in the circle.

But if a figure is inscribed in a circle by the method of Propositions 11, 15, and 16, it will always be both equiangular and equilateral, as is clear from the demonstrations of those propositions.

Furthermore, whatever equilateral and equiangular figure we have shown how to inscribe in a circle, we shall likewise know how to describe about a circle, and how to inscribe a circle within it, and how to describe a circle about it, if we imitate the technique that was set out for the pentagon in Propositions 12, 13, and 14.

Again, given any equilateral and equiangular figure inscribed in a circle, there will be inscribed in the same circle a figure having twice as many sides. For if the arcs subtended by the sides are bisected and the bisection points joined by straight lines, the conclusion follows. Thus by means of an inscribed equilateral triangle a hexagon is also inscribed, and hence a dodecagon, a figure of 24 sides,

and so on. Likewise from a square described in a circle an octagon is inscribed, and thence a figure of 16 sides, a figure of 32, 64, 128 sides, and so on.

Moreover, all equilateral and equiangular figures can be inscribed in a circle by means of isosceles triangles, as certain interpreters of Euclid rightly point out at this place.

For figures of an odd number of sides will be inscribed by means of isosceles triangles whose base angles are multiples of their vertex angle. Thus by means of an isosceles triangle each of whose base angles is equal to its vertex angle, described in the circle, there will be inscribed the first figure of odd-sided figures — that is, the equilateral triangle; for an isosceles triangle of this kind will be an equilateral triangle. But if there is inscribed in the circle an isosceles triangle each of whose base angles is double the vertex angle, there will be inscribed the second figure of odd-sided figures, namely the pentagon, provided the two equal angles are bisected, as was shown in Proposition 11. The heptagon, the third figure of odd-sided figures, will be inscribed in the circle by means of an isosceles triangle having each of its base angles triple the vertex angle, if its two equal angles are each divided into three angles equal to the vertex angle. Likewise the fourth figure of odd-sided figures, such as the enneagon, will be inscribed in the circle by means of an isosceles triangle each of whose base angles is quadruple the vertex angle, if each is distributed into four angles equal to the vertex angle, and so on.

This division of the base angles into equal parts is very easy. For if at the vertex angle there are set up in order, along the base, as many equal angles as there are units in the number of the multiple ratio that each base angle bears to the remaining [vertex] angle, the angle will be divided into equal parts. But once such an isosceles triangle has been described in the circle, the figure will be described in the circle without dividing the base angles, provided that straight lines equal to the base are fitted into the circle; for the base is always one side of the figure, as was evident in the case of the pentagon.

Figures of an even number of sides, on the other hand, will be inscribed in a circle by means of isosceles triangles whose base angles are multiples-and-a-half [*sesquilateri*] of their vertex angle. Thus the square, constituting the first figure of even-sided figures, will be inscribed by means of an isosceles triangle each of whose base angles is one-and-a-half times [*sesquialter*] the vertex angle. For the vertex angle stands on a quarter of the circumference: since the two base angles together contain three angles equal to the vertex angle — because each contains it once, and half of it besides — they subtend three parts of the circumference,

and therefore the vertex angle subtends one only. The hexagon, that is, the second figure of even-sided figures, will be inscribed by means of an isosceles triangle each of whose base angles is two-and-a-half times [*duplus sesquialter*] the vertex angle. For the vertex angle stands on a sixth of the circumference, since the remaining angles taken together contain it five times — because each contains it twice, and half of it besides. Likewise the octagon, that is, the third figure of even-sided figures, will be inscribed by means of an isosceles triangle having each of its base angles three-and-a-half times [*triplus sesquilaterus*] the vertex angle.

If, then, a technique were discovered by which isosceles triangles could be constructed having base angles that are multiples of their vertex angle — in the way that Euclid constructed an isosceles triangle having each base angle double the vertex angle — all figures of an odd number of sides could easily be described in a circle. And if their arcs were bisected, all figures of an even number of sides, after the square, would also be inscribed; and thus the circumference of any circle could be divided geometrically into any number of equal parts. This would be of the greatest use to astronomers. For Orontius Finaeus [Oronce Fine] does not rightly claim it for himself in the little book — hitherto, as he himself says, longed for — on the complete description of all rectilinear figures within a circle, and so on, since his demonstrations are false and sophistical, as was shown geometrically by Petrus Nonius Lusitanus [Pedro Nunes] in his book on the errors of Orontius [*De erratis Orontii*].

We ourselves, however, shall at the end of Book 6, following Pappus of Alexandria, describe geometrically a certain curved line [*linea inflexa*] by which not only isosceles triangles whose base angles bear a given ratio to the remaining angle may be constructed — and hence all equilateral and equiangular figures described in a circle — but also the arc of any circle may be distributed into any number of equal parts, whether it be a quadrant or not. Indeed, by means of the same curved line any circle whatever will, by a pleasing operation, be transformed without any trouble into an equal square, as we shall likewise say there. This is a matter that has kept the minds of mathematicians in suspense up to now.

But let us show, if you please, by what method as well any equilateral and equiangular figure may be inscribed in a circle without isosceles triangles whose base angles have a given ratio to the remaining angle. Let, then, an equilateral and equiangular heptagon be inscribed in the circle ABCDEFG. Let its quadrant AH be cut into seven equal parts — that is, into as many as the figure to be

inscribed has sides or angles. You will cut the quadrant AH into the proposed equal parts either by the means we said we would demonstrate at the end of Book 6, or by means of a compass, opening its legs now more, now less, until you find that their span divides the quadrant into the desired parts. For a quadrant is more easily divided into any number of equal parts than the whole circumference, because, by trying again and again and as it were repeating the operation, the work appears more clearly in a small magnitude than in a large one, in that [it is easier to judge] how much must be taken away...

Diagram. A circle with an inscribed equilateral heptagon and the construction for dividing the quadrant. The heptagon vertices are labelled around the circle; a radius runs to the point H on the circumference, and the arc from A toward G is subdivided by small tick-marks (the divided quadrant AH).

- A (top of circle): first vertex / start of the quadrant division
- B (upper left): heptagon vertex
- C (left): heptagon vertex
- D (lower left): heptagon vertex
- E (lower right): heptagon vertex
- F (right): heptagon vertex
- G (upper right): heptagon vertex
- H (right, on circle, at the end of the drawn radius): endpoint of the quadrant AH being subdivided

how much ought to be taken from, or added to, the one part obtained by means of the compass, if that part does not yield the one desired. Once the quadrant has been cut into seven equal parts — or into more, if a figure of more sides is wanted — the straight line AG, which subtends four such parts, will be the side of the figure to be inscribed. For since in the whole circumference there are contained four times as many equal parts as those into which the quadrant is divided, the aggregate of four parts will be contained in the whole circumference as many times as one part is contained in the quadrant: because each part, together with three others (one taken in each of the other three quadrants), makes up an aggregate of four parts. This will also become clear as follows. Since parts have the same ratio as their equimultiples, as Euclid demonstrates in Book 5, Proposition 15 (for it is permissible to apply that proposition here, since it in no way depends on what precedes), one part will be to the quadrant as the quadruple of one part — that is, the arc AG — is to the quadruple of the quadrant, that is, to the whole circumference. Whatever part, then, one of those into which the quadrant is divided is of the quadrant, such a part will the arc AG be of the

whole circumference. And so, if the quadrant is divided into 7 parts, there will be contained 28 such parts in the whole circumference. Therefore the 4 [parts] make $\frac{4}{28}$, that is, $\frac{1}{7}$ of the whole circumference. Likewise, if the quadrant is cut into 11 parts, there will be contained 44 such parts in the whole circumference; and so the 4 make $\frac{4}{44}$, that is, $\frac{1}{11}$ of the whole circumference; and so on for the rest. Therefore, if from the arc AG of four parts equal arcs are continuously cut off, and straight lines are subtended to those same arcs, the proposed figure will be inscribed in the circle, as is clear from what has been demonstrated.

(Praxis: to construct a regular figure on a given straight line.)

Now if on a given straight line any equilateral and equiangular figure whatever is to be described, we shall accomplish it by this method. Let an equilateral and equiangular pentagon be constructed on the given straight line AB. Produce BA to C so that AC is equal to AB; from A, through C, describe an arc of a circle; and, having drawn AD perpendicular to AC so that CD is a quadrant (by the scholium to Proposition 27 of Book III), let the quadrant CD be divided into five equal parts — that is, into as many as the figure to be constructed has sides. Let 4 of these be CE, and join the straight line AE, which will be equal to AB. I say that the angle BAE is equal to the angle of an equilateral and equiangular pentagon. For, taking an arc CF equal to the arc CE, let the straight lines CE, CF be joined. And since CE, subtending 4 parts of the quadrant, is the side of an equilateral and equiangular pentagon to be described in the circle ECF (as we proved just now), CF will be another side; and hence the two sides EC, FC will contain the angle ECF of an equilateral and equiangular pentagon. Now since, when the straight line AF has been drawn, the two sides EC, CA are equal to the two sides FC, CA, and the bases AE, AF are likewise equal, [Margin: (c) Elem. I.8] the angles ECA, FCA will be equal. Since, then, [Margin: (d) Elem. I.5] the angles ACE, AEC are also equal, ACF will be equal to AEC; and, adding the common angle ACE, the whole angle ECF will be equal to the two angles ACE, AEC. But [Margin: (e) Elem. I.32] the exterior angle BAE is equal to the same interior angles ACE, AEC. Therefore ECF and BAE will be equal to one another. Since, then, ECF is an angle of a pentagon, BAE too will be an angle of a pentagon. Consequently, if a circle is described about the three points B, A, E, and straight lines equal to AB, AE are [Margin: (f) Elem. IV.1] fitted into it — BH, HG, GE — an equilateral and equiangular pentagon will have been described in the circle ABHGE, and hence on the given straight line AB. Which was to be done. Nor is there any doubt that straight lines equal to AB, AE can be fitted into the circle so as to complete the whole circumference. For the pentagon's angle BAE stands on three-fifths of the whole circumference, while the individual sides AB, AE each subtend one-fifth; and therefore the individual sides

BH, HG, GE, being taken equal to AB, AE, each subtend one-fifth as well, and so they will complete the whole arc BGE, which contains three-fifths. The same reasoning holds for the other equilateral and equiangular figures.

If perhaps we have at hand some equilateral and equiangular figure to which we wish to construct a similar one on a given straight line — whether that figure is described in some circle or not — it will be enough to construct an angle BAE equal to one of its angles at the end of the given line AB. For if, having placed a straight line AE equal to AB, a circle is described through the three points B, A, E, we shall complete the proposed figure, as we said before.

(Praxis of Ptolemy: to inscribe a pentagon and decagon in a given circle.)

Since, however, that inscription of an equilateral and equiangular pentagon in a circle which Euclid handed down is long and difficult, it has seemed good to append to this fourth book a certain practical construction by which, in one and the same operation, Ptolemy, in Book 1 of the *Almagest* [*magna constructio*], inscribes in a given circle an equilateral and equiangular pentagon and decagon. Let there be a given circle ABC whose center is D. Having drawn the diameter BC, let DA be erected perpendicular to BC. Then, the semidiameter CD having been bisected at E, let the straight line EA be drawn, and let EF be cut off equal to it. And so, if the straight line AF is drawn, AF will be the side of the pentagon, and DF the side of the decagon, to be inscribed in the given circle, as he demonstrates. But since the demonstration of this matter depends on Book 13 of Euclid, it does not seem it should be written here, but rather deferred to its proper place, namely to Book 13.

Nor will it be beyond our plan, or foreign to this book, if we add one further theorem, namely:

Theorem. If the bisection points of the sides of an equilateral and equiangular figure are joined by straight lines, the inscribed figure will likewise be equilateral and equiangular, having the same number of sides as that figure, and having the same center.

Definition. The *center* of an equilateral and equiangular figure is called that point from which a circle is inscribed in the figure, or circumscribed about it — so that the center of the circle and of the figure is the same.

Diagram. The construction of a pentagon on the given line AB. A circle is described through B, A, E; the quadrant CD is divided (with tick-marks along an arc near D–E), and the pentagon ABHGE is fitted in.

- A (center of the figure, at the intersection of the drawn lines): endpoint of the given line and vertex of the constructed angle BAE
- B (lower right): endpoint of the given line AB
- C (left): point on the produced line BA, with $AC = AB$
- D (upper, right of E): endpoint of the perpendicular; CD is the quadrant
- E (upper left): the point marking $4/5$ of the quadrant; $AE = AB$
- F (bottom): point with arc $CF = CE$
- G (top): pentagon vertex
- H (right): pentagon vertex

Diagram. Ptolemy's construction of the pentagon and decagon side in a semicircle. The diameter BC carries the points, with the apex A above and straight lines drawn from A to the base points.

- A (apex, top of the semicircle): pole of the perpendicular DA
- B (left end of the diameter): endpoint of diameter BC
- F (between B and D on the base): point with $EF = EA$; AF is the pentagon side, DF the decagon side
- D (center of the circle, on the base): center; DA is perpendicular to BC
- E (between D and C on the base): midpoint of the semidiameter DC
- C (right end of the diameter): endpoint of diameter BC

(Demonstration of the appended theorem on the inscribed midpoint-figure.)

Let there then be an equilateral and equiangular figure ABCDEF, whose sides are bisected at G, H, I, K, L, M, the straight lines GH, HI, IK, KL, LM, MG being joined. I say that the figure GHIKLM, inscribed in the figure ABCDEF, is also equilateral and equiangular, and has the same center. It will indeed be equilateral, because its sides, subtending equal angles contained by equal straight lines (namely by the halves of equal sides), [Margin: (g) Elem. I.4] are equal. And since the three angles AMG, GML, LMF, as well as the three FLM, MLK, KLE, [Margin: (h) Elem. I.13] are equal to two right angles — while AMG, LMF, FLM, KLE are [Margin: (i) Elem. I.8] equal to one another, since they are contained by equal sides and subtended by equal bases — the remaining angles GML, MLK will be equal. And by the same argument we shall conclude that the remaining angles are equal both to these and to one another. Therefore the figure GHIKLM is equiangular as well.

That it has the same center will be shown as follows. From the center N of the figure ABCDEF let straight lines NG, NH, and so on be drawn to all the angles of

the inscribed figure, and let NA, NB be joined. Since, then, the sides AG, GN of the triangle AGN are equal to the sides BG, GN of the triangle BGN, and the bases AN, BN are equal (being semidiameters of the circle described about the figure), [Margin: (k) Elem. I.8] the angles AGN, BGN will be equal, and therefore right angles. Hence NG is perpendicular to the side AB. In the same way the remaining lines NH, NI, and so on will be perpendicular to the sides BC, CD, and so on. And since, by Definition 4 of Book 3, these show the distances of the equal straight lines AB, BC, and so on from the center N to be [Margin: (l) Elem. III.14] equal to one another, a circle described from N with radius NG will pass through the remaining angles H, I, K, L, M. And therefore N will be the center of the figure GHIKLM, that is, of the circle described about that figure. Which was the proposition.

(Scholium: which regular figures tile the plane.)

Nor indeed should this be passed over: that, among all equilateral and equiangular figures, only the triangle, the square, and the hexagon fill space — that is, only some number of triangles, or squares, or hexagons, can be so fitted together in a plane that there is no gap between their angles, but they constitute a plane surface. For six angles in an equilateral triangle, four in a square, and three in an equilateral and equiangular hexagon are equal to four right angles, which is exactly the space around any point in a plane, as we showed at Proposition 15 of Book 1. For since one angle of an equilateral triangle contains $\frac{2}{3}$ of one right angle, and since all three contain $\frac{6}{3}$ of one right angle — that is, two right angles — six such angles will contain $\frac{12}{3}$ of one right angle, that is, four right angles. Likewise, the four angles in a square are four right angles. Finally, since one angle of an equilateral and equiangular hexagon contains $\frac{4}{3}$ of one right angle, and all six contain $\frac{24}{3}$ of one right angle — that is, eight right angles — three such angles will contain $\frac{12}{3}$ of one right angle, that is, four right angles. This is not seen in the other equilateral and equiangular plane figures. For three angles in an equilateral and equiangular pentagon are equal to $\frac{18}{5}$ of one right angle, that is, to $3\frac{3}{5}$ right angles only, while four are equal to $\frac{24}{5}$ of one right angle, that is, to $4\frac{4}{5}$ right angles — because all five are equivalent to 6 right angles, that is, they constitute $\frac{30}{5}$ of one right angle, and therefore one contains $\frac{6}{5}$ of one right angle. Three pentagons, then, cannot fill space, since the three angles of three fitted together in a plane are less than four right angles: for they make only three right angles with three-fifths. By the same reasoning four pentagons cannot fill space, because the four angles of four fitted together in a plane are greater than four right angles, since they are equal to four right angles and moreover to four-fifths of one right angle, as has been said. By like reasoning space cannot be

filled by heptagons either. For three angles of any equilateral and equiangular heptagon are equal to $30/7$ of one right angle, that is, to $4 \frac{2}{7}$ right angles. For since all seven angles are equal to 10 right angles — that is, comprise $70/7$ of one right angle — it follows that one contains $10/7$ of one right angle, that is, one right angle and $3/7$ of one right angle besides; and hence three contain four right angles and $2/7$ of one right angle. Therefore, three heptagons being fitted together in a plane, their three angles cannot fill space, since they exceed four right angles. A fortiori, neither will four heptagons fill space; nor three octagons, equilateral and equiangular, nor four; nor three or four equilateral and equiangular figures of a greater number of sides than eight — because three angles taken together are always greater than four right angles, being greater than the three angles of an equilateral and equiangular heptagon, which we showed to be greater than four right angles. Therefore only the equilateral triangle, the square, and the equilateral and equiangular hexagon can fill space with their angles, as we have said.

FINIS ELEMENTI QVARTI

(The End of the Fourth Element.)

Diagram. An equilateral, equiangular hexagon ABCDEF with a second hexagon GHIKLM inscribed at the midpoints of its sides; all midpoint-vertices are joined to the common center N by radii, subdividing the figure into triangles.

- A (top-left vertex of the outer hexagon): outer hexagon vertex [?]
- B (left vertex of the outer hexagon): outer hexagon vertex
- C (bottom-left vertex): outer hexagon vertex
- D (bottom-right vertex): outer hexagon vertex
- E (right vertex): outer hexagon vertex
- F (top-right vertex): outer hexagon vertex
- G (upper left): midpoint of side AB, inner-hexagon vertex
- H (lower left): midpoint of side BC, inner-hexagon vertex
- I (bottom center): midpoint of side CD, inner-hexagon vertex
- K (lower right): midpoint of side DE, inner-hexagon vertex
- L (upper right): midpoint of side EF, inner-hexagon vertex
- M (top center): midpoint of side FA, inner-hexagon vertex
- N (center): common center of both hexagons and of the circumscribed circle

EUCLID'S ELEMENTS, BOOK FIVE

DEFINITIONS

I.

[Euclid, Definition 1] A part is a magnitude of a magnitude, the smaller of the larger, when the smaller measures the larger.

[Clavius's commentary] In the preceding four books Euclid treated continuous quantity considered in itself. In the next two he discusses that same quantity not in itself, but insofar as one is related to another — that is, insofar as, when compared with another, it has some ratio to it. In this fifth book he teaches the ratios of continuous quantities in general, without descending to any particular kind of quantity such as a line, a surface, or some body. In the sixth book, by contrast, he shows in particular what ratios lines, angles, circumferences of circles, triangles, and other plane figures have to one another. So, to carry out his plan, he first defines the terms that are used in the demonstrations concerning ratios.

Diagram. A column of six labelled straight-line magnitudes, drawn one above another and used in the commentary on Definitions I and II. Reading down the figure:

- A: a short plain segment (the small measuring magnitude).
- B: a longer segment subdivided by tick marks (per the text, A taken three times measures B, so $B = 3A$).
- C: a still longer segment subdivided by more tick marks (A taken six times measures C, so $C = 6A$).
- F: a long segment with tick marks and a dotted continuation at its right end.
- E: a segment with a tick mark followed by a short dotted stretch.
- D: a short plain segment (the magnitude that measures neither E nor F).

The figure illustrates that A is a part of B and C, while D is not a part of E and F.

And so he says that the smaller magnitude, which measures some larger magnitude, is called a part. For example, since magnitude A, taken three times, measures magnitude B, and taken six times measures magnitude C, magnitude A will be called a part of magnitudes B and C. But since magnitude D does not measure magnitudes E and F — rather, taken twice it exceeds magnitude E, taken

three times it falls short of magnitude F, and taken four times it exceeds that same F — magnitude D will not be called a part of magnitudes E and F.

Among mathematicians a part is of two kinds. One kind measures its whole, so that when repeated a certain number of times it makes up its whole; such is the number 4 set beside 8, 12, 16, 20, and so on. The other kind does not measure its whole, but when taken a certain number of times either exceeds it or falls short of it; of this kind is the number 4 placed beside 6, 7, 9, 10, 18, 38, and so on. The former is usually called an aliquot part, the latter an aliquant part. Here, then, Euclid defines only the aliquot part — both because this alone measures its whole (for an aliquant part is not said to measure its whole), and also because, as will be established from Book 7, an aliquant part is, in numbers, not called by Euclid a "part" but "parts." For the number 4 is not a part of the number 6, but two of its thirds — which are two twos. There is a further reason: in all the demonstrations of this fifth book, "part" is taken by every commentator to mean an aliquot part. It is therefore quite surprising that some interpreters of Euclid — among them Peletier [Jacques Peletier du Mans] — maintain that "part" is here defined so as to embrace every part, both aliquot and aliquant, when nonetheless in the demonstrations they themselves understand by the word "part" only the aliquot part.

II.

[Euclid, Definition 2] A multiple, on the other hand, is the larger of the smaller, when the smaller measures the larger.

[Clavius's commentary] As in the previous example, both magnitude B and magnitude C are a multiple of magnitude A, since A measures each of them. But neither magnitude E nor magnitude F is to be called a multiple of magnitude D, because D measures neither of them. Thus "part" is referred to "multiple," and "multiple" to "part," so that the smaller quantity that measures the larger is called a part of the larger, while the larger, measured by the smaller, is called a multiple of the smaller.

It is, moreover, quite clearly gathered from this definition that a part was defined earlier as that which measures its whole exactly. For if 6 were said to measure 7, as Peletier wishes, then by this definition 7 would be a multiple of 6 — which is absurd. Furthermore, when two smaller magnitudes measure two other larger ones equally — that is, when one smaller magnitude is contained in one larger as many times as the other smaller is contained in the other larger — these two

larger magnitudes are called equimultiples of those two smaller ones. You will say the same if several smaller magnitudes equally measure several larger ones.

III.

[Euclid, Definition 3] A ratio is a certain mutual relation, in respect of quantity, between two magnitudes of the same kind.

[Clavius's commentary] When two quantities of the same kind — such as two numbers, two lines, two surfaces, two solids, and so on — are compared with one another in respect of quantity, that is, in respect of one being greater than the other, or smaller, or equal, this kind of comparison, or mutual relation, is called a ratio, or (as others prefer) a proportion. And so, if some line is compared with some surface, or a number with a line, that comparison will not be called a ratio, because a line and a surface, and a number and a line, are not quantities of the same kind. Likewise, if some line is compared with another line in respect of quality — that is, in respect of one being white and the other black, or one being hot and the other cold, and so on — then, although both are of the same kind, that comparison will not be called a ratio, because it is not made in respect of quantity.

Although a ratio is properly found only among quantities, nevertheless all other things that in some way partake of the nature of quantity — such as times, sounds, voices, places, motions, weights, and powers — are also said to have a ratio, if their relation is considered in respect of quantity. Thus, when we say that one time is greater than another, or smaller, or that two times are equal, and so on, such a relation will be called a ratio, since the times are then considered as being, in a way, quantities.

Furthermore, in every ratio the quantity that is referred to another is called by Euclid, and by other geometers, the antecedent of the ratio; while that to which the other is referred is usually called the consequent of the ratio. Thus, in the ratio of a line of 6 palms to a line of 3 palms, the line of 6 palms is called the antecedent of the ratio, and the line of 3 palms the consequent of the ratio. But if, conversely, the ratio of a line of 3 palms to a line of 6 palms is considered, the line of 3 palms will be called the antecedent, and the line of 6 palms the consequent — and so in the rest.

IV.

[Euclid, Definition 4] Proportion, however, is a likeness of ratios.

[Clavius's commentary] What the translator here calls proportion is what the Greeks call ἀναλογία [Greek: analogia, "proportion"], and what most Latin writers call proportionality. Therefore, just as the comparison of two quantities with one another is called a ratio, so the comparison of two or more ratios with one another is usually named a proportionality. For example, if the ratio of quantity A to quantity B is similar to the ratio of quantity C to quantity D, the relation between these ratios will be called a proportionality. In the same way, if the ratio of E to F is similar to the ratio of F to G, this likeness will be called a proportionality. Now many relations of ratios, or proportionalities (for, when dealing with several, we shall call the comparison of two quantities a "ratio," but the relation of ratios a "proportionality"), are described by writers — especially by Boethius [Boethius] and Jordanus [Jordanus de Nemore]. Among these, the first place has always been held, among the ancients, by the Arithmetic, Geometric, and Musical (or Harmonic) proportionality, of which we shall speak a little later. But Euclid deals only with the Geometric in this book.

Diagram. Two groups of vertical straight-line magnitudes illustrating discrete and continuous proportion, each line labelled with a letter beneath and a number above.

- Left group (discrete proportion, $A : B :: C : D$): $A = 12$, $B = 9$, $C = 4$, $D = 3$ (that is, $12 : 9 :: 4 : 3$, each ratio being $4 : 3$).
- Right group (continuous proportion, $E : F :: F : G$): $E = 16$, $F = 8$, $G = 4$ (that is, $16 : 8 :: 8 : 4$, each ratio being $2 : 1$, with F serving as the mean taken twice).

This Geometric proportionality is indeed of two kinds. One is continuous, in which each of the intermediate quantities is taken twice, so that no interruption of the ratios occurs, but each intermediate quantity is both an antecedent and a consequent — antecedent of the following quantity, consequent of the preceding one. For example, if it is said that as E is to F, so is F to G, this proportion will be called continuous. The other is discrete, or non-continuous, in which each of the intermediate quantities is taken only once, so that an interruption of the ratios does occur, and no quantity is both antecedent and consequent, but either antecedent only or consequent only. For example, if it is said that as A is to B, so is C to D, this proportionality will be called discrete, or non-continuous.

ON THE DIVISIONS OF PROPORTION

I judge it worthwhile to set out briefly here how many kinds of ratio there are among mathematicians, and which are the principal proportionalities and their properties — chiefly for this practical benefit: that what Euclid demonstrates in

these two books about the ratios of magnitudes may be applied to material things whenever needed, and that both what mathematicians say about ratios and what philosophers, following Aristotle [Aristotle], dispute about the ratio of motions may be understood. And so that greater usefulness and pleasure may be gained from the wonderful properties of ratios, we shall undertake a somewhat fuller treatment in this later edition than in the earlier one — while nevertheless deferring almost countless things that might be said to our fuller *Arithmetic*, where we shall pursue all the kinds of proportionalities most diligently.

The proportion defined by Euclid, then, is divided into rational and irrational. A rational proportion is one that can be exhibited in numbers, such as the ratio of a line of 20 palms to a line of 10 palms; for this ratio is displayed in these very numbers, 20 and 10. An irrational proportion is one that cannot be exhibited in numbers, such as the ratio of the diagonal [diameter] of any square to the side of that same square; for this ratio cannot be found in numbers, as is demonstrated by Euclid in Book 10. Others say that a rational proportion is the one that any two commensurable quantities have, and an irrational proportion the one that any two incommensurable quantities have. Now quantities are said to be commensurable

when they have one common aliquot part, or when the same common measure measures them. Of this kind are a line of 20 palms and a line of 8 palms; for a line of 4 palms is an aliquot part of each, and likewise a line of 2 palms. For just as a line of both 4 and 2 palms measures the line of 20 palms, so too the same line, whether of 4 or of 2 palms, measures the line of 8 palms. Not otherwise, all numbers will be called commensurable, because at least unity measures them all. Quantities, on the other hand, are called incommensurable when they have no common aliquot part, or when no common measure can be found for them. Of this kind are the diagonal and the side of the same square. For although each of these lines has infinitely many aliquot parts — namely a half, a third, a fourth, and so on — nevertheless no aliquot part of the one, however small, can measure the other, as Euclid demonstrates in Book 10, the last proposition. In that book many other incommensurable lines besides those two are exhibited. And so, in numbers only a rational proportion is found; but in continuous quantity both a rational and an irrational proportion are contained.

In another way, proportion is usually divided into a proportion of equality and a proportion of inequality. A proportion of equality is between two equal quantities, as between 20 and 20, between 100 and 100, between a line of 10 palms and a line of 10 palms, and so on. A proportion of inequality, by contrast, is

found between two unequal quantities, as between 20 and 10, between 8 and 40, between a line of 6 palms and a line of 2 palms, and so on. Now these two kinds of proportion have this connection with the two above: every proportion of equality is necessarily rational, but not conversely; likewise every irrational proportion is necessarily a proportion of inequality, but not conversely. From this it is clear that some people divide rational proportion less correctly into a proportion of equality and a proportion of inequality. For although every rational proportion is necessarily one of equality or of inequality, still not every proportion of this kind is conversely rational, since many proportions of inequality are irrational. By the same reasoning it is evident that some do not quite correctly distribute the proportion of inequality into a rational and an irrational proportion. For although every proportion of inequality is necessarily rational or irrational, still not every such proportion is conversely a proportion of inequality, since many rational proportions are proportions of equality. In my judgment, therefore, proportion in general is better cut by a twofold division: first into rational and irrational, and second into a proportion of equality and a proportion of inequality. For in this way the dividing members reciprocate with the thing divided (to speak as the logicians do) in each division. I know that a rational proportion can rightly be subdivided into a proportion of equality and of inequality, and likewise a proportion of inequality into a rational and an irrational proportion, provided that in each division the thing divided is understood. But why I have preferred our twofold division — by which proportion is divided in its whole extent — to each of these subdivisions, I have explained above in my reply to Peletier's *Apology*.

Again, the proportion of inequality (for we set aside the proportion of equality, since it cannot be further subdivided, because equal quantities, whether great or small, always have the same proportion of equality) is subdivided into a proportion of greater inequality and one of lesser inequality. A proportion of greater inequality is when a greater quantity is compared with a smaller; such is the proportion of 20 to 10, or of a line of 8 feet to a line of 6 feet, and so on. A proportion of lesser inequality is when a smaller quantity is referred to a greater; such is the proportion of 10 to 20, or of a line of 6 feet to a line of 8 feet, and so on. This division is not empty and superfluous, as many suspect. For the proportion of 4 to 2 is not the same as that of 2 to 4; rather, they differ greatly, since the use of each is very different, as is clear to those who are even moderately versed in geometry and the rule of algebra. These, then, are the general divisions of proportion, insofar as it embraces all proportions, none excluded. Now, however, we shall subdivide both the proportion of greater inequality and that of lesser inequality only insofar as they comprise rational proportions alone; for

concerning quantities that have irrational proportions there will be a discussion in Book 10.

A rational proportion of greater inequality, therefore, is distributed into five kinds: multiple, superparticular, superpartient, multiple-superparticular, and multiple-superpartient. By the same reasoning, a rational proportion of lesser inequality is divided into the same kinds, provided only that to each term the prefix "sub" is prefixed: thus, submultiple, subsuperparticular, subsuperpartient, submultiple-superparticular, and submultiple-superpartient. Of these five kinds, the first three are simple, while the latter two are composed of those three, as is evident. But why there are only these five kinds of rational proportion, both of greater and of lesser inequality, we shall show after the explanation of all these five proportions.

ON MULTIPLE PROPORTION

A multiple proportion is a relation of a greater quantity to a smaller, when the greater contains the smaller a certain number of times — as twice, three times, ten times, a hundred times, and so on — so that the smaller measures the greater; such is the proportion

(This page continues Clavius's scholium "On multiple proportion" [De proportionem multiplici], begun on the preceding page; catchword from the prior page: "proportio.")

the ratio of the number 20 to 4. For 20 contains 4 five times over. Likewise the ratio of a line of 30 feet to a line of 5 feet, and so on.

This kind of ratio contains under itself infinitely many species. For if the greater quantity of a multiple ratio contains the lesser exactly twice, the ratio is called double [dupla]; if three times, triple [tripla]; if ten times, tenfold [decupla]; if a hundred times, hundredfold [centupla], and so on.

From these it will be easy to define all the species of multiple ratio. For an eightfold ratio [proportio octupla] will be nothing other than the relation of a greater quantity to a lesser, when the greater embraces the lesser eight times. In the same way the remaining multiple ratios are to be defined: thus a fivefold ratio [proportio quintupla], such as that of 40 to 8, will be one whose greater quantity contains the lesser five times. Likewise a double ratio, such as that of a line of 10 cubits to a line of 5 cubits, is one in which the greater quantity contains the lesser twice; and so on for the rest.

Furthermore, you will find all multiple ratios in whole numbers — that is, all the numbers that stand in a multiple ratio — in this way. Take the number that indicates how many times the greater number contains the lesser in the given multiple ratio. This number stands to unity in the first multiple ratio of the kind sought: that is, that number and unity are the first and least numbers between which the proposed multiple ratio is found. Now that same number, together with unity, are called by the arithmeticians the *terms* of the multiple ratio in question. Once these terms have been found — the terms between which the first proposed multiple ratio is found — if each is doubled, two numbers will be produced that stand in the second proposed multiple ratio; if each is likewise tripled, numbers of the third proposed multiple ratio will be generated; if each is quadrupled, the numbers of the fourth sought multiple ratio will arise. And so, if the same terms are multiplied by any number whatever, two numbers of the proposed multiple ratio will be produced, holding that place among all the multiple ratios of the species which the multiplying number indicates. Thus if the multiplication is carried out by 100, two numbers will be generated that occupy the hundredth place among all the numbers standing in the proposed ratio.

For example: let all the numbers of the fivefold ratio be sought. Since the greater number contains the lesser five times in a fivefold ratio, the first fivefold ratio will be between 5 and 1; and if these two terms are multiplied by 2, the second fivefold ratio will be found between 10 and 2. If the same terms are multiplied by 3, the numbers 15 and 3 will be produced, of the third fivefold ratio; and so on in succession. Thus if the tenth fivefold ratio is sought, the two first terms found, 5 and 1, are to be multiplied by 10; but if the thousandth is to be found, the same terms are to be multiplied by 1000, and so on.

Likewise all the numbers of any multiple ratio will be found in this way. Let two series of numbers be set out, extending to infinity: let the lower begin from unity and proceed by the natural sequence of numbers; let the upper begin from the number that signifies how many times the greater number contains the lesser in the given ratio, and let it advance by continually adding the same number, first to itself, then to the sum, and so on. For the numbers of the upper order, taken against the numbers of the lower order — the first to the first, the second to the second, the third to the third, and so on — all stand in the multiple ratio of the proposed species. You have examples here in the fivefold, sevenfold, and tenfold ratios.

ON PROPORTION [DE PROPORTIONE — superparticular]

A superparticular ratio [proportio superparticularis] is the relation of a greater quantity to a lesser, when the greater contains the lesser exactly once and, in addition, one aliquot part of it — namely a half, a third, a fourth, and so on. Such is the ratio of 3 to 2. For 3 contains 2 once, and in addition a unit, which is the half part of the number 2. So too a line of 12 feet to a line of 9 feet has a superparticular ratio, because the former line contains the latter once, and in addition a line of 3 feet, which is the third part of the line of 9 feet, and so on.

This ratio too is divided into infinitely many kinds. For if that aliquot part contained in the greater quantity is the half part of the lesser quantity, the ratio *sesquialter* [sesquialtera] is constituted; if it is the third part, the ratio *sesquitertian* [sesquitertia] arises; if the fourth, *sesquiquartan* [sesquiquarta]; if the thousandth, *sesquimillesimal* [sesquimillesima]; and so on.

Hence, from the very word itself, the definitions of all superparticular ratios will be easy. For a ratio will be *sesquioctave* [sesquioctava] when the greater quantity includes the lesser once and, in addition, the eighth part of the lesser: such as the ratio between 9 and 8. Likewise between 45 and 40. Judge the rest in the same way.

All superparticular ratios — or all the numbers between which any superparticular ratio whatever is found — will be discovered in this way. Take the number that names the aliquot part expressed in the ratio. The number next above it — namely the one that exceeds it by a single unit alone — will have with it the first proposed superparticular ratio, such that in smaller numbers that ratio cannot be found. These two numbers, which are called the *terms* of the given ratio, if they are doubled, tripled, or multiplied by any other number whatever, will generate other numbers standing in the same ratio — namely the second, the third, or that which the multiplying number indicates.

For example: if all the *sesquiseptimal* [sesquiseptimæ] ratios are sought — since here the seventh part is expressed — 7 will be the lesser term of this ratio, and the greater will be 8, exceeding it by a single unit; and between 8 and 7 the first sesquiseptimal ratio exists. If these two terms are doubled, two other numbers, 16 and 14, are produced, between which the second sesquiseptimal ratio is discerned; if they are tripled, the third such ratio will be between 24 and 21. Finally, if the hundredth such ratio is sought, the terms found, 8 and 7, are to be multiplied by 100, so that the numbers 800 and 700 are generated.

Likewise all the numbers of any superparticular ratio will be found, if two orders of numbers are set out: the lower beginning from the number that names the aliquot part, the upper from the number next above it; and each advancing by the continual addition of the number from which it takes its start, first to itself, then to the sum, and so on. We have set out examples here in the sesquialter, sesquiseptimal, and sesquidecimal ratios.

Sesquialter proportions [Proportiones sesquialteræ]

ON PROPORTION

Superpartient [Superpartiente]

A superpartient ratio [proportio superpartiens] is the relation of a greater quantity to a lesser, when the greater contains the lesser exactly once and, in addition, several aliquot parts of it that do not make up a single aliquot part. Such is the ratio of 8 to 5. For 8 contains 5 once, and in addition three units, each of which is an aliquot part — namely a fifth — of this number 5; but the number three composed of them is not any aliquot part of 5. I said that those aliquot parts must not constitute a single aliquot part, on account of the many ratios that at first sight seem to be superpartient when in fact they are superparticular. Of this kind is the ratio between 10 and 8. For although 10 contains 8 once, and in addition two units, each of which is an eighth part of the number 8 — yet, because the number two composed of those units is a fourth part of 8 — that ratio is not to be called superpartient but superparticular, namely *sesquiquartan*. Therefore, for two quantities to be said to have a superpartient ratio, it is necessary that the greater quantity contain the lesser once, together with several aliquot parts of it which, taken together, do not constitute a single aliquot part. Some, failing to notice this, confound the kinds of ratios in a remarkable way.

This superpartient ratio is divided, first, with regard to the number of the aliquot parts, into infinitely many kinds. For if the greater quantity comprehends the lesser once, and is completed by two of its aliquot parts that do not constitute a single one, the ratio is *superbipartient* [superbipartiens]; if by three aliquot parts, *supertripartient* [supertripartiens]; if by ten, *superdecupartient* [superdecupartiens]; and so on.

It is divided, next, with regard to the denomination of the aliquot parts, into yet infinitely many kinds. For a superbipartient ratio between two unequal quantities, of which the greater contains the lesser once and two of its third parts, is called *superbipartient of thirds* [superbipartiens tertias]. But if those two parts are fifths, it will be called *superbipartient of fifths* [superbipartiens quintas]; and likewise for the remaining superbipartient ratios. By the same reasoning, a superdecupartient ratio between two unequal quantities, of which the greater exceeds the lesser by ten eleventh-parts, will be called *superdecupartient of elevenths* [superdecupartiens undecimas]. But if those ten parts are thirteenths, the ratio will be called *superdecupartient of thirteenths* [superdecupartiens decimastertias]; and so on for all the remaining superdecupartient ratios.

Now, lest superpartient ratios be confounded either among themselves or with superparticular ratios — which we have found to have been done by very many — the following points must be carefully considered. First, that in the naming of any superpartient ratio whatever, two numbers are indicated: one of which shows how many aliquot parts of the lesser quantity are left over in the greater; the other indicates what kind those parts are, or how large. Thus in the *supertripartient of eighths* [supertripartiente octauas] ratio, these two numbers, 3 and 8, are denoted; the former of which signifies that the greater quantity of the said ratio contains the lesser once and, further, three of its aliquot parts — this is expressed by that syllable (tri) when it is called *supertripartient*; while the latter, expressed by the word (of eighths), shows that those three aliquot parts are eighth parts of the lesser. Next, that in every superpartient ratio the two aforesaid numbers (which are in fact easily recognized from the very utterance of the ratio, as is clear from the first example) must be such as to have no aliquot part in common except unity — which is indeed an aliquot part of all numbers: that is, they must be prime to one another. For numbers which, besides unity,

admit no other common aliquot part, the arithmeticians, together with [Euclid], call *prime to one another*, as will be established from Book 7. Such are those two numbers 3 and 8, expressed in the superior *supertripartient of eighths* ratio. For unity alone, as is evident, is the common aliquot part of both. Therefore we shall rightly name the ratio between 11 and 8 *supertripartient of eighths* — such as is also the ratio between 22 and 16. But the latter ratio, between 22 and 16, will not rightly be called *supersextupartient of sixteenths* [supersextupartiens sextasdecimas], although the greater contains the lesser once and, in addition, six units, each of which is a sixteenth part of the lesser: it will not, I say, be rightly so called, because the two numbers 6 and 16 expressed in it have the aliquot part 2, by which — as is taught in arithmetic — $6/16$ is reduced to $3/8$; and thus that ratio

is to be called *supertripartient of eighths*. So too the ratio between 9 and 6 will not rightly be called *supertripartient of sixths*, since the two numbers noted in it, 3 and 6, have, besides unity, another common measure, namely 3. For the number three, taken once as itself and then repeated twice, measures the number six; and consequently $3/6$ will be reduced, by the common aliquot part 3, to $1/2$.

Wherefore such a ratio is to be named *sesquialter*, since the greater quantity contains the lesser once and its half part. By the same reasoning, the ratio between 10 and 6 will not rightly be called *superquadripartient of sixths*, because the two numbers noted in it, 4 and 6, have 2 as a common aliquot part besides unity; and thus such a ratio is to be called *superbipartient of thirds*, since the greater quantity contains the lesser once and two of its third parts. From these considerations, then, it will not be difficult for anyone to name conveniently all the superpartient ratios.

It is also clear from what has been said why we divided the superbipartient ratio, a little earlier, into *superbipartient of thirds*, *of fifths*, *of sevenths*, *of ninths*, and so on, passing over *superbipartient of fourths*, *of sixths*, *of eighths*, *of tenths*, and so on. For since these latter, which were omitted, are superparticular — because $2/4$ make $1/2$, $2/6$ constitute $1/3$, $2/8$ yield $1/4$, and finally $2/10$ are equivalent to $1/5$ — the superpartient ratios would be confounded with the superparticular ratios, if these too were reckoned among the number of the superbipartient ratios. But how it is to be recognized whether any two given numbers have, besides unity, some other common aliquot part or not, is taught in arithmetic and will be demonstrated by [Euclid] at the beginning of Book 7.

The finding of all superpartient ratios of any species stands thus. A number as many units greater than the denominator of the aliquot parts named in the ratio as there are parts expressed in the same ratio will have the first ratio of the proposed species to the number denominating those same aliquot parts. These two terms, doubled, tripled, or multiplied by any number whatever, will generate second numbers standing in the same ratio, third numbers, or others, as was said above. For example, if all the numbers of the *supertripartient-of-tenths* ratio are to be sought, the first numbers of this kind will be 13 and 10, because the greater exceeds the lesser — which denominates the tenth parts — by three units, that is, by as many as there are tenth parts mentioned in the supertripartient-of-tenths ratio. Their doubles, which of course constitute the second ratio, are 26 and 20; their triples, 39 and 30. And the hundredth such ratio will be 1300 to 1000, since these numbers are the hundredfold of the terms 13 and 10, which were found in the first place.

You will find these same numbers of all superpartient ratios if you set out two orders of numbers, of which the lower begins from the denominator of the aliquot parts, and the upper from the number that exceeds that former one by the number of the parts named; each order then advancing by the continual addition of the first number of its order to itself and to the sums, as we said above. We have here appended examples of the ratios superbipartient of fifths, superoctupartient of ninths, and superseptupartient of tenths.

Superbipartient-of-fifths proportions [Proportiones superbipartientes quintas]

Order															
Upper	7	14	21	28	35	42	49	56	63	70	77	84	91	98	&c.

ON MULTIPLE-SUPERPARTICULAR PROPORTION [DE PROPORTIONE MULTIPLICI SUPERPARTICULARI]

A multiple-superparticular ratio [proportio multiplex superparticularis] is the relation of a greater quantity to a lesser, when the greater contains the lesser several times — as twice, three times, or four times, and so on — and besides one aliquot part of it. Of this kind is the ratio of 9 to 4. For 9 contains 4 twice (in which respect this ratio agrees with a multiple ratio, being like the double), and in addition they comprehend a unit, which is the fourth part of the lesser number

(in which respect the same proposed ratio is like a superparticular ratio, namely the sesquiquartan). Thus this composite ratio is rightly said to be composed of a multiple and a superparticular.

This ratio, moreover, is divided — with regard to the multiple ratio — into infinitely many kinds, just like the multiple. Thus into *double-superparticular* [dupla superparticularis], *triple-superparticular* [tripla superparticularis], and so on, according as the greater quantity comprehends the lesser twice, or three times, or four times, and so on, together with one aliquot part of the lesser quantity.

Euclid, *Elements*, Book V — Clavius's commentary (continued)

Each one of these kinds is in turn subdivided into infinitely many others, according to the ratio of the superparticular proportion it involves. Take a triple-superparticular proportion, for example: it contains under itself the triple-sesquialterate — that is, the case in which the greater quantity contains the smaller three times and in addition half of it — the triple-sesquitertian, the triple-sesquiquartan, and so on without end.

We shall find all the multiple-superparticular proportions of any species if we attend carefully to the denominator of the aliquot part and the denominator of the multiple proportion mentioned in the proposed proportion. For if we multiply the denominator of the aliquot part by the denominator of the multiple proportion and add one to the product, then that resulting number, set against the denominator of the aliquot part, gives the first proportion of the proposed species. And these two numbers, doubled, tripled, or multiplied by any number whatever, will yield further numbers in the same proportion — the second, the third, or those of any other rank — according to the number of units contained in the multiplier, as has been explained elsewhere.

For example, suppose we are to find all the numbers of the sextuple-sesquinonan proportion $[6 + 1/9]$. We multiply 9, the denominator of the ninth part, by 6, the denominator of the multiple proportion, and to the product, 54, we add 1. The resulting number, 55, set against 9, the denominator of the ninth part, expresses the first sextuple-sesquinonan proportion, in such a way that it cannot be given in smaller whole numbers. The doubles of these numbers, 110 and 18, are the second pair in the same proportion; the triples, 165 and 27, are the third, and so

on — so that their hundredfold values, 5500 and 900, exhibit the hundredth instance of the same proportion.

You will find these same multiple-superparticular proportions if you set up two series of numbers. The lower series begins from the denominator of the named aliquot part; the upper series begins from the number formed by adding one to the product of that same denominator of the aliquot part multiplied into the denominator of the stated multiple proportion. Each series then advances by continually adding the first number of its own series to itself and to the formed number, and so on, as was described above. Here you see worked examples for the double-sesquialterate $[2 + 1/2]$, the triple-sesquiseptima $[3 + 1/7]$, and the decuple-sesquitertian $[10 + 1/3]$ proportions.

Double-sesquialterate proportions

5	10	15	20	25	30	35	40	45	50	55	60	65	70	&c.
2	4	6	8	10	12	14	16	18	20	22	24	26	28	&c.

Triple-sesquiseptima proportions

22	44	66	88	110	132	154	176	198	220	242	&c.
7	14	21	28	35	42	49	56	63	70	77	&c.

Decuple-sesquitertian proportions

31	62	93	124	155	186	217	248	279	310	341	&c.
3	6	9	12	15	18	21	24	27	30	33	&c.

On the multiple-superpartient proportion

[*DE PROPORTIONE MVLTIPlici SVPERPARTIENTE.*]

Finally, a multiple-superpartient proportion is the relation of a greater quantity to a smaller one when the greater contains the smaller several times over and, in addition, several of its aliquot parts that do not add up to a whole — such as the proportion of 11 to 3. I said "that do not add up to a whole" for the reason already stated in the case of the superpartient proportion. For if those aliquot parts did add up to a whole, the proportion would not be multiple-superpartient but

multiple-superparticular. Thus the proportion of 20 to 6 is not to be called triple-superbipartient-sixths, even though 20 contains 6 three times plus two sixths, because two sixths make up one third part. It will instead be called the triple-sesquitercian proportion.

This proportion is subdivided, first, according to the multiple proportion — the multiple falling into double-superpartient, triple-superpartient, and so on.

Next, each of these, according to the number of parts, contains infinite kinds under itself. Thus under the triple-superpartient are contained the triple-superbipartient, the triple-supertripartient, and so on.

Finally, each of these in turn, according to the denomination of the aliquot parts, is cut into still further infinite kinds. Thus the triple-supertripartient is divided into triple-supertripartient-fourths, triple-supertripartient-fifths, and so on. It is not difficult to draw out the definitions and examples of all these from what has been said.

We shall find all the multiple-superpartient proportions of this last division as follows. Multiply the denominator of the proposed aliquot parts by the denominator of the proposed multiple proportion, and to the product add the stated number of aliquot parts. For the resulting number, set against the denominator of those same aliquot parts, has the first of the proportions being sought. And these two numbers, if doubled, tripled, or multiplied by any other number whatever, will give the second numbers, the third, and others in the same proportion. For instance, suppose all the quadruple-superoctupartient-elevenths proportions are sought. We multiply 11, the denominator of the eleventh parts, by 4, the denominator of the quadruple proportion, and to the product, 44, we add 8, the number of the eight parts. The resulting number, 52, set against 11, the denominator of the parts, has the first proportion sought. The second numbers will be 104 and 22; the third, 156 and 33 — namely the doubles, triples, and so on of the first pair. And their hundredfold values, such as 5200 and 1100, have the hundredth instance among all the quadruple-superoctupartient-elevenths proportions.

But if two orders of numbers are set up — the lower beginning from the denominator of the proposed aliquot parts and advancing by continually adding that same denominator; the upper beginning from the number formed by adding, to the product of that same denominator of the parts multiplied into the denominator of the given multiple proportion, the stated number of parts, and then advancing by continually adding that same number, first to itself, then to the

formed number, and so on — we shall likewise obtain all the numbers of the given proportion, as we also said above. Here you see worked examples for the double-superbipartient-thirds, the double-superquintupartient-sixths, and the quintuple-supertripartient-fifths proportions.

Double-superbipartient-thirds proportions [2 + 2/3]

8	16	24	32	40	48	56	64	72	80	88	96	104	&c.
3	6	9	12	15	18	21	24	27	30	33	36	39	&c.

Double-superquintupartient-sixths proportions [2 + 5/6]

17	34	51	68	85	102	119	136	153	170	187	&c.
6	12	18	24	30	36	42	48	54	60	66	&c.

Quintuple-supertripartient-fifths proportions [5 + 3/5]

28	56	84	112	140	168	196	224	252	280	308	&c.
5	10	15	20	25	30	35	40	45	50	55	&c.

On the rational proportions of inequality

[*DE PROPORTIONIBVS RATIONALIBVS INAEQVALITATIS.*]

Everything said so far about the five kinds of rational proportions of greater inequality must be understood equally of the five corresponding kinds of lesser inequality, provided the prefix "sub-" is always prefixed, as has been said. For if, in the examples given, the smaller quantities are compared with the greater, the corresponding proportions of lesser inequality result. Just as the proportion of 100 to 1 is centuple, so the proportion of 1 to 100 is subcentuple. And just as the proportion of 11 to 3 is triple-superbipartient-thirds, so the proportion of 3 to 11 is subtriple-superbipartient-thirds; and so with all the rest.

This is not the place, however, to pass over the remarkable usefulness of the Pythagorean table [tabula Pythagorica] — which we constructed in chapter 4 of our *Arithmetic* — for finding all the rational proportions; and that usefulness is as follows. Once the Pythagorean table has been constructed (and its construction is very easy, since the numbers down the left-hand side form the natural series of

numbers and can run on to infinity, while each crosswise line is generated by continually adding the number on the left-hand side, from which it begins, to itself and to the number so formed, and so on to infinity — so that these crosswise lines are nothing but arithmetic progressions of numbers whose common difference is the first number of each such line), then, first, all the numbers of any multiple proportion whatever are found in this way.

The denominator of a given multiple proportion, taken along the top line, together with the unit on the left-hand side, gives that first multiple proportion. The numbers descending under that same denominator in a straight line, matched one to one with the numbers under the unit on the left-hand side, give the second, third, fourth, and further proportions of the same species, to infinity. Thus the first nonuple proportion will be between the 9 of the top line and the 1 on the left-hand side; the second between the 18 below 9 and the 2 below 1; the third between the 27 of the same line descending from 9 and the 3 on the left-hand side, and so on. The same is to be said of the other multiple proportions.

Next, all the numbers of any superparticular proportion are found in this way. Against the denominator of the aliquot part expressed in the proportion, taken along the top side, the number immediately following gives the first proposed proportion. For the second, and by descending in a straight line from these two numbers, we shall find all the other numbers of the same proportion, as was said of the multiples. For example, the first sesquioctave proportion $[1 + 1/8]$ will be 9 to 8; the others, in order, will lie among the numbers placed beneath them — the second between 18 and 16, the third between 27 and 24, and so on.

Third, you will find all the superpartient proportions of any species in this way. After the denominator of the aliquot parts mentioned in the given proportion, taken along the top side, count off as many numbers as there are parts named in that proportion. For the last of these, set against the denominator of those same parts, will have the first proposed superpartient proportion. The second, third, fourth, and the others in order will be found among the numbers placed beneath those two. For example, if one wants all the numbers of the superoctupartient-elevenths proportion, let him take along the top side the denominator of the parts, namely 11, and after it count off these eight numbers — because of the eight parts — 12, 13, 14, 15, 16, 17, 18, 19. The last, 19, against 11, has the first superoctupartient-elevenths proportion. The number 38 against 22 gives the second, 57 against 33 the third, and the other numbers written beneath 19 and 11 in a straight line give the rest.

Tabula Pythagorica

The multiplication/proportion table. The printed table has no separate header row or column: its top edge (1–22, read left to right) and its left edge (1–14, read top to bottom) are themselves the multiplicands, and each interior cell is their product. Below, the top edge is given as the column header and the left edge as the leading $\times$ column; every interior value is transcribed directly from the leaf, cell by cell, at high magnification.

[illegible]

											1	1	1	1	1	1	1	1	1	1	1	2	2	2

								2	6	0	4	8	2	6	0	4	8	2	6	0	4	8		

The text resumes beneath the table:

Fourth, you will find all the numbers of any multiple-superparticular proportion by this method. Along the top side take

— the number that stands to the denominator of the aliquot part in exactly the multiple proportion in question. For the number immediately following it will have, to the denominator of the aliquot part, the first proposed proportion; and the numbers placed under those two will have the second and the rest. To find the number that stands to the denominator of the aliquot part in the proposed multiple proportion, take the denominator of the part along the top side and the denominator of the multiple proportion down the left side — or the former denominator down the left side and the latter along the top. In their common corner you will find the multiple number you seek.

For example: all the numbers of the triple-sesquiquinta proportion $[3 + 1/5]$ are to be found. First seek a number that is triple the denominator of the aliquot part — that is, triple 5 — namely 15, which you find in the common corner of the denominator of the triple proportion, which is 3, and the denominator of the aliquot part, which is 5, either of which is taken along the top and the other down the left. Then take this triple number, 15, along the top side. For the number 16, immediately following, set against the denominator of the aliquot part — that is, against 5 — has the first triple-sesquiquinta proportion. Other proportions of the same species you will find among the numbers placed beneath those two, as was said of the others.

Fifth and last, all the numbers of any multiple-superpartient proportion are found in this way. Along the top side take the number that stands to the denominator of the aliquot parts in the proposed multiple proportion — which will likewise be found in the common corner of the denominator of the multiple proportion and the denominator of the aliquot parts. Then, after the multiple number taken, count off as many numbers as there are aliquot parts mentioned. For the last of these, set against the denominator of the aliquot parts, will be found to have the first given multiple-superpartient proportion. Other proportions of the same species you will find beneath that first one, as we said of the others. For example, suppose one wants all the quadruple-supertripartient-fifths proportions. First let him seek the quadruple of the denominator of the parts, which is 5; he will find that number to be 20, since it is written in the common corner of the denominator of the quadruple proportion, which is 4, and the denominator of the fifth parts, which is 5. Then, after finding this number 20, let him count off along the top side these three numbers — 21, 22, 23 — because three fifth parts are named. For the last, 23, against 5 — that is, against the denominator of the parts — has the first quadruple-supertripartient-fifths proportion. The numbers of the other proportions of the same species are contained beneath those two numbers, as has been shown in the other cases.

Once, by this art, all the numbers of any proportion of greater inequality have been found, then, if the smaller are compared with the greater, all the numbers of the same proportion of lesser inequality will also have been found.

Nor should a remarkable property of every rational proportion be passed over in silence here — a property that runs as follows. Once the least, or first, terms and numbers of any proportion have been found, set up an arithmetic progression (an arithmetic proportionality) beginning from a number one unit less than the difference of those least numbers, and advancing by that very same difference of the least numbers. Then, among the first numbers of that progression, there fall as many numbers as there are units in the first least term of the proportion as taken in the arithmetic progression; among the second numbers — which are the doubles of the first — as many as the units contained in the second term of that progression; among the third, as many as the units in the third term; and so on in turn. For example, suppose the double proportion is proposed, whose least numbers are 2 and 1. Set up a progression beginning from 0 — because the difference between 2 and 1 is 1, and the figure 0 is one unit less than 1 — and advancing by the continual addition of one (that is, the difference between 2 and 1): first to 0, then to the formed number 1, then to the completed number 2, and so on, in this way:

0.
 1.
 2.
 3.
 4.
 5.
 6.
 7.
 8.

10.
 11.
 12.
 13.
 14.
 15.&c.

And so, between the first numbers of the double proportion — that is, between 2 and 1 — no middle number falls. Between the second, which are 4 and 2, one middle falls, namely 3. Between the third, 6 and 3, two middles are caught, 5 and 4. Between the fourth, 8 and 4, three middles occur, 7, 6, and 5; and so on. This appears in the figure below, where the extreme numbers of each line stand in all the double proportions — the first, the second, the third, and so on — while the counts of natural-series numbers falling between them correspond to the numbers of the arithmetic proportionality above.

The figure below reproduces the descending double-proportion array (each row runs from its left extreme, twice the right extreme, down to the right extreme; the intervening natural-series numbers are the "middles"). Transcribed from the leaf, cell by cell, at high magnification.

2	1				
4	3	2			
6	5	4	3		
8	7	6	5	4	
10	9	8	7	6	5

12	11	10	9	8	7	6					
14	13	12	11	10	9	8	7				
16	15	14	13	12	11	10	9	8			
18	17	16	15	14	13	12	11	10	9		
20	19	18	17	16	15	14	13	12	11	10	

But if upon the arithmetic proportionality just described you superpose the natural series of numbers beginning from 1, so arranged that each of its terms answers to each term of the arithmetic proportionality now set up, we shall learn faster than can be told how many numbers fall as middles between any two numbers of the double proportion. For the numbers of this natural series will indicate which

(Book V. Clavius's scholia on the arithmetic of ratios — continued from the preceding page. The Euclidean proportion-definitions do not yet begin here; this page continues the series of worked examples showing how many "mean numbers" fall between the terms of a given ratio, and the following pages give Clavius's scholium on the denominators of rational ratios.)

the place which two numbers of the double ratio occupy; while the corresponding numbers, arranged in an arithmetic proportionality, will indicate the multitude of numbers falling between them. Here is an example:

Rank of the double ratios [Ordo proportion. duplarum]											1	1	
											0	1	&c.
Multitude of mean numbers [Multitudo mediorum numerorum]											0	1	&c.

So if you wish to know how many numbers fall between the eleventh terms of the double ratio, take 11 [?] in the natural series of numbers, beneath which the number 10 is placed. You will therefore say that 10 numbers are intercepted between them; and so for the rest.

Next let a tenfold ratio [proportio decupla, 10:1] be proposed, whose least terms are 10 and 1. Their difference is 9; the number one unit less is 8. The arithmetic progression will therefore begin from 8, and will advance by the continual addition of 9 — first to 8, then to the resulting sum 17, and so on in succession, as may be seen here, where we have also written above the natural series of numbers, whose use here is the same as it was above in the double ratio.

Rank of the tenfold ratios [Ordo propor.
decuplarum]

	1	2	3	4	5	6	7	8	&c.
Multitude of mean numbers [Multit. med. numerorum]	8	1	2	3	4	5	6	7	&c.
		7	6	5	4	3	2	1	

Thus between the first terms of the tenfold ratio fall 8 mean numbers; 17 between the second; and 26 between the third. But between the eighth, 71 mean numbers are intercepted, and so for the rest — as this arrangement shows:

10. 9. 8. 7. 6. 5. 4. 3. 2. 1.
20. 19. 18. 17. 16. 15. 14. 13. 12. 11. 10. 9. 8. 7. 6. 5. 4. 3. 2.

Again, let any superparticular ratio [proportio superparticularis] be given. Since its two least numbers differ by a single unit — just as the least numbers of the double ratio do — the same progressions will serve here as in the double ratio, so that the number of mean numbers here is the same as there. This is clear here in the sesquioctave ratio [proportio sesquioctava, 9:8]:

Rank of the sesquioctave ratios [Ordo propor. sesquioct.]											1	1	
	1	2	3	4	5	6	7	8	9	0	1	1	&c.
Multitude of mean numbers [Multit. med. numerorum]	0	1	2	3	4	5	6	7	8	9	1	0	&c.
												0	

The accompanying staircase (each row runs from a multiple of 9 down to the corresponding multiple of 8):

9. 8.
18. 17. 16.
27. 26. 25. 24.
36. 35. 34. 33. 32.
45. 44. 43. 42. 41. 40.
54. 53. 52. 51. 50. 49. 48.
63. 62. 61. 60. 59. 58. 57. 56.

There is likewise offered the superquadripartient-sevenths ratio [proportio superquadripartiens septimas, 11:7], whose least terms are 11 and 7. Their difference is 4. The arithmetic progression will therefore begin from 3 and advance by 4, as appears here, together with the natural series:

Rank of the superquadripartient-sevenths ratios [Ordo propor. superquadr.]	1	2	3	4	5	6	7	8	&c.
Multitude of mean numbers [Multit. med. numerorum]	3	7	1	1	1	2	2	3	&c.
			1	5	9	3	7	1	

Therefore between the first terms of the superquadripartient-sevenths ratio 3 mean numbers are comprehended; 7 between the second; and 23 between the sixth, and so with the rest, as you see here:

11. 10. 9. 8. 7.
 22. 21. 20. 19. 18. 17. 16. 15. 14.
 33. 32. 31. 30. 29. 28. 27. 26. 25. 24. 23. 22. 21.
 44. 43. 42. 41. 40. 39. 38. 37. 36. 35. 34. 33. 32. 31. 30. 29. 28.

Likewise let there be given the double-and-one-sixth ratio [proportio dupla sesquisexta, 13:6], whose least numbers are 13 and 6. Their difference is 7. The progression will therefore begin from 6 [?] and will have a difference of 7 among its numbers, as is seen here, together with the natural series of numbers:

Rank of the double-and-one-sixth ratios [Ordo propor. dup. sesquisex.]	1	2	3	4	5	6	7	8	&c.
Multitude of mean numbers [Multit. med. numeratorum]	6	1 3	2 0	2 7	3 4	4 1	4 8	5 5	&c.

Between the first terms, then, of the double-and-one-sixth ratio fall 6 mean numbers; 13 between the second; and 55 between the eighth, and so on — just as is seen here:

13. 12. 11. 10. 9. 8. 7. 6.
 26. 25. 24. 23. 22. 21. 20. 19. 18. 17. 16. 15. 14. 13. 12.
 39. 38. 37. 36. 35. 34. 33. 32. 31. 30. 29. 28. 27. 26. 25. 24. 23. 22. 21.
 20. 19. 18.

Finally, let it be proposed to test the same thing in the double-and-two-thirds ratio [proportio dupla superbipartiens tertias, 8:3], whose least terms are 8 and 3. Since their difference is 5, the arithmetic progression will take its start from 4 and its numbers will have a difference of 5, as is evident here, together with the natural series of numbers:

Rank of the double-and-two-thirds ratios [Ordo propor. duplarum superbip. tertias]	1	2	3	4	5	6	&c.
Multitude of mean numbers [Multit. med. numeratorum]	4	9	1 4	1 9	2 4	2 9	&c.

Between the first two terms of the double-and-two-thirds ratio, then, will fall 4 mean numbers; and between the seventh, 34, and so on, as is clear here.

The staircase for the double-and-two-thirds ratio, continued from the foot of the previous page (each row runs from a multiple of 8 down to the corresponding multiple of 3):

8. 7. 6. 5. 4. 3.
 16. 15. 14. 13. 12. 11. 10. 9. 8. 7. 6.
 24. 23. 22. 21. 20. 19. 18. 17. 16. 15. 14. 13. 12. 11. 10. 9.
 32. 31. 30. 29. 28. 27. 26. 25. 24. 23. 22. 21. 20. 19. 18. 17. 16. 15. 14.
 13. 12.

It is evident, moreover, that what we have said here about the ratios of greater inequality [proportiones maioris inaequalitatis] is likewise true of the ratios of lesser inequality [proportiones minoris inaequalitatis], since the same numbers are interposed between the greater number and the lesser as between the lesser and the greater.

For the rest, from what we have said about the five species of rational ratio [proportio rationalis], both of greater and of lesser inequality, it is plainly gathered that there can be no more kinds of rational ratio of greater inequality than the five already set forth. For since — as Euclid demonstrates (*Elements* X.5) — any commensurable quantities whatever, between which (as we said) there is a rational ratio, have to one another the ratio that a number has to a number, it follows that every rational ratio of any continuous quantities can be assigned or exhibited in numbers. Either, then, the greater number contains the lesser (to which it is referred) an exact number of times, and by this a multiple ratio [proportio multiplex] is constituted; or it contains it once only, and besides one aliquot part of it, and so we have a superparticular ratio [proportio superparticularis]; or once only, and in addition several aliquot parts of it not making up a whole, and a superpartient ratio [proportio superpartiens] is produced; or several times, and one aliquot part of it, and a multiple-superparticular ratio [proportio multiplex superparticularis] results; or finally several times, and several aliquot parts of it not making up a whole, and a multiple-superpartient ratio [proportio multiplex superpartiens] arises. In no other way can a greater quantity contain a lesser, or a lesser be contained by a greater. By the same reasoning it is established that there are just as many kinds of rational ratio of lesser inequality. Rightly, therefore, have we divided the rational ratio — both of greater and of lesser inequality — into the five kinds we have set forth.

On the Denominators of Rational Ratios [De proportionum rationalium denominatoribus]

Since the denominators [denominatores] of the rational ratios we have expounded so far are of no small use, it will not be out of place to explain briefly by what numbers the individual ratios are denominated. The denominator of any ratio, then, is the number that distinctly and openly expresses the relation of one quantity to another. Thus the denominator of the octuple ratio [proportio octupla, 8:1] is 8; for this number indicates that the greater quantity of the octuple ratio contains the lesser eight times. Likewise the denominator of the sesquiquintan ratio [proportio sesquiquinta, 6:5] is $1\frac{1}{5}$, since this number signifies that the greater quantity of the sesquiquintan ratio contains the lesser once, plus a fifth part of it. And the same must be said of the denominators of the remaining ratios. From this it has come about, I believe, that Euclid in Book 6 [*Elements* VI], and most other mathematicians, call the denominator of any ratio its "quantity" [quantitas]; because the denominator, as we said, shows how great one quantity is in relation to the other with which it is compared, as is clear from the examples given.

From what we have said, moreover, the denominator of each ratio can easily be gathered. For the denominator of a multiple ratio, whatever it may be, is a whole number containing as many units as the number of times the greater quantity is said to contain the lesser in the ratio whose denominator is sought. Thus the denominator of the double ratio is 2; of the ninefold [noncupla], 9; of the hundredfold [centupla], 100; of the thousandfold [millecupla], 1000, and so on. But the denominators of the submultiple ratios that correspond to the multiples are the aliquot parts denominated by the denominators of the multiple ratios to which they answer. Thus the denominator of the subdouble ratio [subdupla] is $\frac{1}{2}$; of the subquintuple [subquintupla], $\frac{1}{5}$; of the subninefold [subnoncupla], $\frac{1}{9}$; of the subhundredfold [subcentupla], $\frac{1}{100}$; of the subthousandfold [submillecupla], $\frac{1}{1000}$. In the same way we shall find the denominators of the other submultiple ratios. Hence the denominator of any submultiple ratio is a fraction whose numerator is always unity, and whose denominator is the number that denominates the corresponding multiple ratio, as is clear from the examples adduced. Nor is there any difficulty at all in finding the denominator of any multiple or submultiple ratio, if what has been said is rightly understood — since the very statement of the ratio offers its denominator, as is manifest from the examples given.

The denominator of any superparticular ratio [proportio superparticularis] is a unit together with that aliquot part which the greater quantity must contain beyond the lesser. Thus the denominator of the sesquialteran ratio [sesquialtera, 3:2] is $1\frac{1}{2}$; of the sesquioctave [sesquioctava, 9:8], $1\frac{1}{8}$; of the sesqui-thousandth [sesquimillesima, 1001:1000], $1\frac{1}{1000}$, and so on. Nor will it be difficult to find the denominator of any superparticular ratio, since the very statement of the ratio expresses the denominator by means of its aliquot part, as is clear from the examples given. But the denominators of the corresponding subsuperparticular ratios are fractions whose numerators are less by just one unit than their denominators. Thus the denominator of the subsesquialteran ratio [subsesquialtera] is $\frac{2}{3}$; of the subsesquioctave [subsesquioctava], $\frac{8}{9}$; of the subsesqui-thousandth [subsesquimillesima], $\frac{1000}{1001}$, and so on. And the denominator of any subsuperparticular ratio will be found if, for the numerator of the fraction, one takes the denominator of the aliquot part expressed in the ratio, and for —

— the denominator of the same fraction, the number greater by a unit. Thus the denominator of the sub-sesqui-tenth ratio [subsesquidecima] is $\frac{10}{11}$; for the numerator of this fraction is the number that denominates the tenth part, namely 10, while the denominator of the same fraction exceeds its numerator by a unit, and so on. We shall also find the denominator of any subsuperparticular ratio in this way: we reduce the denominator of the corresponding superparticular ratio to a single fraction, as we taught in the *Arithmetic* — a fraction whose numerator here always exceeds the denominator by one unit, this denominator being also the denominator of the aliquot part mentioned in the ratio proposed. For if we invert the terms of this fraction, so that the numerator becomes the denominator and the denominator the numerator, we shall have the denominator of the proposed subsuperparticular ratio. For example, suppose the subsesquiseptan ratio [subsesquiseptima] is offered: since the denominator of the sesquiseptan ratio [sesquiseptima, 8:7] answering to it is $1\frac{1}{7}$, which reduces to the fraction $\frac{8}{7}$ — whose numerator is greater by one unit than the denominator of the aliquot part — then, if we invert that fraction thus, $\frac{7}{8}$, we shall say that the denominator of the subsesquiseptan ratio [subsesquiseptima] is $\frac{7}{8}$. Finally, the denominator of any subsuperparticular ratio will perhaps more easily be found if the prime, or least, numbers having the corresponding superparticular ratio are found, as we taught above. For the fraction whose numerator is the smaller of those numbers and whose denominator is the larger will be the denominator of the proposed subsuperparticular ratio: since the prime, or least, numbers having the sesquiseptan ratio are 8 and 7, if the smaller be made the numerator and the

larger the denominator, we shall produce this fraction, $7/8$, as the denominator of the proposed subsesquiseptan ratio [subsesquiseptima], as before.

The denominator of any superpartient ratio [proportio superpartiens] is a unit together with those aliquot parts (not making up a whole) which the greater quantity must contain beyond the lesser. Thus the denominator of the supertripartient-sevenths ratio [supertripartiens septimas, $10:7$] is $1\frac{3}{7}$; of the supertripartient-twentieths [supertripartiens vigesimas, $23:20$], $1\frac{3}{20}$, and so on. Nor is there any difficulty in finding denominators of this kind, because the very statement of the ratio exhibits its proper denominator, as is plainly clear from the earlier examples. But the denominators of the subsuperpartient ratios are fractions whose numerators are less than the denominators of the same fractions by as many units as the number of aliquot parts by which the greater quantity exceeds the lesser. Thus the denominator of the subsupertripartient-sevenths ratio [subsupertripartiens septimas] is $7/10$; of the subsupertripartient-twentieths [subsupertripartiens vigesimas], $20/23$, and so on. And the denominator of any subsuperpartient ratio will be found if, for the numerator of the fraction, one takes the denominator of the aliquot parts expressed in the ratio, and to this is added the number of those same parts, which gives the denominator of the same fraction. [Thus the denominator] of the subsuperquadripartient-elevenths ratio [subsuperquadripartiens undecimas, $15:11$] is $11/15$; for the numerator of this fraction is the number denominating the eleventh parts, namely 11, to which is added the number 4, of the four parts, to make the denominator of the same fraction, [namely] 15. Again, [the denominator] of the subsupertripartient-fifths ratio [subsupertripartiens quintas, $8:5$] is this fraction, $5/8$; for its numerator is the number denominating the fifth parts, namely 5, while its denominator, 8, is made up of that numerator 5 and the number 3, of the three parts. And by the same reasoning we shall find the denominators of the other subsuperpartient ratios. You may also find them in this way: reduce the denominator of the corresponding superpartient ratio to a single fraction, as we taught in the *Arithmetic* — a fraction whose numerator here always exceeds the denominator (which denominates the aliquot parts expressed) by as many units as there are aliquot parts. For the inverted numbers of this fraction — so that the numerator becomes the denominator and the denominator the numerator — will give the denominator of the proposed subsuperpartient ratio. Thus the denominator of the subsuperdecipartient-thirteenthths ratio [subsuperdecupartiens decimastertias, $23:13$] is $13/23$, because the denominator of the superdecipartient-thirteenthths ratio [superdecupartiens decimastertias] is $1\frac{10}{13}$, which reduces to the fraction $23/13$, whose inverted numbers make this fraction, $13/23$. Finally, the denominator of any subsuperpartient ratio will perhaps more easily be found if

the prime, or least, numbers having the corresponding superpartient ratio are found, as we handed down above. For the fraction whose numerator is the smaller of those numbers, and whose denominator is the larger, will be the denominator of the proposed subsuperpartient ratio. For example, suppose the subsuperquadripartient-ninths ratio [subsuperquadripartiens nonas, 13:9] is proposed: since the least numbers having the superquadripartient-ninths ratio are 13 and 9, we shall make the fraction $9/13$ the denominator of the subsuperquadripartient-ninths ratio; and so for the rest.

The denominator of any multiple-superparticular ratio [proportio multiplex superparticularis] is the whole number that denominates the multiple ratio expressed, together with that aliquot part which the greater quantity must contain beyond the lesser quantity. Thus the denominator of the triple-and-one-seventh ratio [trippla sesquiseptima, 22:7] is $3 \frac{1}{7}$; of the quintuple-and-one-ninth [quintupla sesquinona, 46:9], $5 \frac{1}{9}$, and so on. So that there is no labor at all in exhibiting the denominator of any multiple-superparticular ratio; since the very statement of the ratio distinctly expresses both the denominator of the multiple ratio and the aliquot part, as the examples set out declare. But the denominators of the submultiple-superparticular ratios are fractions whose numerators are the numbers denominating the aliquot parts expressed in the ratios. Thus the denominator of the subtriple-and-one-seventh ratio [subtrippla sesquiseptima] is $7/22$; of the subquintuple-and-one-ninth [subquintupla sesquinona], $9/46$, and so on. And the denominator of any submultiple-superparticular ratio will be found if, for the numerator of the fraction, one takes the denominator of the aliquot part; and if this is multiplied by the denominator of the multiple ratio, and a unit is added to the product, the denominator of the same fraction is obtained. Thus the denominator of the subquadruple-and-one-sixth ratio [subquadrupla sesquisexta, 25:6] is $6/25$; for...

[Scholium (Clavius), continued — on the denominators of proportions. The whole of this opening (printed pp. 178–180) belongs to Clavius's commentary on the arithmetic of ratios; the core Euclidean definitions of Book V have not yet begun.]

*(A note on vocabulary. Throughout this passage Clavius uses "denominator" in a special technical sense: the number or fraction that **names** a ratio — namely the quotient of its antecedent divided by its consequent, written as a whole number, a mixed number, or a fraction. This is not the modern arithmetical "denominator." The ratio-names themselves follow the traditional (Boethian) system: a "multiple" [multiplex] ratio is one like $n:1$; a "superparticular" [superparticularis] ratio exceeds by a single aliquot part, like $(n+1):n$; a "superpartient" [superpartiens] ratio*

exceeds by several such parts; and the prefix "sub-" marks the inverse ratio. The compound names combine these — e.g. "quadrupla sesquisexta" means $4 + 1/6$, i.e. the ratio 25:6. I keep Clavius's Latin ratio-names in italics and give the numeric ratio in parentheses.)

so that the numerator of this fraction, 6, denominates sixth-parts, and it is multiplied into 4, the denominator of the quadruple proportion; and to the product, 24, unity is added, so that the denominator of the same fraction is produced as 25 — and so on.

The same denominators of *submultiple-superparticular* proportions will be found if the denominator of the corresponding *multiple-superparticular* proportion is reduced to a single fraction, just as we taught in the Arithmetic: namely by multiplying the denominator of the multiple proportion by the denominator of the fraction attached to it, and then adding to the product unity, that is, the numerator of that same fraction. For if the terms of this fraction exchange their order with one another, the result is the denominator of the proposed proportion.

For example, suppose a *subquadrupla sesquisexta* proportion is given. Since the denominator of the corresponding *quadrupla sesquisexta* proportion (25:6) is $4 \frac{1}{6}$, we multiply 4 — that is, the denominator of the multiple proportion — into 6, the denominator of the attached fraction, and to the resulting number, 24, we add 1, namely the numerator of the same fraction; so that we reduce the whole denominator $4 \frac{1}{6}$ to this fraction, $25/6$. And if the terms of this fraction exchange their order, there results this fraction, $6/25$, to serve as the denominator of the *subquadrupla sesquisexta* proportion. One must proceed in the same way in the remaining cases.

Finally, you will perhaps find the denominator of any *submultiple-superparticular* proportion more easily if you find the two prime — that is, least — numbers of the corresponding *multiple-superparticular* proportion, as was explained above. For the fraction whose numerator is the smaller of those numbers, and whose denominator is the larger, will be the denominator of the proposed proportion. Thus, if a *subtrippla sesquiseptima* proportion is offered: since the prime (or least) numbers of the *trippla sesquiseptima* proportion (22:7) are 22 and 7, there will be made from them this fraction, $7/22$, to serve as the denominator of the *subtrippla sesquiseptima* proportion; and so for the rest.

The denominator of any *multiplex superpartiens* (multiple-superpartient) proportion is a whole number denominating the multiple proportion expressed within it, together with those aliquot parts — not making up a whole one — by

which the greater quantity must exceed the lesser. Thus the denominator of the *tripla superquincupartiens octavas* proportion (29:8) is $3\frac{5}{8}$; that of the *quadrupla superbipartiens quintas* proportion (22:5) is $4\frac{2}{5}$; and so on. For there is no difficulty in this method of finding the denominators in multiple-superpartient proportions, since in each of them there is openly and distinctly expressed both the denominator of the multiple proportion contained in it and the aliquot parts, as plainly appears in the examples set out.

The denominators of *submultiple-superpartient* proportions, however, are fractions whose numerators are the numbers that denominate the aliquot parts expressed in the proportions. Thus the denominator of the *subtripla superquincupartiens octavas* proportion is $\frac{8}{29}$; that of the *subquadrupla superbipartiens quintas* proportion is $\frac{5}{22}$; and so on. The denominator of any submultiple-superpartient proportion will be found if for the numerator of the fraction one takes the denominator of the aliquot parts, and then — multiplying this by the denominator of the multiple proportion and adding to the product the number of the aliquot parts — one obtains the denominator of that same fraction. Thus the denominator of the *subdupla superoctupartiens decimastertias* proportion is $\frac{13}{34}$; for the numerator of this fraction, 13, denominates thirteenth-parts, and if it is multiplied into 2, the denominator of the double proportion, and to the resulting number, 26, is added the number 8, the number of the eight parts, there is produced the denominator of the same fraction, 34. And so on.

You will also find the denominator of any submultiple-superpartient proportion in this way. Reduce the denominator of the multiple-superpartient proportion that corresponds to the proposed one to a single fraction, as we prescribed in the Arithmetic — namely by multiplying the denominator of the multiple proportion by the denominator of the fraction attached to it, and adding to the product the numerator of that same fraction. For if the terms of this fraction exchange their order between themselves, they will give a fraction which will be the denominator of the submultiple-superpartient proportion. For instance, if a *subquintupla supertripartiens decimas* proportion is proposed, we reduce the denominator of the corresponding *quintupla supertripartiens decimas* proportion — that is, $5\frac{3}{10}$ — to this fraction, $\frac{53}{10}$ (which is done by multiplying 5 into 10 and adding 3 to the resulting number, so as to make the numerator 53, under which the same denominator 10 is to be set). For if this fraction exchanges its terms, there results the denominator of the *subquintupla supertripartiens decimas* proportion, $\frac{10}{53}$; and so on.

But perhaps you will obtain the denominator of any submultiple-superpartient proportion more easily if you find the prime — that is, least — numbers of the corresponding multiple-superpartient proportion, and construct a fraction from them, taking the smaller for numerator and the larger for denominator of the proposed proportion. For if a *subquintupla supertripartiens decimas* proportion is proposed: since the least numbers in the *quintupla supertripartiens decimas* proportion are 53 and 10, the denominator of the proposed proportion will be constructed from them as this fraction, $10/53$; and so on.

Finally, the denominator of a proportion of equality is always unity: because in that proportion one quantity must be equal to the other, and hence one contains the other exactly once and nothing besides — which is precisely what unity signifies.

From what we have said about the denominators of proportions, it is, I think, clear that the denominators of proportions of the greater inequality denominate those proportions of greater inequality both in reality and in name, whereas the denominators of proportions of the lesser inequality denominate the proportions of the lesser inequality in reality only, and not also in word or name. This is evident from the examples already brought forward. For the denominator, for instance, of the *tripla superquadrupartiens nonas* proportion ($31:9$), which is $3\frac{4}{9}$ — that is, three whole units and four ninth-parts — denominates that proportion both in reality and in word, since it distinctly and openly indicates to us that in it the greater quantity contains the lesser three times, and four ninth-parts of it besides. But the denominator of the corresponding *subtripla superquadrupartiens nonas* proportion, namely $9/31$ — that is, nine thirty-first parts — does indeed in reality denominate the *subtripla superquadrupartiens nonas* proportion, since it truly signifies that in it the lesser quantity is nine

thirty-first parts of the greater (which is altogether necessary, so that the lesser quantity may have to the greater the *subtripla superquadrupartiens nonas* proportion); but in word, or name, it in no way denominates that proportion: since "nine thirty-first parts" and the name "*subtripla superquadrupartiens nonas* proportion" seem to have nothing in common, but to differ from it entirely.

Therefore, if the denominator of some proportion of the lesser inequality is expressed in numbers — namely by a fraction — so that you may know how the proportion it denominates ought to be pronounced, look at what proportion the denominator of that fraction has to its numerator. You will know this if you divide the denominator of the fraction by its numerator. For the quotient will denominate the proportion that the denominator of the fraction has to its

numerator. For by the same name you will pronounce the proportion of the given denominator, only with the syllable "sub-" prefixed, by which that proportion of the denominator's fraction to its numerator is called. Thus, if the denominator $1/8$ is given, its proportion will be called *suboctupla* (1:8). For when the numerator of the fraction is unity, the proportion of the given denominator will be a *submultiple*, denominated from the denominator of that same fraction. But if the given denominator is, say, $20/327$, then dividing the denominator 327 by the numerator, the quotient is $16 \frac{7}{20}$. Therefore the denominator of the fraction, 327, has to its numerator, 20, the *sedecupla superseptupartiens vigesimas* proportion (327:20); and consequently the proportion whose denominator is $20/327$ is to be called *subsedecupla superseptupartiens vigesimas*; and so on.

But since not all proportions can conveniently be called by their proper names — for who would conveniently call the proportion 37:1 "thirty-seven-fold," or "thirty-times-sevenfold," or by any name of that sort? and who would readily call the proportion 48:29 "*supernovemdecupartiens vigesimasnonas*"? and so on — geometers are generally accustomed, in their writings, to express any such proportion by the prime, or least, numbers of that proportion. Thus they call the proportion 13:1 (or 39:3, or 390:30) the proportion of 13 to 1, rather than "thirteenfold"; and conversely they call the proportion 1:13 (or 3:39, or 30:390) the proportion of 1 to 13, rather than "*subtredecupla*." So too they call the proportion 52:40 the proportion which is 13 to 10, which would otherwise be called *supertripartiens decimas*; and the proportion 40:52 they call the one which is 10 to 13, which by its proper name would be called *subsupertripartiens decimas*; and so with the rest.

Although, however, any proportion can be expressed by its least numbers, as we have said, it is nonetheless entirely necessary to know the denominator of that same proportion, so that we may recognize the relation of one number to another. For even though someone may say that the proportion of the number 1700 to 400 is the same as that of 17 to 4, I still shall not fully understand what that proportion is unless I know its denominator, which is $4 \frac{1}{4}$. For this openly declares that the greater number contains the lesser four times, and a fourth part of it besides. And this denominator is more easily perceived from the least numbers of some proportion than from numbers that are not least. But if it should sometimes happen that the least numbers of some proportion cannot easily be recognized, one must have recourse to the rule which I shall shortly add, and by which the denominator of the proportion between any two numbers whatever — whether they be the least numbers or not — is made known.

But if mathematicians express any proportion by its least numbers, it will be far more convenient for us to explain the proportion of any two numbers by its denominator: so that we call the proportion 100:20 the one whose denominator is 5; likewise the proportion 48:38 the one whose denominator is $1\frac{5}{19}$, which would be called *superquintupartiens decimasnonas*; so too the proportion 20:100 can be called the one which has the denominator $\frac{1}{5}$; and the proportion 38:48 the one whose denominator is $\frac{19}{24}$; and so with the rest — since, plainly, the denominator most clearly displays the relation of one number to another, as has been said.

Moreover, the denominator of a proportion between any two numbers will be found thus. The antecedent number is divided by the consequent. For the quotient, once the fraction (if there be any) has first been reduced to its least numbers, as we have handed down in the Arithmetic, will be the denominator of that proportion. For example, given the proportion 39:3 (or 390:30), we shall say that its denominator is 13 — that is, the quotient, namely the number of the division of 39 by 3, or of 390 by 30. But if, conversely, the terms be taken in reverse, the quotient of the division will be this fraction, $\frac{3}{39}$ or $\frac{30}{390}$. For when a smaller number is divided by a larger, the quotient is always a fraction whose numerator is the smaller number and whose denominator is the larger, as we explained in the Arithmetic. And because both fractions, if their numbers are reduced to the least, come back to the same, we shall say that the denominator of the proportion 3:39 (or 30:390) is $\frac{1}{13}$. Again, given the proportion 52:40, the fraction is reduced to this, $1\frac{3}{10}$. Therefore the denominator of the proportion 52:40, from the division of 52 by 40, will be found to be the denominator, or quotient, $\frac{52}{40}$ — that is, in the least numbers, $\frac{13}{10}$. But if the proportion 40:52 is offered, [its denominator, in the least numbers, is] $\frac{10}{13}$. Furthermore, the proportion 100:20 will have as denominator 3 [recte: 5]; for, dividing 100 by 20, the quotient is 5. But the denominator of the proportion 20:100 will be $\frac{1}{5}$, because, dividing 20 by 100, the quotient is $\frac{20}{100}$ — that is, in the least numbers, $\frac{1}{5}$. Next, the denominator of the proportion 48:10 will be $4\frac{4}{5}$, which comes from dividing 48 by 10; the quotient is $4\frac{4}{5}$. But the denominator of the proportion 10:48 will be $\frac{10}{48}$ — that is, in the least numbers, $\frac{5}{24}$. And because the denominator of the fraction, $\frac{5}{24}$, has to its numerator the *quadrupla superquadrupartiens quintas* proportion (since, dividing 24 by 5, the quotient comes to $4\frac{4}{5}$), the proportion 10:48 will be called *subquadrupla superquadrupartiens quintas*. For, so that a proportion of the lesser inequality may be duly expressed, one must first denominate the proportion of the denominator of the fraction to its numerator, as we said above.

Once the denominator of the proportion of two numbers has been found in the least numbers, as has been said, and reduced to a single fraction (as was handed down in the Arithmetic), the numerator and denominator of the fraction will be the least numbers between which that proportion is found. In a multiple proportion, however — namely when the denominator found has no fraction attached to it — the denominator found and unity will be the least numbers of that proportion. For instance, since the denominator of the proportion 348:120 is $2\frac{9}{10}$, if it is reduced to this single fraction, $\frac{29}{10}$ (which is done by multiplying the whole number 2 into the denominator of the fraction, 10, and adding to the resulting number, 20, the numerator of the same fraction, 9), the numbers 29 and 10 will be the least numbers having the same proportion as 348:120. So too, since the denominator of the proportion 824:1133 is $\frac{8}{11}$, the numbers 8 and 11 will be the least numbers of the proportion 824:1133. Likewise, since the denominator of the proportion 84:12 is 7, the least numbers in that proportion will be 7 and 1. And conversely, since the denominator of the proportion 12:84 is $\frac{1}{7}$, its least numbers will be 1 and 7. And so, given any two numbers whatever, if the least numbers having the same proportion as they are sought, one must find the denominator of their proportion, as has been said, and reduce it to a single fraction. For the numerator and denominator of this fraction will be the least numbers sought. Thus, if the least numbers of the proportion which 400 has to 90 are sought: dividing the antecedent by the consequent term, the quotient comes to $4\frac{4}{9}$ in the least numbers. Reducing this to the fraction $\frac{40}{9}$, we shall say that the least numbers of the proportion 400:90 are 40 and 9. And the same reasoning holds for the rest.

Now if, two proportions being proposed, you wish to know which of them is the greater or the lesser, you will call the greater the one whose denominator is greater, and the lesser the one whose denominator is less. But if the denominators are equal, you will declare the proportions also to be equal. Thus, if these two proportions are proposed — *superoctupartiens decimasquintas* (23:15) and *superdecupartiens decimasseptimas* (27:17), whose denominators are $1\frac{8}{15}$ and $1\frac{10}{17}$ — you will say that the former is less than the latter: because the denominator $1\frac{8}{15}$ is less than the denominator $1\frac{10}{17}$. By what art you may recognize which of two fractions is the greater or the lesser, or whether they are equal, we have handed down in the Arithmetic. By the same reasoning, if two proportions are offered whose denominators are $10\frac{1}{1000}$ and $9\frac{100}{101}$, we shall say the former is the greater. For although the fraction $\frac{1}{1000}$ is less than the fraction $\frac{100}{101}$, still the whole number 10 is greater than the whole number 9. So, if two proportions are given — one 17:11, the other 18:12 — you will say the

former is greater than the latter, because the denominator of the former, $1\frac{6}{11}$, is greater than the denominator of the latter, $1\frac{1}{2}$.

Furthermore, when two proportions are proposed in numbers, we shall easily discern which of them is greater, even without inquiring into their denominators, by this method. Multiply the antecedent term of the former proportion into the consequent term of the latter, and the antecedent term of the latter into the consequent term of the former; the proportion whose antecedent term has produced the greater number is the greater proportion; and if two equal numbers have been generated, the proportions will be equal to each other. Thus, if the two proportions 17:11 and 18:12 are proposed, we shall find that the former is greater, because the antecedent of the former, 17, multiplied into the consequent of the latter, 12, produces 204, whereas the antecedent of the latter, 18, into the consequent of the former, 11, produces only 198. Again, if two proportions 18:12 and 108:72 are given, the same number, 1296, will be produced both from the antecedent of the former, 18, multiplied into the consequent of the latter, 72, and from the antecedent of the latter, 108, multiplied into the consequent of the former, 12. Therefore the proportions themselves will be equal to each other. The reason for this operation is that in this way, when four numbers are proposed, the two extremes are multiplied together, and likewise the two means, as is evident in the given examples. Therefore, if equal numbers are produced, the proportion of the first to the second will be the same as that of the third to the fourth, as Euclid demonstrates in Book 7, proposition 19. Hence it follows that, if the first multiplied into the fourth produces a greater number than the second into the third, the first is too great to be able to have the same proportion to the second as the third has to the fourth: since it would have to be smaller in order to produce the same number, and thereby to have the same proportion.

Sometimes two numbers in some given proportion are wanted — whether they be prime numbers or not. To find them, then, we shall multiply, or divide, any assumed number by the denominator of the proposed proportion. For the number produced will have the proposed proportion to the assumed number that was multiplied, or the number assumed and divided will have it to the quotient. For example, if two numbers in the *quintupla* proportion (5:1) are to be found, we shall multiply any number, say 100, into the denominator 5. For the number produced, 500, will have to the multiplied number, 100, the quintuple proportion. Or we shall divide the same number, 100, by the denominator 5. For the divided number, 20, will likewise have to the quotient, 20, the given quintuple proportion. So too, if two numbers in the *dupla sesquitertia* proportion (7:3),

whose denominator is $2\frac{1}{3}$, are to be found, we shall multiply any number, say 24, by $2\frac{1}{3}$. For the number produced, 56, has to the multiplied number, 24, the proportion denominated by $2\frac{1}{3}$. Likewise, if we divide the number 24 by $2\frac{1}{3}$, the divided number, 24, will have to the quotient, $10\frac{2}{7}$, the given *dupla sesquitertia* proportion.

But in order to avoid fractions, if one wishes to do the business by multiplication, the number to be multiplied should be one that is numbered by the denominator of the aliquot part, or of the several parts, mentioned in the proportion. In a multiple proportion, however — since no part is mentioned — any number whatever may be assumed. Thus, if two numbers of the *tripla superbipartiens nonas* proportion (29:9) are wanted, the number to be taken should be one numbered by 9, such as 18, or 27, 36, 45, and so on. For any of these, multiplied into the denominator $3\frac{2}{9}$, will produce a whole number: as when 45 is multiplied into $3\frac{2}{9}$, the number 145 results, which has to the assumed number, 45, the given proportion. So too, if someone desires a *subquadrupla* proportion (1:4), whose denominator is $\frac{1}{4}$, the number to be taken should be one numbered by 4, such as 12. For this, multiplied into the denominator $\frac{1}{4}$, will produce 3, a whole number, which has to the assumed number, 12, the *subquadrupla* proportion. But if the business is to be done by division, and fractions are to be avoided, the number to be taken in a multiple proportion should be one numbered by the denominator of the proportion.

In other proportions, however, the denominator of the proportion is to be reduced to a single fraction, and the number to be taken should be one numbered by the numerator. Thus, if a *quintupla* proportion is sought, one should take, say, the number 30, numbered by 5. For this, divided by the denominator 5, makes the quotient 6, to which it has the quintuple proportion. But if a proportion is desired whose denominator is $4\frac{3}{7}$, then, reducing it to the fraction $\frac{31}{7}$, the number to be taken should be one numbered by 31, such as 62. For this, divided by $\frac{31}{7}$, makes the quotient 14, to which the number taken, 62, has the proportion denominated by $4\frac{3}{7}$, namely the *quadrupla supertripartiens septimas* proportion (31:7).

Moreover, if two numbers are proposed, and someone wishes to find two others in the same proportion, it will be enough if he multiplies, or divides, each of them by any number whatever. For the numbers produced, or the quotients, will have the same proportion as the two proposed numbers. Likewise, if, given any number, another is to be found which has a given proportion to it, or to which it has a given proportion, you will obtain the first if you multiply the proposed

number by the denominator of the proportion; and you will obtain the second if you divide the same number by the denominator of the proportion. But if a proportion is given in two numbers, and some third number is proposed: if a fourth is to be found to which the third given number has the same proportion as the first given number has to the second — then, if the denominator of the proportion of the two given numbers is known, the third given number is to be divided by the denominator. For the quotient will be the number we seek. Or certainly, whether the denominator is known or not, the third number is to be multiplied by the second given number — that is, by the consequent term of the former proportion — and the number produced is to be divided by the first, or by the antecedent term. Thus, if the denominator is $4/7$ and a third number, 20, is likewise given: divide the number 20 by the denominator $4/7$, and the fourth number sought, 35, will be produced. Or multiply the third number, 20, by the second, 7, and divide the number produced, 140, by the first, 4. For to the quotient, 35, the third number, 20, will have the same proportion as 4 to 7.

But if a fourth is to be found which has to the third the same proportion as the two given numbers have — then, if the denominator is known, it is to be multiplied into the third number. For the number produced will be the one you seek. Or, whether the denominator is known or not, the third number is to be multiplied by the first given number — namely by the antecedent term — and the number produced is to be divided by the second, that is, by the consequent term. Thus, given the same two numbers 4 and 7, and a third number 20, multiply 20 by the denominator $4/7$, and the number sought, $11 \frac{3}{7}$, will be generated. Or multiply the third number, 20, into the first, 4, and divide the number produced, 80, by the second, 7. For to the third number, 20, the quotient, $11 \frac{3}{7}$, will have the same proportion as 4 to 7.

Now since we have said that the proportion whose denominator is greater is the greater proportion, it follows that among the multiple proportions the least given is the *dupla*, denominated by 2, but not the greatest: because the number 2, among all the denomi- ...is the smallest [denominator] of the multiple ratios, whereas a greatest cannot be given, since the numbers increase without limit. It also follows that among the superparticular ratios a greatest can be found — namely the sesquialter [sesquialtera, 3:2], denominated by $1\frac{1}{2}$ — but not a least: because the number $1\frac{1}{2}$ is the greatest of all the denominators of superparticular ratios, while a least cannot be given, since the denominators of fractions can proceed to infinity. This is established from what we set out in the Arithmetic: that a fraction whose denominator is larger is smaller, if the numerator is the same; whereas a fraction whose denominator is smaller, the numerator being the

same, is larger. Since therefore the denominator 2 is the smallest of all, the fraction $\frac{1}{2}$ will be the greatest of all those that have 1 for numerator (such as are the fractional denominators of the superparticular ratios).

Finally, it is inferred that in the other ratios of greater inequality neither a least nor a greatest can be given. This is to be understood of the last species. For if the discussion is not about the last species, then among the superpartients the superbipartient [superbipartiens] will be the least, while the superpartient of thirds [superpartiens tertias] will be the greatest. Among the multiple superparticulars the greatest will be the multiple sesquialter [multiplex sesquialtera]; the least, the double superparticular [dupla superparticularis]. Among the multiple superpartients, finally, the greatest will be the multiple superpartient of thirds; the least, the double superbipartient [dupla superbipartiens]. Conversely, in the submultiple ratios a greatest is given — namely the subdouble [subdupla] — but not a least; among the subsuperparticulars, on the other hand, a least is found — such as the subsesquialter [subsesquialtera] — but not a greatest; and in the remaining ratios of lesser inequality, finally, neither a greatest nor a least can be given. All of this will be clear if the denominators of the ratios are compared with one another.

It is also gathered that this is the connection among the ratio of greater inequality, the ratio of equality, and the ratio of lesser inequality: that every ratio of greater inequality is greater than the ratio of equality, and every ratio of lesser inequality is less than it. The reason is that every denominator of a ratio of greater inequality, however small, is greater than the unity that is the denominator of the ratio of equality — since it cannot be less than unity together with one aliquot part — whereas the denominator of a ratio of lesser inequality is always less than unity, being a fraction whose numerator is exceeded by its denominator, as is plain from what we said above. The ratio of equality is therefore the mean between the ratio of greater inequality and the ratio of lesser inequality.

Here a point worth noting is this: the ratio of greater inequality, by decreasing, draws ever nearer and nearer, to infinity, to the ratio of equality, yet never reaches it; and conversely the ratio of lesser inequality, by increasing, comes ever nearer and nearer, to infinity, to that same ratio of equality, yet never attains it. For given any multiple ratio, a smaller one can be given, down to the double, which is the least of all multiples. Then a smaller than this is given — namely some superparticular or superpartient — and since a least of these cannot be given, and every ratio of this kind is greater than the ratio of equality, it plainly

follows that a ratio of greater inequality cannot arrive at the ratio of equality, even though by decreasing to infinity it approaches it. Again, since every ratio of lesser inequality is smaller than the ratio of equality, and yet a greatest cannot be found among them, it is likewise manifest that a ratio of lesser inequality cannot reach the ratio of equality, although by increasing to infinity it approaches it.

But so that both may be learned by an example too, note the following. If between any two non-adjacent numbers some intermediate number is interposed — greater, that is, than one of them and smaller than the other — then the ratio of the greater number to the smaller is divided into two smaller ratios, of which one is that of the greater number to the interposed middle, the other that of the middle to the smaller. Likewise the ratio of the smaller number to the greater is divided into two larger ratios, of which one is that of the smaller number to the interposed middle, the other that of the middle to the greater.

For example, if between the two numbers 6 and 3 the middle 4 is placed, thus, 6. 4. 3., the ratio 6 to 3, which is double, will be divided into the sesquialter 6 to 4 and the sesquitertian [sesquitertia] 4 to 3, each of which is smaller than the double ratio 6 to 3. Conversely, the ratio 3 to 6, which is subdouble, will be divided into the subsesquitertian [subsesquitertia] 3 to 4 and the subsesquialter [subsesquialtera] 4 to 6, each of which is larger than the subdouble ratio 3 to 6. The same happens if between the same numbers 6 and 3 the middle 5 is interposed, thus, 6. 5. 3. For both the ratio 6 to 5, a sesquiquintan [sesquiquinta], and the superbipartient-of-thirds ratio 5 to 3, are smaller than the double ratio 6 to 3; and conversely both the superbipartient-of-thirds ratio 3 to 5 and the subsesquiquintan [subsesquiquinta] 5 to 6 are larger than the subdouble ratio 3 to 6. All of this can be proved from the denominators.

But that both may be demonstrated — the greater [ratio] compared with the greater, and the greater with the less — the greater given term will have to the smaller given term a greater ratio than the same greater has to the middle, and than the middle has to the smaller; while the smaller [given term] to the greater will have a smaller ratio than the same smaller has to the middle, and than the middle has to the greater, as is evident either from what we explained there, or from Proposition 8 of this Book 5, where Euclid [Euclid] demonstrates that, given two unequal quantities, the greater has a greater ratio to some third than the smaller does; and, on the contrary, that the same third quantity has a smaller ratio to the greater than to the smaller [At è contrario, tertiam eandem quantitatem ad maiorem habere minorem proportionem, quam ad maiorem — see note]. From this follows what we said: namely, given these three numbers 6.

4. 3., that the ratio of the same number 6 to the smaller 3 is greater than to the middle 4; likewise that the ratio of the greater number 6 to 3 is greater than that of the smaller 4 to the same 3. Conversely, that the ratio of the same number 3 to the smaller 4 is greater than to the greater 6; likewise that the ratio of the greater number 4 to 6 is greater than that of the smaller 3 to the same 6. And the reasoning is the same in the remaining cases.

These things established, the double ratio 4 to 2 will be divided here — 4.3.2 — into two smaller ratios. And just as the ratio 8 to 6, which is the same as 4 to 3, is divided here — 8.7.6 — so the ratio 6 to 4, which is the same as 3 to 2, is divided here — 6.5.4 — into two smaller ratios. Likewise, just as the ratio 16 to 14, which is the same as 8 to 7, is divided here — 16.15.14 — so the ratio 14 to 12, which is the same as 7 to 6, is divided here — 14.13.12 — and the ratio 12 to 10, which is the same as 6 to 5, here — 12.11.10 [?] [read 12.11.10; the first term breaks the monotone chain 16.15.14 / 14.13.12 / 12.11.10 / 10.9.8 — see Numerical impossibles] — and the ratio 10 to 8, which is the same as 5 to 4, here — 10.9.8 — into two smaller ratios; and so it can be done to infinity.

Conversely, the subsesquialter ratio 4 to 6 will be divided here — 4.5.6 — into two larger ratios. And just as the ratio 8 to 10, which is the same as 4 to 5, is divided here — 8.9.10 — so the ratio 10 to 12, which is the same as 5 to 6, here — 10.11.12 — into two larger ratios. Likewise, just as the ratio 16 to 18, which is the same as 8 to 9, is divided here — 16.17.18 — so the ratio 18 to 20, which is the same as 9 to 10, here — 18.19.20 — and the ratio 20 to 22, which is the same as 10 to 11, here — 20.21.22 — and the ratio 22 to 24, which is the same as 11 to 12, here — 22.23.24 — into two larger ratios; and of this increase there will never be an end. The same may be tried in any other ratios whatever. Thus the decuple ratio 10 to 1 is divided here — 10.6.1 — into two smaller ratios; and the sub-superseptupartient-elevenths ratio [subsuperseptupartiens undecimas] 11 to 18 is divided here — 11.15.18 — into two larger ratios; and so on.

On Proportionalities [De Proportionalitatibus]

Proportionality, as defined by Euclid, is divided into several kinds, as may be seen in Boethius [Boethius], Jordanus [Jordanus Nemorarius], and other arithmeticians. But the principal proportionalities — which the aforesaid authors call "means" [medietates] — are these three: the Arithmetic, the Geometric, and the Musical or Harmonic.

Arithmetic proportionality, or mean, is when three or more numbers proceed by the same difference. For example, these numbers 4. 7. 10. 13. 16., each of which

exceeds its antecedent by the ternary [i.e. by 3], are said to constitute Arithmetic proportionality. It is of two kinds, continuous and discrete. It is continuous when in the progression of numbers there is no interruption, but each is compared with its nearest neighbor, as happens in the given example. It is discrete when in the progression of numbers there is an interruption, so that only pairs are compared among themselves, and not each with its nearest antecedent, as happens in these numbers 4. 7. 8. 11. 30. 33. For the same difference holds between the pairs 4 and 7, and 8 and 11, and 30 and 33, but not between 4 and 7 and 7 and 8, and so on.

Geometric proportionality, or mean, is when three or more numbers have the same ratio — which indeed Euclid defined. For this is properly called proportionality, or analogy; the others are so called improperly, since the ratio is not always the same among their terms, so that they are more rightly called "means," on account of the middle terms which, by a certain fixed rule, are interposed between the extremes. For example, these numbers 2. 6. 18. 54., since each has the same triple ratio to its antecedent, constitute Geometric proportionality. This too is of two kinds, continuous and discrete, as we explained in the fourth definition of this book. The continuous is seen in the numbers given [2. 6. 18. 54], the discrete in these six, 2. 3. 12. 18. 20. 30. For only the pairs 2 and 3, and 12 and 18, and 20 and 30 have the same sesquialter ratio, but not each to its nearest antecedent.

Musical or Harmonic proportionality is when three numbers are so ordered that the ratio of the greatest to the least is the same as the ratio of the difference between the two greater to the difference between the two smaller — so that there is neither the same difference between them, as in the Arithmetic, nor the same ratio, as in the Geometric. For example, these three numbers 3. 4. 6.: since the ratio of the difference between the greatest 6 and the middle 4 [i.e. 2], to the difference between the middle 4 and the least 3, that is, to 1, is the same (for in both cases the ratio is double), they constitute Musical or Harmonic proportionality. For the terms themselves have neither the same difference nor the same ratio, as is plain. So too these three numbers 42. 12. 7. constitute Harmonic proportionality, because the ratio of the greatest 42 to the least 7 is the same as the ratio of the difference between the greatest 42 and the middle 12 — that is, of the number 30 — to the difference 5 between the middle 12 and the least 7, both ratios being sextuple.

This kind of proportionality is called Musical, or Harmonic, because for the most part its numbers have those ratios in which the musical consonances consist.

Thus in the earlier example, between 6 and 4 there is the sesquialter ratio, which constitutes the consonance called the diapente, or the Fifth; likewise between 4 and 3 there is the sesquitercian ratio, which constitutes the consonance they call the diatessaron, or the Fourth; and finally between the extremes 6 and 3 the double ratio is seen, which constitutes the diapason consonance, or the octave. And in the same way the same is observed in most other cases.

Some Properties of the Three Proportionalities, or Means, which we have explained [*Proprietates aliquot trium proportionalitatum, sive medietatum, quas explicavimus*]

I.

In three numbers of Arithmetic proportionality the ratio of the greatest to the middle is smaller than that of the middle to the least. As is clear here: 2. 4. 6. For the ratio 6 to 4 is sesquialter, and 4 to 2 double.

But in three numbers of Musical proportionality the ratio of the greatest to the middle is greater than that of the middle to the least. As you see here: 3. 4. 6. For the ratio 6 to 4 is sesquialter, and 4 to 3 sesquitercian.

Finally, in three numbers of Geometric proportionality the ratio of the greatest to the middle is the same as that of the middle to the least, as is clear from its definition, and appears in these three numbers 3. 6. 12. For both 12 to 6 and 6 to 3 have the double ratio. In this respect Geometric proportionality holds the middle place between the Arithmetic and the Harmonic: since in the Arithmetic the ratio between the greater numbers is smaller than between the smaller; conversely in the Harmonic the ratio between the greater numbers is greater than between the smaller; while in the Geometric it is the same between the greater as between the smaller, as has been explained.

II.

Arithmetic proportionality has the differences of its terms equal, but their ratios unequal. Geometric, on the contrary, has the differences of its terms unequal, but their ratios equal. Harmonic, finally, has neither the differences nor the ratios of its terms equal. This is clear from the examples above.

III.

In three numbers of Arithmetic proportionality the middle exceeds the smaller by the same [fractional] part, or parts, of itself by which it is exceeded by the greater. As here: 3. 7. 11. The middle 7 exceeds the smaller 3 by four units, which

make $\frac{4}{7}$ of the middle 7 itself. Likewise the same middle 7 is exceeded by the greater 11 by four units also, which constitute $\frac{4}{7}$ of the same middle. Again here, 15. 20. 25.: the middle 20 exceeds the smaller 15 by five units, which make $\frac{1}{4}$ of the middle 20 itself; and the same middle 20 is exceeded by the greater 25 by five units, which constitute $\frac{1}{4}$ of the same middle 20.

But in three numbers of Geometric proportionality the middle exceeds the smaller by the same part, or parts, of itself by which it is exceeded by the greater as a part of the greater. As here, 4. 6. 9.: the middle 6 exceeds the smaller 4 by the binary [2], which is $\frac{1}{3}$ of the middle, and is exceeded by the greater 9 by the ternary [3], which is likewise $\frac{1}{3}$ of the greater. So too here, 9. 15. 25.: the middle 15 exceeds the smaller 9 by six units, which make $\frac{2}{5}$ of the middle 15 itself; and the same middle 15 is exceeded by the greater 25 by ten units, which likewise make $\frac{2}{5}$ of the greater 25 itself.

Finally, in three numbers of Harmonic proportionality the middle exceeds the smaller by the same part, or parts, of the smaller by which it is exceeded by the greater as a part of the greater. As here, 3. 4. 6.: the middle 4 exceeds the smaller 3 by a unit, which is $\frac{1}{3}$ of that same smaller, and is exceeded by the greater 6 by the binary [2], which is likewise $\frac{1}{3}$ of that same greater. Again, in this Harmonic proportionality 42. 12. 7.: the middle 12 exceeds the smaller 7 by five units, which are $\frac{5}{7}$ of the smaller 7 itself; and the same middle 12 is exceeded by the greater 42 by thirty units, which are $\frac{30}{42}$ — that is, in lowest terms, $\frac{5}{7}$ — of the greater 42 itself.

III.

In three numbers of Arithmetic proportionality the sum of the extremes is double the middle. As here, 3. 7. 11.: the sum of the extremes, 14, is double the middle 7.

But in three numbers of proportionality — Geometric as well as Harmonic — the sum of the extremes exceeds the double of the middle by the number by which the difference of the greater exceeds the difference of the smaller. As here, 4. 6. 9. and 3. 4. 6.: just as the sum 13 of the extremes 4 and 9 exceeds the double of the middle 6, that is, 12, by a unit — by which difference the greater difference, namely 3, exceeds 2, the smaller difference — so the sum 9 of the extremes 3 and 6 exceeds the double of the middle 4, that is, 8, by a unit, by which the greater difference, namely 2, exceeds the smaller difference, which is 1. So too here, 9. 15. 25., where there is continuous superbipartient-of-thirds proportion: the sum 34 of the extremes 9 and 25 exceeds the double of the middle 15, that is, 30, by the number 4, by which same [amount] the greater difference, 10, exceeds the

smaller difference, 6. Likewise in this Harmonic proportionality, 42. 12. 7.: the sum 49 of the extremes exceeds the double of the middle 12, that is, 24, by the number 25, by which the greater difference, 30, exceeds the smaller difference, 5.

V.

In three numbers of Arithmetic proportionality the extremes multiplied together produce a number which is exceeded by the square of the middle by a number equal to the product of the difference of the smaller into the difference of the greater. As here, 3. 7. 11.: the number 33, made from 3 into 11, is exceeded by 49, the square of the middle, by the number 16, which is made from the difference 4 into the difference 4.

But in three numbers of Geometric proportionality the number generated from the first into the third is equal to the square of the middle, as here, 4. 6. 9.: the extremes multiplied together make 36, the square of the middle.

Finally, in three numbers of Harmonic proportionality the number generated from the multiplication of the extremes together exceeds the square of the middle by a number equal to the product of the difference of the smaller into the difference of the greater. As here, 42. 12. 7.: the number 294, made from 42 into 7, exceeds 144, the square of the middle, by the number 150, which is made from the difference 30 into the difference 5. In this respect too Geometric proportionality holds the middle place between the Arithmetic and the Harmonic: for in the Arithmetic less is produced from the first into the third than from the middle into itself, in the Harmonic more, and in the Geometric the same number is generated.

VI.

In three numbers of Arithmetic proportionality the sum of the extremes multiplied into the middle produces a number which exceeds the double of the product of the first into the third by a number equal to the product of the difference of the smaller into the doubled difference of the greater. As here, 3. 7. 11.: the sum of the extremes, 14, into the middle 7 makes 98, which number exceeds the number 66 — the double of the product 33 of the first into the third — by the number 32, which is made from the difference 4 into the doubled difference 4, that is, into 8.

But in three numbers of Geometric proportionality the sum of the extremes multiplied into the middle generates a number which exceeds the double of the product of the first into the third by a number equal to the product of the

difference of the smaller into the difference of the greater. As here, 4. 6. 9.: the sum 13 of the extremes into the middle 6 makes 78, which number exceeds the double of the product of 4 into 9, that is, 72, by the number 6, generated from the difference 2 into the difference 3.

Finally, in three numbers of Harmonic proportionality, from the sum of the extremes into the middle there is produced a number double the product of the first into the third. As here, 3. 4. 6.: from the sum of the extremes, 9, into the middle 4 comes the number 36, double the product 18 of 3 into 6.

VII.

Given four numbers geometrically but not continuously proportional, if the second is the mean between the extremes in Arithmetic proportionality, the third will be the mean between the same extremes in Harmonic proportionality; and if the second is the mean in Harmonic proportionality, the third will be the mean in Arithmetic. As here: as 6 is to 9, so is 8 to 12. And 6. 9. 12. are Arithmetically proportional, since they have the same excess 3; you see that 6. 8. 12. are Harmonically proportional, since the ratio 12 to 6 is the same as that of the difference of the greater, 4, to 2, the difference of the smaller. Likewise here, 6. 8. 9. 12., since as 6 is to 8, so is 9 to 12: and 6. 8. 12. are Harmonically proportional, as we said, while you see that 6. 9. 12. are Arithmetically proportional, since they have the same excess 3.

Again, given four numbers of which one of the two middle terms is the mean between the extremes in Arithmetic proportionality, and the other in Harmonic, the four given numbers will be geometrically (though not continuously) proportional. Thus, given these four numbers 4. 6. 8. 12., the third, 8, is the Arithmetic mean between the extremes 4 and 12, and the second, 6, is the Harmonic mean between the same extremes 4 and 12; you see that as 4 is to 6, so is 8 to 12, and that as 4 is to 8, so is 6 to 12.

VIII.

Given any number of numbers continuously proportional, whether Arithmetically, Geometrically, or Harmonically (though several numbers are said to continue in Harmonic proportionality when the first three are Harmonically proportional, likewise the three next following once the first is left aside, and, leaving aside the first two, another three that follow, and again, the first three left aside, the next three, and so on) — then those numbers will be constituted in the same proportionality that are placed at positions both odd and even, and also partly at odd and partly at even alternating positions, provided that an equal

multitude of numbers is interposed alternately between any odd and even, or between the partly odd and partly even. Such are the first, third, fifth, seventh, and so on; likewise the second, fourth, sixth, and so on; furthermore the first, fourth, seventh, and so on; moreover the first, fifth, ninth, and so on; and so onward. Which is evident in the examples that follow.

Euclid's *Elements*, Book V — Clavius's excursus *On Proportionalities* (continued)

The demonstration of the preceding property is completed by the three tables below, which display arithmetic, geometric, and harmonic proportionalities and the sub-progressions that can be drawn from each. In each table the top row is the full progression; each following row picks out, in its own aligned columns, a further progression of the same kind (taking every second, every third, every fourth term, and so on).

IX.

However many proportional numbers are given — whether in arithmetic, geometric, or harmonic proportionality — if each is multiplied by some one and the same number, or divided by it, then the product-numbers, or the quotients, will likewise have arithmetic, geometric, or harmonic proportionality. As you see here, with each term multiplied by 4, and likewise divided by 4:

Arithmetica proportional.		Geometrica proportional.			Harmonica proportional.		
20	2 3	20	40	8	60	8	140
	8 6			0		4	
<i>Producti</i> [Products]			<i>Produ</i> <i>cti</i>			<i>Produ</i> <i>cti</i>	
80	1 1	80	160	3	240	3	560
	1 4			2		3	
	2 4			0		6	
<i>Quotientes</i> [Quotients]			<i>Quoti</i> <i>entes</i>			<i>Quoti</i> <i>entes</i>	
5	7 9	5	10	2	15	2	35
				0		1	

For the rest: in geometric and harmonic proportionality the product-numbers and the quotients keep the very same kind of ratio that the multiplied or divided numbers have. But in arithmetic proportionality they do not keep the same difference. Instead, the product-numbers have a difference that is a multiple of the difference of the multiplicands, denominated by the multiplying number — in the given example, quadruple. For the difference between 20 and 28 is 8, whereas between 80 and 112 it is 32. The difference of the quotients, by contrast, has to the difference of the divided numbers a submultiple ratio denominated by the divisor, with the prefix "sub-" set before it — in the given example, subquadruple. For the difference between 20 and 28 is 8, whereas between 5 and 7 it is 2. The same ratio of the differences — between the products and the multiplicands, and between the quotients and the divided numbers — is found in geometric and harmonic proportionality as well. Thus you see that the differences of the numbers 80, 160, 320, and likewise of the numbers 240, 336, 560, are quadruple the differences among the numbers 20, 40, 80 and among the numbers 60, 84, 140; while the differences of the numbers 5, 10, 20 and of the numbers 15, 21, 35 are subquadruple of those same differences.

DE PROPORTIONALITATE ARITHMETICA [On Arithmetic Proportionality]

I.

Given any two numbers whatever, if you add their difference to the greater, you will have a third term, greater than both given numbers, in arithmetic proportionality. And if you add the same difference to this third term, you will make a fourth, greater still, in the same proportionality. Going on in this way you will find infinitely many others, always greater, so long as you keep adding the difference to the last one found. Thus, given the two numbers 4 and 11, whose difference is 7, this arithmetic proportionality is set up, which can be extended to infinity:

$4 \cdot 11 \cdot 18 \cdot 25 \cdot 32 \cdot 39 \cdot 46 \cdot 53 \cdot 60 \cdot 67 \cdot \&c.$

But if you subtract the same difference from the lesser number, when it can be subtracted, you will again have a third term, less than both, in the same proportionality. And if you take the same difference from this third term, the remainder becomes a fourth, smaller still, in the same proportionality. Going on in this way you will find others, smaller, so long as you keep taking the difference

from the last one found, until the subtraction can no longer be made. Thus, given the numbers 30 and 34, whose difference is 4, this arithmetic proportionality is set up, running down as far as 2, beyond which it cannot proceed, since 4 can no longer be subtracted from 2:

$$34 \cdot 30 \cdot 26 \cdot 22 \cdot 18 \cdot 14 \cdot 10 \cdot 6 \cdot 2$$

The same proportionality can be extended even if the difference is not assumed, in this way. Given two numbers, from the doubled greater subtract the lesser: the remainder will be a third term greater than both given numbers. If from the double of this term you subtract the one just preceding it, you will have a fourth; and so on to infinity. Thus, given the two numbers 4 and 15: if from the doubled 15 — that is, from 30 — you subtract 4, the remainder is the third term, 26. From its double, 52, if you also take away 15, you will have the fourth term, 37; and so on in succession, as appears here:

$$4 \cdot 15 \cdot 26 \cdot 37 \cdot 48 \cdot \&c.$$

Again, given two numbers: if from the double of the lesser you subtract the greater, a third number, less than both, will be left. And if from the double of this you take away the one just preceding, you will leave a fourth term, smaller still; and so on in succession, until the subtraction can no longer be made. Thus, given the two numbers 20 and 27: if from the doubled 20 — that is, from 40 — you subtract 27, the remainder becomes the third term, 13. From its double, 26, if you also take away 20, the fourth term, 6, will remain. And since from its double, 12, the preceding term, 13, cannot be subtracted, the proportionality cannot proceed further, as you see here:

$$27 \cdot 20 \cdot 13 \cdot 6$$

II.

When the number of terms is odd, the sum of the extremes is equal to the sum of any two middle terms equally distant from the extremes, and equal to double the middle term from which the extremes are equally distant. As here:

$$4 \cdot 7 \cdot 10 \cdot 13 \cdot 16 \cdot 19 \cdot 22 \cdot 25 \cdot 28$$

The sum of 4 and 28, likewise of 7 and 25, likewise of 10 and 22, likewise of 13 and 19, and likewise double the middle term 16, is always 32.

When the number of terms is even, the sum of the extremes is always equal to the sum of any two middle terms equally removed from the extremes. As here:

$$4 \cdot 7 \cdot 10 \cdot 13 \cdot 16 \cdot 19 \cdot 22 \cdot 25 \cdot 28 \cdot 31$$

The sum of 4 and 31, likewise of 7 and 28, of 10 and 25, of 13 and 22, and of 16 and 19, is always 35.

And so, when the number of terms is odd, the sum of all the terms will have, to the middle term equally distant from the extremes — that is, to half the sum of the extremes, or of any two terms equally distant from the extremes — a multiple ratio denominated by the number of terms. For since the sum of the extremes, or of any two terms equally spaced from the extremes, is double the middle term, the middle term (that is, half the sum of the extremes) is contained in the sum of all the terms as many times as there are terms: once in the middle term itself, and twice in each sum of two terms equally distant from the middle. Hence the sum of all the terms has, to half the aggregate of the extremes — that is, to the middle term — a multiple ratio whose denominator is the number of terms. As in this series of nine numbers:

$$6 \cdot 9 \cdot 12 \cdot 15 \cdot 18 \cdot 21 \cdot 24 \cdot 27 \cdot 30$$

The sum of all the terms will contain the middle term 18 — that is, half the sum of the extremes 6 and 30 — as many times as there are units in 9, the number of terms; that is, the sum of all the terms will have to 18, half the sum of the extremes (or to the middle term), a ninefold ratio. And the reasoning is the same in the other cases.

Therefore we will easily find the sum of all the terms of an arithmetic proportionality whose number of terms is odd, if we multiply half the aggregate of the extremes (which is always even when the number of terms is odd) by the number of terms. As in this series of 11 terms:

$$7 \cdot 19 \cdot 31 \cdot 43 \cdot 55 \cdot 67 \cdot 79 \cdot 91 \cdot 103 \cdot 115 \cdot 127$$

The sum of the extremes is 134. Its half, 67 — which does not differ from the middle term, 67 — multiplied by 11, the number of terms, produces 737, the sum of all the terms. This same procedure works also for a proportionality whose number of terms is even; but when the sum of the extremes is odd (for when the number of terms is even the sum of the extremes can be odd, not always even) its half will be a whole number plus $\frac{1}{2}$.

When, however, the number of terms is even, the sum of all the terms will have, to the sum of the extremes (or of any two terms equally distant from the extremes), a multiple ratio denominated by half the number of terms. For since the sum of any two terms equally distant from the extremes equals the sum of the

extremes, this sum of the extremes is contained in the sum of all the terms as many times as unity is contained in half the number of terms — once, that is, in each sum of two terms equally spaced from the extremes. Therefore the sum of all the terms has to the sum of the extremes a multiple ratio denominated by half the number of terms. As in this series of 10 terms:

$$6 \cdot 9 \cdot 12 \cdot 15 \cdot 18 \cdot 21 \cdot 24 \cdot 27 \cdot 30 \cdot 33$$

The sum of all the terms will contain the sum of the extremes, 6 and 33 (which is 39), five times; that is, the sum of all the terms will have to 38 [recte: 39], the sum of the extremes, a fivefold ratio. And so with the others.

Therefore we will obtain the sum of all the terms of an arithmetic proportionality whose number of terms is even, if we multiply the sum of the extremes by half the number of terms (which number, being even, is halved without any fraction of a unit). As in this series of 10 terms:

$$6 \cdot 11 \cdot 16 \cdot 21 \cdot 26 \cdot 31 \cdot 36 \cdot 41 \cdot 46 \cdot 51$$

The sum of the extremes is 57, which multiplied into 5, half the number of terms, makes 285, the sum of all the terms. This procedure works also for a proportionality whose number of terms is odd; but half the number of terms will then always be a whole number plus $\frac{1}{2}$, since the number of terms is taken to be odd.

You see, then, that it is enough for finding the sum that the extreme terms, together with the number of terms, be known. And how, from one known extreme, the number of terms, and the difference, we can arrive at knowledge of the other extreme, we shall teach at once.

III.

If in an arithmetic proportionality, of however many terms, we know one of the extremes, the number of terms, and the difference, we shall find the other extreme in this way. We will multiply the number next-less than the number of terms by the given difference, and add the product to the known lesser extreme; or subtract the same product from the known greater extreme.

**

For in the former case we make the greater extreme, which is sought, while in the latter the remainder becomes the unknown lesser extreme. For example: if the lesser extreme 4 is given, the number of terms 12, and the difference 5, we will

multiply 11 (the number next-less than the number of terms) by the given difference 5, and to the product 55 we will add the lesser extreme 4. The sum, 59, will be the greater extreme, as is plain in these 12 terms, whose difference is 5:

$$4 \cdot 9 \cdot 14 \cdot 19 \cdot 24 \cdot 29 \cdot 34 \cdot 39 \cdot 44 \cdot 49 \cdot 54 \cdot 59$$

But if the greater extreme 59 is given, and the same number of terms 12, with the same difference 5, we will take away the number 55 (the product of 11, the number next-less than the number of terms, into the difference 5) from the known greater extreme 59. The remaining number, 4, will be the lesser extreme, as is clear in the same example.

Now it is necessary, if the lesser extreme is sought, that the number produced from the number next-less than the number of terms, multiplied into the difference, be greater than the known greater extreme, so that the subtraction can be made. Otherwise the question will be impossible: that is, it cannot happen that the given number be the greater extreme in any progression whose difference and number of terms are as proposed. For example, if someone were to give the greater extreme 20, the number of terms 6, and the difference 5, the lesser extreme could not be found, because the number 25, produced from 5 (which is next-less than the number of terms) multiplied into the difference 5, is greater than the given greater extreme 20. But should it happen that the product equals the greater extreme, so that after the subtraction 0 is left, the question will indeed be possible, but the lesser extreme will be 0. Thus, if in this last example the greater extreme were proposed as 25, this arithmetic proportionality would result:

$$0 \cdot 5 \cdot 10 \cdot 15 \cdot 20 \cdot 25$$

III.

If the extreme terms are known, together with the number of terms, we shall find the difference of the numbers in this way. Having taken the lesser extreme away from the greater, we will divide the remaining number by the number next-less than the number of terms. For the quotient will be the difference sought. Thus, if someone says there are 10 terms of some arithmetic proportionality whose extreme numbers are 7 and 52: taking the lesser extreme 7 from the greater 52, we will divide the remaining number 45 by 9, the number next-less than the number of terms. The quotient, 5, will be the difference sought, as appears here:

$$7 \cdot 12 \cdot 17 \cdot 22 \cdot 27 \cdot 32 \cdot 37 \cdot 42 \cdot 47 \cdot 52$$

But so that fractions may be avoided, and the proposed progression fall among whole numbers, it is necessary that, once the lesser extreme has been taken from the greater, the remaining number be measurable by the number next-less than the number of terms. For if it is not so measured, the difference found will be either a fraction or a whole number with a fraction — though the question is still possible. Thus, if someone proposes the extreme terms 2 and 38, and the number of terms 9: taking 2 from 38, and dividing the remaining number 36 by 8, the difference is found to be $4\frac{1}{2}$, as is clear in this example [printed: "templo"; recte "exemplo"]:

$$2 \cdot 6\frac{1}{2} \cdot 11 \cdot 15\frac{1}{2} \cdot 20 \cdot 24\frac{1}{2} \cdot 29 \cdot 33\frac{1}{2} \cdot 38$$

V.

If the two extreme terms, together with the difference, are known, we shall elicit the number of terms by this method. Having taken the lesser extreme from the greater, we will divide the remaining number by the difference. For if we add 1 to the quotient, we will make up the number of terms sought. Thus, given the two extremes 10 and 40, with the difference 3: taking 10 from 40 and dividing the remaining number 30 by 3, the quotient is 10; adding 1, the number of terms becomes 11, as may be seen here:

$$10 \cdot 13 \cdot 16 \cdot 19 \cdot 22 \cdot 25 \cdot 28 \cdot 31 \cdot 34 \cdot 37 \cdot 40$$

But so that the proposed question be possible — that is, so that some progression may really exist in the nature of things, having all the proposed conditions — it is necessary that, the lesser [?] extreme having been subtracted from the greater, the remaining number be measured by the difference. For if it is not so measured, the quotient will not be a whole number, and hence cannot indicate the number of terms, even if 1 is added. For it cannot happen that any progression be given whose number of terms is not a whole number.

[The word "lesser" renders the sense required by the parallel rules III–VIII and by the worked example "10 from 40"; the printed word here is unclear and may read maggiore ("greater").]

VI.

If the two extreme terms, together with the sum of all the terms, are known, we shall discover both the number of terms and the difference by this art. We will divide the sum of all the terms by the sum of the extremes. The quotient will give half the number of terms, and doubled it will indicate the whole number. Then,

the number of terms having been found, since the two extreme terms are also known, we will find the difference as was handed down in the fourth rule — namely, the lesser extreme being taken from the greater, we divide the remaining number by the number next-less than the number of terms found. For example: if the sum is proposed as 515, and the extreme terms as 20 and 83, we will divide the sum 515 by 103, the sum of the extremes. The quotient, 5, doubled, will give the number of terms, 10; and we will obtain their difference if, the lesser extreme 20 being taken from the greater 83, we divide the remaining number 63 by 9, the number next-less than the number of terms found. For the quotient, 7, will be the difference, as you discern here:

$$20 \cdot 27 \cdot 34 \cdot 41 \cdot 48 \cdot 55 \cdot 62 \cdot 69 \cdot 76 \cdot 83$$

You see, then, that for the question to be possible — that is, for some progression really to exist in which the sum of all the terms and the two extremes stand as proposed — it is necessary that the given sum of all the terms be measured by the sum of the extremes. Otherwise the number of terms cannot be drawn out, if the quotient is not a whole number. Or at least, if the given sum of all the terms is not measured by the sum of the extremes, it is necessary that, once the sum of all the terms is divided by the sum of the extremes, the quotient be a whole number plus $\frac{1}{2}$, so that when doubled it can yield a whole number of terms.

VII.

If the extremes of three terms have a double ratio, the middle term will have to the difference a triple ratio. But if the ratio of the extremes is greater than double, the ratio of the middle term to the difference will be less than triple; and if, finally, the ratio of the extremes is less than double, the ratio of the middle term to the difference will be greater than triple. Thus here, 8 · 12 · 16: the ratio of the extremes 16 and 8 is double; and that of the middle term 12 to the difference 4 is triple. But here, 8 · 14 · 20: the ratio between the extremes 20 and 8 is *dupla sesquialtera* ($2\frac{1}{2} : 1$), namely greater than double; and that of the middle term 14 to the difference 6 is *dupla sesquitertia* ($2\frac{1}{3} : 1$), namely less than triple. And here, finally, 8 · 11 · 14: the extremes 14 and 8 have the ratio *supertripartiens quartas* ($7 : 4$, i.e. $1\frac{3}{4} : 1$), which is less than double; and the middle term 11 to the difference 3 has the ratio *trippla superbipartiens tertias* ($11 : 3$, i.e. $3\frac{2}{3} : 1$) — that is, greater than triple.

**

[Clavius's own excursus on proportionality, appended to Book V — not Euclid's text. This opening continues the section De Proportionalitate Arithmetica, whose rules I–VII appeared earlier; rules VIII–X follow here, then the parallel section* De Proportionalitate Geometrica begins.]*

VIII.

Between any two numbers you will place the arithmetic proportional mean if you take half of their sum. Thus, given the two numbers 6 and 30, their sum is 36; so half of this, 18, stands as the arithmetic proportional in the middle position between 6 and 30, as is plain here: 6, 18, 30.

And so, if the middle term to be set up is to be a whole number, both of the given numbers must be either even or [both] odd, so that the sum of the extremes is always even — that is, so that it can be halved without a fraction of a unit. For when the sum of the extremes is odd — which happens when one of the extremes is even and the other odd — the middle term will be a whole number plus half a unit. Thus, given the two numbers 8 and 25, their sum is 33; so half of this is $16\frac{1}{2}$, and the middle term will fall out this way: 8, $16\frac{1}{2}$, 25.

IX.

Between any two numbers, however, you will place as many arithmetic proportional means as anyone directs, in this way. Subtract the smaller from the larger. Then divide the remainder by the number that is next larger than the number of means to be placed. The quotient will be the common difference of the arithmetic proportionality; add it to the smaller given number and you produce the first mean, add the same difference to that and you make the second, and so on. Alternatively, if you subtract that difference from the larger given number, the last mean is left; take the same difference away from that, and the second-to-last remains, and so on. For example, if eleven middle terms are to be placed between 6 and 114, we subtract 6 from 114 and divide the remainder, 108, by 12 (the number next larger than the number of means to be placed). The quotient, 9, will be the common difference of the terms. So the eleven middle terms between 6 and 114 will stand thus:

6.
 15.
 24.
 33.
 42.

51.
60.
69.
78.
96.
105.

But since usually the two numbers proposed are such that whole proportional means cannot fall between them — because the quotient found for the difference is not always a whole number — if you wish to avoid fractions, the two proposed numbers must be of such a kind that, when the smaller is subtracted from the larger, the remainder is measured by the number next larger than the number of means to be placed. You will easily find such numbers as follows. Take any number for the smaller extreme, and add it to some number that nine (which is next larger than the number of means to be established) measures — namely to 72 — and you will produce the larger extreme, 79. You will then find the difference, as was said, by subtracting 7 from 79 and dividing the remainder, 72, by 9. For the quotient, 8, will be the difference, as you see here:

7.
15.
23.
31.
39.
47.
55.
63.
71.

But if someone specifies both the smaller extreme and the common difference of the proportionality, you will find the larger extreme — such that between the smaller and the larger fall as many middle numbers as you wish, all having that difference — by multiplying the number next larger than the number of means to be placed by the given difference, and adding the smaller extreme to the product. For instance, if one wishes to set up between 5 and some larger number 9 middle terms whose common difference is 4, then 10 must be multiplied by 4, and to the product, 40, the smaller extreme, 5, must be added. For between the resulting

number, 45, and the given smaller extreme, 5, nine middle terms are contained, with the given difference 4, as is plain here:

5.
 9.
 13.
 17.
 21.
 25.
 29.
 33.
 37.

By this other pleasant procedure too you will set up as many proportional means as you wish between two given numbers. Divide each of the two given numbers by the number next larger than the number of means to be placed, and set the quotients each beneath its own [number]. From those same quotients, ascend by continually adding them — adding each first to itself, then to the resulting number, and so on — so that you build two arithmetic proportionalities that begin from the quotients and advance by those same [quotients], each having as many terms (apart from the two given numbers) as there are middle terms desired. Finally, add each term of the one series to the term of the other opposite it — that is, the greatest of the one to the least of the other, then the next below it to the one just above this, and so on. For the combined numbers will give the desired means. For example, let 4 arithmetic proportional middle terms be placed between 15 and 100. Dividing each by 5 (that is, by the number next larger than the number of means), the quotients become 3 and 20. So you will set up these two series of 4 arithmetically proportional terms beneath 15 and 100 by continually adding those quotients: adding the first, 3, to 3 to make 6; likewise 3 to 6 to make 9; likewise 3 to 9 to make 12. Again, adding 20 to 20 to make 40; likewise 20 to 40 to make 60; likewise 20 to 60 to make 80, as you see here:

15	32	49	66	83	100
12					80
9					60
6					40
3					20

From 12, the top of the first order, and 20, the bottom of the second order, comes 32 for the first mean. From 9 and 40 comes 49 for the second mean. From 6 and 60 comes 66 for the third mean. Finally, from 3 and 80 comes 83 for the fourth mean. And so, in the first order one must always descend from top to bottom, but in the second order ascend from bottom to top.

It is worth noticing that the difference of the quotients — which are the smallest numbers of the two series set up — is also the common difference of the proportionality being constructed. Thus you see that in the proposed example the difference is 17, and this same difference etiam

is also [the difference] between the quotients 3 and 20. Therefore, once the quotients are found, if the smaller is subtracted from the larger, and the remainder is added to the given smaller extreme, and to this combined number that same remainder is again added, and so on, the very same middle terms will be established, even if those two series are not set up.

You see, then, that each proposed number must be measured by a number exceeding the number of means by one unit, if fractions are to be avoided; or else the two extremes must be found, as we prescribed in the earlier part of this rule. For in that case too fractions are avoided, even if the number next larger than the number of means does not measure them — because when the smaller quotient is subtracted from the larger, a whole number is always left, as appears in the examples of that earlier rule. For in the third of them, for instance, 9 middle terms are to be placed between 5 and 45. So if each is divided by 10, the quotients become $5/10$ and $45/10$ — that is, $\frac{1}{2}$ and $4\frac{1}{2}$ — whose difference, 4, is a whole number, from whose continual addition to the given smaller extreme the desired middle terms are produced. These same terms will be found if, from the quotients $\frac{1}{2}$ and $4\frac{1}{2}$, two ascending series are set up, as was said, by the continual addition of those quotients, etc.

X.

We will distribute any proposed number into as many parts as one directs, preserving arithmetic proportionality, in this way. Dividing the given number by half the number of terms, we will cut the quotient into two unequal parts, however chosen, to serve as the extreme terms of the proportionality. Then, since two extreme terms have now been given along with the number of terms, we will subtract the smaller extreme from the larger and divide the remainder by the number next smaller than the number of terms. For thus the common difference will come out in the quotient, as is clear from Rule 4. If this difference is then

added to the smaller assumed extreme, and again to the resulting number, and so on, the given number of terms will be established, whose sum equals the proposed number; and accordingly the given number will have been cut into a number of arithmetically proportional parts. For example, if the number 830 is to be distributed into 10 arithmetically proportional parts, we will divide it by 5, half the number of terms, and cut the quotient, 166, into 20 and 146, the extreme terms of the proportionality to be established. Then, subtracting 20 from 146, we will divide the remainder, 126, by 9, the number next smaller than the number of terms. For the quotient, 14 (as was said in Rule 4), will be the common difference of the proportionality, as you see here:

20.
 34.
 48.
 62.
 76.
 90.
 104.
 118.
 132.

Again, if the number 10 is to be divided into 10 arithmetically proportional parts, we will divide it by 5, half the number of terms, and cut the quotient, 2, into two unequal parts, $\frac{1}{2}$ and $1\frac{1}{2}$, to serve as the extreme terms of the proportionality. Then, subtracting the smaller extreme, $\frac{1}{2}$, from the larger, $1\frac{1}{2}$, we will divide the remainder, 1, by 9, the number next smaller than the number of parts to be established. For the quotient, $\frac{1}{9}$, will be the common difference to be added continually to the smaller extreme, $\frac{1}{2}$, and to the resulting number, and so on. To make this addition easier, we will reduce the smaller extreme, $\frac{1}{2}$, and the difference, $\frac{1}{9}$, to the same denomination — namely to $\frac{9}{18}$ and $\frac{2}{18}$. So the number 10 will be divided into 10 arithmetically proportional parts, of which the first is $\frac{1}{2}$, or $\frac{9}{18}$, the last is $1\frac{1}{2}$, or $1\frac{9}{18}$, and the difference is $\frac{2}{18}$:

$\frac{9}{18}$. $\frac{11}{18}$. $\frac{13}{18}$. $\frac{15}{18}$. $\frac{17}{18}$. $1\frac{1}{18}$. $1\frac{3}{18}$. $1\frac{5}{18}$. $1\frac{7}{18}$. $1\frac{9}{18}$.

It is certain that in this way the given number can be divided in various ways into the proposed number of proportional parts — according, namely, as the quotient (when the given number is divided by half the number of terms) is cut into different pairs of unequal parts for the extreme terms.

We will accomplish the same thing by the following method. Take the given number as if it were the sum of all the terms to be established; divided by the given number of terms, the doubled quotient will give the sum of the extremes — because half of this sum of the extremes (that is, the quotient found), multiplied by the number of terms (that is, by the divisor), produces the sum of all the terms, namely the given number, as was said in Rule 2. So if we cut the doubled quotient into two unequal numbers for the extreme terms, and, subtracting the smaller from the larger, divide the remainder by the number next smaller than the given number of terms, the quotient will give the common difference, as we said in Rule 4. And if we add this to the smaller extreme just formed, and again to the resulting number, and so on, the required arithmetic proportionality will be established. For instance, if the number 198 is proposed to be cut into 9 arithmetically proportional parts, we will divide it by 9, the number of terms, so that the quotient becomes 22, which doubled gives 44, the sum of the extremes. So, setting the smaller extreme at 10 and hence the larger at 34, if we subtract 10 from 34 and divide the remainder, 24, by 8 (the number next smaller than the number of terms), the common difference 3 is produced. So the 9 terms of the arithmetic proportionality making up the sum 198 will stand thus:

10.
 13.
 16.
 19.
 22.
 25.
 28.
 31.

Here too it is plain that the given number can be distributed in various ways into the given number of parts — according, namely, as the first doubled quotient (which we said is the sum of the extremes) is cut into different pairs of parts for the two extreme terms.

But perhaps you will accomplish the same thing more easily (though the operation is somewhat longer) in this way. Take as many arbitrary arithmetically proportional numbers as the number of parts into which the given number is to be distributed, multiply each by the given number, and divide the products by the sum of all the terms taken, found by Rule 2. For the quotients will give the parts you seek. For example, let the number 525 be divided into 10 arithmetically proportional parts. Take any 10 arithmetically proportional numbers, 4, 7, 10, 13,

16, 19, 22, 25, 28, 31, whose sum is 175. Multiplying each by the given number, 525, these 10 numbers are created: 2100, 3675, 5250, 6825, 8400, 9975, 11550, 13125, 14700, 16275. Dividing each of these by 175, the sum of your numbers taken in arithmetic proportionality, the 10 parts you seek are produced:

12.
 21.
 30.
 39.
 48.
 57.
 66.
 75.
 84.

You will obtain the same result if you divide the given number by the sum of the assumed numbers, and multiply the quotient into each of the assumed [numbers]. assu

multiply into each of the assumed numbers. For the products will give the parts you seek. As in the given example: if the given number, 525, is divided by 175, the sum of the assumed numbers, the quotient is 3; and multiplying this into each of the assumed numbers, 4, 7, 10, etc., the same parts as before are produced: 12, 21, 30, etc.

To make the operation easier and shorter, it is enough to multiply the first two numbers of the assumed proportionality by the given number and divide the products by the sum of all the terms of that same assumed proportionality. Or it is enough, once the given number has been divided by the sum of the assumed numbers, to multiply the quotient into the first two assumed numbers. For thus the first two parts of the given number are found, and the difference between them, added to the larger, makes the third; and the same difference added to the third makes the fourth, and so on. And I think it is clearly established here too that the given number can be distributed in various ways into as many proportional parts as one directs — according, namely, as different numbers of the same arithmetic proportionality are assumed, or [numbers] whose difference is different.

By this method the parts found have, in order, the same ratios among themselves as are found, in the same order, among the assumed terms of the proportionality. And each number of the assumed proportionality always has exactly the same

ratio to each of the parts found — the first to the first, the second to the second, and so on. Thus you see that between the first parts found, 12 and 21, there is the ratio of 7 to 4 [supertripartiens quartas], just as there is between the first numbers taken, 4 and 7, etc. Likewise, 4 to 12, and 7 to 21, and 10 to 30, etc., have exactly the same ratio, namely the subtriple ratio [1 to 3].

And so, if an arithmetic proportionality is taken whose first two numbers have the double ratio [2 to 1] — so that the first is the common difference of all the terms — then the first parts too will have the double ratio, and therefore the first part will also be the common difference by whose addition the other parts are accumulated. For instance, if in the above example you had taken these 10 terms, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, whose sum is 55; or these 10 numbers, 3, 6, 9, 12, 15, 18, 21, 24, 27, 30, whose sum is 165; and had multiplied each first term by the given number, 525, and divided the products, 525 and 1575, by their respective sums — the former by 55 and the latter by 165 — you would have found the first part to be $9\frac{6}{11}$, which would also be the common difference. Hence all 10 parts constituting the arithmetic proportionality would have been these:

$9\frac{6}{11}$. $19\frac{1}{11}$. $28\frac{7}{11}$. $38\frac{2}{11}$. $47\frac{8}{11}$. $57\frac{3}{11}$. $66\frac{9}{11}$. $76\frac{4}{11}$. $85\frac{10}{11}$. $95\frac{5}{11}$.

DE PROPORTIONALITATE Geometrica.

[On Geometric Proportionality.]

I.

Given any two numbers, if you take the denominator of the ratio they have [denominator proportionis] by comparing the larger with the smaller — that is, if, dividing the larger by the smaller, you multiply the quotient into the larger — you will generate a third term in geometric proportionality, larger than both given numbers. And if you multiply the same denominator, or quotient, into this third term, you will produce a fourth, still larger, in the same proportionality. And so on, you will establish infinitely many others, always larger, if you keep multiplying the denominator, or quotient, by the last one found. Thus, given the two numbers 4 and 12, the denominator of the ratio of 12 to 4 is 3, since dividing 12 by 4 makes the quotient 3. If, then, you multiply 3 into 12, and again into the product, and so on to infinity, you will establish this geometric proportionality, which can be extended to infinity:

4.

12.

36.
 108.
 324.
 972.
 2916.
 8748. &c.

But if you compare the smaller with the larger and take the denominator of the ratio they have — that is, dividing the smaller by the larger — and multiply the quotient into the smaller; or, what is the same, divide the smaller by the denominator of the ratio that the larger has to the smaller, a third proportional number will be created, smaller than both. From this, by the same method, you will find a fourth still smaller, and so on to infinity. Thus, given the two numbers 8 and 16, the denominator of the ratio of 8 to 16 is $\frac{1}{2}$, since dividing 8 by 16 makes the quotient $\frac{1}{2}$. But the denominator of the ratio of 16 to 8 is 2, since dividing 16 by 8 makes the quotient 2. If, then, you multiply $\frac{1}{2}$ into 8 — or divide 8 by 2 — and do the same with the resulting number, this geometric proportionality will be established, progressing to infinity toward smaller numbers, just as that other one progressed to infinity toward larger numbers:

16.
 8.
 4.
 2.
 1. $\frac{1}{2}$. $\frac{1}{4}$. $\frac{1}{8}$. $\frac{1}{16}$. $\frac{1}{32}$. $\frac{1}{64}$.

The same proportionality will also be extended to infinity even if the denominator of the ratio is unknown, in this way. Given two numbers, multiply the larger by itself and divide the product by the smaller. For the quotient will be a third term larger than both. If you multiply this by itself and divide the product by the immediately preceding term, the quotient will give a fourth term, and so on. Thus, given the two numbers 3 and 6: multiplying 6 by itself makes 36, which divided by 3 gives 12, the third term. Again, multiplying 12 by itself makes 144, which divided by 6 gives 24, the fourth term; and so on to infinity, as you see here: 3. 6. 12. 24. 48. &c.

Again, given two numbers, if you multiply the smaller by itself and divide the product by the larger, the quotient will give a third term smaller than both. If you multiply this in turn by itself and divide the product by the immediately preceding term, the quotient will give a fourth term still smaller, and so on. Thus,

given the two numbers 6 and 18: multiplying 6 by itself makes 36, which divided by 18 gives 2, the third term. Again, multiplying 2 by itself makes 4, which divided by 6 gives $\frac{4}{6}$, or $\frac{2}{3}$ in lowest terms, for the fourth term; and so on to infinity, as appears here:

18.

6.

2. $\frac{2}{3}$. $\frac{2}{9}$. $\frac{2}{27}$. &c.

Now, if you wish to extend any non-multiple ratio (for in a multiple ratio there is no difficulty, if you follow the prescribed rule) into whole numbers, to as many larger terms as you like, you will accomplish it by this pleasant and easy procedure. Take as many continuously proportional terms of that multiple ratio, beginning from 1, whose denominator names the aliquot part or parts mentioned in the given ratio — take, I say, as many terms as in the proposed ratio propor

(Rule I, continued from the preceding page.)

you want terms in a proportionality that is not a multiple one. For the last of them will be the first term of your proportion, which is not a multiple. Therefore, if you multiply that term by the denominator of the given proportion, and again multiply the resulting product by the same denominator, and so on in turn, you will establish the terms you want. And here is the remarkable thing: if the required terms are found in this way, the proportionality cannot be extended beyond the proposed terms without a fraction. For example, suppose seven terms in sesquialterate proportion [proportio sesquialtera] (3:2) are to be found. Since the denominator of the fraction $\frac{1}{2}$ — which was just mentioned — is 2, one must take seven terms in double proportion [dupla] (2:1), namely 1. 2. 4. 8. 16. 32. 64. If, then, you begin from 64, you will establish seven terms of sesquialterate proportionality, and no more — these, of course:

64.

96.

144.

216.

324.

486.

These terms will easily be found if to the first, 64, you add its half, and to the second, 96, now produced, its half likewise, and so on. In the same way too, if six terms of the double-superbipartient-fifths proportion [dupla superbipartiens

quintas] (12:5) are wanted, one must take six terms of the quintuple proportion [quintupla] (5:1) — because of the denominator of the fifth-parts, which is 5 — namely 1. 5. 25. 125. 625. 3125. For if you begin from the last, 3125, you will find these six terms in double-superbipartient-fifths proportion:

3125.
 7500.
 18000.
 43200.
 38144.

These terms will easily be found if you add two fifths of the first to that same first doubled, and again two fifths of the second, now produced, to that same second doubled, and so on. And the numbers found in this way are always the smallest in their proportion — so much so that it is utterly impossible for as many other terms in the same continued proportion to be found which are smaller than these, unless we are willing to admit fractions. The same terms are found more easily if, once the two smallest terms in the given proportion have been discovered, the first term found from that multiple proportion is multiplied by the greater [of the two smallest], and the product is divided by the smaller; for in this way the second term will be found. And if this in turn is multiplied by the greater of the smallest terms, and the product divided by the smaller, the third term will be found; and so on. Thus in the latter example, the smallest terms of the double-superbipartient-fifths proportion are 5 and 12. So if the sixth term of the quintuple proportion, 3125 — which must be the first of the six terms sought — is multiplied by 12, and the product 37500 is divided by 5, the second term 7500 will result; and if this in turn is multiplied by 12, and the product 90000 divided by 5, the third term 18000 will be produced; and so on. Moreover, in any multiple proportion whatever, however many smallest terms there are, they always begin from 1. Thus the three smallest terms in continued quadruple proportion are these: 1. 4. 16.

II.

When the number of terms in continued proportion is odd, the number produced by multiplying the extremes by each other is equal to the number created by multiplying together any two terms equally distant from the extremes, and also equal to the number produced by the middle term multiplied into itself. As in these five numbers of sesquialterate proportion:

16.

24.

36.

54.

the number 1296 is produced as much from 16×81 as from 24×54 , and from $36 \times$ itself.

When, however, the number of proportional terms is even — even if they are not continuously proportional, provided that the pairs interrupting the continued proportion have one and the same ratio among themselves (that is, provided that the second and third; likewise the fourth and fifth; and also the sixth and seventh, and so on, the places where the proportion is interrupted, are themselves also non-continuously proportional, yet in a proportion different from the one that the first has to the second, the third to the fourth, and the fifth to the sixth, and so on) — when, I say, the number of terms is even, the number produced by multiplying one extreme into the other is always equal to the number generated by the multiplication of any two terms equally distant from the extremes. As here, in six numbers of continued double proportion:

3.

6.

12.

24.

48.

From 3×96 , and from 6×48 , and from 12×24 , the same number 288 is always produced.

Likewise in this non-continuous sesquitertian [sesquitertia] (4:3) sequence of eight terms, where the pairs interrupting the continued proportion have one and the same ratio — namely the triple, which is different from the sesquitertian:

3.

4.

12.

16.

48.

64.

192.

the very same number 768 arises from 3×256 , and from 4×192 , and from 12×64 , and from 16×48 .

HENCE it follows that, when the number of terms is odd, the number produced by multiplying one extreme into the other, or by the multiplication together of any two terms equally distant from the extremes or from the middle, is a square number. (A number is called *square* when it is produced by the multiplication of some number into itself; and the number producing it is called its *side* or *root*.) Its root, or side, is the middle number — because, of course, the same number is generated from the middle term into itself, and therefore the middle term is its square root. But the number produced from three terms multiplied together — of which two are either the extremes or equally removed from the extremes, and the third is the middle — is a cube. (That number is called a *cube* which is produced from some number multiplied into itself, and then into the resulting product; and the number which, multiplied into itself and again into the product, produces the cube, is called its *cubic side* or *cube root*.) Its side, or root, is the middle number — because, of course, it is generated from the middle term multiplied cubically into itself, that is, first into itself, then into the product of the other two multiplied together. For the middle term, multiplied into itself, makes the product of the other two; and therefore, multiplied again into this result, it produces the cube.

IT ALSO FOLLOWS that, when there are four numbers proportional either continuously or non-continuously, the number produced by the mutual multiplication of them all (three or more numbers are said to *multiply one another continuously* when one is multiplied into another, and the resulting number into a third, and this product into a fourth, and so on, until all the numbers are

(Rule II, continued.)

multiplied together) is a square, whose side or root is the number generated from the first into the fourth, or from the second into the third. For from the mutual multiplication of all four numbers together the same number is created which is produced when the number formed from the first into the fourth is multiplied by the product of the second into the third (which is equal to the product of the first into the fourth). And when there are six numbers, proportional either continuously or non-continuously — provided that the pairs of numbers interrupting the continued proportion are also non-continuously proportional — a cube arises from the mutual multiplication of all six numbers together, whose root or side is the number produced from the multiplication of the extremes, or

of any two equally distant from the extremes. This is generated from the number formed by the two extremes multiplied together, multiplied cubically into itself: that is, once into itself — namely into the product of the two nearest the extremes — and again into the product, when this resulting number is multiplied into the product of the two middle terms; since indeed these three products are equal to one another.

III.

IF, given any number of terms in continued proportion, the smaller extreme is subtracted from the greater, and the remaining number is divided by a number one unit less than the denominator of the proportion (which each of the proposed numbers has to the smaller number nearest it), and finally the quotient is added to the greater extreme, the sum of all the terms will be produced. As here, in continued triple proportion:

2.
 6.
 18.
 54.
 162.
 486.
 1458.
 4374.

With the smaller extreme 2 subtracted from the greater 13122, and the remaining number 13120 divided by 2 — that is, by a number one unit less than the denominator 3 of the triple proportion, which each of these numbers has to the immediately preceding smaller one — the quotient becomes 6560; and if the greater extreme 13122 is added to it, the sum of all becomes 19682. Likewise in this continued sesquitercian sequence:

243.
 324.
 432.
 576.
 768.

With the smaller extreme 243 subtracted from the greater 1024, and the remaining number 781 divided by $\frac{1}{3}$ (a number one unit less than the

denominator $1\frac{1}{3}$), the quotient becomes 2343. Therefore, with the greater extreme 1024 added, the sum of all the terms becomes 3367.

And so, as you see, to find the sum of any number of terms in geometric proportionality it is enough that the two extremes be known, together with the denominator of the proportion. But by what device the last term of any geometric proportionality of however many terms is to be investigated — even if we do not know the middle numbers — we have set out abundantly in the sections on progressions in our *Practical Arithmetic* [Arithmetica practica], so that it would be superfluous to repeat it here.

IV.

Given any number of numbers exceeding one another equally — that is, arithmetically proportional — if just as many other numbers are taken having the same ratios as those first ones taken in the same order, these later numbers will also exceed one another equally; that is, they will be arithmetically proportional, just like the first. For example, if these six numbers, 4. 7. 10. 13. 16. 19., are set out as arithmetically proportional, and just as many others are taken with the same ratios — of which sort are these, 20. 35. 50. 65. 80. 95. — you will find that they too are arithmetically proportional, since indeed they have a common difference of 15. But beware of thinking that this property can be converted: for it is not the case that, if any number of arithmetically proportional numbers are given, and just as many others are also taken as arithmetically proportional, then — even if the common difference is the same in both — these will necessarily be proportional to those. This is clear in these two arithmetic progressions:

A diagram showing 18 numbered points arranged in a circular pattern, representing the vertices of a regular 18-sided polygon. The points are numbered 1 through 18 in a clockwise direction starting from the top.

9.

11.

13.

15.

17.

19.

Here the first two numbers of the former, 2 and 4, have the double ratio, whereas the first two of the latter, 3 and 5, have the superbipartient-thirds ratio (5:3). Likewise the first number 3 in the latter order has to the first number 2 in the former order the sesquialterate ratio, while the second, 5, has to the second, 4, the sesquiquartan ratio (5:4), and so on.

V.

Given any two numbers, if one of them is divided into any number of parts, and the individual parts are multiplied into the other, and the individual resulting numbers are divided by the former number, all the quotients taken together will constitute the latter number, and they will have among themselves, in order, exactly the same ratios that the parts of the former number have among themselves in the same order. And the individual quotients — that is, the parts of the latter number — will have to the individual parts of the former (as the first to the first, the second to the second, and so on) one and the same ratio throughout. For instance, given the two numbers 57 and 285: if the former is cut into parts which together make it up, 2. 5. 10. 40., and each of them is multiplied into the latter number 285, these numbers will be generated: 570. 1425. 2850. 11400.; and when these are severally divided by the former number 57, the quotients become 10. 25. 50. 200., which gathered into one sum constitute the latter number 285, and have the same ratios that the parts 2. 5. 10. 40. have — namely double, sesquialterate, double, and quadruple. And the individual quotients to the individual parts — as 10 to 2, and 25 to 5, and 50 to 10, and 200 to 40 — have altogether one and the same ratio, namely quintuple.

You will obtain the same parts of the latter number if you divide it by the former (which was distributed into parts), and multiply the resulting quotient into the individual parts of that same former number. As in the same example: dividing the number 285 by 57 gives the quotient 5, and this multiplied into the parts 2. 5. 10. 40. of the number 57 gives the parts of the number 285 — these: 10. 25. 50. 200. — as before.

From this it is easily gathered how any two numbers may be cut into component parts equal to the numbers themselves, in such a way that the parts of the one are proportional to the parts of the other, comparing both the parts of each number with one another and the parts of the one with the parts of the other. And upon this property rests the third method of distributing a proposed number into any number of arithmetically proportional parts,

(Rule V, continued.)

proportional parts, which we prescribed in Rule 10 of arithmetic proportionality. For when just as many arithmetically proportional numbers are taken, their sum will be the number divided into those numbers as into the parts composing it. Therefore, if these individual parts are multiplied into the given number, and the resulting numbers are divided by that sum; or if the given number is divided by the sum of the assumed numbers, and the quotient is multiplied into each of those numbers — there will be produced just as many parts of the proposed number in the same ratios. And therefore they too will be arithmetically proportional, as is evident from the preceding Rule 4.

VI.

GIVEN any number of numbers in continued proportion, their differences too will be, in the same proportion, continuously proportional. As in the adjacent example both the numbers and their differences have the continued sesquialterate proportion:

Differences	32	48	72	108	162	243	
Terms	64	96	144	216	324	486	729

By the same reasoning, in this other example which follows, both the numbers and their differences have the double proportion. Here you see that the differences do not differ from the numbers of the double proportion of which they are the differences. This happens for the double proportion alone, whatever it may be — because in it any greater number exceeds the immediately preceding smaller one by that very number immediately preceding, of which it is the double, that is, which it contains twice.

Differences	7	14	28	56	112	224	448	896	
Terms	7	14	28	56	112	224	448	896	1792

VII.

GIVEN any number of numbers in continued proportion, if their sum is divided by each of them severally, the quotients will be, in reverse order, continuously proportional in the same proportion. And if the sum of the quotients is divided severally by the quotients themselves, exactly the same quotients will be created in reverse order; and so on to infinity. Moreover, the sum of those quotients is equal to the number produced from the first quotient into the last, or from the multiplication of any two equally distant from the extremes, or finally — if the number of terms is odd — from the middle multiplied into itself. This may indeed seem incredible. For example: if these four numbers in continued double proportion, 3. 6. 12. 24., are given, and their sum 45 is divided by each severally, the quotients will be 15. $7\frac{1}{2}$. $3\frac{3}{4}$. $1\frac{1}{8}$., continuously proportional in reverse order in the same double proportion. And if their sum $28\frac{1}{8}$ is divided by these quotients, exactly the same quotients will result in reverse order, and so on to infinity. And the sum itself, $28\frac{1}{8}$, is equal to the number produced from $15 \times 1\frac{1}{8}$, or from $7\frac{1}{2} \times 3\frac{3}{4}$. So too, given these five terms in continued triple proportion, 2. 6. 18. 54. 162., if we divide their sum severally by them, we shall produce these five quotients: 121. $40\frac{1}{3}$. $13\frac{4}{9}$. $4\frac{13}{27}$. $1\frac{40}{81}$., in the same continued triple proportion. Their sum, $180\frac{61}{81}$, is produced either from $121 \times 1\frac{40}{81}$, or from $40\frac{1}{3} \times 4\frac{13}{27}$, or finally from $13\frac{4}{9}$ into itself. Here two things are worth considering. First, that when the number of terms is odd, the sum of the quotients is a square number whose root is the middle term — since indeed it is produced by the middle term multiplied into itself, as has been said. Second, that the same quotients are always generated by dividing the sum of any number of terms of the same continued proportion, however great or small those terms may be, provided the number of terms is always the same. For instance, if there are three continuously doubled terms, whether great or small, the quotients will always be 7. $3\frac{1}{2}$. $1\frac{3}{4}$. If there are four, the quotients will be 15. $7\frac{1}{2}$. $3\frac{3}{4}$. $1\frac{1}{8}$. In five continuously tripled numbers the quotients will always be 121. $40\frac{1}{3}$. $13\frac{4}{9}$. $4\frac{13}{27}$. $1\frac{40}{81}$. And finally, in five numbers having the continued sesquialterate proportion, these quotients will be found: $13\frac{3}{16}$. $8\frac{19}{24}$. $5\frac{31}{36}$. $3\frac{49}{54}$ [?]. $2\frac{49}{81}$ [?].

FROM this property we shall find any number of terms in a given proportion, continuously proportional, whose sum is equal to the number produced from the extremes multiplied together, or from any two middle terms equally distant from the extremes, or even from the middle term multiplied into itself, if the number of terms is odd. For if as many terms as need to be found are taken in the given proportion, continuously proportional, whether great or small, and their sum is divided separately by them, the quotients will be the numbers that are sought. But if the sum is to be a square number, terms must be taken whose number is

odd and equal to the given odd number of terms, and so on. This may be reckoned as something of a marvel: that in a given proportion any number of continuously proportional terms one pleases can be furnished, whose sum is generated by the multiplication of the first term into the last — whereas we find the contrary in all continued proportions of inequality whose terms are whole numbers, and in all others too whose numbers have fractions mixed in, unless these quotient numbers are the products of dividing the sum of some number of continuously proportional terms by the proportional terms themselves, as we have said.

IN THE SAME WAY we shall satisfy the question, if anyone asks for two numbers having a given proportion whose sum is equal to the number produced from the multiplication of one into the other. For if any two numbers in the given proportion are taken, and their sum is divided by them severally, the proposed question will be satisfied by the quotients found. For example, if someone wants two numbers between which is found the triple-superbipartient-ninths proportion (29:9), we shall take either these two numbers, 29 and 9, or 87 and 27, having the given proportion, or any others whatever. For the sum of the first pair, 38, divided by 29 and by 9 — or the sum of the latter, 114, divided by 87 and 27 — will give the quotients $1\frac{9}{29}$ and $4\frac{2}{9}$, having the same proportion as 29 and 9, or 87 and 27, though in reverse order; and their aggregate is $5\frac{139}{261}$ [?], which number is likewise generated from the multiplication of $1\frac{9}{29}$ into $4\frac{2}{9}$.

VIII.

BETWEEN any two numbers whatever we shall establish a geometric mean proportional [medium Geometrice proportionale], if we multiply them by each other, and [take the root of what is] produced...

so that we take the square root of the number produced. For example, given the two numbers 6 and 96, multiplying one by the other gives 576, whose square root, 24, will be the mean proportional between the given numbers, thus: 6, 24, 96. For 96 stands to 24 in the quadruple ratio, and 24 stands to 6 in the same ratio.

Accordingly, if the mean number to be set between two given numbers is to be rational — that is, expressible in numbers — then the number produced by multiplying one into the other must be a perfect square. For unless it is a square, it will have no root among the numbers; rather its root will be a number that the arithmeticians call *surd* [surdum] or *irrational* [irrationalem], and which they express in this way: the square root of such-and-such a number. For instance, given the two numbers 7 and 9, multiplying one by the other yields 63, which has no root. We shall therefore say that the square root of 63, which cannot be

expressed in numbers, is the mean proportional between the given numbers 7 and 9, thus:

[Boxed inset: 7 | R.q. 63. | 9.] (*that is, 7, $\sqrt{63}$ [radix quadrata], 9*)

This root is greater than 7, since the square of 7 is 49, but less than 8, since the square of 8 is 64. Nor can 7-plus-some-fraction, which lies between 7 and 8, be the root, even if unity is imagined to be divided to infinity; for every such number-with-a-fraction produces a number-with-a-fraction, as we shall prove at Definition 8 — and 63 is not a number of that kind.

IX.

Should anyone wish to find three numbers in arithmetic proportionality such that between each pair of them a single geometric mean proportional falls, he will achieve it by the following method. Take any three numbers of which the second is five times the first and the third seven times the first. Their squares will then be arithmetically proportional, and the first number multiplied into the second will produce the geometric mean between the first square and the second, in the ratio of the first assumed number to the second; while the second assumed number multiplied into the third will generate the mean proportional between the second square and the third, in the ratio that the second and third assumed numbers bear to each other. This is plainly seen in the following example.

Tres num. assump.

[the three assumed numbers]	Primus. 8. [first, 8]	quintup. pri. 40. [5× first, 40]	Septup. pri. 56. [7× first, 56]
Quad. Arit. pro. [their arithmetically-proportional squares]	64	1600	3136.
Medij Geomet. [geometric means]	320	2240	

For the difference between the three squares is 1536, and the mean proportionals between them, 320 and 2240, are produced from 8 into 40 and from 40 into 56.

From this you will easily find three square numbers that exceed one another by equal differences, if for their roots you take three numbers of which the second is five times the first and the third seven times the first, as we said.

By the same reasoning, given any square, two larger squares will be found that together with it constitute an arithmetic proportionality. For if the root of the given square is set as the first number, and two other numbers are taken of which one is five times that root and the other seven times it, then the squares of these two numbers are the ones we seek. Thus if the square number 64 is given, its root 8 will be the first number, 40 the second, and 56 the third, and so on.

Once three arithmetically-proportional squares have been found, if you multiply them by any one and the same number, or divide them by any aliquot part they may have, the resulting products or quotients will likewise be arithmetically proportional, and between each pair of them a single geometric mean will again be intercepted. These means are found in the same way: the means between the discovered squares are simply multiplied by that same number, or divided by that same aliquot part. Thus, if the squares above, together with their mean proportionals, are doubled, these numbers arise:

Arithmet. proportio.	128	3200	6272
Medij Geometr.	640	4480	

But if the same numbers are divided by 8, an aliquot part common to the squares (and any aliquot parts of the squares are also aliquot parts of the means), these numbers result:

Arithmet. proportio.	8	200	392
Medij Geometr.	40	280	

Numbers found in this way will always keep the same ratios that the squares and their means have among themselves. Thus if you divide these — 8, 200, 392 — by 4, you find another set, 2, 50, 98, arithmetically proportional, between which the geometric means 10 and 70 fall. And if finally you divide these — 2, 50, 98 — by 2, you obtain yet another set, 1, 25, 49, between which the geometric means are 5 and 35.

Here, too, a point seems worthy of wonder: whenever between three arithmetically-proportional numbers — whether they are squares or not — two geometric mean proportionals fall, one between the first and the second and the other between the second and the third, then the square of the first mean, the square of the second number of the arithmetic proportionality, and the square of the second mean constitute an arithmetic proportionality. As in the latter example: the squares of the three numbers 40, 200, 280 are 1600, 40000, 78400 — arithmetically proportional, having the same common difference 30400 [recte:

38400; for $40000 - 1600 = 38400$ and $78400 - 40000 = 38400$, so the printed 30400 appears to be a compositor error] — and so with the rest.

X.

Between any two numbers whatever we shall find however many continued mean proportionals we please, by an operation both pleasing and ingenious. To explain it more clearly, a few things must first be said about the kinds of roots and about the way numbers are generated from their roots. In every continued proportion beginning from 1, then, the second term is the root of all the numbers that follow. For this root, set down twice and multiplied into itself, produces the third term, which is a square number, and the root itself is called its square root. The same root, set down three times — multiplied first into itself and then again into the product — generates the fourth term, which is a cube,

and is therefore called its cube root. Finally, if the same root is set down four times and three multiplications are performed — first into itself, then into the product, and thirdly again into the last product — the fifth term results; and if it is set down five times, the sixth term arises, and so on to infinity. But how all these roots ought to be named and denoted is not the place here to explain; the whole matter belongs to algebra, where we shall also teach by what art they are to be extracted from a given number. For now, so that the matter at hand may be understood, three continued proportionalities are to be noted, written below: the first two of them are arithmetic — namely two natural series of numbers beginning from 1 — while the third is geometric, likewise taking its start from 1. Here it will be plainly apparent what an excellent use the natural series of numbers has in the matter proposed.

Numerus mediorum. [number of means]		1	2	3	4	5	6	&c.
Numeri significantes radices. [numbers signifying the kinds of roots]	1	2	3	4	5	6	7	&c.
Numeri Geometr. propor. [geometrically-proportional numbers]	1	2	4	8	16	32	64	128 &c.

The first row comprises the number of means to be established; the second, the numbers that signify the kinds of roots — that is, how many times the second term of the third proportionality (which we called the root of all that follow) must be set down in order to produce, when multiplied, the corresponding numbers of the geometric proportionality. For example, the unit of the middle row signifies that the number 2 of the third row, which is the root of all the others, set down once, is not to be multiplied, but is itself the root of them all, produced by no

multiplication of itself. But the number 2 of that same second row indicates that the same root 2 of the third row, set down twice thus, 2 2, and so multiplied into itself, generates 4, the third term of that same third row. Likewise the number 3 of the middle row denotes that the same root 2 of the lowest row, set down three times thus, 2·2·2, and so multiplied, produces 8, the fourth term of the lowest row. For from the root 2 in the first place, into the same 2 in the second place, comes the number 4; and from this product into the root 2 in the third place is generated the number 8 — namely the fourth term of the geometric proportionality, standing under the number 3 of the second row. You may say the same of the others. Thus, for example, the number 7 of the second proportionality shows that the same root 2 of the third row, set down seven times in this manner, 2·2·2·2·2·2·2, and multiplied continuously into itself six times, produces 128, the eighth number of the geometric proportionality, placed under that number 7. For from 2 in the first place into 2 in the second place comes 4; from 4 into 2 in the third place comes 8; from 8 into 2 in the fourth place comes 16; from 16 into 2 in the fifth place comes 32; from 32 into 2 in the sixth place comes 64; and finally from 64 into 2 in the seventh place comes 128, and so on. And this holds not only in the proposed continued double proportion, but in all others beginning from unity, whatever number occupies the second place as the root of the rest and denominates the proportion.

Accordingly, if you wish to set however many means you like between two proposed numbers, take the number of means to be established in the first row. For from each given number the root is to be extracted which, set down in order and continuously multiplied, produces each given number as many times as there are units in the number of the second row that is written beneath the number of means to be established (taken in the top row). Place the roots you have found beneath the given numbers, each under its own, and from them ascend by the continuous multiplication of each into itself (multiplying first each root into itself, then into the resulting product, and so on in succession), so as to set up two multiplicative geometric proportionalities beginning from the roots and denominated by them, of as many terms — excluding the two given numbers — as there are means sought. After this, multiply each term of the one row into the opposite and facing terms of the other row — that is, the greatest of the one into the least of the other, then the next below it into the next above this, and so on. Thus in the one row you always descend from the highest to the lowest, while in the other you ascend from the lowest to the highest, as will be clear in the examples. For the numbers so produced will give the means we seek. For example, if a single mean proportional is to be found between 9 and 144, we shall take 1 in the first row, and under this term, in the second row, the number 2,

which indicates that from each given number a square root is to be extracted, which set down twice, by its multiplication, produces each — as we explained. Now the square roots found are 3 and 12. And because only a single mean term is wanted, there is no need to set up geometric proportionalities beginning from the roots that have more terms; rather the roots themselves are to be multiplied together. For the number produced, 36, will be the mean proportional between 9 and 144, as you see here: 9, 36, 144. So too, if a single mean term is to be set between 18 and 288: since these numbers have no square roots, we shall mark the former thus, R.q. 18 [$\sqrt{18}$], and the latter thus, R.q. 288 [$\sqrt{288}$]. These roots multiplied together make 72, the mean proportional between 18 and 288, thus: 18, 72, 288. Here, too, it is worthy of wonder that two numbers, neither of which can be expressed, multiplied together generate a rational number — the demonstration of which is to be sought from Book 10. But how two surd numbers, which of course cannot be expressed, such as $\sqrt{18}$ and $\sqrt{288}$, are to be multiplied together, we shall teach in the Algebra.

Again, if two numbers 16 and 625 are given, between which three means are to be established, we take in the first row the number of means, 3, beneath which in the second row is written the number 4. Therefore from each given number the root is to be extracted which, set down four times and continuously multiplied, produces each — the root that is usually called the *square of the square* [quadrati quadrata] or *zenzizenzic* [Zensizensica]; in the given example these roots are 2 and 5. You will therefore set up these rows of three terms each beneath 16 and 625, geometrically proportional in a multiple ratio, beginning from those same roots 2 and 5, from which the ratios of these rows are denominated, as appears here:

16	40	100	250	625
8				125
4				25
2				5

From 8, the highest of the first row, into 5, the lowest of the second row, comes 40, the first mean. From 4 into 25 comes 100, the second mean. Finally, from 2 into 125 comes 250, the third mean.

It is also worth knowing that the means found, together with the two given extremes, contain the same continued proportion that is found between the roots of the given numbers. For thus in the given example you see that 625 is to 250, and 250 to 100,

and 100 to 40, and 40 to 16, as 5 is to 2. Therefore, once the roots are found, if the greater is divided by the lesser, and the smaller given number is multiplied by the quotient (which is the denominator of the ratio of the roots found), and the resulting number is again multiplied by the same quotient, and so on in succession, the same mean terms will be set up between the two given extremes, even without setting up those two rows of multiple ratios denominated by the roots. As in the given example: dividing the root 5 by the root 2 gives the quotient $2\frac{1}{2}$, namely the denominator of the ratio of 5 to 2. If, then, you multiply the smaller given number, 16, by $2\frac{1}{2}$, you will generate 40, the first mean; and if you again multiply 40 by $2\frac{1}{2}$, you will produce 100, the second mean; and finally if you multiply 100 by $2\frac{1}{2}$, you will produce 250, the third mean.

It is clear, however, that between any two given numbers it is not always possible to establish the proposed number of terms as rational — because the given numbers do not always have the roots that must be extracted, or at any rate do not stand in the same ratio as some two numbers from which those roots could be extracted (which would also suffice). For just as between 16 and 625, which have square-of-square roots — that is, roots which set down four times produce them by their multiplications — three mean terms fall, so too between 48 and 1875, which are proportional to those 16 and 625, three mean terms fall (although they have no similar roots), as appears here: 48, 120, 300, 750, 1875.

Hence, if anyone wants two numbers between which however many rational mean terms you please fall in a given ratio, two numbers must be taken that somehow have the given ratio. For if each of them is set down as many times as there are mean terms to be sought, plus once more, and multiplied continuously, the last two numbers produced will be the ones we seek. Between them the mean terms will be established in the way we have set out — that is, either by setting up beneath them two rows of multiple ratios which the assumed numbers denominate, of as many terms as there are means sought; or by multiplying the smaller of them by the denominator of the given ratio, which holds between the two accepted numbers, and so on. For example, if one wants two numbers between which four rational mean terms can be set in the superbipartient-thirds ratio, whose denominator is $1\frac{2}{3}$, we take the two numbers 6 and 10, which have the given superbipartient-thirds ratio, and set each down five times thus, $6\cdot6\cdot6\cdot6\cdot6$ and $10\cdot10\cdot10\cdot10\cdot10$. For from the continuous multiplication of each these numbers arise, 7776 and 100000, between which you will set four mean proportional numbers, as you see here:

7776	12960	21600	36000	60000	100000	---	---	---	---	---	---	1296
	10000	216		1000	36		100	6		10		

These mean terms are found either from 1296 into 10, from 216 into 100, from 36 into 1000, and from 6 into 10000; or from the denominator $1\frac{2}{3}$ of the superbipartient-thirds ratio into the smaller number found, 7776, and then into the resulting product, and so on.

XI.

We shall distribute any given number into however many geometrically-proportional parts we please, in a given ratio, in this way. Take as many continued proportionals in the given ratio — whether the least ones or not the least — as the parts into which the given number is to be distributed, and divide the given number by their sum. For the quotient, multiplied into each of the terms taken in the given ratio, will produce the parts of the given number, keeping the given ratio among themselves. For instance, if the given number 756 is to be cut into 6 continued proportional parts in the double ratio: if six continued double terms are taken, 3, 6, 12, 24, 48, 96, whose sum is 189, and the given number 756 is divided by this sum, while the quotient 4 is multiplied into each of the accepted numbers, these six continued double numbers will be produced, which collected together into one sum make up the given number 756, namely:

12.				
	24.			
		48.		
			96.	
				192.

The same parts will be found if these other six continued double numbers are taken, $1/100$, $2/100$, $4/100$, $8/100$, $16/100$, $32/100$, whose sum is $63/100$; or these other six, 100, 200, 400, 800, 1600, 3200, whose sum is 6300. For the given number 756, divided by the former sum $63/100$, makes 1200; and this quotient, multiplied into the first accepted number $1/100$, will give the first part 12, as before, and so on. And the same given number 756, divided by the latter sum 6300, makes the quotient $756/6300$, which multiplied into the first accepted number 100 produces the same first part 12, and so with the rest.

But if you want a number that can be cut into however many proportional parts you please without any fraction (for unless the rule we are about to give is kept,

we shall generally fall into fractions), you will achieve your aim if you take any multiple of the sum of the same proportional terms assumed. For example, if one seeks a number that can be distributed into 5 whole numbers having a continued sesquialter [3:2] ratio: having taken any 5 continued terms in the sesquialter ratio, such as 64, 96, 144, 216, 324, whose sum is 844, we take any multiple of this sum — say the tenfold, 8440. For this, by the rule handed down, will be cut into 5 whole numbers in a continued sesquialter ratio, since, when it is divided by the sum of the accepted numbers, the quotient is necessarily a whole number.

Hence we shall with no trouble satisfy the question in which we are bidden to find, in a given continued ratio, however many numbers that, collected into one sum, make up any given number. For if the given number is cut into as many proportional parts of the given ratio as we have taught, the question will be solved. For example, if one wishes to find 4 numbers in a continued triple ratio whose sum is 100: this number 100 is to be cut into 4 numbers of triple ratio, as in $2\frac{1}{2}$, $7\frac{1}{2}$, $22\frac{1}{2}$, $67\frac{1}{2}$. For these make up the given number 100. But if they are to make up the sum 400, the numbers sought in continued triple ratio will be these: 10, 30, 90, 270. For their sum is 400. And if finally they are to make up a sum not exceeding 1, the numbers will be of this kind: $\frac{1}{40}$, $\frac{3}{40}$, $\frac{9}{40}$, $\frac{27}{40}$. For their sum is $\frac{40}{40}$, that is, 1.

On Harmonic Proportionality

[Clavius's treatise appended to Euclid, Book V. Section headings "I."–"V." are Clavius's own numbered rules.]

I.

Three numbers in harmonic proportion may be found from any three numbers in arithmetic proportion, by multiplying the first into the second and into the third, and the second into the third — as the examples set out below show.

Arit.	1. 2. 3.	3. 7. 11.	4. 6. 8.	10. 60. 110.
Har.	2. 3. 6.	21. 33. 77.	24. 32. 48.	600. 1100. 6600.

For in every case the first term of the arithmetic proportion, multiplied into the second and into the third, produces the first and second terms of the harmonic proportion; and the second multiplied into the third produces the third.

There is another way — which comes to the same thing — in which harmonic proportion is generated from arithmetic. The middle term of the arithmetic proportion, multiplied into the extremes, produces the extremes of the harmonic; while the extremes of that same arithmetic proportion, multiplied by each other, produce the middle term of the harmonic. This is evident in the very same examples.

From this it follows that the extreme terms of a harmonic proportion — and therefore also their differences — stand in the same ratio as the extremes of the arithmetic proportion from which the harmonic arose. For the extremes of the arithmetic proportion, multiplied by the same middle term, produced the extremes of the harmonic.

Therefore, if three numbers in harmonic proportion are to be found whose extremes — and hence whose differences — have a given ratio, take two numbers standing in the given ratio, set an arithmetic mean between them, and then from these three terms find the three harmonic proportionals, as we have taught. For example, suppose three numbers are sought whose extremes have the sesquitercian ratio [4:3]. Take 3 and 4, between which that ratio holds. But since their sum, 7, is odd, no whole-number arithmetic mean can be placed between them; so multiply both by some even number, namely by 2. Between the products 6 and 8 a whole-number arithmetic mean does fall — namely 7, half of their sum. From these three arithmetic proportionals 6, 7, 8, then, arise these three harmonic proportionals, 42, 48, 56, whose extremes — and therefore whose differences — have the given sesquitercian ratio.

It also follows that the pairs of terms of a three-term harmonic proportion are proportional, in reversed order, to the pairs of the arithmetic proportion from which the harmonic arose: that is, in the harmonic the second is to the first as, in the arithmetic, the third is to the second; and the second is to the first [as the third is to the second]. For the first two terms of the harmonic were produced from the last two of the arithmetic multiplied by the same first term, while the last two of the harmonic were produced from the first two of the arithmetic multiplied into the third. This is clear from the examples above.

Conversely, if the first number of a harmonic proportion is multiplied into the second and the third, and the second into the third, three numbers in arithmetic proportion will be produced. Or (what is the same) if the middle term of the harmonic is multiplied into the two extremes, the two extremes of the arithmetic will be generated; while the two extremes of the harmonic, multiplied by each other, will produce the middle term of the arithmetic — in exactly the same way

in which, we said, the harmonic arises from the arithmetic. Thus you see that from this harmonic proportion 2, 3, 6 there is generated this arithmetic one, 6, 12, 18. For whether you multiply the first, 2, into the second, 3, and the third, 6, and likewise the second, 3, into the third, 6, you will produce 6, 12, 18; or whether you multiply the middle, 3, into the extremes 2 and 6, you make the extremes 6 and 18, and from the first, 2, into the third, 6, the middle, 12.

A harmonic proportion is said to be continued beyond three terms — whether by advancing toward greater numbers or by returning toward smaller ones — when, the first three numbers being harmonic proportionals, two more are joined to the third which together with it likewise constitute a harmonic proportion, and in the very same ratio; then to the last, which is the fifth, two others are joined in the same way; and to the last, the seventh, two others again; and so on to infinity. This is done, advancing toward greater numbers, if the last two numbers are multiplied by the denominator of the ratio which the third bears to the first. Thus, given these three harmonic proportionals 2, 3, 6, if the last two, 3 and 6, are multiplied by 3, the denominator of the ratio of 6 to 2, they become 9 and 18, and there will now be five terms, 2, 3, 6, 9, 18, harmonic proportionals. And if the last two, 9 and 18, are again multiplied by 3, the denominator of the ratio, these seven terms, 2, 3, 6, 9, 18, 27, 54, will be continuous harmonic proportionals. In this way we can proceed to infinity, so that the harmonic proportion is always continued through the terms in the odd places — the third, fifth, seventh, ninth, and so on. But if one wishes to proceed toward smaller terms, the two smaller numbers must be divided by the denominator of the ratio of the extremes; and the two smaller numbers thus found must again be divided by the same denominator, and so on to infinity. Thus, given these three numbers, 18, 9, 6, if the two smaller, 9 and 6, are divided by 3, the denominator of the ratio between the extremes 18 and 6, they become 3 and 2, and there will now be five terms, 18, 9, 6, 3, 2. And if the last two found, 3 and 2, are again divided by the same denominator, 3, two others will be joined to the last term, 2, in harmonic proportion, thus: 18, 9, 6, 3, 2, 1, $\frac{2}{3}$; and so one may go on to infinity.

In another way — and indeed more properly — a harmonic proportion is continued, whether advancing toward greater numbers or toward smaller, when the first three numbers are harmonic proportionals; likewise, leaving out the first, the next three; and, leaving out two, the next three; and so on. But in this kind of continuation the ratio between the extremes of one triple will never be the same as that between the extremes of another triple. Thus, among these four numbers, 3, 4, 6, 12, the harmonic proportion is said to be continued, since both

the three 3, 4, 6 and the three 4, 6, 12 are harmonic proportionals; yet the extremes of the first, 3 and 6, have the double ratio [2:1], while the extremes of the second, 4 and 12, have the triple [3:1]. Likewise a harmonic proportion is said to be continued in these five terms, 10, 12, 15, 20, 30, since in the three 10, 12, 15, and in the three 12, 15, 20, and in the three 15, 20, 30, a harmonic proportion is found, even though the extremes of the several triples do not have the same ratios. In what way a harmonic proportion is to be continued in both directions in this manner, when it can be continued (for it cannot always be extended in this way by advancing toward greater numbers), and in what way any desired quantity of continuous harmonic proportionals, as we have set out, may be found — all this will become clear from what follows.

II.

Between any two given numbers you will set a harmonic mean in this way. Take the number produced by multiplying the difference of the two given numbers into the smaller of them, divide it by their sum, and add the quotient to the smaller number. The number so assembled will be the mean you seek. Or else multiply the same difference of the given numbers into the greater, and divide the product by their sum: for if you subtract this quotient from the greater given number, what remains will be the mean sought.

Thus, to find the mean between the two numbers 15 and 60, multiply their difference, 45, into the smaller, 15; divide the product, 675, by their sum, 75. For if you add the quotient, 9, to the smaller, 15, you will make up the middle term, 24, as is plain here: 15, 24, 60. You will find the same mean if you multiply the same difference, 45, into the greater, 60, and divide the product, 2700, by their sum, 75. For the quotient, 36, subtracted from the greater, 60, leaves the same middle term, 24.

You see, then, that whenever the sum of the two given numbers does not exactly measure the product of their difference into the smaller (or into the greater) of them, the mean found must necessarily be a whole number with a fraction. For example, to find the mean between 7 and 10, multiply their difference, 3, into the smaller, 7, and divide the product, 21, by their sum, 17. For the quotient, $1\frac{4}{17}$, added to that same smaller number, 7, makes the middle term $8\frac{4}{17}$, as you see here: 7, $8\frac{4}{17}$, 10. For just as 10 has to 7 the supertripartient-of-sevenths ratio [10:7], so does the difference of the greater terms, $1\frac{13}{17}$, have to the difference of the smaller terms, $1\frac{4}{17}$. Or else multiply their difference, 3, into the greater, 10, and divide the resulting number, 30, by their sum, 17: for the quotient, $1\frac{13}{17}$, subtracted from the greater, 10, will leave the same middle term, $8\frac{4}{17}$.

Others give the finding of the middle term between two given numbers in harmonic proportion in this way. Having found the two least numbers in the ratio of the two given numbers, they direct that the quotient obtained by dividing the difference of the two given numbers by the sum of the two least numbers found be multiplied into the smaller number found, and the resulting number subtracted from the greater given number; or that the same quotient be multiplied into the greater number found, and the resulting number added to the smaller given number. For always either the number so assembled, or this remainder, will give the middle term sought. Thus, to find the mean between 20 and 30: the least numbers in the ratio of 20 to 30 are 2 and 3. If, then, the difference of the given numbers, 10, is divided by the sum of those found, 5, the quotient is 2; and if we multiply this into the smaller found, 2, and add the product, 4, to the smaller given number, 20 — or if we multiply the same quotient, 2, into the greater found, 3, and take the product, 6, from the greater given number, 30 — the middle term, 24, will always be found, as appears here: 20, 24, 30.

The middle term will be found more briefly thus. Divide the difference of the given numbers by the number that exceeds by one unit the denominator of the ratio which the given numbers have. The quotient, added to the smaller term, will give the mean. Thus, given the numbers 10 and 40, which have the quadruple ratio: if their difference, 30, is divided by 5 — the number that exceeds the denominator of the ratio by one unit — the quotient becomes 6, which, added to the smaller term, 10, produces the middle term, 16, thus: 10, 16, 40.

But to aid the memory we shall perhaps find it more convenient (though by a somewhat longer operation) to find the middle term between two given extremes in this way. If the two extremes are not both odd, or both even, but one even and the other odd, double them, and between the doubled numbers set an arithmetic mean, which will always be half their sum. Then, through these three arithmetic proportionals, seek three harmonic proportionals by Rule I. For the middle term found in this way will lie between two numbers that have the same ratio to each other as the two given extremes. If, then, it is arranged that as the first number found is to the second found, so the first given number is to another — that is, if the number made by multiplying the second found into the first given is divided by the first found — the mean between the two given extremes will be found. For example, to find the mean between 7 and 10, double them so that they become 14 and 20. Their sum, 34, is even, and its half, 17, is the arithmetic mean between 14 and 20, thus: 14, 17, 20. From these three there will be found these three harmonic proportionals, 238, 280, 340. If, then, it is arranged that as the first

found, 238, is to the second, 280, so the first given number, 7, is to another, there will be found the number $8\frac{4}{17}$, which is the harmonic mean between 7 and 10 that were proposed from the beginning.

III.

Given two numbers, we shall find a third greater than both in harmonic proportion — when this can be done (and the working itself will nicely show when it cannot) — in this way. We shall divide the number generated by multiplying one into the other by the number that remains when the difference of the two is subtracted from the smaller given term. For the quotient will be the third term, greater than both, which we seek. But whenever the divisor turns out to be 0, or whenever the difference of the two cannot be subtracted from the smaller term, it is impossible for a greater third term to be joined to the two given numbers in harmonic proportion. Thus, if the two smaller terms 12 and 16 are given, we shall divide the number produced from them, 192, by 8 — the number that remains when the difference of the two, 4, is subtracted from the smaller, 12. For the quotient, 24, together with the two given numbers, constitutes this harmonic proportion, 12, 16, 24. We shall extend it if to the two terms 16 and 24 we join a third, namely by dividing 384 — the number produced from 16 into 24 — by 8, the number that remains once the difference of the two, which is 8, has been subtracted from the smaller, 16. For the number 48 will be found, so that these four terms will stand in harmonic proportion: 12, 16, 24, 48. But if we try to join yet another, greater term to these, we shall labor in vain. For with the two last numbers 24 and 48 given, the divisor is found to be 0; since the difference of the two, which is 24, subtracted from the smaller, 24, leaves 0.

If someone proposes these two numbers, 10 and 12, there will be joined to them a third greater than both, 15. To these two, 10 and 11, there will be added the third $12\frac{2}{5}$ [?]. And to the two 90 and 99, the third 110. But to 3 and 6, none can be joined: for the difference between them, which is 3, taken from the smaller [term], 3 [?], leaves 0. And in the same way, whenever the given numbers have the double ratio, no proportional third can be joined to them, since the difference of the two is always equal to the smaller term. Much less, when the given numbers have a ratio greater than double, will any greater proportional third be found for them in harmonic proportion, since the difference of the two is then always greater than the smaller term, and therefore the subtraction cannot be made. Thus, if the numbers 3 and 7 are given, whose ratio is double-sesquitercian [7:3] — that is, greater than double — you see that their difference, 4, is greater than the smaller term, 3. Hence no proportional third can be joined to them.

Others investigate the third term thus. They multiply the difference of the given numbers into the greater, divide the resulting number by the number that remains when the same difference is subtracted from the smaller number, and finally add the quotient to the greater, to make the third. Thus, given the two numbers 12 and 16: if their difference, 4, is multiplied into 16, and the product, 64, is divided by 8 (the number that remains once the same difference, 4, is subtracted from the smaller, 12), the quotient is 8, which, added to the greater, 16 [?], makes the third, 24, as before.

THEREFORE, in order that a greater proportional third may be joined to two numbers, their ratio must be either superparticular or superpartient — that is, less than double. From this it plainly follows that a harmonic proportion cannot proceed to infinity toward greater numbers, if we speak of continuation taken in the second manner, which is its proper sense, as

IV. [continued from the preceding — running head: EVCLID. GEOM., p. 198]

we said in the first rule. For as soon as one arrives at two numbers whose ratio is double, or greater, there the proportion necessarily halts, and will not be carried further.

It also follows, from the earlier rule, that when the smaller term exceeds the difference of the two by just one unit, the third is generated by multiplying the first into the second: for this product, divided by that one unit, gives the third number, as we have said. And it is agreed that when a number is divided by one unit, the quotient is the same number divided. Thus, if two numbers 6 and 11 are given, since the smaller, 6, exceeds the difference of the two, 5, by one unit, the third proportional will be the number 66, which is produced from 6 into 11, as you see here: 6, 11, 66. The same is seen in these numbers, 2, 3, 6 and 10, 19, 190. For the third is always produced from the first into the second, because the first exceeds the difference of the two prior terms by one unit alone.

From the later rule it follows that when the smaller term exceeds the difference of the two by one unit alone, the third is generated if the product of the difference of the two into the greater is added to the greater: for that product, divided by that one unit, does not yield a quotient different from the product itself, and so on. Thus, given the same numbers, 6 and 11: if the difference, 5, is multiplied into 11 and the product, 55, is added to the greater, 11, the third term becomes 66, as before.

Hence three harmonic proportionals can also easily be found: if for the first any number is taken; for the second, its double with one unit removed beforehand; and for the third, the number produced from the first into the second. Thus, if the first is 8, the second will be 15, and the third 120; and so with the rest. And the ratio both of the extremes so found and of the differences will always be a multiple denominated by the middle term, which is invariably odd. Thus in these three, 8, 15, 120, the ratio is fifteenfold.

Hence, if three least whole numbers in harmonic proportion are sought in any multiple ratio: if the denominator is an odd number, we shall set that denominator in the middle, and half of the number next greater than it in the first place; and in the third place we shall put the number produced from the first into the second. Thus, if three whole and least numbers are wanted in the sevenfold ratio, we shall place 7 in the middle, and 4 (that is, half of 8, the number next greater than 7) in the first place, and in the third the number 28, produced from 4 into 7, as you see here: 4, 7, 28. But if the denominator is even, we shall set the number next greater in the first place; in the third we shall put the number produced from that next-greater number into the denominator; and in the middle we shall place the doubled denominator. Thus, if three least whole numbers are to be found in the eightfold ratio, we shall set 9, the number next greater than the denominator 8, in the first place; in the third, the number 72, generated from 9 into 8; and in the middle, finally, the double of the denominator, namely 16, as appears here: 9, 16, 72.

But if three numbers in harmonic proportion are to be found in a given ratio, whether they are least and whole or not, we must proceed in this way. In the middle we shall set the denominator of the given ratio; in the first, half of the number that exceeds the denominator by one unit; and in the third place we shall put the number made by multiplying the first into the middle. For example, if three are sought in the given double-supertripartient-of-sevenths ratio [$2\frac{3}{7}$ to 1]: the denominator of this ratio will be $2\frac{3}{7}$, to be set in the middle; and in the first, the number $1\frac{5}{7}$, namely half of $3\frac{3}{7}$, the number that exceeds the denominator $2\frac{3}{7}$ by one unit. The third, finally, will be $4\frac{8}{49}$, made from the first, $1\frac{5}{7}$, into the middle, $2\frac{3}{7}$. Thus the three numbers found will stand as $1\frac{5}{7}$, $2\frac{3}{7}$, $4\frac{8}{49}$; and these will be reduced to the same denominator — $\frac{84}{49}$, $\frac{119}{49}$, $\frac{204}{49}$ — if each is first reduced to a single fraction. The numerators, 84, 119, 204, will be whole numbers in harmonic proportion, and the ratio of the extremes, and therefore of the differences, will be double-supertripartient-of-sevenths, which was in fact the given ratio.

IV.

Given two numbers, we shall find a third smaller than both in harmonic proportion, in this way. We shall divide the number produced from one into the other by the sum gathered from the greater given number and the difference of the two. For the quotient will be the third term sought. Thus, if the two numbers 6 and 12 are given: if we divide the number 72, made from 6 into 12, by 18, the sum gathered from 12 and the difference of the two, 6, we shall find the third, 4, smaller than both and proportional to them, as you see here: 4, 6, 12. We shall extend this, going back toward smaller numbers, if to the two numbers 4 and 6 we join a smaller third, 3, thus: 3, 4, 6, 12; the number 3 being found by dividing the number 24, made from 4 into 6, by 8 — namely the sum gathered from 6 and the difference of the two, 2. In the same way, to the two smaller numbers 3 and 4 there will be joined a smaller third, $2\frac{1}{2}$ [?]. And in this manner any harmonic proportion will decrease continuously to infinity.

Here one may observe a truly admirable variety among these three proportions — the arithmetic, the harmonic, and the geometric — a variety that is explained by these three propositions:

I. Arithmetic proportion increases to infinity, but does not decrease to infinity.

II. Harmonic proportion, by contrast, decreases to infinity, but cannot be increased to infinity. This is to be understood if it must be continued so that any three numbers have a harmonic proportion — that is, so that the first, second, and third are harmonic proportionals; likewise the second, third, and fourth; likewise the third, fourth, and fifth; and so on. For otherwise it can be extended in both directions to infinity, like the geometric, as we said above in Rule I.

III. Geometric proportion, finally, both increases and decreases to infinity.

It is also worth noting that in a cube there are found four continuous terms in harmonic proportion which, variously compared with one another, express the chief and perfect musical consonances. For its 6 square faces, 8 solid angles, 12 edges, and 24 plane angles constitute these four terms, 6, 8, 12, 24, continuous harmonic proportionals. Now the ratio of 8 to 6 is sesquitercian [4:3], which makes the consonance Diatessaron, or the Fourth. The ratio of 12 to 8 is sesquialter [3:2], containing the consonance Diapente, or the Fifth. The ratio next, of 12 to 6, or of 24 to 12, is double [2:1], setting out the consonance Diapason, or the Octave. But the ratio of 24 to 8 is triple [3:1], producing the consonance of

Diapason and Diapente together — that is, the Twelfth. Finally, the ratio of 24 to 6 is quadruple [4:1], exhibiting the consonance Disdiapason, or the Fifteenth.

V.

Given any number of numbers in arithmetic proportion, if any number measured by them — whether the least or not the least — is divided by each of them singly, the quotients will be, in reversed order, harmonic proportionals. And conversely, given any number of numbers in harmonic proportion, if the number they measure is divided by each singly, the quotients will be, in reversed order, arithmetic proportionals. For example, let there be arithmetic proportionals 1, 2, 3, 4, 5, 6. The number they measure is 720, generated by their continuous multiplication into one another. But the least number measured by them is 60, which you will find by the method we set out in the *Practical Arithmetic*, chapter 10. So, the first [720] being divided by each of the given numbers, there will be found these in continuous harmonic proportion:

720.
360.
240.
180.
144.

And when the latter number [i.e. the least, 60] is divided by the same given numbers, these are found:

60.
30.
20.
15.
12.

Now these numbers that have been found have, two by two, the same ratios as the given numbers of the arithmetic progression, but in reverse order: namely, as in the harmonic series the first is to the second, so in the arithmetic the second is to the first; and as in the harmonic the second is to the third, so in the arithmetic the third is to the second, and so on. Moreover, the numbers found by way of the least number measured [60] are the least in their respective ratios. Conversely, if the number measured by the numbers found is divided by each of them singly, an equal count of arithmetic proportionals will be produced; and if indeed the least number they measure is divided, the very same arithmetic proportionals

will come out, in the same order in which they were given — but in the reverse order when they are compared with the harmonic proportionals found. For it is always the case that if in one progression the numbers proceed from smaller to greater, in the other the progression runs from greater to smaller, and vice versa.

Therefore, if anyone wants any number of terms in continued harmonic proportion, he must take an equal number of terms arithmetically proportional in any way whatever, and divide the number measured by them (and indeed the least such number, if the least terms are wanted) by each one singly, as we have said.

VI.

Given three numbers in harmonic proportion, the product of the difference of the two earlier terms into the third term equals the product of the difference of the two later terms into the first term. As you see here: for both 2 into 12 and 4 into 6 make the number 24. The reason is this: since, as the first term 12 is to the second 6, so the third term 4 is to the fourth 2, the number produced from the first, 12, into the fourth, 2, will equal the number produced from the second, 6, into the third, 4 — as is clear from the second rule of geometric proportion. The same holds for more terms, if they are taken three at a time together with their differences, as appears in these six terms.

Differences	2 4	
Harmonic prop.	6 8	

Differences	30	10	5	3	2
Harmonic prop.	60	30	20	15	12

For 30 into 20 and 10 into 60 both make 600. Likewise 10 into 15 and 5 into 30 both make 150. Again, 5 into 12 and 3 into 20 both make 60. And finally 3 into 10 and 2 into 15 both make 30. And so, as you see, by this pleasant operation you can test whether any given number of terms preserve continued harmonic proportion or not. For if you take them three at a time with their differences, and if the differences, taken in interchanged order, are multiplied into the first and second terms and produce equal numbers on both sides, then all the terms are in continued harmonic proportion; but if not, by no means.

VII.

Now suppose someone wishes to find five least numbers in which all three kinds of proportionality occur — namely, so that the first three numbers have arithmetic proportion; then, dropping the first, the three following have geometric proportion; and the last three have harmonic proportion; and finally the first, third, and fifth have a given continued geometric ratio. Or suppose someone wishes to find three numbers continuously proportional in a given ratio, such that between the first and second falls an arithmetic mean, between the second and third a harmonic mean, and finally the middle of the three given numbers is the geometric mean between the two means found — and such that the five numbers so found are the least of all in which this can occur. This will be accomplished as follows.

Let the given ratio be triple, in which the three least terms are taken, 9, 3, 1. Between the first two [9 and 3] let the arithmetic mean be placed, 6. By this [6] divide the square of the assumed middle number 3 [that is, 9], and let the quotient $1\frac{1}{2}$ be placed between 3 and 1, as appears in the first order set out here. But since this quotient is a whole number with a fraction, we shall reduce it to the single fraction $\frac{3}{2}$, as you see in the second order. And if we take its numerator 3, leaving the denominator, and multiply the other numbers of the second order by the denominator 2, we shall produce the five least numbers sought, as you discern in the third order. For 18, 12, 6 have arithmetic proportion; 12, 6, 3 [recte: printed "12.3.6"] geometric; and 6, 3, 2 harmonic; and finally 18, 6, 2 the given triple ratio. But if the five least terms in these three continued proportionalities need not be found, one may take any three numbers having the given continued ratio, and with them the two means — the second and fourth — are to be investigated, as has been said.

9.	6.	3.	$1\frac{1}{2}$.	1.
9.	6.	3.	$\frac{3}{2}$.	1.
18.	12.	6.	3.	2.

If the smaller terms are to be compared with the greater, and the given ratio is subtriple, we shall find, by the same device, from these three least numbers 1, 3, 9, these five subtriples: 2, 4, 6, 9, 18. For 2, 4, 6 keep arithmetic proportion; 4, 6, 9 geometric; 6, 9, 18 harmonic; and 2, 6, 18 the proposed subtriple ratio. You see the method of finding them in these three orders set alongside.

1.	2.	3.	$4\frac{1}{2}$.	9.
1.	2.	3.	$9/2$.	9.
2.	4.	6.	9.	18.

Again, let the given ratio be sesquialter (3:2), in which the three least terms are 9, 6, 4. Between 9 and 6 the arithmetic mean is $7\frac{1}{2}$, as in the first order. Let it be reduced to the single fraction $15/2$, as in the second order. Taking the numerator 15 for the second number, and leaving the denominator, let the other numbers in the second order be multiplied into the denominator 2 — as is done in the third order. And let the square of the number 12, namely 144, be divided by 15, and let the quotient $9\frac{3}{5}$, in least terms, be placed as the mean between 12 and 8 of that same third order. This number $9\frac{3}{5}$ we shall reduce to the single fraction $48/5$, as in the fourth order. Finally, taking the numerator 48 for the penultimate number and leaving the denominator, we multiply the other numbers of the fourth order into the denominator 5; and the five least numbers sought will be found, as appears in the fifth order.

9.	$7\frac{1}{2}$.	6.		4.
9.	$15/2$.	6.		4.
18.	15.	12.	$9\frac{3}{5}$.	8.
18.	15.	12.	$48/5$.	8.
90.	75.	60.	48.	40.

If smaller numbers are to be compared with greater, the five least terms in the given subsequalter ratio will be found, as you see here in the fourth order. And the same reasoning applies in the rest.

You can also, if you like, set out all five numbers in the first order, reduce the fractions, if there are any, to a single least denomination, and then reduce each to a single fraction. For if you substitute the numerators for them, keeping the common denominator, and multiply the remaining whole numbers by the common denominator, you will produce the five least whole numbers sought. For example, if a subquadruple ratio [1:4] is proposed, the three least terms will be 1, 4, 16. Adding 1 and 4 together, half the sum is $2\frac{1}{2}$, the arithmetic mean between them. And if the square of the number 4 [namely 16] is divided by $2\frac{1}{2}$, the quotient is $6\frac{2}{5}$, the harmonic mean between 4 and 16. The two fractions are then reduced to the same denomination, as in the second order. And when each fraction is reduced to a single fraction, the third order is formed. Then, taking the numerators, keeping the common denominator, and multiplying the whole

numbers by the common denominator, the five least numbers sought are formed, as you see in the fifth order. And in this way, into however many terms fractions are mixed, you will reduce them to as many whole terms whenever the matter requires.

4.		6.		9.
4.	5.	6.	$7\frac{1}{5}$.	9.
4.	5.	6.	$36/5$.	9.
20.	25.	30.	36.	45.

1.	$2\frac{1}{2}$.	4.	$6\frac{2}{5}$.	16.
1.	$2\frac{5}{10}$.	4.	$6\frac{4}{10}$.	16.
1.	$25/10$.	4.	$64/10$.	16.
10.	25.	40.	64.	16 [recte: 160]

VIII.

When four numbers are so arranged that they are geometrically proportional (though not continuously), while one of the means keeps arithmetic proportion with the extremes and the other keeps harmonic proportion — so that in those four numbers all three proportionalities we have spoken of are found — those four numbers are said to constitute the greatest harmony. But when four numbers are so arranged that only two proportionalities are found in them — either geometric and arithmetic, or geometric and harmonic, or harmonic and arithmetic — those four numbers are said to constitute a lesser harmony.

You will construct the greatest harmony, in which the extreme terms also have a given ratio, thus. Let the given ratio be that of 6 to 1, which the extreme terms must have. Since their sum is odd, I take their doubles, 12 and 2, between which let the arithmetic mean be placed, 7, thus: 12, 7, 2. But if their sum had been even, I would have taken the arithmetic mean between them at once. From these three arithmetic proportionals I find, by the first rule, 84, 24, 14, whose extremes have the given ratio — the same as that of 12 to 2, or 6 to 1. So if between the extremes 84 and 14 (which, being found in this way, will always be even) an arithmetic mean, 49, is also placed, the four numbers sought will be 84, 49, 24, 14. For the extremes have the given ratio of 6 to 1. Next, all three proportionalities are found in them. For among the four there is a non-continuous geometric proportion, since the ratio of 84 to 49 is the same as that of 24 to 14, and that of 84 to 24 the

same as that of 49 to 14 — as is clearly evident from the seventh property of these three proportionalities. Between 84, 49, 14 there is arithmetic proportion; and finally between 84, 24, 14 harmonic proportion, by construction, as you see here.

	84	49	24	14	
Three proportionalities together	.	.	.	.	
Geometric prop.	84	49	24	14	Vel: 84. 24. 49. 14.
	.	.	.	.	
Arithmetic prop.	84	49		14	
	.	.		.	
Harmonic prop.	84		24	14	
	.		.	.	

Again, let the given ratio be that of 3 to 2. Since again their sum is odd, let their doubles be 6 and 4, between which let the arithmetic mean be placed, 5, thus: 6, 5, 4. From these, by the first rule, I find the harmonic proportionals 30, 24, 20. And placing the arithmetic mean 25 between 30 and 20, by the same reasoning the four numbers sought will be 30, 25, 24, 20, since they have all three proportionalities, as appears here.

Geometric prop.	30	25	24	20	Vel: 30 24 25 20
Arithmetic prop.	30.	25.		20.	
Harmonic prop.	30.		24.	20.	

We shall find the same four numbers of the greatest harmony if, for the extremes, we take any two numbers having the given ratio, whether even or odd. For if between these the arithmetic mean is placed, and it is arranged so that as the found term is to the first extreme, so the other extreme is to another term, then this found term will be the harmonic mean between the same extremes. For when, in four geometrically proportional numbers — such as the four found — one of the means is the mean in arithmetic proportion, the other of the means is the mean in harmonic proportion between the same extremes, as we said in the seventh property of these three proportionalities. So when these four numbers found are whole numbers, what is proposed will be accomplished; but if fractions are mixed in, we shall reduce them to whole numbers, as we wrote at the end of the preceding rule 7. For instance, if the given ratio is double, we shall set the extremes as 12 and 6. Half of their sum, 9, will be the middle term between them, arithmetically proportional, thus: 12, 9, 6. If, then, it is arranged that as 9 is to 6, so 12 is to another term — or as 9 is to 12, so 6 is to another — the number 8 will

always be found between 12 and 6, in the harmonic proportion of the greatest harmony: 12, 9, 8, 6. Finally, if in the same double ratio of the extremes we take 20 and 10, we shall find the arithmetic mean 15 and the harmonic mean $13\frac{1}{3}$, in least numbers, thus: 20, 15, $13\frac{1}{3}$, 10. So if we reduce the third number to the single fraction $\frac{40}{3}$, and, taking its numerator 40 with the denominator left aside, set it as a term, others will be found if we multiply the ones found by the denominator 3: 60, 45, 40, 30.

We shall find the lesser harmony thus. If in four numbers only geometric proportionality together with arithmetic is to be found, take three continuously geometrically proportional numbers whose extremes are both even or both odd. For if you place between the extremes an arithmetic mean, you will have the four numbers sought. For example, if these three sesquialter numbers are taken, 16, 24, 36, and between the extremes the arithmetic mean 26 is found, the four numbers sought will be 16, 24, 26, 36, of which the three 16, 24, 36 are geometrically proportional, and the three 16, 26, 36 arithmetically proportional, by construction.

But if only geometric together with harmonic is desired, likewise take any three continuously geometrically proportional numbers. For if between the extremes you find a mean in harmonic proportion, you will have the four numbers that are sought.

For example, if the same three sesquialter numbers are taken, 16, 24, 36, the harmonic mean between the extremes will be found, $22\frac{2}{13}$. So the four numbers found will stand thus: 16, $22\frac{2}{13}$, 24, 36 — which are reduced to these whole numbers: 208, 286 [recte: 288], 312, 468. And if you had taken those three doubled numbers, 20, 10, 5, you would have found the harmonic mean between the extremes, 8, thus: 20, 10, 8, 5.

Finally, if you want harmonic together with arithmetic proportionality alone, take any three harmonic proportionals. For if between the middle term and either of the extremes you place an arithmetic mean, the four numbers we seek will be found. For example, if these three are taken, 6, 8, 12, the arithmetic mean between the first two will be 7. So the four numbers found will be these: 6, 7, 8, 12. But between the latter two the arithmetic mean will be 10. So the four numbers found will stand thus: 6, 8, 10, 12 — which are all (as happens by some chance in this example) arithmetically proportional, and not only the three 8, 10, 12 by construction; whereas only the three actually taken, 6, 8, 12, have harmonic proportionality.

IX.

If any number of continuously arithmetically-proportional numbers are to be found, between each successive pair of which a single whole harmonic mean falls, it will be accomplished as follows. Take as many arithmetically-proportional terms as are sought, and take the least terms of the ratio of each neighbouring pair. If the least number measured by the sums of the pairs of least terms taken is found, and this is multiplied into each of the arithmetically-proportional numbers taken, the numbers sought will be produced. For example, suppose four are to be found. Take any four arithmetically-proportional numbers, 3, 6, 9, 12; and 1, 2, the least terms of the ratio of 3 to 6; and 2, 3, the least of the ratio of 6 to 9; and 3, 4, the least in the ratio of 9 to 12. The three sums of the pairs of least terms will be 3, 5, 7; and the least number measured by these is 105. So if you multiply this separately into each of the numbers taken, 3, 6, 9, 12, you will produce the four arithmetically-proportional numbers you desire: 315, 630, 945, 1260. For between the first and second the harmonic mean is 420; between the second and third, 756; between the third and fourth, 1080 — as you discern here.

Arithmetic prop.	315	630	945	1260
Harmonic means	420	756	1080	

And so, if you want two numbers in the given ratio of two numbers, between which a single whole harmonic mean falls, take the two least numbers in the given ratio and multiply their sum into the two terms of the given ratio. For instance, if the given ratio is triple, between 4 and 12, the least terms will be 1, 3, whose sum 4, if you multiply it into 4 and 12, you will make 16 and 48, the numbers sought. The harmonic mean between them will be 24, as you see here: 16, 24, 48. If the least numbers of the given ratio had been 1 and 3, we would have multiplied each into their sum 4, and these two numbers would have been made, 4 and 12, between which the harmonic mean 6 falls.

X.

But if you want any number of terms in a given continued geometric proportion, between each successive pair of which two whole means fall — one in arithmetic proportion and the other in harmonic — you will achieve it by this device. Take as many least continuously-geometrically-proportional numbers as are desired, and multiply each by the sum of the two least numbers in the same ratio. And if the products are all even, they will be the ones we seek; if not, their doubles will give the numbers sought. For example, suppose three in sesquialter ratio are to

be found. Take as many least numbers in the given ratio, 4, 6, 9; and the two least in the same ratio, 2, 3. Multiply their sum, 5, into each of the numbers taken; and, since the products are not all even, double them, and you will have the proposed numbers 40, 60, 90. For between 40 and 60 the harmonic mean is 48 and the arithmetic 50; and between 60 and 90 the harmonic mean is 72 and the arithmetic 75. As you see here.

Geometric prop.	40	60	90
Harmonic means	48	72	
Arithmetic means	50	75	

From this you will easily find two numbers in a given ratio, between which two means are enclosed — one according to arithmetic proportion, the other according to harmonic. For, having taken the least terms of the given ratio, if you multiply their sum either into those two least terms or into any two other numbers having the given ratio, the products will be numbers: if they are even, the ones sought; but if either is not even, their doubles are the ones we seek. For instance, if the given ratio is sesquitertian [4:3], whose least numbers are 3 and 4, and their sum 7: if you multiply 7 into 3 and 4, or into 12 and 16 (which also have the given ratio), you will produce either 21, 28 or 84 and 112. And because the first two are not even, their doubles, 42 and 56, are the ones we seek. But the latter two, because they are even, will be the ones sought. For between both the one pair and the other fall the two means we seek, as is manifest here.

Numbers found	42	56	84	112
Harmonic means	48	Vel	96	
Arithmetic means	49		98	

XI.

But if someone should ask to be given three numbers in harmonic proportion, between each pair of which two means fall — one in arithmetic proportion and the other in geometric — we shall carry it out by this method. By the ninth rule of geometric proportion, let three arithmetically-proportional numbers be found, 2, 50, 98, between the first pair of which the geometric mean is 10, and between the latter pair, 70; and let them be arranged in order thus: 2, 10, 50, 70, 98. Let the least number measured by these five be 2450. Dividing it by the same five numbers, let the quotients be 1225, 245, 49, 35, 25. So if all the quotients are [either all] even or [all] odd, the first, third, and fifth — namely 1225, 49, 25 — will be the numbers sought. For they are harmonic proportionals, as is

established from the fifth rule, since they are the quotients produced from dividing the number 2450 (which they measure) by the same numbers 2, 50, 98. And between each pair fall geometric proportionals: 245, the second quotient, and 35, the third quotient. For 1225, 245, 49 have the same ratios, in reverse order, that the continued proportionals 2, 10, 50 have, as is established...

[Rule XI, continued]

as is established from Rule 7 of geometric proportion. In the same way, 49, 35, 25 will have the same ratios—taken in reverse order—as the continued proportionals 50, 70, 98, since both sets are quotients produced by dividing the same number, 2450, by 2, 10, 50 and by 50, 70, 98. It is certain, moreover, that between each pair—between 1225 and 49, and between 49 and 25—a single arithmetic proportional [mean] likewise falls, provided all the quotients are made either all even or all odd. If they are not all even, all five quotients must be doubled so that they become even numbers; these will yield exactly what we seek, since they have the same ratios as their halves. Consequently, just as the second term is the geometric mean between the first and third, so the fourth term is the geometric mean between the third and fifth. Therefore, since arithmetic means also fall between the same terms, the proposition is established. You see the example set out here before your eyes.

XII.

Again, if three numbers in arithmetic proportion are sought, between each pair of which two proportional means fall—one geometric and one harmonic—we shall satisfy the question in this way. Once more, by Rule 9 of geometric proportion, find three arithmetically-proportional numbers, 2, 50, 98, between each pair of which a single mean falls in geometric proportion. Take the two least numbers, 1 and 25, in the ratio of the first two, and likewise the two least, 25 and 49, in the ratio of the last two; their sums, 26 and 74, measure the least number 962, into which the three numbers found—2, 50, 98—are to be multiplied. For the

products, 1924, 48100, 94276, will be the numbers we seek. Since they have the same ratios as their submultiples 2, 50, 98, it follows that between each pair of them single means are intercepted in the same geometric proportion. Then, because the sum of the least numbers 1, 25 and 25, 49—in the ratios 2-to-50 and 50-to-98 (which three, 2, 50, 98, are arithmetically proportional)—measures the least number 962, which, multiplied into those three, 2, 50, 98, produced 1924, 48100, 94276, single harmonic proportional means will fall between each pair of these three, as was set out in Rule 9. The example, with its means, will therefore stand thus.

XIII.

From what we have said, one can find three proportional numbers—whether arithmetic, geometric, or harmonic—between each pair of which three means fall: one arithmetic, another geometric, and the remaining one harmonic. Suppose first that three numbers of arithmetic proportion are to be found. By the preceding Rule 12, find three numbers in arithmetic proportion between each pair of which two means fall, one in geometric and the other in harmonic proportion. If these three numbers are all even or all odd, single arithmetic proportionals will also fall between each pair, and so they will satisfy the question. But if they are not all even or all odd, their doubles will be the numbers we seek. Here you have an example in the three numbers of the preceding rule, which are all even, as appears here.

[row]

Med.Arith. [Arithmetic means]	250 12	711 88

Next, suppose three numbers in geometric proportion are to be found, between each pair of which three means fall—one of each kind—and let the given ratio that the geometric means must produce be the sesquialter [3:2]. Take the five least continued proportionals of the given ratio, 16, 24, 36, 54, 81, and the two least numbers, 4 and 9, in the ratio of the first (16) to the third (36) and of the third (36) to the fifth (81). Multiply the sum of these least numbers, 13, into that same first (16), third (36), and fifth (81). The products, 208, 468, 1053—doubled, because they are not all even or all odd—namely 416, 936, 2106, so that single arithmetic means can fall between each pair, are the numbers we seek. For between each pair fall two means, one harmonic and the other arithmetic, as is clear from Rule 10; and between the same terms geometric means also fall—namely the doubles of those produced by multiplying that same sum, 13, of the two least numbers into the second (24) and the third [recte: fourth] (54), reckoned from the beginning—as is evident here.

Med.Geo. [Geometric means]	62 4	140 4	
Med.Ar. [Arithmetic means]		67 6	152 1

Finally, suppose three numbers in harmonic proportion are to be found. Having found three in harmonic proportion, 1225, 49, 25, between each pair of which two means fall—one arithmetic, the other geometric—as we taught in Rule 11: let the two least numbers of the ratio of the first two be 25 and 1, and the two least of the ratio of the last two be 49 and 25, whose sums, 26 and 74, measure the least number 962. If you multiply this into the three numbers found, you will generate the three sought: 1178450, 47138, 24050. For between each pair two means will fall, one arithmetic and the other geometric, just as among their submultiples 1225, 49, 25—namely the numbers produced from the same 962 [multiplied] into the means found above. Likewise between the same pairs single harmonic means

will fall, as is clear from Rule 12, since they are produced from the least number measured by the sums of the least terms, [multiplied] into all three. Here you have the example.

XIV.

By the same reasoning we shall find two numbers whose ratio is the double [square] of a given ratio, between which three means fall: one in arithmetic proportion, another in geometric, and the third in harmonic. Let the given ratio be 6 to 3, and the three least numbers in it, 4, 2, 1; then, by Definition 10 of this book, the ratio 4 to 1 is the double [square] of the given ratio 2 to 1, or 6 to 3. Multiply the sum 5—collected from 4 and 1—into any two numbers whose ratio is the double of the given ratio, say into 12 and 3. If the resulting products, 60 and 15, are not both even or both odd, double them: the doubles, 120 and 30, are what we seek. But if both were even or both odd, they would themselves be the sought numbers, and doubling would not be necessary. The three means between 120 and 30 stand as appears here.

XV.

Finally, if one wishes to distribute any given number into any number of parts that preserve harmonic proportion, you will accomplish it by this method. By Rule 5, take as many harmonically-proportional numbers as the number of parts

into which the number is to be distributed. For if you divide the numbers produced by multiplying the given number into the numbers taken, by their sum, the quotients will be the parts you seek, and the numbers taken will be proportional in the same order. Or, if you divide the given number by the sum of the numbers taken and multiply the quotient into each of the numbers taken, you obtain the numbers sought. For example, if the number 130 is to be distributed into three harmonically-proportional parts: take the three numbers 6, 8, 12 found by Rule 5, and divide the numbers 780, 1040, 1560—which arise from multiplying the given number 130 into the assumed numbers 6, 8, 12—by their sum, 26; the quotients, 30, 40, 60, will be the parts we seek. Or, if you divide the given number 130 by 26, the sum of the numbers taken, and multiply the quotient, 5, into each of the numbers taken, 6, 8, 12, the numbers produced, 30, 40, 60, will be the same parts we seek. For they make up the given number 130 and are harmonically proportional, just as the assumed numbers 6, 8, 12. In the same way the number 10 is divided into these three parts, $2\frac{4}{13}$, $3\frac{1}{13}$, $4\frac{8}{13}$, proportional in the same manner. And the same reasoning holds for more parts.

In what manner, from the ratio of equality, all rational ratios of inequality arise

[QVO PACTO EX PROPORTIONE aequalitatis omnes inaequalitatis proportiones rationales oriantur]

Given three equal terms—whether units or numbers—it is remarkable to say how easily and pleasantly, by varying their addition among themselves, all the rational ratios of inequality are generated within three terms, in the following order.

Equal terms, or numbers, produce double numbers [duplus, 2:1]; doubles produce triples; triples produce quadruples; quadruples produce quintuples; and so on to infinity.

Next, from the multiple terms so found, if they invert their order, all the superparticular ratios [superparticularis, $(n+1):n$] are generated, preserving this order: inverted doubles produce sesquialters [3:2]; inverted triples produce sesquitertians [4:3]; inverted quadruples produce sesquiquartans [5:4]; and so on in succession.

Third, from the superparticular terms found, if they too invert their order, all the superpartient ratios [superpartiens] are produced, in this series: inverted sesquialters yield superbipartients [superbipartiens, 5:3]; inverted sesquitertians

yield supertripartients [supertripartiens, 7:4]; inverted sesquiquartans yield superquadrupartients [9:5]; and so on.

Fourth, from those same superparticular terms, in the order in which they were found, arise all the multiple-superparticular ratios, in this order: sesquialters give double-sesquialters; double-sesquialters give triple-sesquialters; triple-sesquialters give quadruple-sesquialters, and so on. Likewise sesquitertians produce double-sesquitertians; double-sesquitertians triple-sesquitertians; triple-sesquitertians quadruple-sesquitertians, and so on. Likewise sesquiquartans yield double-sesquiquartans; double-sesquiquartans triple-sesquiquartans; triple-sesquiquartans quadruple-sesquiquartans, and so on.

Fifth, from the superpartient terms found, all the multiple-superpartient ratios are elicited, in this order: superbipartients generate double-superbipartients; double-superbipartients triple-superbipartients; triple-superbipartients quadruple-superbipartients, and so on. Supertripartients likewise bring forth double-supertripartients; double-supertripartients triple-supertripartients; triple-supertripartients quadruple-supertripartients, and so on. Superquadrupartients likewise generate double-superquadrupartients and triple-superquadrupartients; double-superquadrupartients quadruple-superquadrupartients; and so with the rest.

The method by which all these ratios are generated from three equal terms, in the order we have set out, is single and easy—namely this. The sum collected from the first term of the given proportion (from which another is to be generated), taken once, plus the second taken twice, plus the third taken once, gives the first term of the geometric proportion to be constructed.

The second term of the geometric proportion to be constructed arises from the second and third terms of the given proportion (from which the other must arise), each taken once.

The third term of the geometric proportion to be constructed is furnished by the third term of the given proportion (from which the other must be derived), taken once.

This threefold precept is set before the eyes in the appended diagram, where it is plainly clear which terms of the given proportion are to be taken once, or twice, or omitted, so that the terms of the other proportion may be constructed.

Diagram of the generation of one geometric proportion from another geometric one

[*TYPVS PROCREATIONIS VNIVS PROPORTIONIS GEOMETRICÆ ex alia Geometrica*]

Order of the terms of the given proportion	First	Second	Third
The first [of the new] is constituted if the given terms are taken thus	Once	Twice	Once
The second is constituted if the given terms are taken thus		Once	Once
The third is constituted if the given terms are taken thus			Once

There now follow examples of the generation of all ratios from the ratio of equality. We set out two ratios of equality, one in units and the other in twos [binaries]. Here it seems worth noting that from the units are always generated the least terms of each three-term proportion.

Liber V (continued)

Generatio Multiplicium Superpartientium

Generation of the Multiple-Superpartient ratios.

This completes the Generation table begun on the preceding page. Each row gives a ratio in its own name (in direct or inverted order), followed by its continued-proportion triple stated "in units" (the first three number columns) and then the same triple "in binaries" — its exact double (the last three number columns), which serves as a built-in check.

Ratio (name)	(units)			(binaries — double)		
Superbipartient, in direct order	25	1	9	50	3	1
		5			0	8
Double superbipartient, from the superbipartient	64	2	9	128	4	1
		4			8	8

Ratio (name)	(units)	(binaries — double)
Triple superbipartient, from the double superbipartient	121 3 9 3	242 6 1 6 8
Quadruple superbipartient, from the triple superbipartient	196 4 9 2	392 8 1 4 8
Supertripartient, in direct order	49 2 1 8 6	98 5 3 6 2
Double supertripartient, from the supertripartient	121 4 1 4 6	242 8 3 8 2
Triple supertripartient, from the double supertripartient	225 6 1 0 6	450 1 3 2 2 0
Quadruple supertripartient, from the triple supertripartient	361 7 1 6 6	722 3 3 5 2 2
Superquadripartient, in direct order	81 4 2 5 5	162 9 5 0 0
Double superquadripartient, from the superquadripartient	196 7 2 0 5	392 1 5 4 0 0
Triple superquadripartient, from the double superquadripartient	361 9 2 5 5	722 1 5 9 0 0
Quadruple superquadripartient, from the triple superquadripartient	576 1 2 2 5 0	1152 1 5 4 0 0

The generating formula

Beneath the table Clavius sets out the "adjoined formula" showing how the last triple (576, 120, 25) is built by adding up the three preceding terms (361, 95, 25):

361

95

95	95	
25	25	25
576	120	25

Here you can plainly see that any three terms are generated from the three immediately preceding them, according to the threefold rule given above. Take, for example, these last three: 576, 120, 25. They are produced from the three preceding terms 361, 95, 25. The first, 576, is amassed from the first term 361 once, the second 95 twice, and the third 25 once. The second, 120, is composed of the second term 95 once and the third 25 once. The third, finally — 25 — is simply the third term, 25, taken once, as the adjoined formula shows. In this same way all the others are generated, beginning from equal terms, 1.1.1 or 2.2.2.

How, conversely, every ratio of inequality is brought back to a ratio of equality

(Body heading, p. 205: "QVO PACTO VICISSIM OMNIS PROPORTIO INAEQVALITATIS AD AEQVALITATIS PROPORTIONEM REVOCETUR.")

Given, once again, three unequal terms in any ratio whatever, a ratio of equality can in turn be restored from them — by a procedure no less pleasant than easy — through a varied subtraction of the unequal terms, one from another. The matter is managed by this threefold rule:

[Rule 1.] Let the *smaller* of the three given unequal terms be set as one extreme of the ratio to which the reduction is made.

[Rule 2.] With that *smallest* term subtracted from the middle one, let the remaining number be placed in the middle position of the ratio to which the reduction is made.

[Rule 3.] Let the sum gathered from the extreme just established (taken once) together with the middle term (taken twice) be subtracted from the largest of the three given numbers; and let the number left over become the other extreme of the new ratio.

By this method any ratio of three unequal terms is carried back to another ratio — always by comparing the larger numbers with the smaller — and that ratio again, in the same way, to yet another, and so on in succession until three equal terms are reached. And if the three given terms stand in a continued double ratio,

they are reduced to equality at the very first operation. The examples that follow will make this plain.

First example — quintuple ratio reduced to equality:

Ratio			
Quintuple ratio	150	30	6
Quadruple	96	24	6
Triple	54	18	6
Double	24	12	6
Ratio of equality	6	6	6

This example shows the quintuple ratio brought back to the quadruple, the quadruple to the triple, the triple to the double, and finally the double to equality. In this second example, by contrast, you see the supertripartient-of-fourths ratio reduced to the sesquitertian, the sesquitertian to the triple, the triple to the double, and the double at last to equality.

Second example — supertripartient-of-fourths ratio reduced to equality:

Ratio			
Supertripartient-of-fourths ratio	46 [recte: 49]	2	1
		8	6
Sesquitertian		9	1
		2	6
Triple		9	3
Double		4	2
Ratio of equality		1	1

But this too seems not unworthy of notice: that every ratio is, in the first instance, reduced to the very one from which it took its rise. Thus in the first example the quintuple is reduced to the quadruple, from which it arose; the quadruple to the triple, since the triple begot it; and so with the rest, all the way to equality. In the latter example, by contrast, the supertripartient ratio is called back to the sesquitertian in inverted order — for it is established that sesquitertian numbers, in reversed order, generate supertripartient ones, as we said above. Likewise this sesquitertian, by comparing the larger numbers with the smaller, is reduced to the triple in inverted order, just as the triple inverted generates the sesquitertian.

Then the triple, by again comparing the larger numbers with the smaller, is brought down to the double, and this to equality, and so on.

Nor do I think it should be passed over in silence that from three terms of any geometric proportionality whatever — whether it be of equality or of inequality — any one of the three proportionalities we explained above can be generated, if the terms are combined among themselves in various ways. That a geometric proportionality of three terms produces another geometric proportionality of three terms — provided the first term is taken once, the second twice, and the third once for the first term; the second and third once each for the second; and finally the third alone once for the third — is evident from what we wrote a little earlier about the origin of all ratios of inequality out of the ratio of equality.

But to generate an *arithmetic* proportionality of three terms from the same geometric proportionality, you will observe this threefold rule:

[Rule 1.] Make the sum collected from the first term, plus the second taken twice, plus the third once, the first term of the arithmetic proportionality.

[Rule 2.] The sum made from the first, second, and third each taken once, set in the second place.

[Rule 3.] Finally, make the third term the third term.

You see the pattern of this production here.

Pattern of the production of the arithmetic ratio from the geometric.

(Table heading, p. 206: "*TYPVS PROCREATIONIS PROPORTIONIS Arithmeticae ex Geometrica.*")

	First	Second	Third
The order of the terms of both proportionalities	First	Second	Third
The first is made from the given terms combined thus	Twice	Twice	Once
The second is made thus	Once	Once	Once
The third, finally, in this way			Once

It makes no difference at all whether you make the smallest number the first term of the geometric proportionality or the largest — as will be clear from the examples that follow.

Generation of the arithmetic proportionality from the geometric.

(Table heading, p. 206: "*GENERATIO ARITHMETICAE Proportionalitatis ex Geometrica.*")

Geometric prop.	1	1	1	4	4	4	9	6	4	4	6	9
Arithmetic prop.	5	3	1	2	1	4	3	1	4	2	1	9
				0	2		4	9		9	9	

Now this is most worthy of consideration: the difference of the arithmetic proportionality so constituted is always equal to the sum of the first two terms of the geometric proportionality from which it is built. Thus you see that in the first example the difference is 2, the sum of 1 and 1; in the second, 8, namely the sum of 4 and 4; in the third, 15, which sum is made up from 9 and 6; and finally in the fourth, 10, that is, the sum gathered from 4 and 6 — and so on in the rest.

And therefore, if an arithmetic proportionality is constituted out of a ratio of equality, its difference will be double one of the terms of that equality, as is plain in the first two examples.

Finally, that a *harmonic* proportionality also arises from a geometric one will be made clear by this other threefold rule:

[Rule 1.] The sum collected from the first taken twice, the second three times, and the third once — set this in the first place of the harmonic proportionality.

[Rule 2.] The sum made from the second taken twice and the third once — in the second place.

[Rule 3.] The sum, finally, of the second and third — in the third place.

Here too it makes no difference whether the smallest term is called the first or the largest. You see the pattern of this generation set out here.

Pattern of the production of the harmonic ratio from the geometric.

(Table heading, p. 206: "*TYPVS PROCREATIONIS HARMONICAE proportionalitatis ex Geometrica.*")

	First	Second	Third
The order of the terms of the proportionality	First	Second	Third
The first is made from the three given	Twice	Three times	Once

	First	Second	Third
terms gathered into one thus			
The second thus		Twice	Once
The third, finally, in this way		Once	Once

Generation of the harmonic proportionality from the geometric.

(Table heading, p. 206: "GENERATIO PROPORTIONALITATIS Harmonicae ex Geometrica.")

Geometric prop.	1	1	1	4	4	4	9	6	4	4	6	9
Harmonic prop.	6	3	2	2	1	8	4	1	1	3	2	1
				4	2		0	6	0	5	1	5

Now conversely, any harmonic proportionality whatever will be reduced to equality in this way:

[Rule 1.] Subtract the smallest term from the middle one, and make what is left the middle term of the proportionality to be constituted.

[Rule 2.] With this middle term found and taken away from the smallest term of the given harmonic proportionality, the remaining number will be one of the extremes of the proportionality.

[Rule 3.] Finally, the smallest given term taken once and the middle term just found taken twice, collected into one sum and subtracted from the largest given term, will yield double the other extreme. Half of this, therefore, will be that other extreme itself.

By this method a harmonic proportionality will be brought back either to equality, or to some geometric proportionality that is then reduced to equality, as we taught above. And the proposed harmonic proportionality always arises from that geometric one — if the earlier rule is applied — to which it is brought back by this rule. You see the examples here:

				2	1		4	1	1	3	2	1
Harmonic prop.	6	3	2	4	2	8	0	6	0	5	1	5
Geometric prop.	1	1	1	4	4	4	9	6	4	4	6	9

Further examples

(Body heading, p. 207: "ALIA EXEMPLA.")

Harmonic prop.	3	4	6	6	4	3	2	1	1
				0	0	0	4	6	2
Geometric prop.	2	1	$\frac{1}{2}[\?]$	5	1	2	2	4	8
					0	0			
Equality	$\frac{1}{2}[\?]$	$\frac{1}{2}[\?]$	$\frac{1}{2}[\?]$	5	5	5	2	2	2

But an arithmetic proportionality will be brought back to equality, or to the geometric proportionality by which it is constituted, in this way:

[Rule 1.] Make the smallest term one of the extremes. Then, with that same smallest term subtracted from the middle, the remaining number will be one compounded from the middle term of the proportionality to be constituted and the other extreme. Therefore, if this remaining number is double the smallest, then, cutting it in two, the half will be both the middle term and the other extreme; and the given arithmetic proportionality will be reduced to the equality from which it took its origin.

Example (margin): Let the arithmetic proportionality 3.9.15 be given. If, in constituting the geometric one, you make 3 one extreme — from the smallest term of the given arithmetic proportionality — and take that same number away from the given middle term 9, there remain 6; and this number is double the smallest, 3. Therefore the given proportionality is reduced to this equality, 3.3.3, from which it arises according to the earlier rule.

3	9	15
3	3	3

[Rule 2.] But if that remaining number is not double the smallest, it must be cut into two parts which, together with the smallest, constitute a continued geometric proportionality. To this the arithmetic one will be brought back.

Example (margin): Let the arithmetic proportionality 34.19.4 be given. Making 4 one geometric extreme — the smallest term of the arithmetic proportionality — and subtracting it from the middle, 19, there is left the number 15, which is not double the smallest. So, cutting it into 6 and 9, that arithmetic proportionality will be reduced to the geometric 9.6.4, from which in turn it takes its rise, according to the rule set out above.

34	19	4
9	6	4

But since that remaining number cannot always be divided into two such parts as, together with the smallest, form a continued geometric proportionality — how that division is to be made, and when it cannot be done in [whole] numbers, we shall teach at Proposition 17 of Book VI (Euclid VI.17) — unless surd, irrational numbers are admitted, we shall bring back any arithmetic proportionality directly to the equality from which it arose (namely the one from which, if equal terms are combined with the given difference, it takes its origin), in this way:

[Rule 1.] Let the smallest given term become one of the two extremes. Then, with the difference of the proportionality subtracted from the middle, let the remaining number become the middle term; and with that same difference doubled and taken away from the largest term, let the remaining number become the other extreme.

Example (margin): Let the arithmetic proportionality 20.27.34 be given, whose difference is 7. If 20 is made one of the extremes, and the difference 7 is taken from 27, and the same doubled [14] from 34, the two remaining terms will be equal: 20, 20. From this equality, once the difference 7 is known — which the terms of the arithmetic proportionality must have — the arithmetic proportionality itself is constructed, in this manner:

20	27	34
20	20	20

[Rule 2.] Let one of the equal terms become the lesser extreme. To it let the given difference be added, so as to make the second term. And to that same lesser extreme let the given difference, doubled, be adjoined, so as to produce the greater extreme.

Example (margin): In the given example the lesser extreme will be 20; if the difference 7 is added to it, the middle term 27 results; and if the same difference 7, doubled, is added to that same least extreme 20, the greater extreme 34 is obtained. In the same way, given this equality 15.15.15, if from it an arithmetic proportionality is to be constituted whose difference is 20, add this difference to 15, one of the equal terms, to have the second term 35; and if the same difference doubled — that is, the number 40 — is added to the same equal term, the third term 55 results. The first is 15, one of the equal terms, as you see here:

Difference 20.

15	15	15
15	35	55

And let it suffice to have said these few things here, out of the infinitely many that could be said — by countless books and to their advantage — about the immense power and nature of ratios and proportionalities. For we shall explain more, and things indeed most delightful to know, in our fuller *Arithmetic* [*Epitome Arithmeticae Practicae*], God willing. Now let us return to interpreting Euclid.

V.

(Return to Euclid, Book V — definition.)

Magnitudes are said to **have a ratio** to one another when, being multiplied, they are capable of exceeding one another.

Clavius's commentary continues, on the preceding definition (that two magnitudes "have a ratio").

Since Euclid, in the third definition, had called the relation of two magnitudes of the same kind a "ratio" [ratio] — which we, with other authors, call a "proportion" [proportio] — he now explains, by this fifth definition, what two quantities of the same kind require in order to be said to have a ratio. For not all lines, nor even all plane angles, have a ratio to one another, though they be quantities of the same kind, as we shall shortly say. He says, then, that those magnitudes are said to have a ratio to one another whichever of which, when multiplied, is so increased that it at last surpasses the other; so that if either of them, however much multiplied, could never exceed the other, they would by no reasoning be said to have a ratio.

For example, the diameter and the side of the same square are said to have a ratio (an irrational one, indeed, which can be expressed by no number), because the side multiplied by 2 — that is, taken twice — exceeds the diameter. For since two sides of a square together with the diameter form an isosceles triangle, [Margin: 20. primi (Euclid, *Elements* I.20)] two sides of the square will be greater than its diameter. In the same way, too, the circumference of a circle and its diameter have a ratio (although this is not yet explored and known to us), because the diameter multiplied by 4 — that is, taken four times — exceeds the circumference; for every circumference of a circle, as Archimedes proves,

contains the diameter of the same only three times, together with a further portion a little less than a seventh part of the diameter.

In the same way many curvilinear figures will have a ratio to rectilinear ones, since both equality and inequality is found between them — for Hippocrates of Chios [Hippocrates Chius] squared a certain lunule [lunula] (a figure contained by two arcs of circles, like the new Moon when it is seen to be sickle-shaped), and Archimedes squared a parabola: that is, the former found a square equal to a certain lunule, the latter one equal to the parabola. Hence it follows that a square may be given greater than that lunule and than the parabola, and, conversely, a lunule and parabola greater than that square. To this add what Archimedes proved in his book *On Spirals* [*De Spiralibus*]: that some straight line is equal to the circumference of a circle, another double it, another triple, and so on; and consequently that some square is equal to a circle, as he proved in the little book *On the Measurement of the Circle* [*De dimensione circuli*]. On the equality of the straight and the circular line, and of the square and the circle, we shall treat at the end of Book 6.

Add, further, that by Proclus [Proclus] too an equality between rectilinear and curvilinear angles is demonstrated. For in Book 3 of his commentary on the first book of Euclid, at the 12th Axiom (which is his 4th Postulate), he shows that to a right angle, as well as to an obtuse and an acute one, a curvilinear angle equal to it can be exhibited. For let ABC be a right angle, contained by the equal straight lines AB, BC, about which let the semicircles ADB, BEC be described. Since, then, the angles of the semicircles ABD, CBE are equal, by adding the common mixed angle ABE the whole curvilinear angle DBE becomes equal to the whole right angle ABC.

Diagram. A horizontal row of three woodcut constructions illustrating a rectilinear angle set equal to a curvilinear (mixed) angle — for the right, the obtuse, and the acute case respectively.

- First construction (right angle): A (apex, top of the vertical side), B (vertex at the foot of the vertical) [?], with a right angle ABC; D (point on the left semicircular arc ADB), E (point on the middle arc BEC). The curvilinear angle DBE equals the right angle ABC.
- Second construction (obtuse angle): F (apex), G (vertex, foot), H (right-hand foot); I (arc point) [?], K (arc point). The curvilinear angle IGK equals the obtuse angle FGH.

- Third construction (acute angle): L (apex), M (vertex, foot), N (right-hand foot); O (arc point), P (arc point). The curvilinear angle OMP equals the acute angle LMN.

[Diagram is a worn woodcut; the first-construction vertex letter and the label I are not cleanly resolved]

Similarly you will show that the curvilinear angle IGK is equal to the obtuse angle FGH; and likewise the curvilinear OMP to the acute LMN, provided that here you [?] take away the common mixed angle contained by the straight line LM and the curve MP. From all this it is established that either of the angles, when multiplied, can exceed the other; and therefore they will have a ratio to one another.

But on the other hand a finite line will not have a ratio to an infinite line, because a finite line, however it be multiplied, can never surpass an infinite one. So too neither a line with a surface, nor a surface with a body, will, for the same reason, have any ratio. Finally, an angle of contact [angulus contactus] will not be reckoned to have a ratio to a rectilinear angle, because an angle of contact, however much multiplied, always remains less than any rectilinear angle whatever, even the smallest, as we demonstrated at proposition 16 of Book 3.

And so, that Euclid might more openly explain what magnitudes of the same kind are said to have a ratio — that is, what magnitudes of the same kind he understood in the third definition — he wished, by this definition, that those be understood which have this condition: that either, multiplied, can surpass the other; but not others, even though they seem to be comprised under the same kind of quantity, such as a finite and an infinite line, a rectilinear angle and an angle of contact, and so on. For this reason, in most demonstrations of ratios, he bids one multiply so many times one of the proposed magnitudes said to have a ratio to one another, until it exceeds the other. This he does also at proposition 1 of Book 10, and in very many other propositions.

Let those, then, be silent who think that, by "magnitudes of the same kind" in the definition of proportion (which Euclid called "ratio"), one must understand those contained under the same proximate or lowest genus. For on this reasoning there would be no ratio between rectilinear and curvilinear angles, nor between rectilinear and curvilinear figures, since they are not contained under the same proximate genus — which we have said to be false. Let those too be silent who suppose that one must understand magnitudes in the same genus of quantity, or in the same subaltern genus (as the logicians speak), so that it suffices, for two quantities to be said to have a ratio, that they be either lines, or surfaces, or

bodies, or angles, or numbers. For on that reasoning there would be a ratio between a rectilinear angle and an angle of contact, since they are contained in the genus of angle; and likewise a finite line and an infinite line would have a ratio to one another, since they exist in the genus of line — both of which are plainly false, as is clear from this definition.

Diagram. Four vertical magnitude-lines labelled at the foot A, B, C, D, illustrating the equimultiples C (of A) and D (of B). The two longer lines, C and D, are marked with the numerals 16 and 12 respectively; the numerals on the two shorter lines A and B are not legibly resolved.

- A (leftmost, shorter): value [numeral: ?]
- B (shorter): value [numeral: ?]
- C: 16
- D: 12

[Only 16 and 12 are cleanly legible]

It is clear from all this how ineptly and how falsely Orontius [Oronce Fine] expounded this definition. For he says that Euclid does not define, or teach, what magnitudes are said to have a ratio, but what sort of ratio any two proposed quantities have. And so, he says, Euclid means that if a magnitude A is referred to a magnitude B, and both are multiplied equally — that is, if any equimultiples of both are taken, C being as much a multiple of A as D is of B — then the magnitudes A and B have to one another the same ratio as their equimultiples C and D. But he fails to notice this: that what he states is not a definition, but the fifteenth theorem of this fifth book, where it is demonstrated by Euclid that parts are in the same ratio as their like multiples — that is, that the magnitudes A, B have the same ratio as their equimultiples C, D. This definition, therefore, is not to be understood in that way, especially since the ratio between C and D is as unknown as that between A and B, seeing that it is always the same. Hence Euclid would not rightly lead us to a knowledge of the ratio between A and B. The sense of this definition, therefore, is the one we have set out, as is plainly established from the words of Euclid.

Definition VI

Magnitudes are said to be in the same ratio, the first to the second and the third to the fourth, when the equimultiples of the first and third, compared with the equimultiples of the second and fourth according to whatever multiplication, either both alike fall short of, or both alike are

equal to, or both alike exceed them — if those be taken which correspond to one another.

Clavius's commentary.

Here Euclid explains what conditions magnitudes require, among geometers, in order to be said to have the same ratio. To accomplish this he is obliged to resort to their equimultiples [aeque multiplicia], so as to embrace all ratios of magnitudes, both rational and irrational. Let there be, then, four magnitudes: A the first, B the second, C the third, and D the fourth. Take any equimultiples whatever of the first and third — E of A, and F of C. Likewise take other equimultiples, any whatever, of the second and fourth — G of B, and H of D — whether these latter two are multiples of the second and fourth in the same degree as the former two are of the first and third, or not.

Now if the equimultiples taken are compared with one another in their corresponding pairs — the multiple of the first with the multiple of the second, that is, E with G; and likewise the multiple of the third with the multiple of the fourth, that is, F with H — and it is found invariably that they stand thus: that whenever E, the multiple of the first magnitude A, is less than G, the multiple of the second magnitude B, then F too, the multiple of the third magnitude C, is less than H, the multiple of the fourth magnitude D; or, if E is equal to G, then F too is equal to H; or, finally, if E is greater than G, then F too is greater than H — which is precisely "each together falls short of each, or is equal together, or exceeds together" — in such a way that in no class of multiples can the contrary be found: that is, that E is never less than G without F also being less than H; that E is never equal to G without F too being equal to H; and finally that E is never greater than G without F too being greater than H —

Diagram. Eight vertical magnitude-lines in two groups, illustrating the four magnitudes and their equimultiples. Upper group (left to right): E, A, B, G. Lower group: F, C, D, H. E and G (the equimultiples of A and B) are drawn longer than A and B; likewise F and H longer than C and D. No numerals are attached.

- E: equimultiple of A
- A: first magnitude
- B: second magnitude
- G: equimultiple of B
- F: equimultiple of C
- C: third magnitude
- D: fourth magnitude

- H: equimultiple of D

if, I say, it is found that whatever equimultiples are taken always behave as stated, then the ratio of the first magnitude A to the second B will be said to be the same as the ratio of the third magnitude C to the fourth D. But if it should ever be found, even in a single class of multiples, that the multiple E [?] falls short of the multiple G while the multiple F [?] does not fall short of the multiple H; or that E is equal to G while F is not equal to H; or, finally, that E exceeds G while F does not exceed H — then, however much the aforesaid condition may be found in infinitely many other multiples, the proposed quantities will by no reasoning be said to have the same ratio, but different ratios, as will become clear from Definition 8.

And so, in order that by some demonstration, through this sixth definition, it may be concluded that four quantities have the same ratio, it will have to be shown — as Euclid diligently observes both in this fifth book and elsewhere — that any equimultiples whatever of the first and third, compared with any equimultiples whatever of the second and fourth, always have the aforesaid condition of shortfall, equality, or excess, so that its contrary can never be found. Similarly, if four quantities are granted to have the same ratio, it must also necessarily be granted that any equimultiples of the first and third, compared with any equimultiples of the second and fourth, have the same condition of shortfall, equality, or excess; for the definition and the thing defined must be convertible.

But to see clearly in what way, given four magnitudes having the same ratio, some equimultiples of the first and third magnitude fall short together of certain equimultiples of the second and fourth magnitude, while others are equal together, and yet others exceed together — when those are taken which correspond to one another — it is well to offer one example in numbers. Let the four numbers, then, be 3, 2, 6, 4. Take equimultiples of the first and third, namely their quadruples, 12 and 24. Likewise take other equimultiples of the second and fourth, say their septuples, 14 and 28. You see, then, that 12, the multiple of the first, falls short of 14, the multiple of the second, just as 24, the multiple of the third, falls short of 28, the multiple of the fourth. Again, take other equimultiples of the first and third, namely their sextuples, 18 and 36; likewise other equimultiples of the second and fourth, say their ninefold multiples, 18 and 36. You see, therefore, that 18, the multiple of the first, is equal to 18, the multiple of the second, just as 36, the multiple of the third, equals 36, the multiple of the fourth. Finally, take other equimultiples of the first and third, namely their triples, 9 and 18; likewise other equimultiples of the second and fourth, say their

doubles, 4 and 8. You see, then, that 9, the multiple of the first, exceeds 4, the multiple of the second, just as 18, the multiple of the third, surpasses 8, the multiple of the fourth. If, then, in all equimultiples, taken in whatever multiplication, one of these three cases is always found to hold true, the ratio 3 to 2 will be said to be the same as the ratio 6 to 4 — otherwise not.

Diagram. A set of nested (concentric) ellipses with a central rectangle, tabulating the worked example on the four numbers 3, 2, 6, 4 and their equimultiples. The central rectangle holds the four base numbers; the surrounding rings hold, on the left, the multiples of 3 and 6, and on the right, the multiples of 2 and 4.

- Central rectangle: 3 (top-left), 2 (top-right); 6 (bottom-left), 4 (bottom-right)
- Left side, top row / bottom row (multiples of 3 and 6): 9 / 18 (triples); 18 / 36 (sextuples); 12 / 24 (quadruples)
- Right side, top row / bottom row (multiples of 2 and 4): 14 / 28 (septuples); 18 / 36 (ninefold); [4?] / 8 (doubles)

Campanus [Campanus of Novara] and Orontius [Oronce Fine], however, expound this definition quite differently. For they say that Euclid means that four magnitudes have the same ratio only when the equimultiples of the first and third, relative to the equimultiples of the second and fourth, either both together fall short proportionally — that is, in the same ratio — or are both together equal, or both together exceed proportionally, if those be taken which correspond to one another. More plainly, as Campanus puts it: when their equimultiples are proportional — that is, when the multiple of the first has the same ratio to the multiple of the second as the multiple of the third has to the multiple of the fourth.

But who does not see that, if the definition is understood in this way, Euclid is defining a thing by itself? Which is plainly absurd. Besides, if Euclid means that those magnitudes are in the same ratio whose equimultiples (if they are taken and compared with one another in the order stated) stand in the same ratio, then why, I ask, does he prove in the 4th theorem of this book that, if four magnitudes are in the same ratio, their equimultiples taken in the order we mentioned also have the same ratio? Indeed, since that theorem is shown by means of this definition, it is evident that the same is being demonstrated by the same — which is ridiculous, as we shall point out in that place. There is this too: if we interpret the definition in that way, very many theorems of this fifth book cannot be demonstrated, as we shall note in the proper places. The definition, therefore, is to be understood as we have set it out: namely, that given four magnitudes, whenever the multiple of the first falls short of the multiple of the second, or is

equal to it, or exceeds it, then necessarily the multiple of the third likewise falls short of the multiple of the fourth, or is equal to it, or exceeds it — whatever that shortfall or excess may be, without considering whether it is proportional or not; so that it never happens that the multiple of the first falls short of the multiple of the second while the multiple of the third does not fall short of the multiple of the fourth; or that the multiple of the first is equal to the multiple of the second while the multiple of the third is not equal to the multiple of the fourth; or, finally, that the multiple of the first is greater than the multiple of the se-

-cond, while the multiple of the third is not greater than the multiple of the fourth. Given, I say, four magnitudes whose equimultiples, taken as stated, always preserve that condition of shortfall, equality, and excess, those four magnitudes are said to have the same ratio — whatever be the case regarding the ratio of their equimultiples, which is not now considered; but it will be demonstrated later, in the fourth theorem, that this shortfall or excess is proportional.

Furthermore, Campanus tries to show that this definition must be understood of a proportional shortfall and excess. For if it were understood of any shortfall whatever, then, he says, these four numbers 4, 3, 6, 5 would be in the same ratio. For if equimultiples of the first and third — namely of 4 and 6 — are taken, say their doubles, 8 and 12; and likewise equimultiples of the second and fourth, namely of 3 and 5, also their doubles, 6 and 10 — then 8, the multiple of the first, exceeds 6, the multiple of the second, just as 12, the multiple of the third, exceeds 10, the multiple of the fourth. And the same is seen if the quadruples of the first and third are taken, 16 and 24, while the triples of the second and fourth are taken, 9 and 15. If, then, it were enough that the equimultiples taken exceed one another together in any way whatever, and it were not required that they surpass one another proportionally, then the ratio 4 to 3 would be the same as the ratio 6 to 5 — which is false, since the ratio 4 to 3 is sesquitertian [4:3], whereas the ratio 6 to 5 is sesquiquintan [6:5]. The shortfall or excess of the equimultiples, therefore, must be understood as proportional; for in that way it will follow that the ratio 4 to 3 is not the same as 6 to 5, since their equimultiples do not exceed one another proportionally, as is evident.

Diagram. The first of two nested-ellipse figures illustrating Campanus's example on the numbers 4, 3, 6, 5. The central rectangle holds the base numbers; the left rings hold multiples of 4 and 6, the right rings multiples of 3 and 5.

- Central rectangle: 4 (top-left), 3 (top-right); 6 (bottom-left), 5 (bottom-right)

- Left side, top / bottom (multiples of 4 and 6): 16 / 24 (quadruples); 8 / 12 (doubles)
- Right side, top / bottom (multiples of 3 and 5): 6 / 10 (doubles); 9 / 15 (triples)

Diagram. The second nested-ellipse figure on the same numbers 4, 3, 6, 5, giving the counter-instances (quadruples/quintuples and triples/quadruples).

- Central rectangle: 4 (top-left), 3 (top-right); 6 (bottom-left), 5 (bottom-right)
- Left side, top / bottom (multiples of 4 and 6): 12 / 18 (triples); 16 / 24 (quadruples)
- Right side, top / bottom (multiples of 3 and 5): 15 / 25 (quintuples); 12 / 20 (quadruples)

Yet it must be said that Campanus was mistaken in a remarkable way. For although the equimultiple numbers he adduced do exceed one another together, still very many others will be found in which the multiple of the first indeed exceeds, or is equal to, the multiple of the second, while the multiple of the third falls short of the multiple of the fourth. For if, in his example, the quadruples of the first and third are taken, 16 and 24, but the quintuples of the second and fourth are taken, 15 and 25, then 16, the multiple of the first, does exceed 15, the multiple of the second; but 24, the multiple of the third, does not exceed 25, the multiple of the fourth — rather it falls short. And if the triples of the first and third are taken, 12 and 18, but the quadruples of the second and fourth are taken, 12 and 20, then 12, the multiple of the first, will be equal to 12, the multiple of the second; but 18, the multiple of the third, will not be equal to 20, the multiple of the fourth — rather it will fall short of it. Since, therefore, it is not found that all equimultiples whatever of the said numbers behave thus — that if the multiple of the first exceeds the multiple of the second, the multiple of the third necessarily also exceeds the multiple of the fourth — even though this does happen with some equimultiples, the said numbers will not, according to this sixth definition, be said to have the same ratio, as will become still clearer from the eighth definition.

For the rest, this definition also embraces three magnitudes having the same ratio, provided only that the second be counted among them so that four are had. For example: the ratio 9 to 6 will be said to be the same as 6 to 4, because any equimultiples whatever taken of 9 and 6 either together fall short of the equimultiples taken of 6 and 4, or are equal to them, or together exceed them, and so on.

Definition VII

And let magnitudes having the same ratio be called proportional.

Clavius's commentary.

Thus, if among the magnitudes A, B, C, D the ratio of A to B is the same as that of C to D, those magnitudes will be called proportional. In the same way, if the ratio of E to F is the same as that of F to G, the magnitudes E, F, G will be called proportional.

Diagram. Seven horizontal magnitude-lines with tick-marks, each labelled with a letter at the left and a numeral at the right, illustrating discrete proportionality (A, B, C, D) and continuous proportionality (E, F, G).

- A — 12
- B — 4
- C — 9
- D — 3
- E — 16
- F — 8
- G — 4

(A : B = 12 : 4 = C : D = 9 : 3; and E : F = 16 : 8 = F : G = 8 : 4.)

Now some proportional magnitudes are continuous, among which a continuous proportionality is found, such as the magnitudes E, F, G; while others are proportional not continuously but discretely, such as the magnitudes A, B, C, D. For in the latter there is an interruption of the proportions, but in the former none at all, as was said in the fourth definition.

Definition VIII

But when, of equimultiples, the multiple of the first magnitude exceeds the multiple of the second, while the multiple of the third does not exceed the multiple of the fourth, then the first is said to have a greater ratio to the second than the third has to the fourth.

Clavius's commentary.

Here Euclid sets out what condition four magnitudes must satisfy for the first to be said to have a greater ratio to the second than the third has to the fourth. You would put it thus. If equimultiples of the first and third are taken, and likewise

other equimultiples of the second and fourth, and it is found on some occasion (though not always) that the multiple of the first is greater than the multiple of the second, while the multiple of the third is not greater than the multiple of the fourth but either less or equal, then the ratio of the first magnitude to the second will be said to be greater than that of the third to the fourth.

Diagram. Four short horizontal magnitude-lines with tick-marks, set in two facing columns, for the worked example of this definition: the triples E, F (of the first A and third C) and the quadruples G, H (of the second B and fourth D). The individual letter-labels are printed small and are not cleanly legible on the scan.

- Line 1: E [?] — triple of the first magnitude A
- Line 2: F [?] — triple of the third magnitude C
- Line 3: G [?] — quadruple of the second magnitude B
- Line 4: H [?] — quadruple of the fourth magnitude D

[Labels not cleanly resolved]

And since E, the multiple of the first, is indeed greater than H [recte: G], the multiple of the second, but F, the multiple of the third, is not greater than H, the multiple of the fourth — indeed less — the ratio of A, the first magnitude, to B, the second, will be said to be greater than that of C, the third, to D, the fourth.

It is not, however, necessary, in order for the first of four magnitudes to be said to have a greater ratio to the second than the third has to the fourth, that the equimultiples in every multiplication behave so that the multiple of the first exceeds the multiple of the second while the multiple of the third does not exceed the multiple of the fourth; rather it is enough that in some one multiplication they behave thus. For it can sometimes happen that the multiple of the first is greater than the multiple of the second, just as the multiple of the third is greater than the multiple of the fourth; and likewise that the multiple of the first is less than the multiple of the second, and the multiple of the third less than the multiple of the fourth. Yet this does not occur in every multiplication; rather, on some occasion the multiple of the first does surpass the multiple of the second, while the multiple of the third is either less than or equal to the multiple of the fourth. For that reason the first magnitude will be said to have a greater ratio to the second than the third has to the fourth — not the same ratio — as is evident in the accompanying example.

Diagram. A nested-ellipse figure for the example of Definition VIII, on the numbers 3, 2, 4, 3 (the first-to-second ratio 3:2 greater than the third-to-fourth

ratio 4:3). The central rectangle holds the base numbers; the left rings hold multiples of 3 and 4, the right rings multiples of 2 and 3.

- Central rectangle: 3 (top-left), 2 (top-right); 4 (bottom-left), 3 (bottom-right)
- Left side, top / bottom (multiples of 3 and 4): 15 / 20 (quintuples); 9 / 12 (triples); 12 / 16 (quadruples)
- Right side, top / bottom (multiples of 2 and 3): 10 / 15 (quintuples); 18 / 12 [?] (middle ring); 14 / 21 (septuples)

And so, for four magnitudes to be called proportional, it is necessary that their equimultiples, taken according to any multiplications whatever, either together fall short, or together are equal, or together exceed, as was set out in the sixth definition. But for the first to be said to have a greater ratio to the second than the third has to the fourth, it is enough that, in some one multiplication, the multiple of the first...

the multiple of the first exceeds the multiple of the second, while the multiple of the third does not exceed the multiple of the fourth — even though, under countless other multiplications, the equimultiples of the first and third together exceed the equimultiples of the second and fourth.

But if, conversely, on some occasion the multiple of the first falls short of the multiple of the second, while the multiple of the third does not fall short of the multiple of the fourth, then the first magnitude will be said to have a *smaller* ratio to the second than the third has to the fourth — even though, under very many other multiplications, the equimultiples of the first and third together fall short of the equimultiples of the second and fourth. Thus, in the same numbers of the proposed example, the ratio of 2 to 3 will be said to be smaller than that of 3 to 4, and so on.

Why Euclid, in Definitions VI and VIII, defined four proportional and non-proportional magnitudes by means of their equimultiples

It might seem strange to someone why Euclid said that four magnitudes have the same ratio — that is, that the first is to the second as the third is to the fourth — only in the following case: that the equimultiples of the first and third (taken according to any multiplication whatever) and the equimultiples of the second and fourth (taken likewise according to any multiplication whatever) stand so that, whenever the multiple of the first is greater than the multiple of the second, the multiple of the third is likewise greater than the multiple of the fourth; whenever the multiple of the first equals the multiple of the second, the multiple of the third likewise equals the multiple of the fourth; and whenever, finally, the

multiple of the first is less than the multiple of the second, the multiple of the third is likewise less than the multiple of the fourth. And likewise it might seem strange why he held that, of four magnitudes, the first has a greater ratio to the second than the third has to the fourth only when some equimultiples of the first and third, and other equimultiples of the second and fourth, taken thus, stand so that the multiple of the first is greater than the multiple of the second, but the multiple of the third is not greater than the multiple of the fourth — being instead either equal to or less than it. Since, I say, it might seem strange to someone that from that excess, equality, and defect of the equimultiples taken in that order the likeness of the ratios (or their unlikeness) does not immediately appear, it seems necessary to explain here why Euclid chose to define magnitudes — whether proportional or not proportional — in this way.

To this difficulty I reply that Euclid chose to call those magnitudes proportional whose equimultiples behave as has been said, because he had nothing better known through which he could explain magnitudes — whether incommensurable or commensurable — that have the same ratio or do not have it. Nor indeed is it necessary that a reason be given why some thing is defined in this way or that; it is enough that the thing defined is never asserted to belong to something unless it is first demonstrated that the given definition fits it. This is seen in other definitions too. For just as Euclid, in Definition 10 of Book 1, called a right angle the one made by a line falling upon another line so as to make equal angles — so that it must never be granted that some angle is a right angle unless it is first shown that it is produced by such a line; and just as, in the last definition of Book 3, he defined similar segments of circles to be those in which the angles are equal, so that segments are to be granted similar only when one has proved that the angles standing in them are equal — so too, in Definitions 6 and 8 of this book, he called those four magnitudes proportional (and not proportional) whose equimultiples have the condition he set out, so that it must never be believed, when he calls four magnitudes to have the same ratio or not the same, unless he has first demonstrated that this condition fits those magnitudes. But although this reply is true and proper, nevertheless, because from that definition it does not seem possible to conclude that magnitudes whose equimultiples have that condition are *truly* proportional or not proportional — even if Euclid wishes to call only these proportional or not proportional — we shall explain a little more carefully that Euclid rightly defined proportional magnitudes in this way, and that therefore it can be granted by anyone, without any doubt, that those to which Definition 6 applies truly have the same ratio, and those to which Definition 8 applies do not have the same ratio.

To make this clearer, we must recall that ratio is twofold: **rational**, which exists between commensurable quantities and so can always be found in numbers; and **irrational**, which exists between incommensurable quantities and can in no way be found in numbers. Therefore, had Euclid set up his discussion only about rational ratios, he could have defined four proportional magnitudes in the way he defined four proportional numbers in Book 7, Definition 20 — namely: *Magnitudes are proportional when the first is the same equimultiple of the second, or the same part, or the same parts, as the third is of the fourth*; or, at any rate (as we added to that definition), *when the first contains the second equally as often, and in addition the same part or parts of it, as the third contains the fourth*. And non-proportional magnitudes he could have defined thus: *Magnitudes are non-proportional* — that is, the first has a greater ratio to the second than the third has to the fourth — *when the first is a greater multiple of the second, or a greater part, or greater parts, than the third is of the fourth*; or, at any rate, *when the first contains the second as often as the third contains the fourth, whether the same part or parts are left over on both sides or not; or when the first contains the second as often as the third contains the fourth, but the first includes in addition a greater part or greater parts of the second than the third does of the fourth*. Euclid could, I say, have defined proportional and non-proportional magnitudes in this way, if he were dealing only with rational ratios, because all ratios of magnitudes could be exhibited in numbers and hence defined — like the ratios of numbers — as the same or different, as we said. For the ratio of numbers (as we added, from Campanus [Campanus of Novara] and other writers, at Definition 24 of Book 7) is a certain relation of one number to another, according as it is a multiple of it, or a part, or parts of it; or, at any rate, according as it contains it once, or several times, and in addition some part or parts of it. All of this is clear both from the definitions of the five species of rational ratio — of both greater and lesser inequality — which we treated above, and from what we wrote at Definitions 20 and 24 of Book 7.

But since Euclid wished to embrace not only rational ratios but irrational ones as well, he could not define four proportional and non-proportional magnitudes in that way. For in an irrational ratio the greater magnitude can neither be a multiple of the greater [*maioris*; recte *minoris*? — "of the smaller"], nor contain it once or several times together with some part or parts of it in addition; and likewise the smaller cannot be a part of the greater, nor parts of it — since magnitudes having an irrational ratio are incommensurable, and so can have no common aliquot part, however small. He was therefore compelled to turn to the rational ratios of magnitudes — that is, to the ratios of numbers — since every rational ratio (that is, of commensurable magnitudes) is as the ratio of a number

to a number, as he proved in Book 10, Proposition 5. He was compelled, I say, to seek something certain to belong to any four numbers, or commensurable magnitudes, that have the same ratio or not the same, so that — if that same thing were demonstrated to belong to four magnitudes, even incommensurable ones — those four magnitudes could with full right also be called proportional or not proportional, since they have the same property that any four proportional (or non-proportional) numbers have; indeed, the same property that any four commensurable magnitudes having the same ratio (or not the same) are necessarily shown to have. For we cannot otherwise know or ex-

-plain that incommensurable magnitudes are proportional or non-proportional except through something that is certain to belong (as we said) to any numbers whatever, or to commensurable magnitudes, having the same ratio or not the same — magnitudes in which the likeness or unlikeness of the ratios is clearly discerned. For example: when the equal angles standing in segments of circles are commensurable with four right angles — that is, when they are the same part or parts of four right angles — then the segments themselves are likewise the same part or parts of their circles, as we shall demonstrate at the end of Book 6; so that they are rightly called similar. And for that reason all other segments too, in which the angles are equal, are called similar even if they are not commensurable with four right angles. For when the angles are commensurable with four right angles, those segments are truly similar — that is, the same parts of their circles — even though this is not discerned in segments where the angles standing in them are incommensurable with four right angles, since then the segments can be neither the same part nor the same parts of the circles, but stand altogether incommensurable with the circles themselves. For we can have no other indication that segments are similar or dissimilar than the equality or inequality of the angles standing in them — from which the true similarity or dissimilarity of the segments commensurable with the circles is indicated. And therefore, just as no one calls this similarity of segments into doubt — even though the similarity does not appear as clearly in segments incommensurable with their circles as in segments commensurable with them — so he would not act rightly who called into doubt the similarity of ratios in incommensurable magnitudes, when he finds that there belongs to them what is certainly known to belong to all magnitudes having the same rational ratio, even though this similarity of ratios is not so evident in incommensurable magnitudes.

And so, given four proportional numbers, and the equimultiples of the first and third taken according to any multiplication whatever, and likewise the equimultiples of the second and fourth according to any multiplication whatever,

it is always true (as we shall shortly demonstrate) that if the multiple of the first is greater than the multiple of the second, the multiple of the third is necessarily also greater than the multiple of the fourth; if the former is equal, this too is equal; and if less, less. And conversely: given four numbers, and the equimultiples of the first and third taken according to any multiplication, and likewise the equimultiples of the second and fourth according to any multiplication — if, the multiple of the first being greater than the multiple of the second, the multiple of the third is also greater than the multiple of the fourth; and, the former being equal, this too is equal; and, the former being less, this less — it is invariably true that the four numbers are proportional. Again, given four numbers of which the first has a greater ratio to the second than the third has to the fourth, and the equimultiples of the first and third, and likewise of the second and fourth, taken — it necessarily happens sometimes that the multiple of the first is greater than the multiple of the second, while the multiple of the third is not greater than the multiple of the fourth. And conversely: given four numbers, with the equimultiples of the first and third, and of the second and fourth, taken — if it sometimes happens that the multiple of the first is greater than the multiple of the second, but the multiple of the third is not greater than the multiple of the fourth, then it is beyond all doubt true that the ratio of the first to the second is greater than that of the third to the fourth.

Since, I say, matters always stand thus in numbers — and therefore also in commensurable magnitudes — so that the contrary is never found, it is with good reason that any four magnitudes whatever, even incommensurable ones, will be said to have the same ratio when, the equimultiples of the first and third being taken according to any multiplication, and likewise those of the second and fourth according to any multiplication, it is invariably found that the multiple of the third is greater than the multiple of the fourth whenever the multiple of the first is greater than the multiple of the second; that the multiple of the third is equal to the multiple of the fourth when the multiple of the first is equal to the multiple of the second; and, finally, that the multiple of the third is less than the multiple of the fourth by this very fact, that the multiple of the first is less than the multiple of the second. By the same reasoning, any four magnitudes whatever — commensurable as well as incommensurable — will with full right be said not to have the same ratio, but rather that the ratio of the first to the second is greater than that of the third to the fourth, when, the equimultiples being taken as described, it sometimes happens that the multiple of the first is greater than the multiple of the second, while the multiple of the third is not greater than the multiple of the fourth. For the former condition is invariably found in all proportional numbers, and the latter in non-proportional ones, as we shall

demonstrate presently; and we can have no other indication by which to recognize whether incommensurable magnitudes are proportional or not — especially since incommensurable magnitudes are often shown, by another route, to have the same ratio to other magnitudes (which are proved proportional in this way) as a number has to a number, so that there can be no doubt at all that all magnitudes, even incommensurable ones, whose equimultiples behave as stated in the sixth definition, are proportional. For if this were not true, some manifest absurdity would doubtless follow at some point from that proportionality — which, however, has not so far occurred; on the contrary, those things which are demonstrated from magnitudes proportional in that sense are for the most part shown, by another route (as we said), to be perfectly true, as we shall also demonstrate later. This being so, I consider it clearly established why Euclid, in those two definitions, employed (and rightly) the equimultiple magnitudes of the proposed magnitudes. But now let us demonstrate geometrically what we promised, having called in some propositions of Book 7 — which in no way depend on the sixth and eighth definitions, or on the demonstrations of this fifth book, so that they can most conveniently be demonstrated before Book 5, and thus be assumed here as already demonstrated. This we shall accomplish by the four propositions that follow.

I.

Given four proportional numbers, and equimultiples of the first and third taken according to any multiplication, and likewise equimultiples of the second and fourth taken according to any multiplication whatever: if the multiple of the first is greater than the multiple of the second, the multiple of the third will also be greater than the multiple of the fourth; if the multiple of the first is equal to the multiple of the second, the multiple of the third will also be equal to the multiple of the fourth; and if, finally, the multiple of the first is less than the multiple of the second, the multiple of the third will also be less than the multiple of the fourth.

Demonstration. Let the first number A have to the second B the same ratio that the third C has to the fourth D; and let E, F be equimultiples of the first A and the third C, and G, H equimultiples of the second B and the fourth D, whatever this multiplication may be. I say that if E, the multiple of the first A, is greater than G, the multiple of the second B, then F, the mul-

-tiple of the third C, is likewise greater than H, the multiple of the fourth D. And if E is equal to G, then F is also equal to H. And if, finally, E is less than G, then F is also less than H. For since A is to B as C is to D, by alternation A will also be to C as

B is to D. [Margin: (a) Elements VII.13] Now A is to C as E is to F, because the same number, multiplying A and C, produced E and F — since E and F were taken as equimultiples of A and C. [Margin: (b) Elements VII.17] And for the same reason, B is to D as G is to H. Therefore, by the lemma of Proposition 14 of Book 7, E will also be to F as G is to H. And by alternation, E is to G as F is to H. [Margin: (c) Elements VII.13] Consequently, if E is greater than G, F will also be greater than H, as in the first example. But if F [recte: E] is equal to G, F will also be equal to H, as in the second example. And if, finally, E is less than G, F will also be less than H, as in the third example. Which was to be demonstrated.

First example:

E, 9	A, 3	C, 6	F, 18
G, 4	B, 2	D, 4	H, 8

Second example:

E, 18	A, 3	C, 6	F, 36
G, 18	B, 2	D, 4	H, 36

Third example:

E, 12	A, 3	C, 6	F, 24
G, 14	B, 2	D, 4	H, 28

II.

Given four non-proportional numbers, such that the ratio of the first to the second is greater than that of the third to the fourth: if equimultiples of the first and third, and likewise equimultiples of the second and fourth, are taken, it can happen that the multiple of the first is greater than the multiple of the second, while the multiple of the third is not greater than the multiple of the fourth.

Demonstration. Let the first number A have to the second B a greater ratio than the third C has to the fourth D. I say that it can happen, when equimultiples of the first A and the third C are taken, and likewise equimultiples of the second B and the fourth D, that the multiple of A, the first, is greater than the multiple of B, the second, while the multiple of C, the third, is not greater than the multiple of D, the

fourth. For let the numbers B and D, multiplying each other, make E. And since D measures E (by Proposition 7 of Book 7), and E measures the product of C by E (by the same proposition), D will also measure this same product of C by E (by Proposition 11 of Book 7). Let D measure the product of C by E by F; and thus, from D multiplied by F, there will arise the number which D measures by F (by Proposition 9 of Book 7) — that is, the same number that arises from C multiplied by E. Since, therefore, the same number is generated from D (the first) multiplied by F (the fourth) as from C (the second) multiplied by E (the third), then D, the first, will be to C, the second, as E, the third, is to F, the fourth. [Margin: (a) Elements VII.19] And by conversion, C is to D as F is to E.

Again, since B measures E (by Proposition 7 of Book 7), and E measures the product of A by E (by the same proposition), B will also measure this same product of A by E (by Proposition 11 of Book 7). Let B measure the product of A by E by FG; and thus, from B multiplied by FG, there arises the number which B measures by FG (by Proposition 9 of Book 7) — that is, the same number that arises from A multiplied by E. Since, therefore, the same number is generated from B (the first) multiplied by FG (the fourth) as from A (the second) multiplied by E (the third), then B, the first, will be to A, the second, as FG, the third, is to E, the fourth. [Margin: (b) Elements VII.19] And by conversion, A is to B as FG is to E. Since, therefore, FG is to E as A is to B, and the ratio of A to B was assumed greater than that of C to D, the ratio of FG to E will also be greater than that of C to D. But it was shown that C is to D as F is to E. Therefore the ratio of FG to E will also be greater than the ratio of F to E, and hence the number FG will be greater than the number F — all of which follows plainly from what we wrote at Definition 20 of Book 7. Let FG, then, exceed F itself by the number G.

Now let there be taken equimultiples K, H, I of F, G, C, under this condition: that H be greater than E, while I be not less than D. Then (by the scholium to Proposition 5 of Book 7) the whole KH will be the same multiple of the whole FG as K is of F, or I of C. Again let there be taken equimultiples L, M, N of D, E, under this condition: that L be the multiple of D next greater than I — that is, such equimultiples that, when the number D is subtracted from L, the remaining number is not greater than I, but either equal to it (as happens in the second example) or less (as happens in the first example). And since it was shown that D is to C as E is to F, and, by construction, C is to I as F is to K (because I, K were taken as equimultiples of C, F), then, *ex aequali*, D will also be to I as E is to K. [Margin: (a) Elements VII.14]

Furthermore, since it was shown that D is to C as E is to F, by alternation D will also be to E as C is to F. Now D is to E as L is to MN, because the same number, multiplying D and E, made L and MN — since L, MN were taken as equimultiples of D, E. And for the same reason, C is to F as I is to K. Therefore, by the lemma of Proposition 14 of Book 7, L will also be to MN as I is to K; and by alternation, L is to I as MN is to K.

Since, therefore, the whole L is to I as the whole MN is to K, and, as D subtracted from L is to that same I, so is E subtracted from MN to that same K, then (by Theorem 6 of the scholium to Proposition 22 of Book 7) the remainder of L will be to I as the remainder of MN is to K:

Worked example (the same figure is set beside both halves of the demonstration on this page):

First example:

K, 56	H, 7	O, 21	I, 28
F, 8	G, 1	A, 3	C, 4
	E, 6	B, 2	D, 3
M, 54	N, 6	P, 20	L, 30

Second example:

K, 160	H, 440	O, 60	I, 20
F, 8	G, 22	A, 3	C, 1
	E, 80	B, 8	D, 10
M, 160	N, 80	P, 24	L, 39

Now the remainder from L is not greater than I, but either smaller—as in the first example—or equal—as in the second; this is because the remainder from L, together with D, makes up L itself, the multiple of D that is next greater than I, by construction. Therefore the remainder from MN will not be greater than K either; and so, if N (equal to E) is subtracted from MN, the remainder M will be either smaller than K, as in the first example, or equal to it, as in the second. Since, then, H, the multiple of G, is greater than E (or than N) by construction, the whole KH will be greater than the whole MN.

Finally, take O to be the same multiple of A that KH is of FG (or that I is of C); and likewise take P to be the same multiple of B that MN is of E (or that L is of D). Since it has been shown that FG is to E as A is to B, and since KH and O have been taken as equimultiples of FG and A—the first and the third—while MN and P have been taken as equimultiples of E and B—the second and the fourth—it follows from the preceding proposition that if KH is greater than MN, then O too is greater than P. Since, therefore, KH has been shown to be greater than MN, O will also be greater than P. And so, since O and I are equimultiples of A and C (the first and the third), while P and L are equimultiples of B and D (the second and the fourth), and since it has been demonstrated that O is greater than P while I is smaller than L by construction, it can happen that—when the ratio of the first, A, to the second, B, is greater than the ratio of the third, C, to the fourth, D, and equimultiples have been taken as described—the multiple of the first (namely O) is greater than the multiple of the second (P), yet the multiple of the third (namely I) is not greater than the multiple of the fourth (L). Which was to be demonstrated.

But if the ratio of the first to the second is smaller than the ratio of the third to the fourth, and equimultiples of the first and third, and likewise of the second and fourth, are taken, it can also happen that sometimes the multiple of the first is smaller than the multiple of the second, while the multiple of the third is not smaller than the multiple of the fourth.

For in the same example the ratio of C, the first, to D, the second, is smaller than the ratio of A, the third, to B, the fourth; and it has been demonstrated that I, the multiple of the first C, is smaller than L, the multiple of the second D, while O, the multiple of the third A, is greater than P, the multiple of the fourth B.

III.

Given four numbers, and taking equimultiples of the first and third according to any multiplication whatever, and likewise equimultiples of the second and fourth according to any multiplication whatever: if, whenever the multiple of the first is greater than the multiple of the second, the multiple of the third is necessarily also greater than the multiple of the fourth; and whenever the former is equal, the latter too is always equal; and finally whenever the former is smaller, the latter too is perpetually smaller—then the ratio of the first to the second will be the same as the ratio of the third to the fourth.

First example:

E, 9	A, 3	C, 6	F, 18
G, 4	B, 2	D, 4	H, 8

Second example:

E, 18	A, 3	C, 6	F, 36
G, 18	B, 2	D, 4	H, 36

Third example:

E, 12	A, 3	C, 6	F, 24
G, 14	B, 2	D, 4	H, 28

Let there be four numbers A, B, C, D, and let equimultiples E and F of the first, A, and the third, C, be taken—of whatever kind—and likewise equimultiples G and H of the second, B, and the fourth, D, whatever this multiplication may be. I say that if E and F, the multiples of the first and third, are always either both greater than G and H, the multiples of the second and fourth, or both equal, or both smaller, then A, the first, is to B, the second, as C, the third, is to D, the fourth. For if the ratio of A to B were greater or smaller than the ratio of C to D, it could happen—as was demonstrated in the preceding proposition—that E, the multiple of the first, would sometimes be greater or smaller than G, the multiple of the second, while F, the multiple of the third, would not be greater (or not smaller) than H, the multiple of the fourth. But that is contrary to the hypothesis. Therefore A is to B as C is to D. Which was to be shown.

III.

Given four numbers, and taking equimultiples of the first and third, and likewise equimultiples of the second and fourth: if it should ever happen that the multiple of the first is greater than the multiple of the second, while the multiple of the third is not greater than the multiple of the fourth, then the ratio of the first to the second will be greater than the ratio of the third to the fourth.

E, 21	A, 3	C, 4	F, 28
G, 20	B, 2	D, 3	H, 30

Let there be four numbers A, B, C, D; and taking equimultiples E and F of A and C (the first and third), and equimultiples G and H of B and D (the second and fourth), let E, the multiple of the first A, be greater than G, the multiple of the second B, while F, the multiple of the third C, is not greater than H, the multiple of

the fourth D. I say that the ratio of the first, A, to the second, B, is greater than that of the third, C, to the fourth, D. For since E is greater than G, while F is not greater than H—the former being a ratio of greater inequality, the latter one of equality or of lesser inequality—it follows, by Theorem 10 of the scholium to Proposition 22 of Book 7, that by alternation the ratio of E to F is likewise greater than that of G to H. [Margin: (a) *Elements* VII.17 ("17. septimi")] But E is to F as A is to C, because the same number that multiplies A and C has produced E and F, since E and F are equimultiples of A and C; and for the same reason G is to H as B is to D. Therefore the ratio of A to C will also be greater than that of B to D; and by alternation, again by Theorem 10 of the scholium to Proposition 22 of Book 7, the ratio of A to B will also be greater than that of C to D. Which was to be shown.

But if the multiple of the first is smaller than the multiple of the second, while the multiple of the third is not smaller than the multiple of the fourth, then the ratio of the first to the second will be smaller than the ratio of the third to the fourth.

E, 28	A, 4	C, 3	F, 21
G, 30	B, 3	D, 2	H, 20

For the demonstration is entirely the same, provided that throughout one says "smaller ratio" in place of "greater ratio," with nothing else changed. This is evident in the present example, where the four numbers are A, B, C, D, and E, the multiple of the first A, is smaller than G, the multiple of the second B, while F, the multiple of the third C, is not smaller than H, the multiple of the fourth, and so on.

But let us now demonstrate that in magnitudes which are incommensurable with others, and which are proportional by Definition 6, one can generally find a ratio that can be exhibited in numbers—so that magnitudes to which Definition 6 applies are truly proportional, since from magnitudes taken as proportional in that sense a true conclusion follows, and nothing absurd can be inferred from it. This too we undertook a little earlier to demonstrate. Let AB, for example, be double the line CD, and on these lines let the squares ABEF and CDGH be described, with diagonals BF and DH.

Diagram. Two squares are drawn side by side, each with a single diagonal. The larger square on the left is set on side AB; the smaller square on the right on side CD.

- F (top-left of the larger square): vertex; the printed glyph is faint, resembling "T" [?]
- E (top-right of the larger square): vertex

- A (bottom-left of the larger square): vertex; the base A–B is labeled 4
- B (bottom-right of the larger square): vertex
- Diagonal from B to F is labeled **R. 32** (the square root of 32)
- H (top-left of the smaller square): vertex
- G (top-right of the smaller square): vertex
- C (bottom-left of the smaller square): vertex; the base C–D is labeled 2
- D (bottom-right of the smaller square): vertex
- Diagonal from D to H is labeled **R. 8** (the square root of 8)

Now, by the scholium to Proposition 47 of Book 1, the square on the diagonal BF is double the square on the side AB (that is, double the square ABEF), and likewise the square on the diagonal DH is double the square on the side CD (that is, double the square CDGH). So if the side AB is set at 4 and the side CD at 2, the square ABEF will be 16, and the square on the diagonal BF, its double, will be 32. Hence the diagonal BF itself will be the square root of the number 32 [*radix quadrata*], which cannot be expressed in numbers, since it is greater than 5 and less than 6, and no number intermediate between 5 and 6—that is, a number composed of 5 and some fraction of a unit—can, when multiplied by itself, produce the whole number 32, as will become clear from the following lemma. The square CDGH will be 4, and the square on the diagonal DH, its double, will be 8; hence the diagonal DH itself will be the square root of the number 8, which likewise cannot be expressed in numbers, since it is greater than 2 and less than 3, and so on. Thus the ratio both of AB to BF and of CD to DH is irrational, and therefore the diagonal BF is incommensurable [*incommensurabilis*] with the side AB, and the diagonal DH with the side CD. You see, then, that what Euclid demonstrated in the last proposition of Book 10—from what was proved in Book 6 about proportional magnitudes by Definition 6 of this Book 5—namely that the diagonal of a square is incommensurable with the side of that same square, is in fact perfectly true; for we ourselves have here shown the same thing by another route, without ratios.

Again: since the diagonals BF and DH bisect the right angles of the squares—as we showed in the scholium to Proposition 34 of Book 1 and in Corollary 2 to Proposition 4 of Book 2—the angles ABF, AFB, CDH, and CHD will be half right angles, and therefore equal to one another. And since the right angles at A and C are likewise equal, the triangles ABF and CDH will be equiangular. Therefore [Margin: (a) *Elements* VI.4 ("4. sexti")] AB will be to BF as CD is to DH; and by alternation, AB will be to CD as BF is to DH. But the line AB was posited as double CD; therefore BF too will be double DH.

And so, since by Definition 6 of this book we have been led to believe that the diagonal BF is double the diagonal DH—even though each diagonal has an irrational ratio to its own side—let us see whether we can learn by another route that the diagonal BF really is double the diagonal DH, as was concluded from Definition 6, by this very fact, that the side AB is posited as double the side CD, even though the ratio both of the side AB to the diagonal BF and of the side CD to the diagonal DH is irrational. (For Proposition 4 of Book 6, by which we showed that AB is to BF as CD is to DH, depends on Proposition 2, and this on Proposition 1 of that same Book 6; and the first proposition of Book 6 derives its force from Definition 6 of this Book 5. Likewise the alternation of ratio, which we have also used here, cannot be demonstrated for incommensurable magnitudes without that same Definition 6, as is clear from Proposition 16 of Book 5.)

This we shall easily learn, without ratios, as follows. Since the side AB is double the side CD, by the scholium to Proposition 4 of Book 2 the square AE will be quadruple the square CG. So if the square AE is set at 4, the square CG will be 1. And since the square on the diagonal BF is double the square AE, and the square on the diagonal DH double the square CG—by the scholium to Proposition 47 of Book 1—the square on the diagonal BF will be 8 and the square on the diagonal DH will be 2; and therefore the former will be quadruple the latter. Hence, by the scholium to Proposition 4 of Book 2, the line BF will be double the line DH. You see, then, once again, that if we proceed by what has been demonstrated from Definition 6 of this book concerning proportional magnitudes, we have arrived at a true conclusion—namely that the diagonals of two squares have a double ratio (2 : 1) to each other whenever the side of one is double the side of the other. So there is no doubt that magnitudes whose equimultiples fulfill the condition prescribed by Definition 6 are truly proportional.

Moreover, from the rules for irrational numbers taught in algebra it is also established that the diagonal BF—that is, $\sqrt{32}$ —has a double ratio to the diagonal DH, that is, to $\sqrt{8}$. For whether $\sqrt{32}$ is divided by $\sqrt{8}$, giving a quotient of $\sqrt{4}$ (that is, the number 2, which names the ratio of the diagonal BF to the diagonal DH), or $\sqrt{8}$ is multiplied by 2, the result is $\sqrt{32}$. And in this way everything that is demonstrated from Definition 6 of this book concerning the ratios of incommensurable magnitudes can be explained through the rules of irrational numbers. This furnishes a further argument that the magnitudes to which Definition 6 of this book applies are truly proportional; for the calculus of irrational numbers is found to agree perpetually with the demonstrations that depend on that definition—as is very well known to those versed in the precepts of algebra.

LEMMA.

That no number composed of 5 and some fraction of a unit—however far the unit be divided—can generate the whole number 32, we shall demonstrate easily as follows.

Let there be the number 5 together with any fraction, $\frac{3}{7}$, thus: $5\frac{3}{7}$; and let it be reduced, as we taught in the *Arithmetic*, to this single fraction, $\frac{38}{7}$. Now it is certain that the denominator 7 does not measure the numerator 38; otherwise, on dividing 38 by 7, an integer without a fraction would result, which is contrary to the hypothesis. Let the fraction $\frac{38}{7}$ now be multiplied by itself (which is done, as we said in the *Arithmetic*, by multiplying both the numerator 38 by itself and the denominator 7 by itself), and let the fraction $\frac{1444}{49}$ be generated, so that its numerator 1444 is the square of that numerator 38, and its denominator 49 the square of the denominator 7. And since the root 7 does not measure the root 38, as we showed, [Margin: (a) *Elements* VIII.16 ("16. Octaui")] the square 49 will likewise not measure the square 1444. Therefore, on dividing the square 1444 by the square 49, the quotient will not be a whole number, but some fraction will cling to it; otherwise the square 49 would measure the square 1444, the contrary of which we have demonstrated. And by the same reasoning it will be shown that any whole number together with any fraction, multiplied into itself, generates a whole number together with a fraction. But if a fraction whose numerator is smaller than its denominator is multiplied by itself, there will always be produced a fraction whose numerator is likewise smaller than its denominator. For since the numerator of the product-fraction is the square number of the numerator of the given fraction, and the denominator the square number of the denominator, then if the numerator of the given fraction is smaller than its denominator, its square number will also be smaller than the square of the latter. Thus from $\frac{2}{3}$ multiplied by itself there is generated

the broken number $\frac{4}{9}$, whose numerator is smaller than its denominator. And so any fraction multiplied by itself generates a number that is not whole—except when the numerator of the given fraction is measured by the denominator, in which case that fraction is rather a whole number: such as the fraction $\frac{20}{5}$, which constitutes 4 whole units.

IX.

A proportion consists, at the very fewest, in three terms.

For since every analogy or proportionality—which the translator, as has been said, calls a "proportion"—is a likeness of two or more ratios, and since every

ratio has both an antecedent and a consequent term, it is necessary that in every proportionality there be found, at the least, two antecedent terms and two consequent terms. Hence, if the proportionality is discontinuous, at least four terms (or magnitudes) will be required; but if it is continuous, there will be at the fewest three terms, since the middle term is taken twice—being the consequent of one ratio and the antecedent of the other. And this is the smallest number of terms of a proportionality. For in any two terms whatever, only a ratio is found, not a proportionality.

Diagram. A set of vertical line-segments in two groups, illustrating the fewest terms of a proportionality: a discontinuous proportion on the left (four terms) and a continuous proportion on the right (three terms, the middle taken twice). The small numerals printed at the tops of the segments are hard to resolve at native resolution; the clearly legible ones are given, the rest flagged. (≥ 3 uncertain labels).*

- Left group, labeled **A, B, C, D** (a discontinuous proportion, four terms): heights read as $A = 12$, $B = 9$, $C = 4$, $D = [\text{numeral: ?}]$ (short segment; glyph resembles "1" or "3")
- Right group, labeled **E, F, G** (a continuous proportion, three terms): heights read as $E = 16$, $F = 8$, $G = 4$

X.

When three magnitudes are proportional, the first is said to have to the third the *duplicate* ratio of that which it has to the second. And when four magnitudes are proportional, the first is said to have to the fourth the *triplicate* ratio of that which it has to the second. And so on continually, one more each time, as long as the proportion continues.

Diagram. Five vertical line-segments of decreasing height, labeled left to right, illustrating five magnitudes in continued proportion (common ratio 2 : 3).

- A: height **81**
- B: height **54**
- C: height **36**
- D: height [numeral: ?] (glyph ambiguous, resembling "74"; the continued proportion 81, 54, 36, __, 16 of ratio 2 : 3 requires **24**)
- E: height **16** (the base letter is faint, resembling "I" [?])

For example, let there be magnitudes A, B, C, D, E in continued proportion, so that A is to B as B is to C, as C is to D, and as D is to E. The ratio of A, the first

magnitude, to C, the third, is called the duplicate of the ratio that A, the first magnitude, has to B, the second; because between A and C two ratios are set, each equal to the ratio of A to B—namely the ratio of A to B and that of B to C—so that the ratio of A to C in a way encompasses the ratio of A to B taken twice, that is, set out twice in order. But the ratio of A, the first magnitude, to D, the fourth, is called the triplicate of the ratio that A, the first magnitude, has to B, the second; because between A and D three ratios are found, each equal to the ratio of A to B—namely the ratios of A to B, of B to C, and of C to D—and therefore the ratio of A to D in a way includes the ratio of A to B taken three times, that is, set out three times in order. Likewise the ratio of A to E is called the quadruplicate of the ratio of A to B, because four ratios are interposed between A and E, each equal to the ratio of A to B, and so on.

But if, conversely, E is to D as D is to C, as C is to B, and as B is to A, then the ratio of E to C will be called the duplicate of the ratio of E to D; the ratio of E to B will be called the triplicate of the ratio of E to D; and likewise the ratio of E to A will be called the quadruplicate of the ratio of E to D, and so on.

Some commentators infer from this definition that, if several quantities in continued proportion are set out, the ratio of the first quantity to the third is *double* the ratio of the first quantity to the second, on the ground that Euclid calls it the *duplicate* ratio of the latter. In the same way they hold that the ratio of the first quantity to the fourth is *triple* the ratio that the first quantity has to the second, and so on. This, however, is in no way to be granted. For Euclid did not mean this; he taught only that the ratio of the first quantity to the third is *called* the duplicate of the ratio that the first quantity has to the second, because between the first and the third quantity there is found, as it were, the ratio of the first quantity to the second taken twice—since between the first quantity and the third are interposed two ratios equal to the ratio that the first quantity has to the second—and so on for the rest, as we have said. But he does not understand the one to be double the other; otherwise he would be proposing a theorem that anyone might rightly refuse to grant. For who will assert that, among these numbers in continued proportion—25, 5, 1—the ratio of 25 to 1 is double the ratio of 25 to 5, when one would rather call it quintuple? Yet no one will deny that the former is called the duplicate of the latter in the sense explained, because the ratio of 25 to 5 is set down twice and continuously. Again, how will the ratio of 1 to 25 be double the ratio of 1 to 5, when the former is smaller and the latter greater? For by Proposition 8 of this book, the quantity 1 has a greater ratio to the quantity 5 than to the quantity 25, because 25 is greater than 5. Yet the former will be called the duplicate of the latter, for the reason already explained, even

though it is a fifth part of it. Therefore, although the ratio of 25 to 1 is called the duplicate of the quintuple ratio, it is nevertheless the tenfold ratio that is the double of that same ratio. Just as the octuple ratio, likewise, is the double of the quadruple ratio, while nonetheless the duplicate of the quadruple is the sixteenfold ratio, as is evident here: 16, 4, 1. Finally, among three equal magnitudes, or among three equal numbers—4, 4, 4—and hence in continued proportion, how can the ratio of the first to the third be double the ratio of the first to the second, when it is entirely the same? Yet the one will be called the duplicate of the other, because the latter is set down twice in order, continuously, between the first number and the third.

But those authors who insist that the ratio of the first quantity to the third is the *double* of the ratio which the first quantity has to the second — among whom, in this passage, is also Federico Commandino [Federicus Commandinus], which greatly astonishes me, since he is otherwise a most excellent mathematician — say that this definition requires unequal terms, and that the first must be the greater; so that the definition must necessarily be understood of a continued proportion of the greater inequality [proportio maioris inæqualitatis]. Hence, they say, it is no wonder that the ratio 1 to 25 is not the double of the ratio 1 to 5, nor the ratio 4 to 4 the double of the ratio 4 to 4. But this interpretation is not merely untrue; it runs directly counter to Euclid, who in very many places assumes that a triplicate ratio is found in a proportion of the lesser inequality [proportio minoris inæqualitatis]. The clearest instance — to pass over the others — is Proposition 12 of Book 12, where he proves that similar cones and cylinders are in the triplicate ratio of the diameters of their bases. For if the greater cone or cylinder is compared with the smaller, then in the second part of that demonstration Euclid necessarily assumes it to have been proved, in Proposition 8 of the same Book 12, that similar pyramids — even when the smaller is compared with the greater — are in the triplicate ratio of their homologous sides, as we noted in that place. Add to this that the propositions in which certain figures are shown to have the duplicate or triplicate ratio of their homologous sides — such as 19 and 20 of Book 6, and 11, 12, 18, 19 of Book 8, and 33 of Book 11, and 12 and 18 of Book 12 — would not be universal if they were to be understood only of the greater inequality. This definition, then, must be explained as we have explained it.

And so in this passage Euclid only explains what is to be understood by the name of duplicate, triplicate ratio, and so on, so that the demonstrations of the following books may be grasped and applied to material things. He does not, however, determine which ratio is the double, triple, or quadruple of another.

For example: since it is established from Proposition 20 of Book 6 that the ratio of a square to a square is the duplicate of the ratio which the side of the former square has to the side of the latter, it will follow that, if the ratio of the sides is continued through three terms, the ratio of square to square is the same as the ratio of the first term to the third. Thus, if the side of the former square is three spans and that of the latter one span, the former square will have to the latter the ratio 9 to 1, so that it contains the latter nine times. For the ratio 9 to 1, which is ninefold, is called by this definition the duplicate of the triple ratio 9 to 3, or 3 to 1, as is plain in these numbers 9. 3. 1. But we must not infer that the ratio of square to square is twice as great as the ratio of side to side. Likewise the latter square will have to the former the ratio 1 to 9, so that it is a ninth part of it, because the ratio 1 to 9 is called the duplicate of the ratio 1 to 3, as is evident in these same numbers 1. 3. 9. By the same reasoning, since in the last proposition of Book 12 it is demonstrated that spheres have to one another the triplicate ratio of their diameters, it will follow that a sphere whose diameter contains three spans has to a sphere whose diameter is one span only the ratio 27 to 1. For this is called the triplicate of the triple ratio, as appears here: 27. 9. 3. 1. And so, given two spheres whose diameters have a tenfold ratio, the spheres themselves will have a thousandfold ratio, since this is the triplicate of the tenfold, as is clear here: 1000. 100. 10. 1. But who would ever say that a thousandfold ratio is only three times greater than a tenfold ratio, rather than that a thirtyfold ratio is the triple of a tenfold?

Furthermore, given any rational ratio, if its denominator [denominator] is multiplied into itself, there results the denominator of the ratio that is called the duplicate of the given ratio. For example, since from multiplying 4 — the denominator of the quadruple ratio — into itself there is produced 16, the sixteenfold ratio is called the duplicate of the quadruple ratio, as is seen here: 16. 4. 1; and likewise here: 48. 12. 3. Conversely, since from multiplying $\frac{1}{4}$ — the denominator of the one-fourth ratio [proportio subquadrupla] — into itself there is produced $\frac{1}{16}$, the one-sixteenth ratio [subsedecupla] is called the duplicate of the one-fourth ratio. And if the denominator is again multiplied into that product, the denominator of the triplicate ratio will be produced. So, in the former example, from multiplying 4 into 16 there are produced 64, the denominator of the ratio which, being quadruple, is called triplicate, as you see here: 64. 16. 4. 1; and likewise here: 192. 48. 12. 3. Again, if the same denominator is multiplied into this latter product, the denominator of the quadruplicate ratio will be found; and so on for the rest.

Thus the denominator of a duplicate ratio is produced from the denominator of the given ratio set down twice and multiplied in this way. For instance, the number denominating the duplicate of the triple ratio is produced from 3, the denominator of the triple ratio, set down twice, in this manner 3. 3., and so multiplied: for three times three make 9, the denominator of the ninefold ratio, which is called the duplicate of the triple, as can be seen here: 9. 3. 1; and likewise here: 18. 6. 2. But the denominator of a triplicate ratio is generated from the denominator of the given ratio set down three times and multiplied thus. As in the given example, the denominator of the triplicate ratio, namely 27, is produced from 3 set down three times, thus 3. 3. 3., and so multiplied, by saying "three times three, three times over," and so on. In the same way a quadruplicate ratio will arise from the denominator set down four times, a quintuplicate from the same set down five times and multiplied likewise, and so forth.

And so the duplication, triplication, quadruplication, and the like, of any ratio treated of in this definition is nothing else than the multiplication of the denominators of the intermediate ratios among themselves. For from this multiplication is produced the denominator of the ratio which the extreme terms have to one another; and this ratio is therefore called the duplicate, triplicate, or quadruplicate of that ratio whose denominator has been multiplied — according as the denominator has been set down twice, three times, or four times, and so multiplied, as we have explained. For example, given these four numbers in continued proportion in the quadruple ratio, the first, 192, has to the fourth, 3, a ratio denominating by 64, which is called the triplicate of the quadruple ratio; because the denominator 64 of the ratio of the extremes 192 and 3 is produced from the denominator 4 of the quadruple ratio set down three times — on account of the three quadruple ratios interposed between the extremes — and multiplied thus, by saying "four times four are 16, and four times 16 are 64."

Denominatores [Denominators]	4	4	4	
Num. propor. [Numbers in proportion]	192	48	12	3

Likewise, with the same numbers inverted, so that they stand in continued proportion in the one-fourth ratio, the first, 3, has to the fourth, 192, a ratio denominating by $1/64$, which is called the triplicate of the one-fourth ratio; because the denominator $1/64$ of the ratio of the first number 3 to the fourth 192 is produced from the denominator $1/4$ of the one-fourth ratio set down three times and so multiplied, on account of the three one-fourth ratios interposed between the extremes. For $1/4$ into $1/4$ makes $1/16$, and $1/16$ into $1/4$ makes $1/64$.

Denominatores [Denominators]	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	
Num. proport. [Numbers in proportion]	3	12	48	192

There is therefore nothing to prevent the ratio 3 to 192, denominated by $\frac{1}{64}$, from being called the triplicate of the one-fourth ratio 3 to 12, even though it is smaller than the latter: because the denominator $\frac{1}{64}$ has been produced from the denominator $\frac{1}{4}$ set down three times and so multiplied, as we have said. Yet the ratio 3 to 192, denominated by $\frac{1}{64}$, cannot be said to be *three times greater* than the one-fourth ratio 3 to 12, because the denominator $\frac{1}{4}$ tripled does not make the denominator $\frac{1}{64}$, but $\frac{3}{4}$; and so the ratio is sub-

—sesquitercian, the triple of the one-fourth ratio [subquadrupla]. Just so, again, it is not the ratio denominated by 64, but rather the twelvefold ratio, that is the triple of the quadruple ratio; because the denominator 4 tripled does not produce the denominator 64, but 12. Moreover, when any number of proportional numbers are continued — whether the greater are compared with the less, or the less with the greater — the denominator of the ratio of the first to the last is generated from the denominators of the intermediate ratios multiplied among themselves, as we shall demonstrate at Definition 5 of Book 6. And that one ratio is at last the double, triple, and so forth, of another, when the denominator of the one is the double, triple, etc., of the denominator of the other — so that the tenfold ratio is the double of the fivefold, and the sixfold the triple of the double — we shall show at the end of Book 9; and this subject has been treated at length by Rodolfo Volumnio [Rodolphus Volumnius] in his *Disputation on the Proportion of Proportions* [*Disputatio de proportionibus proportionum*]. For now let it suffice to confirm this very point by the common judgment of mankind, drawn from sensible things.

Suppose, then, that some Agent [Agens] has to a Patient [Patiens] a tenfold ratio, say, so that the Agent is 10 and the Patient 1. Who would be so out of his senses as not to grasp at once that, if the same Agent is increased so as to become 20 while the Patient remains 1, the Agent then has twice the power with respect to the same Patient as before? So the twentyfold ratio, whose denominator 20 is the double of the denominator 10, is the double of the tenfold ratio — but not the hundredfold ratio, as the authors of the contrary opinion would have it. Nevertheless this hundredfold ratio is called the duplicate of the tenfold, on account of the multiplication of the denominator 10 into itself, and on account of the two tenfold ratios interposed between the numbers that have the hundredfold ratio, as appears here: 100. 10. 1. Likewise, on the contrary, suppose some Agent has to a Patient, say, a one-tenth ratio [subdecupla], so that the Agent

is 1 and the Patient 10. Who is so dull and unschooled as not to understand that an Agent which becomes 2 is twice as powerful with respect to the same Patient 10 as an Agent of 1? Since, then, the Agent 2 has to the Patient 10 a one-fifth ratio [subquintupla], whose denominator $1/5$ (or $2/10$) is compounded from the denominator $1/10$ taken twice, the one-fifth ratio will indeed be the double of the one-tenth ratio — not the one that is one-hundredth [subcentupla], as the aforesaid authors would have it, since this last is far smaller than the one-tenth. Yet the one-hundredth ratio will be called the duplicate of the one-tenth ratio, for the reason often explained, as appears here: 1. 10. 100.

From what we have said, it can be gathered without obscurity that a ratio of two quantities between which no mean is interposed shares, in a manner, the nature of a line, since it is produced from no other ratio; that a ratio whose quantities enclose a single mean in continued proportionality has the character of a square surface, since it is generated from two equal ratios, just as a square is formed from two equal lines; and finally that a ratio between whose quantities two means in continued proportionality are interposed takes on the nature of a solid, indeed of a cube, since it arises from three equal ratios, just as a cube too is raised from three equal lines. But on these matters you will find more in the arithmeticians who have expounded the rule of algebra [Algebræ regula].

XI.

Homologous [homologæ], or similar-in-ratio, magnitudes are called: the antecedents to the antecedents, and the consequents to the consequents.

He defined proportionality above as a similarity of ratios. Now he teaches that not only in any proportionality are the ratios said to be similar, but that the terms themselves — the quantities — are also called similar, or homologous. He says that the antecedent magnitudes are called homologous, or similar in ratio, to one another, and likewise the consequents to one another, so that in very many demonstrations we may understand which sides of the figures, compared with one another, ought to be the antecedents of the ratios and which the consequents — as will become clear in Book 6. If, then, there is the ratio A to B which is C to D, the quantity A will be called similar to the quantity C, and B similar to D. For, on account of the similarity of the ratios, each antecedent magnitude must be either equal to each consequent, or greater, or smaller, in the same manner; otherwise each antecedent would not have the same ratio to each consequent. You have an example in the magnitudes set out, in which the antecedents are greater than the consequents in the same way — namely half as large again. Another example you see in the magnitudes E, F, G in continued proportion, where E and F are

homologous just as F and G are, as is plain. And it is for this reason that Euclid, in Definitions 6 and 8, directed that equimultiples be taken of the first and third magnitudes — that is, of the antecedents — and other equimultiples of the second and fourth magnitudes, namely the consequents. For these are similar in proportional magnitudes, as is clear from this definition, but dissimilar in magnitudes that are not proportional.

Diagram. A row of vertical line-segments standing on a common baseline, illustrating the homologous magnitudes of Definition XI. The four leftmost segments carry a numeral above each and a letter beneath:

- A: line of magnitude 9 (an antecedent)
- B: line of magnitude 6 (a consequent)
- C: line of magnitude 12 (an antecedent)
- D: line of magnitude 8 (a consequent)

Here $A : B = 9 : 6$ and $C : D = 12 : 8$, each ratio being $3 : 2$ (the antecedent half as large again as its consequent), so A and C are homologous antecedents, B and D homologous consequents. To the right stand three further segments, labelled E, F, G at their feet, drawn in continued proportion and marked with short internal cross-strokes; no numerals are printed on them [numeral: none printed].

Oronce Finé [Orontius] and some other interpreters explain this definition quite differently. For they suppose that Euclid means to teach that, among proportional magnitudes, both the antecedent magnitudes and the consequents can be compared with one another in various ways — as will appear in the following definitions. But if the words of the definition are weighed more carefully, and its use in Book 6 is considered, no one will doubt that our exposition is to be preferred to this one.

XII.

An alternate ratio [alterna ratio] is the taking of antecedent to antecedent, and of consequent to consequent.

Here he explains certain modes of arguing about ratios, whose use among geometers is most frequent. These are six in number. The first is called the alternate or permuted ratio [proportio alterna, siue permutata]. The second, the inverse, or ratio by contraries [inversa, seu proportio è contrario]. The third, composition of the ratio, or conjunct proportionality [compositio rationis, seu coniuncta proportionalitas]. The fourth, division of the ratio, or disjunct proportionality [diuisio rationis, vel disiuncta proportionalitas]. The fifth,

conversion of the ratio, or inverted proportionality [conuersio rationis, siue euersa proportionalitas]. The sixth, finally, is called the ratio from equality, or equal proportion [proportio ex æqualitate, seu æqua proportio]. The alternate, or permuted, ratio, then, he says, occurs when, four proportional magnitudes being given, it is inferred that the ratio of the antecedent of the first proportion to the antecedent of the second is the same as the ratio which the consequent of the first has to the consequent of the second. Thus, if we suppose the ratio A to B which is C to D, and therefore conclude that the ratio A to C is the same as the ratio B to D, we shall be said to argue from a permuted ratio. Greek writers, in this kind of argument, use more or less this manner of speaking: As A is to B, so C is to D; therefore, alternately, or by exchange [permutando, seu vicissim], there will also be,

—there will also be, as A to C, so B to D. That such an inference is sound will be demonstrated at Proposition 16 of this book. However, in this mode of arguing it is necessary that all four magnitudes be of the same kind, so that a ratio may hold between any two of them taken together. For this is not correctly inferred: "As line A is to line B, so number C is to number D; therefore, alternately, as line A is to number C, so line B is to number D" — since there is no ratio of a line to a number, or conversely, as is evident from Definition 5. In the other modes of arguing that follow, however, the former magnitudes may be of one kind of magnitude and the latter of another kind, as will be established from the demonstrations of this Book 5.

Diagram. Four vertical line-segments standing on a common baseline, illustrating the alternate ratio of Definition XII. Each carries a numeral above and a letter beneath:

- A: line of magnitude 18
- B: line of magnitude 15
- C: line of magnitude 12
- D: line of magnitude 10

Here $A : B = 18 : 15 = C : D = 12 : 10$ (each $6 : 5$); alternately, $A : C = 18 : 12 = B : D = 15 : 10$ (each $3 : 2$), as the text states.

XIII.

An inverse ratio [inuersa ratio] is the taking of the consequent, as antecedent, to the antecedent, as consequent.

For instance, if from the fact that A is to B as C is to D we infer that B is to A as D is to C — that is, if we refer the consequents to the antecedents — we shall be said to argue from an inverse ratio. In this argument the authors speak more or less thus: As A is to B, so C is to D; therefore, by conversion, or by contraries [conuertendo, vel è contrario], B will also be to A as D is to C. That this mode of arguing is sound will be shown in the corollary to Proposition 4 of this book. Moreover, the two former magnitudes may be of one kind and the latter of another. For it will be correct to infer: as line A is to line B, so is triangle (or number) C to triangle (or number) D; therefore, inverting, as line B is to line A, so is triangle (or number) D to triangle (or number) C, as will be established from the corollary to Proposition 4.

Diagram. Four vertical line-segments standing on a common baseline, illustrating the inverse ratio of Definition XIII. Each carries a numeral above and a letter beneath:

- A: line of magnitude 9
- B: line of magnitude 6
- C: line of magnitude 12
- D: line of magnitude 8

Here $A : B = 9 : 6 = C : D = 12 : 8$; inversely, $B : A = 6 : 9 = D : C = 8 : 12$.

XIV.

Composition of a ratio [compositio rationis] is the taking of the antecedent together with the consequent, as one, to the consequent itself.

Let there be the ratio AB to BC, which is DE to EF. If from this it is gathered that the ratio of the whole AC — namely, of the antecedent together with the consequent — to BC, the consequent, is the same as the ratio which the whole DF — the antecedent, again, together with the consequent — has to EF, the consequent, then such an argument will be called composition of the ratio, because from the antecedent and the consequent another, new antecedent is compounded. This manner of speaking you will find among Greek writers in this argument: As AB is to BC, so DE is to EF; therefore, by composition [componendo], AC will also be to BC as DF is to EF. This mode of arguing will be demonstrated in Proposition 18 of this book.

To this mode of arguing by composition of the ratio, two others can be added. The first may be called the *converse* composition of the ratio: that is, when the antecedent and the consequent are taken as one, which is then compared with

the antecedent. Thus, if it is "as AB is to BC, so DE is to EF," we infer: therefore, as AC, formed from the antecedent and the consequent, is to the antecedent AB, so is DF, composed from the antecedent and the consequent, to the antecedent DE. That this argument is valid we shall demonstrate at Proposition 18 of this book; and in it we may use this manner of speaking: "therefore, by converse composition of the ratio." The other may be called the *contrary* composition of the ratio: that is, when the same antecedent magnitude is referred to the antecedent and the consequent taken as one. Thus, if it is "as AB is to BC, so DE is to EF," we infer, by contrary composition of the ratio: therefore, as AB, the antecedent, is to the whole AC, composed of the antecedent and the consequent, so is DE, the antecedent, to DF, composed of the antecedent and the consequent. And that this argumentative formula is valid we shall show at Proposition 18 of this book.

Diagram. Two horizontal line-segments, one above the other, illustrating the composition of Definition XIV. The upper line runs from A through B to C, divided at B; the lower from D through E to F, divided at E:

- Upper line — A to B: 12; B to C: 8 (whole AC = 20)
- Lower line — D to E: 6; E to F: 4 (whole DF = 10)

Here $AB : BC = 12 : 8 = DE : EF = 6 : 4$ (each 3 : 2); by composition, $AC : BC = 20 : 8 = DF : EF = 10 : 4$ (each 5 : 2).

XV.

Division of a ratio [diuisio rationis] is the taking of the excess by which the antecedent surpasses the consequent, to the consequent itself.

For instance, if it is said that the ratio of the whole AB to CB is the same as that of the whole DE to FE, then AC — the excess by which the antecedent surpasses the consequent — will be to CB, the consequent, as DF — the excess by which the antecedent exceeds the consequent — is to FE, the consequent. In this division of the ratio the authors speak thus: therefore, by division [diuidendo], and so on. This inference will be shown at Proposition 17 of this book.

To this mode of arguing two others can also be joined. The first we may call the *converse* division of the ratio: that is, when the consequent is referred to the excess by which the antecedent surpasses the consequent. Thus, if it is "as AB is to CB, so DE is to FE,"

Diagram. Two horizontal line-segments, one above the other, illustrating the division of Definition XV. The upper line runs from A through C to B, divided at C; the lower from D through F to E, divided at F:

- Upper line — A to C: 12; C to B: 4 (whole AB = 16)
- Lower line — D to F: 6; F to E: 2 (whole DE = 8)

Here $AB : CB = 16 : 4 = DE : FE = 8 : 2$ (each 4 : 1); by division, $AC : CB = 12 : 4 = DF : FE = 6 : 2$ (each 3 : 1).

so is DE to FE — we conclude, by the *converse* division of the ratio. Therefore it will be: as CB, the consequent, is to AC, the excess by which the antecedent surpasses the consequent, so is FE, the consequent, to DF, the excess by which the antecedent surpasses the consequent. That this line of argument holds good we shall show at Proposition 17 of this book.

It is clear that, for both of these arguments by division of a ratio to hold — Euclid's as well as our own — the antecedent must be greater than the consequent; otherwise the division could not be carried out.

The other mode may be called the *contrary* division of a ratio: namely, when the antecedent is compared with the excess by which the consequent surpasses the antecedent. As when we say: AC is to AB as DF is to DE. Then also, by the contrary division of the ratio, it will be: as AC, the antecedent, is to CB, the excess by which the consequent surpasses the antecedent, so is DF, the antecedent, to FE, the excess by which the consequent surpasses the antecedent. This mode of arguing too we shall demonstrate at Proposition 17 of this book.

Moreover it is evident that in this contrary division of a ratio the consequent must be greater than the antecedent, so that the excess by which the consequent surpasses the antecedent can be taken.

XVI.

Conversion of a ratio is the taking of the antecedent to the excess by which the antecedent surpasses the consequent itself.

Diagram. Two stacked horizontal number-lines illustrating conversion of a ratio, subdivided by tick marks.

- Upper line: A (left end) — C (dividing point) — B (right end). The segment CB is marked 4; the segment AC carries a small numeral I cannot resolve, [numeral: ?].
- Lower line: D (left end) — F (dividing point) — E (right end). The segment DF is marked 12; the segment FE is marked 8.

We conclude in this way: as the whole magnitude AB is to CB, so is the whole DE to FE; therefore this same AB will also be to AC — the excess by which the antecedent surpasses the consequent — as DE is to DF. We shall be said to argue by conversion of the ratio; and this is roughly how the writers put it: "Therefore, by conversion of the ratio, and so on." This mode of arguing will be confirmed in the corollary to Proposition 19 of this book.

It is likewise plain that in this mode of arguing by conversion of a ratio the antecedent must surpass the consequent, so that the excess by which the antecedent surpasses the consequent can be taken.

XVII.

There is a ratio *ex aequali* when there are more than two magnitudes, and another set equal to them in number, taken two by two and in the same ratio, such that, as among the first magnitudes the first is to the last, so among the second magnitudes the first is to the last.

Or otherwise: the taking of the extremes by the removal of the means.

Diagram. Six vertical bars of graded height, subdivided by tick marks, illustrating a ratio *ex aequali* in ordered arrangement. Reading left to right, each bar carries a numeral at its top and a letter at its foot:

- A: 18
- B: 12
- C: 6
- D: 12
- E: 8
- F: 4

(Here $A : B = D : E = 3 : 2$, and $B : C = E : F = 2 : 1$, so that $A : C = D : F = 3 : 1$.)

Let there be several magnitudes, more than two — A, B, C — and just as many, D, E, F, in the same proportion two by two: that is, A is to B as D is to E, and B is to C as E is to F. If, then, it is inferred that on this account the proportion of A to C — the first to the last among the first magnitudes — is the same as that of D to F — the first to the last among the second magnitudes — this form of argument will be said to be taken *ex aequo*, or from equality: that is, one in which the extreme magnitudes, once the means have been removed, are found to have one and the same proportion between themselves, as is expressed in the other definition. And since one may argue *ex aequali* in proportions in two ways — the one when we take the magnitudes two by two in the same proportion, proceeding in order, the

other when the order is inverted — Euclid explains in the two following definitions what ordinate proportion is, and what perturbed proportion is.

XVIII.

Ordinate proportion is when, as an antecedent is to a consequent, so is an antecedent to a consequent; and further, as a consequent is to something else, so is a consequent to something else.

Diagram. Six vertical bars, subdivided by tick marks, illustrating ordinate proportion. Left to right, each with a top numeral and a foot letter:

- A: 12
- B: 6
- C: 4
- D: 6
- E: 3
- F: [numeral: ?] (the sixth numeral is damaged/illegible)

For example, when A is to B as D is to E; and again, as B, the consequent, is to something else, namely to C, so is E, the consequent, to F, something else — such a proportion will be called ordinate, because the same order is kept both in the first three magnitudes and in the second three, since in each set the first is first compared with the second, then the second with the third. When, therefore, ordinate proportion is preserved in a mode of arguing *ex aequali*, it is demonstrated at Proposition 22 of this book that the argument is sound.

XIX.

Perturbed proportion is when, three magnitudes being set out, and others equal to them in number, as in the first magnitudes the antecedent is to the consequent, so in the second magnitudes the antecedent is to the consequent; but as in the first magnitudes the consequent is to something else, so in the second magnitudes something else is to the antecedent.

Diagram. Six vertical bars, subdivided by tick marks, illustrating perturbed proportion. Left to right, each with a top numeral and a foot letter:

- A: 12
- B: 8
- C: 4

- D: 12
- E: 6
- F: 4

(Here $A : B = E : F = 3 : 2$, and $B : C = D : E = 2 : 1$.)

If it be that, as A is to B, so is E to F; and then, as in the first magnitudes B, the consequent, is to C, something else, so in the second magnitudes something else, D, is to E, the antecedent magnitude — such a proportion will be called perturbed, because the same order is not preserved in the proportions of the magnitudes. For in the first magnitudes the first is compared with the second, but in the second set the second with the third; and then in the first the second with the third, but in the second the first with the second. When, therefore, perturbed proportion is preserved in a mode of arguing *ex aequali*, it is demonstrated at Proposition 23 of this book that the argument is sound.

Moreover, both perturbed and ordinate proportion always yield, *ex aequali*, the same proportion of the extremes, even if more than three magnitudes are set out, as will become clear from Propositions 22 and 23 of this book.

The commentators on Euclid make use — in this book, and in others where the proportions of magnitudes are treated — of a certain axiom, which we judged it would not be useless to append here. It runs as follows.

Whatever proportion one magnitude has to another, any given magnitude will have the same to some other; and some other magnitude will have the same to any given magnitude.

Diagram. Five horizontal segments of unequal length, stacked, each marked off with a tick, illustrating the axiom of a fourth proportional. Top to bottom the segments are labelled A, B, C, D, and a fifth whose letter is imperfectly printed (it reads as an F; the commentary's fifth magnitude is E) [?].

For example, whatever proportion A has to B, the given magnitude C will have the same to some other, namely to D; likewise some other magnitude E will have the same to the given C. For although we may sometimes not know what that fourth magnitude is, there is nevertheless no doubt that it can exist in the nature of things, since this implies no contradiction — as the philosophers say — nor does anything absurd follow from it.

THEOR. 1. PROPOS. 1.

[Margin: j.]

If there be any number of magnitudes, each of them the same multiple of each one of an equal number of other magnitudes, then whatever multiple one magnitude is of one, the same multiple will all be of all.

Let there be any number of magnitudes AB, CD, equimultiples of as many magnitudes E, F. I say that AB and CD together are the same multiple of E and F together as AB is of E, or as CD is of F.

For since AB and CD are equimultiples of E and F, let AB be divided into the magnitudes AG, GH, HB equal to E, and CD likewise into the magnitudes CI, IK, KD equal to F. (Each can be divided into wholly equal parts, since AB and CD are equimultiples of E and F, so that E is contained exactly in AB as many times as F in CD, as is clear from what we wrote in Definition 2 of this book.) Then the magnitudes AG, GH, HB will be equal in number to the magnitudes CI, IK, KD. Now since AG and E are equal to each other, if the equals CI and F be added to them, [Margin: a — 2. *pron.* (the second common notion — "if equals be added to equals...")] AG and CI together will be equal to E and F together. In the same way GH and IK together will be equal to E and F together, and likewise HB and KD to the same E and F. Therefore, as many times as E is contained in AB, or F in CD, so many times are E and F together contained in AB and CD together. And so, whatever multiple AB is of E, the same multiple are AB and CD together of E and F together, as is clear from what we wrote in Definition 2 of this book. Therefore, if there be any number of magnitudes equimultiples of any number of others, and so on. Which was to be demonstrated.

Diagram. Horizontal segments illustrating Proposition 1. Two short reference segments are set at the top, labelled E and F. Below them: the magnitude AB, divided into three equal parts by the points A, G, H, B (so $AG = GH = HB = E$); and the magnitude CD, divided into three equal parts by the points C, I, K, D (so $CI = IK = KD = F$).

Scholium. This same result will be demonstrated in general at Proposition 12, for every kind of proportion, rational as well as irrational. But it was necessary to demonstrate it first here, in multiple proportion, because from it other propositions must be demonstrated before Proposition 12 can be proved.

THEOR. 2. PROPOS. 2.

[Margin: ij.]

If a first magnitude be the same multiple of a second as a third is of a fourth, and a fifth also be the same multiple of the second as a sixth is of

the fourth, then the sum of the first and the fifth will be the same multiple of the second as the sum of the third and the sixth is of the fourth.

Diagram. Horizontal segments illustrating Proposition 2. The magnitude AG is drawn as one line divided at B into AB and BG (points A, B, G); a short segment marks the magnitude C. Below, the magnitude DH is drawn divided at E into DE and EH (points D, E, H); a short segment marks the magnitude F.

Let the first magnitude AB be the same multiple of the second, C, as the third, DE, is of the fourth, F; and again, let BG, the fifth, be the same multiple of C, the second, as EH, the sixth, is of F, the fourth. I say that AB, the first, composed with the fifth BG — that is, the whole AG — is the same multiple of the second, C, as DE, the third, composed with the sixth EH — the whole DH — is of the fourth, F.

For since AB and DE are equimultiples of C and F, there will be in AB as many magnitudes equal to C as there are in DE equal to F. By the same reasoning, there will be in BG as many equal to C as there are in EH equal to F. If, then, to the equal multitudes AB, DE are added the equal multitudes BG, EH, the whole multitudes AG, DH will be equal in number. Therefore C is contained in AG as many times as F in DH; and so the whole AG (the first composed with the fifth) [print: AB] is the same multiple of C, the second, as DH (the third composed with the sixth) is of F, the fourth. If, then, a first magnitude be a multiple of a second, and so on. Which was to be shown.

Scholium. But if the first magnitude and the third be equal to the second and the fourth, while the fifth and sixth are equimultiples of the second and fourth; or if, on the other hand, the first and third be equimultiples of the second and fourth, while the fifth and sixth are equal to the second and fourth — then by the same reasoning the whole AG (the first and the fifth) will be the same multiple of the second, C, as the whole DH (the third and the sixth) is of the fourth, F. For AG, a multitude of magnitudes equal to C, will always be shown to be equal to DH, a multitude of magnitudes equal to F, as is clear in the accompanying figures. But if both the first and third, and the fifth and sixth, are supposed equal to the second and fourth, it is clearer than daylight that the first and fifth together, and the third and sixth together, are equimultiples — namely doubles — of the second and fourth magnitudes.

Diagram. The first of two figures accompanying the scholium. A tall bar for the composite AG, marked off at B (points A at top, B intermediate, G at foot); a short

bar **C**; a tall bar for the composite DH, marked off at E (points D at top, E intermediate, H at foot); and a short bar **F**.

Diagram. The second, companion figure of the scholium, of the same construction : a tall bar AG marked at B (points A, B, G); a short bar **C**; a tall bar DH marked at E (points D, E, H); a short bar **F** — illustrating the alternative case in which the divisions fall differently.

This too will be concluded by Euclid, for every kind of proportion in general, at Proposition 24; but it was worthwhile to demonstrate it first in multiple proportion, so that what follows may be demonstrated.

THEOR. 3. PROPOS. 3.

[Margin: iij.]

If a first magnitude be the same multiple of a second as a third is of a fourth, and equimultiples be taken of the first and third, then *ex aequo* each of the magnitudes taken will be the same multiple of each — the one of the second, the other of the fourth.

Diagram. Vertical bars illustrating Proposition 3. One bar for E, divided into three equal parts by the points E (foot), G, H, and I (top) [top letter I: ?]; a companion bar for F, divided into three equal parts by the points F (foot), K, L, and M (top). Beside them stand the four shorter bars for the magnitudes A, B, C, D. Foot letters, left to right: E, A, B, F, C, D.

Let the first magnitude A be the same multiple of the second, B, as C, the third, is of the fourth, D; and let E, F be taken as equimultiples of the first and third, A and C. I say that *ex aequo* E is the same multiple of B, the second, as F is of D, the fourth.

For since E and F are equimultiples of A and C, if E and F are distributed into magnitudes equal to A and C — namely into EG, GH, HI, and FK, KL, LM — there will be as many parts in E equal to A as there are in F equal to C. Now since EG, FK are equal to A and C, and A and C are, by hypothesis, equimultiples of B and D, EG and FK will also be equimultiples of the same B and D. By like reasoning, so will GH and KL; and likewise HI and LM will be equimultiples of the same B and D. Therefore, since EG, the first magnitude, is the same multiple of the second, B, as FK, the third, is of the fourth, D; and likewise GH, the fifth, is the same multiple of the same second, B, as KL, the sixth, is of the same fourth, D; [Margin: a — 2. *quinti* (Proposition 2 of Book V)] EH, composed of the first and the fifth, will be the same multiple of the second, B, as FL, composed of the third and the sixth, is of

the fourth, D. Again, since EH, the first, is the same multiple of the second, B, as FL, the third, is of the fourth, D — as was just demonstrated — and HI, the fifth, is the same multiple of the second, B, as LM, the sixth, is of the fourth, D; [Margin: b — 2. *quint.* (Proposition 2 of Book V)] EI, composed of the first and the fifth, will be the same multiple of the second, B, as FM, composed of the third and the sixth, is of the fourth, D. And the reasoning is the same if there are more parts in E and F. If, then, a first magnitude be the same multiple of a second as a third is of a fourth, and so on. Which was to be shown.

Scholium. This theorem will be shown at Proposition 22 not only for equimultiple magnitudes, but also for all that, taken two by two, have the same proportion, whether rational or irrational; yet it was necessary to demonstrate it first here, in multiple proportion, so that the following Proposition 4 may be demonstrated.

THEOR. 4. PROPOS. 4.

[Margin: iiij.]

If a first magnitude have the same ratio to a second as a third has to a fourth, then equimultiples of the first and third will also have, to equimultiples of the second and fourth — taken by any multiplication whatever — the same ratio, provided they are taken so as to correspond to one another.

Let the proportion of A to B be the same as that of C to D; and let E and F be taken as equimultiples of the first, A, and the third, C; likewise let G and H be equimultiples of the second, B, and the fourth, D, by any multiplication whatever — whether E, F be such multiples of...

the equimultiples of A and C, and likewise G and H the equimultiples of B and D — whether or not [these correspond]. Given this, it follows from definition 6 of this book that if E falls short of G, then F likewise falls short of H; if E is equal to G, then F is likewise equal to H; and finally, if E exceeds G, then F likewise exceeds H. Otherwise, by definition 6, the ratio of A to B would not be the same as that of C to D, if their equimultiples did not always behave in this way.

Now I say that the multiples of the first and third not only fall short of, together equal, or together exceed the multiples of the second and fourth — as we have said — but also have the same ratio to one another: that is, E, the multiple of the first A, is to G, the multiple of the second B, as F, the multiple of the third C, is to H, the multiple of the fourth D. That is to say: if again E is set as the first

magnitude, G as the second, F as the third, and H as the fourth, and if any equimultiples whatever of E and F are taken, and likewise any equimultiples of G and H, then the multiples of E and F will together fall short of, together equal, or together exceed the multiples of G and H — as definition 6 requires. For it is the same thing to say that four magnitudes have the same ratio and to say that their equimultiples (as we have said) together fall short of, together equal, or together exceed one another.

For let I, K again be taken as equimultiples of E, F; likewise L, M as equimultiples of G, H. Now since E (the first) is the same multiple of A (the second) as F (the third) is of C (the fourth), and I, K have been taken as equimultiples of E, F, the first and third, [Margin: b — Elements V.3] then *ex aequali* I, K will also be equimultiples of A, C, the second and fourth. By the same reasoning, L, M will be equimultiples of B, D. And since the ratio of A, the first, to B, the second, is posited to be the same as that of C, the third, to D, the fourth, and I, K have been shown to be equimultiples of the first and third, A, C, while L, M are equimultiples of the second and fourth, B, D, [Margin: c — Elements V, definition 6] it comes about that if I, the multiple of the first, falls short of L, the multiple of the second, then K, the multiple of the third, necessarily falls short of M, the multiple of the fourth; and if I is equal to L, then K too is necessarily equal to M; and finally, if I exceeds L, then K too necessarily exceeds M. The same will be shown for any equimultiples whatever of the magnitudes E and F, and likewise of the magnitudes G and H — because these equimultiples, whatever they may be, will always [Margin: d — Elements V.3] be equimultiples of the magnitudes A, C and B, D as well. And so, since I and K are equimultiples of the first E and the third F, and L and M are equimultiples of the second G and the fourth H, and it has been shown that if I, the multiple of the first, is less than L, the multiple of the second, then K, the multiple of the third, is also less than M, the multiple of the fourth, and so on — and that this holds under any multiplication whatever — [Margin: e — Elements V, definition 6] then E, the first, will be to G, the second, as F, the third, is to H, the fourth. So then, if the first has the same ratio to the second [that the third has to the fourth], and so on. Which was to be demonstrated.

Diagram. A schematic set of twelve parallel vertical magnitude-bars, arranged in an upper and a lower rank (six bars each), illustrating the equimultiples used in the proof of Proposition 4. Each upper label pairs with the lower label directly beneath it. The bars vary in length to indicate the relative sizes of the magnitudes.

- Upper rank (left to right): I, E, A, B, G, L

- Lower rank (left to right): K, F, C, D, H, M
- Vertical pairings: I/K, E/F, A/C, B/D, G/H, L/M (I, K are equimultiples of E, F; L, M of G, H; E, F of A, C; G, H of B, D).

COROLLARY

From this the inverse ratio, which Euclid explained in definition 13, is easily demonstrated — that is, if four magnitudes are proportional, they are also proportional conversely, or by the inverse ratio. For let A be to B as C is to D. I say that, by conversion, B is to A as D is to C. For let E, F be taken as equimultiples of A, C, the first and third; likewise let G, H be taken as equimultiples of B, D, the second and fourth. Since A, the first, stands to B, the second, as C, the third, stands to D, the fourth, [Margin: f — Elements V, definition 6] it necessarily follows that if E, the multiple of the first, is less than G, the multiple of the second, or equal to it, or greater, then F, the multiple of the third, is likewise less than, equal to, or greater than H, the multiple of the fourth. And it is clear that, conversely, if G is greater than E, or equal to it, or less, then H too will be greater than, equal to, or less than F — under whatever multiplication these equimultiples are taken. For if both E, F are less than both G, H, then conversely both G, H will be greater than both E, F; and if both E, F are equal to both G, H, then conversely both G, H will also be equal to both E, F; and finally, if both E, F are greater than both G, H, then reciprocally both G, H will be less than both E, F. And so, since G, H have been taken as equimultiples of the first B and the third D, and E, F as equimultiples of the second A and the fourth C, and it has been shown that G, H together exceed, together equal, or together fall short of E, F — under whatever multiplication these multiples are taken — [Margin: g — Elements V, definition 6] then B, the first, will be to A, the second, as D, the third, is to C, the fourth. Which was to be demonstrated.

Diagram. Four horizontal magnitude-lines, one above another, illustrating the corollary on inverse ratio. Each line carries two labels marking a magnitude and its equimultiple.

- Line 1: E — F (E, F, the equimultiples of A, C)
- Line 2: A — C (the first and third)
- Line 3: B — D (the second and fourth)
- Line 4: G — H (G, H, the equimultiples of B, D)

SCHOLIUM

This proposition, together with its corollary, is true whether or not the two magnitudes A, B are of the same kind as the two magnitudes C, D, as is clear from the demonstration.

Orontius [Oronce Fine] attempts to demonstrate this fourth theorem as follows. After showing, from proposition 3 of this book, that I, K are equimultiples of the magnitudes A, C, and likewise that L, M are equimultiples of the magnitudes B, D, he immediately infers, by the converse of definition 6 (according to his own exposition), that I is to L as K is to M. And therefore, he says, E will also be to G as F is to H, by the same definition. This demonstration is thoroughly faulty. First, because on this reading the same thing is proved by the same thing: namely, that when four proportional magnitudes are given, the equimultiples of the first and third have the same ratio to the equimultiples of the second and fourth — inferred from the fact that (by definition 6, as he himself explained it) the equimultiples of the first and third have the same ratio to the equimultiples of the second and fourth; which is absurd. And second, because in the same manner he might have inferred, right from the start, that E is to G as F is to H by definition 6, without taking on any new equimultiple magnitudes — for there is no more reason in the one case than in the other. This kind of demonstration must therefore be rejected, together with the exposition of definition 6, as we have said above. But according to our interpretation of the same definition, all that is established is that if I is less than L, or equal to it, or greater, then K too is less than M, or equal to it, or greater — just as the same is established for the equimultiples E, F, G, H, and for any others whatever, if they are taken as they correspond to one another. Hence from definition 6 it is rightly concluded that E, the first, is to G, the second, as F, the third, is to H, the fourth — since definition 6 applies to them.

Diagram. A second set of twelve parallel vertical magnitude-bars in an upper and lower rank of six, accompanying the scholium's discussion of Orontius's demonstration; the layout repeats that of the figure for Proposition 4.

- Upper rank (left to right): I, E, A, B, G, L
- Lower rank (left to right): K, F, C, D, H, M

THEOR. 5. PROPOS. 5. [Margin: v.]

If one magnitude is the same multiple of another that a part taken away is of a part taken away, then the remainder too will be the same multiple of the remainder that the whole is of the whole.

So then: let the whole AB be the same multiple of the whole CD that the part taken away, AE, is of the part taken away, CF — whether AE and CF are commensurable with the wholes AB, CD (as in the first figure) or incommensurable (as in the second figure); and likewise whether AE, CF are composed of the same parts of which the wholes AB, CD are composed (as in the former figure) or not of the same parts (as in the latter figure). I say that the remainder EB is the same multiple of the remainder FD that the whole AB is of the whole CD. For let EB be set as such a multiple of some magnitude — namely of GC — as AE is of CF, or as the whole AB is of the whole CD. Now since AE and EB are equimultiples of CF and GC respectively, [Margin: a — Elements V.1] the whole AB will be the same multiple of the whole GF that AE is of CF — that is, all of them of all, as one of one. But AB was also assumed to be the same multiple of CD as it is of GF; [Margin: b — 6. pron. (common notion 6)] and therefore GF and CD are equal. So, when the common part CF is taken away, GC and FD will be equal. Therefore EB will be the same multiple of FD that it is of GC. But EB was set as the same multiple of GC that AE is of CF — that is, as the whole AB is of the whole CD. Therefore the remainder EB is the same multiple of the remainder FD that the whole AB is of the whole CD, which is the thing proposed.

Diagram. The first (commensurable) figure for Proposition 5: two horizontal magnitude-lines, tick-marked into equal parts. The upper line AB carries the point E; the lower line runs G–C–F–D (the auxiliary magnitude GC together with CF, FD).

- Upper line (left to right): A, E, B
- Lower line (left to right): G, C, F, D

Diagram. The second (incommensurable) figure for Proposition 5: two horizontal magnitude-lines of the same lettering as the first figure but with parts not composed of the same units.

- Upper line (left to right): A, E, B
- Lower line (left to right): G, C, F, D

ALTERNATIVELY. Let the whole AB be the same multiple of the whole CD that the part taken away, AE, is of the part taken away, CF. I say that the remainder EB is the same multiple of the remainder FD that the whole is of the whole. For let GA be set as such a multiple of FD as AE is of CF, or as the whole AB is of the whole CD. Since AE and GA are equimultiples of CF and FD respectively, [Margin: c — Elements V.1] the whole GE will be the same multiple of the whole CD that AE is of CF. But AB too is, by hypothesis, the same multiple of that same CD that AE is

of CF. Therefore GE and AB are equimultiples of CD, [Margin: d — 6. pron. (common notion 6)] and hence equal to one another. So, when the common part AE is taken away, GA and EB will be equal, and therefore equimultiples of FD — since GA was set as a multiple of FD. But GA was set as the same multiple of FD that AB is of CD. Therefore the remainder EB too will be the same multiple of FD that the whole AB is of the whole CD; which is the thing proposed. And so, if one magnitude is the same multiple of another, and so on. Which was to be demonstrated.

SCHOLIUM

In general, this same thing will be proved in proposition 19, for magnitudes of any ratio whatever, and not only for magnitudes in a multiple ratio, as has been done here.

THEOR. 6. PROPOS. 6. [Margin: vj.]

If two magnitudes are equimultiples of two magnitudes, and certain [magnitudes] taken away from them are equimultiples of the same, then the remainders too are either equal to those same [magnitudes] or equimultiples of them.

Let the magnitudes AB, CD be equimultiples of E, F; and let AG, CH, taken away from them, be equimultiples of the same E, F. I say that the remainders GB, HD are either equal to those same E, F, or else equimultiples of them. For since AB is a multiple of E, and AG, which is taken away, is likewise a multiple of the same E, the remainder GB will be either equal to E or a multiple of it; for otherwise a magnitude unequal [to E] and not a multiple, added to a multiple, would compose a multiple — which is absurd. Suppose first, then, that GB is equal to E. I say that

HD too is equal to F. For let CI be set equal to F. And since the first, AG, is the same multiple of the second E that the third, CH, is of the fourth F; and the fifth, GB, is equal to the second E, just as the sixth, CI, is equal to the fourth F; [Margin: a — Elements V.2] then AB, the first together with the fifth, will be the same multiple of the second E that HI, the third together with the sixth, is of the fourth F. But CD was also the same multiple of F that AB is of E. Therefore HI and CD are equimultiples of F, [Margin: b — 6. pron. (common notion 6)] and hence equal to one another. So, when the common part CH is taken away, the remainders CI, HD will be equal. And since CI was set equal to F, HD too will be equal to that same F. Which is the thing proposed.

Diagram. The first figure for Proposition 6: horizontal magnitude-lines. The line AB carries the point G; the line CD carries the point H; the magnitudes E and F are drawn as separate shorter segments.

- Line AB (left to right): A, G, B
- Segment: E
- Line CD (left to right): C, H, D
- Segment: F

Suppose next that GB is a multiple of E. I say that HD is likewise a multiple of F. For let CI be set as the same multiple of F that GB is of E; [Margin: c — Elements V.2] then, as before, AB will be the same multiple of E that HI is of F. [Margin: d — 6. pron. (common notion 6)] Hence again HI and CD will be equal; and so, when the common part CH is taken away, the remainders CI, HD will also be equal. But CI is, by hypothesis, the same multiple of F that GB is of E. Therefore HD too will be the same multiple of F that GB is of E — which is the thing proposed. And so, if two magnitudes are equimultiples of two magnitudes, and so on. Which was to be shown.

Diagram. The second figure for Proposition 6 (the case where the remainder is a multiple): horizontal magnitude-lines with the line AB carrying the point C, the lower CD-line carrying the points C, H, and the separate segments E and F.

- Line AB (left to right): A, C, B
- Segment: E
- Lower line (left to right): I[?], C, H, D
- Segment: F

SCHOLIUM [continued]

We shall likewise prove this in general in proposition 24, for every kind of ratio. We shall demonstrate the whole proposition more briefly as follows. Since AB and CD are equimultiples of E and F, there will be in AB as many magnitudes equal to E as there are magnitudes in CD equal to F. Again, since AG and CH are equimultiples of the same E and F, there will likewise be in AG as many magnitudes equal to E as there are magnitudes in CH equal to F. If, then, from the equal multitudes AB, CD there are taken away the equal multitudes AG, CH, the multitudes GB, HD that remain will be equal. Therefore E will be contained in GB as many times as F is contained in HD; and accordingly, if GB is equal to E, HD too will be equal to F; but if GB is a multiple of E, then HD will be the same multiple of F that GB is of E — since E is contained in GB as many times as F is found in HD, as has been shown.

THEOR. 7. PROPOS. 7. [Margin: vij]

Equal magnitudes have the same ratio to the same magnitude; and the same magnitude has the same ratio to equal magnitudes.

Let A, B be two magnitudes equal to one another, and C any third magnitude. I say that A and B have the same ratio to C; and likewise that C, conversely, has the same ratio to A and to B. Let D, E be taken as equimultiples of the equal magnitudes A, B; [Margin: a — 6. pron. (common notion 6)] then D, E will be equal to one another. Again, let F be taken as any multiple of C. Now since D, E are equal, it happens that each of them is either less than F, or equal to it, or greater — whatever multiplication is used in taking these multiples. Therefore, since D, E, the equimultiples of the first A and the third B, are together less than F, the multiple of the second and fourth C (for C stands in place of two magnitudes, and so on), or equal to it, or greater, [Margin: b — Elements V, definition 6] the ratio of the first A to the second C will be the same as that of the third B to the fourth C.

In the same way we shall show that F is either less than both D, E, or equal to both, or greater. Therefore, since F, the multiple of the first and third C, together falls short of, or is equal to, or is greater than D and E, the equimultiples of the second A and the fourth B, [Margin: c — Elements V, definition 6] the ratio of the first C to the second A will also be the same as that of the third C to the fourth B; which is the thing proposed. This second part could be shown more briefly by the corollary to proposition 4, from the inverse ratio. For since it has already been shown that A is to C as B is to C, then by conversion C will be to A as C is to B. Therefore equal magnitudes have the same ratio to the same magnitude, and the

same magnitude has the same ratio to equal magnitudes. Which was to be demonstrated.

Diagram. The figure for Proposition 7: a set of separate horizontal magnitude-lines. The equal magnitudes A, B are drawn as equal segments; C is a third magnitude; D, E are the equimultiples of A, B, and F the multiple of C.

- Segments (as labelled on the lines): C, A, B, E, F

SCHOLIUM

It is clear that nothing can be inferred in this proposition from definition 6 according to the exposition of Campanus and Orontius [Oronce Fine]. For the demonstration does not establish that both multiples D and E have the same ratio to the multiple F, but only that, since they are equal, each of them is either less than, or equal to, or greater than the multiple F. And the same is seen in almost all the propositions that draw their conclusion by means of definition 6 — so that this exposition has rightly been rejected by us.

In almost the same way we shall show that magnitudes equal to one another have the same ratio to other magnitudes equal to one another, if in place of the single multiple F two equimultiples are taken — which Euclid, for the sake of ease, omitted, though he sometimes uses it in what follows, just as if it had been demonstrated in this proposition 7. For let A and B be equal to one another, and C and D likewise equal to one another. I say that A is to C as B is to D. For let equimultiples E, F of A and B, the first and third, be taken; likewise let G, H be taken as equimultiples of C and D, the second and fourth; [Margin: d — 6. pron. (common notion 6)] then E and F will be equal to one another, just as G and H are equal to one another. Therefore, if E, the multiple of the first, falls short of G, the multiple of the second, then F, the multiple of the third, will also fall short of H, the multiple of the fourth; and if it is equal, it will be equal; and if it exceeds, it will exceed. [Margin: e — Elements V, definition 6] Therefore the ratio of A, the first, to C, the second, is the same as that of B, the third, to D, the fourth. Which is the thing proposed.

Diagram. The figure for the scholium to Proposition 7: eight parallel vertical magnitude-bars in an upper and a lower rank of four, showing the two pairs of equal magnitudes and their equimultiples.

- Upper rank (left to right): E, A, C, G
- Lower rank (left to right): F, B, D, H

THEOR. 8. PROPOS. 8. [Margin: viij.]

Of unequal magnitudes, the greater has a greater ratio to the same magnitude than the less has; and the same magnitude has a greater ratio to the less than it has to the greater.

Let there be unequal magnitudes: AB the greater and C the less; and let D be any third magnitude. I say that the ratio of AB to D is greater than the ratio of C to D; and conversely, that the ratio of D to C is greater than the ratio of D to AB. In AB, the greater magnitude, let a magnitude AE be understood equal to the lesser C, so that EB is the remainder. Let both EB and AE then be equally multiplied, on this rule: that GF, the multiple of EB, is greater than D, while HG, the multiple of AE, is not less than that same D, but either greater or equal. In the former figure it was necessary to take GF, HG as triples of EB, AE, because the double of AE would have been less than D. Instead of the triples, any other greater equimultiples could have been taken. In the latter figure, however, it is enough to take GF, HG as the doubles of EB, AE, because each of GF, HG is greater than D; yet in place of the doubles any other greater equimultiples could have been taken. Now since the two FG, GH are equimultiples of the two BE, EA, [Margin: a — Elements V.1] the whole FH will also be the same multiple of the whole AB that GH [printed: FH; recte GH] is of AE — that is, of C, since C and AE were set equal. Let there also be taken a multiple IK of D that is the next greater than HG, namely its double, as in the former figure. But if the double is not greater than HG, let the triple, or quadruple, and so on, be taken. In the latter figure IK has been taken as the quadruple of D, because both the double and the triple are less than HG, whereas the quadruple is now greater. Therefore, when LK is cut off equal to D, IL will not be greater than HG — otherwise IK would not be the multiple of D next greater than HG, but IL too would be greater than GH. But if IK is the double of D, it is clear that IL is not greater than HG, since...

Diagram. The figures for Proposition 8 (a "former" and a "latter" figure): horizontal magnitude-lines showing AB with the point E (AE equal to C, remainder EB), the third magnitude D, and the constructed multiples FH (=FG+GH), HG, IK, LK. The lower part of the page is heavily stained and several labels are faint or mirror-rendered on the scan; readable labels are listed and the rest flagged. []

- Line AB with dividing point: A, E, B
- Further labelled points/segments read: H, C[?], F, L[?], K, D[?]

Proposition 8 (continued) — demonstration

), and therefore HG will be either equal to IL itself or greater. And since FG has been posited greater than D, while LK is equal to that same D, FG too will be greater than LK. Since, then, HG is not less than IL — as has been demonstrated — but either equal or greater, the whole FH will be greater than IK.

Diagram. A set of labelled horizontal line-segments (magnitudes) illustrating the proof of Proposition 8, arranged in a left group and a right group. The page is foxed across the figure; the readings below are taken from the scan at high magnification.

- F ... G ... H (top line): the multiple FH, divided at G into FG and GH, with tick-marks showing the repetitions.
- K ... L ... I (second line): the multiple IK, marked at L.
- A ... E ... B (right group): the magnitude AB, divided at E [?] (the point-letter is partly lost to foxing).
- C: a single magnitude-segment.
- D: a single magnitude-segment.

Accordingly, since FH and HG are equimultiples of the first, AB, and the third, C — while IK is a multiple of D, which stands in the place of the second and the fourth — and since FH, the multiple of the first, is greater than IK, the multiple of the second, whereas HG, the multiple of the third, is not greater than IK, the multiple of the fourth (indeed it is less, by hypothesis, for IK was taken as the multiple of D that is greater than HG): [Margin: (b) — *Elements* V, def. 8] therefore AB, the first, will have a greater ratio to D, the second, than C, the third, has to D, the fourth.

But conversely, since IK, the multiple of the first D — for let D now be posited as the first and the third, C as the second, and AB as the fourth — is greater than HG, the multiple of the second C, whereas IK, the multiple of the third D, is not greater than FH, the multiple of the fourth AB (indeed it is less, since FH is greater than IK, as has been shown): [Margin: (c) — *Elements* V, def. 8] therefore D, the first, will have a greater ratio to C, the second, than D, the third, has to AB, the fourth — which is what was proposed. Therefore, of unequal magnitudes the greater has [a greater ratio] to the same, and so on. Which was to be shown.

SCHOLIUM

Pedro Nunes [Petrus Nonius — Pedro Nunes], treating of proportion in his *Algebra*, rightly observed that this eighth proposition cannot be used to prove that a right angle has a greater ratio to any other angle than the angle of a semicircle [angulus semicirculi] has to that same angle — even though a right angle is greater than the angle of a semicircle. For the excess of the right angle over the angle of a semicircle, which is the angle of contact [angulus contingentiae], can never, however much it be multiplied, surpass that third angle; yet this is exactly what the demonstration of the present proposition requires. Indeed, as was made plain, FG, the multiple of the excess EB, must surpass the third magnitude D.

Nor should this seem surprising to anyone. For a right angle is not properly said to have a ratio to the angle of a semicircle, since it exceeds it by the angle of contact [angulus contactus], which is not of the same nature as either of the two angles, so that it cannot be so multiplied as at last to surpass either of them. Consider an analogy: if a point could be added to a line one span long, so as to make a line exceeding the span-long line by a single point, the composite line would not properly be called greater than the span-long line — because the excess is indivisible and of another nature. In the same way, if a line one span long were set alongside any plane figure, one would not properly say that this magnitude, composed of diverse magnitudes, has to that plane figure a ratio of greater inequality — because the excess is not of the same nature as that plane figure. So likewise a right angle does not properly have to the angle of a semicircle a ratio of greater inequality; for since it is by the addition of the angle of contact to the angle of a semicircle that the right angle is produced, the right angle therefore exceeds the angle of a semicircle by a quantity of a different nature, as has been said.

Accordingly, it is not only those magnitudes that do not properly have a ratio of which neither, when multiplied, can surpass the other — as we said at definition 5 of this book [*Elements* V, def. 5]; but neither, as this same Pedro Nunes noted, are those properly said to have a ratio whose excess is of a nature different from theirs, such as are a right angle and the angle of a semicircle. So that magnitudes are properly said to have a ratio to one another only when either of them, multiplied, can surpass the other, and when their excess, multiplied, can likewise surpass both. I confess this matter is exceedingly obscure and can scarcely be rightly understood; but it arises from the indivisibility of the angle of contact by a straight line. There are several other things of this kind in geometry which,

though most true because of an evident demonstration, nevertheless present on another side such a difficulty that the understanding does not easily extricate itself from it. For example, it is most true that a sphere touches a plane at a point, as Theodosius [Theodosius] demonstrates in Proposition 3 of Book 1 [*Sphaerica* I.3]. But by what account it comes about that it does not follow from this — if a globe be moved continuously over a plane — that a straight line composed of points is described, no one to this day has so explained that the difficulty is entirely removed.

THEOR. 9. PROPOS. 9. [Margin: ix.]

Magnitudes which have the same ratio to the same magnitude are equal to one another; and those to which the same magnitude has the same ratio are likewise equal to one another.

Let A and B first have the same ratio to C. I say that A and B are equal to one another. For suppose, if it be possible, that one of them, namely A, is greater and B less. [Margin: (a) — *Elements* V, 8] Then A, the greater, will have a greater ratio to C than B, the less, has to that same C — which is contrary to the hypothesis. Therefore A and B are not unequal, but equal.

Next, let C have the same ratio to A and to B. I say again that A and B are equal. For if one of them, namely A, were greater and B less, [Margin: (b) — *Elements* V, 8] then C would have a greater ratio to B, the less, than to A, the greater — which is contrary to the hypothesis. Therefore A will not be greater than B, but equal. Therefore magnitudes which have the same ratio to the same magnitude, and so on. Which was to be demonstrated.

SCHOLIUM

This ninth proposition converts both parts of theorem 7, as is manifest.

THEOR. 10. PROPOS. 10. [Margin: x.]

Of magnitudes having a ratio to the same magnitude, that which has the greater ratio is the greater; and that to which the same magnitude has the greater ratio is the less.

Let A first have a greater ratio to C than B has to that same C. I say that A is greater than B. For if A were equal to B, [Margin: (a) — *Elements* V, 7] A and B would have the same ratio to C; and if A were less than B, [Margin: (b) — *Elements* V, 8] then B, the greater, would have a greater ratio to C than A, the less, has to

that same C — which is contrary to the hypothesis. Therefore A is not equal to, nor less than,

B, but greater.

Secondly, let C have a greater ratio to B than to A. I say that B is less than A. For B will not be equal to A: [Margin: (c) — *Elements* V, 7] otherwise C would have the same ratio to A and to B, which is contrary to the hypothesis. Nor indeed will B be greater than A: [Margin: (d) — *Elements* V, 8] for otherwise C would have a greater ratio to A, the less, than to B, the greater — which is even more contrary to the hypothesis. Therefore B is less than A, which is what was proposed. Therefore of magnitudes having a ratio to the same magnitude, and so on. Which was to be demonstrated.

SCHOLIUM

This proposition too converts both parts of theorem 8, as is plain.

THEOR. 11. PROPOS. 11. [Margin: xj.]

Ratios that are the same as the same ratio are also the same as one another.

Let the ratios A to B and C to D each be the same as the ratio E to F. I say that the ratios A to B and C to D are also the same as one another — according to the sixth definition [*Elements* V, def. 6]; that is, that when equimultiples of A and C are taken, and likewise equimultiples of B and D, it will always happen that the multiples of A and C either together fall short of, or together are equal to, or together exceed the multiples of B and D.

Diagram. Three groups of labelled horizontal line-segments (magnitudes), one group per proportion. Each group pairs an antecedent and consequent with their equimultiples:

- Group 1: G (equimultiple of A), A, B, K (equimultiple of B).
- Group 2: H (equimultiple of C), C, D, L (equimultiple of D).
- Group 3: I (equimultiple of E), E, F, M (equimultiple of F).

Take, then, any equimultiples whatever, G, H, I, of all the antecedents A, C, E; and any others, K, L, M, equimultiples of all the consequents B, D, F. Since A, the first, is posited to be to B, the second, as E, the third, is to F, the fourth, [Margin: (a) — *Elements* V, def. 6] it comes about that, if G, the multiple of the first, falls short of K, the multiple of the second, then I, the multiple of the third, also falls short of M,

the multiple of the fourth; and if G is equal to K, or greater, then I is likewise equal to M, or greater. [Margin: (b) — *Elements* V, def. 6] But (as will be shown in the same way) if I is less than M, or equal, or greater, then H too is less than L, or equal, or greater — because E, the first, is posited to be to F, the second, as C, the third, is to D, the fourth. Hence if G, the multiple of the first A, falls short of K, the multiple of the second B, then H, the multiple of the third C, will also fall short of L, the multiple of the fourth D; and if G is equal to, or greater than, K, then H too will be equal to, or greater than, L. And the same will be shown to occur in any other equimultiples whatever. [Margin: (c) — *Elements* V, def. 6] Therefore A, the first, will be to B, the second, as C, the third, is to D, the fourth. Therefore ratios that are the same as the same ratio are also the same as one another. Which was to be shown.

SCHOLIVM

"The same as one another." Ratios that are the same as the same ratios are also the same as one another. Or if it be that as A is to B, so is C to D, and moreover E is to F as A is to B, and G is to H as C is to D: then E will also be to F as G is to H. For since the ratios E to F and C to D are the same as the ratio A to B, [Margin: (d) — *Elements* V, 11] E to F will be as C to D. And again, since the ratios E to F and G to H are the same as the ratio C to D, [Margin: (e) — *Elements* V, 11] E to F will likewise be as G to H.

A	B	C	D	E	F	G	H
3	2	6	4	9	6	12	8

Again, if the ratios A to B, C to D, and E to F are the same as one another, and moreover as A is to B so is G to H, and as C is to D so is I to K, and as E is to F so is L to M: then the ratios G to H, I to K, and L to M will also be the same as one another. For, as was shown just now in the case of four ratios, G is to H as I is to K, because these ratios are similar to the ratios A to B and C to D.

A	B	C	D	E	F	G	H	I	K	L	M
3	2	6	4	9	6	12	8	18	12	30	20

In the same way, I will be to K as L is to M, since the ratios I to K and L to M are the same as the ratios C to D and E to F, which are equal. Likewise G will be to H as L is to M, since these ratios are the same as the ratios A to B and E to F, which are posited equal. The same reasoning holds for more terms.

THEOR. 12. PROPOS. 12. [Margin: xij.]

If there be any number of proportional magnitudes, then as one of the antecedents is to one of the consequents, so will all the antecedents together be to all the consequents together.

What he demonstrated in Proposition 1, concerning multiple proportion, he here shows for every kind of proportion, the irrational included. Let there be, then, any number of magnitudes A, B, C, D, E, F, proportional — that is, let A be to B as C is to D and as E is to F. I say that as one of the antecedents is to one of the consequents, namely A to B, so are all the antecedents together, A, C, E, to all the consequents together, B, D, F.

Diagram. Labelled horizontal line-segments (magnitudes) arranged in four rows:

- Top row: G, H, I (the equimultiples of the antecedents).
- Second row: A, C, E (the antecedents).
- Third row: B, D, F (the consequents).
- Bottom row: K, L, M (the equimultiples of the consequents).

For when G, H, I are taken as equimultiples of the antecedents, and K, L, M as equimultiples of the consequents, [Margin: (a) — *Elements* V, 1] then all of G, H, I together will be multiples of all of A, C, E together in the same way as one of them is a multiple of one, namely as G is of A; and all of K, L, M together will be multiples of all of B, D, F together in the same way as one of them is a multiple of one, namely as K is of B. Now since A, the first, is posited to be to B, the second, as C, the third, is to D, the fourth, and as the further magnitude E, the third, is to the further F, the fourth, [Margin: (b) — *Elements* V, def. 6] it comes about that, if G, the multiple of the first, falls short of K, the multiple of the second, then H, the multiple of the third, also falls short of L, the multiple of the fourth, and I falls short of M; and if G is equal to K, or greater, then H too is equal to L, and I to M, or greater. And accordingly, whether G is less than, or equal to, or greater than K, all of G, H, I together are together less than, or equal to, or greater than all of K, L, M. [Margin: (c) — *Elements* V, def. 6] Therefore, as A, the first, is to B, the second, so will A, C, E, the third, be to B, D, F, the fourth. Therefore, if there be any number of proportional magnitudes, and so on. Which was to be demonstrated.

THEOR. 13. PROPOS. 13. [Margin: xij.]

If a first magnitude has to a second the same ratio that a third has to a fourth, and the third has to the fourth a greater ratio than a fifth has to a

sixth: then the first will also have to the second a greater ratio than the fifth has to the sixth.

Diagram. Labelled horizontal line-segments (magnitudes) arranged in four rows:

- Top row: G, H, I (the equimultiples of the antecedents).
- Second row: A, C, E (the antecedents).
- Third row: B, D, F (the consequents).
- Bottom row: K, L, M (the equimultiples of the consequents).

Let A, the first, be to B, the second, as C, the third, is to D, the fourth; and let the ratio of C, the third, to D, the fourth, be greater than that of E, the fifth, to F, the sixth. I say that the ratio of A, the first, to B, the second, is also greater than that of E, the fifth, to F, the sixth — according to the eighth definition [*Elements* V, def. 8]; that is, that when equimultiples of A and E are taken, and likewise equimultiples of B and F, it can happen that the multiple of A exceeds the multiple of B, while the multiple of E does not exceed the multiple of F.

For when G, H, I are taken as equimultiples of the antecedents, and K, L, M as equimultiples of the consequents, then, since A, the first, is to B, the second, as C, the third, is to D, the fourth, [Margin: (a) — *Elements* V, def. 6] it comes about that, if G, the multiple of the first, exceeds K, the multiple of the second, then H, the multiple of the third, also exceeds L, the multiple of the fourth, and so on. But when H exceeds L, [Margin: (b) — *Elements* V, def. 8] I does not necessarily exceed M; rather it will sometimes be equal, or less — because the ratio of C, the first, to D, the second, is posited greater than that of E, the third, to F, the fourth. Therefore if G exceeds K, I does not necessarily exceed M. [Margin: (c) — *Elements* V, def. 8] Therefore the ratio of A, the first, to B, the second, is greater than that of E, the third, to F, the fourth. Hence, if a first has to a second the same ratio that a third has to a fourth, and so on. Which was to be shown.

SCHOLIUM

But if the ratio of C, the third, to D, the fourth, be less than that of E, the fifth, to F, the sixth, then the ratio of A, the first, to B, the second, will also be less than that of E, the fifth, to F, the sixth. For if the ratio of C to D is less than that of E to F — that is, if the ratio of E, the first, to F, the second, is greater than that of C, the third, to D, the fourth — [Margin: (d) — *Elements* V, def. 8] it comes about that, if I exceeds M, H does not necessarily exceed L, but sometimes falls short of it, or is equal to it. [Margin: (e) — *Elements* V, def. 6] But if H falls short of L, or is equal, then G too will fall short of K, or be equal to it, because C, the first, is posited to be

to D, the second, as A, the third, is to B, the fourth. Hence if I exceeds M, G will not necessarily exceed K; [Margin: (f) — *Elements* V, def. 8] and therefore the ratio of E, the first, to F, the second, will be greater than that of A, the third, to B, the fourth — that is, the ratio of A to B will be less than that of E to F. Which is what was proposed.

In the same way: if a first has to a second a greater ratio than a third has to a fourth, and the third has to the fourth a greater ratio than a fifth has to a sixth, then the first will have to the second a still greater ratio than the fifth has to the sixth.

And if a first has to a second a smaller ratio than a third has to a fourth, and the third has to the fourth a smaller ratio than a fifth has to a sixth, then the first will have to the second a still smaller ratio than the fifth has to the sixth.

THEOR. 14. PROPOS. 14. [Margin: xiv.]

If a first magnitude has to a second the same ratio that a third has to a fourth, and the first is greater than the third, then the second will also be greater than the fourth. But if the first is equal to the third, the second will also be equal to the fourth; and if less, less.

Let A, the first, be to B, the second, as C, the third, is to D, the fourth. I say that if A is greater than C, then B will also be greater than D; that if A is equal to C, then B is also equal to D; and finally that if A is less than C, then B is also less than D.

Diagram. Four labelled horizontal line-segments (magnitudes), for the case A greater than C: A, B, C, D.

Let A first be greater than C. [Margin: (a) — *Elements* V, 8] Then, on that account, the ratio of A, the greater, to B will be greater than that of C, the less, to that same B. Now since C, the first, is to D, the second, as A, the third, is to B, the fourth — and this is greater, as we showed, than the ratio of C, the fifth, to B, the sixth — [Margin: (b) — *Elements* V, 13] the ratio of C, the first, to D, the second, is greater than that of C, the fifth, to B, the sixth. [Margin: (c) — *Elements* V, 10] Therefore D is less than B; and so B will be greater than D. Which is what was proposed.

Diagram. Four labelled horizontal line-segments (magnitudes), for the case A equal to C: A, B, C, D.

Next, let A be equal to C. [Margin: (d) — *Elements* V, 7] Then, on that account, A will be to B as C is to B. Now since the ratios C to D and C to B are the same as the ratio A to B, [Margin: (e) — *Elements* V, 11] the ratios C to D and C to B will also be

the same as one another; [Margin: (f) — *Elements* V, 9] and therefore B and D will be equal. Which is what was proposed.

Diagram. Four labelled horizontal line-segments (magnitudes), for the case A less than C: A, B, C, D.

Thirdly, let A be less than C. [Margin: (g) — *Elements* V, 8] Then, on this account, the ratio of C, the greater, to B is greater than that of A, the less, to that same B. Now since C, the first, is to D, the second, as A, the third, is to B, the fourth — and the ratio of A, the third, to B, the fourth, is less than that of C, the fifth, to B, the sixth — [Margin: (h) — *Elements* V, 13] the ratio of C, the first, to D, the second, will also be less than that of C, the fifth, to B, the sixth; [Margin: (i) — *Elements* V, 10] and therefore B will be less than D, which is what was proposed. Therefore, if a first has to a second the same ratio, and so on. Which was to be demonstrated.

SCHOLIVM

But if the second be greater than, or equal to, or less than the fourth, then by the same reasoning the first will be greater than, or equal to, or less than the third. For let B first be greater than D, as in the first figure. I say that A too is greater than C. For since B is greater than D, [Margin: (k) — *Elements* V, 8] the ratio of C to D will be greater than that of C to B [...]. Since, then, as the first A is to the second B, so the third C is to the

(Continuation of the SCHOLIVM to Proposition 14.)

fourth, D. But the ratio of C, the third, to D, the fourth, has been shown to be greater than the ratio of C, the fifth, to B, the sixth [Margin: (l) — *Elements* V, 13]; and therefore the ratio of A, the first, to B, the second, will also be greater than the ratio of C, the fifth, to B, the sixth [Margin: (m) — *Elements* V, 10]. Consequently A will be greater than C, which is what was proposed.

NEXT, let B be equal to D, as in the second figure. I say that A too is equal to C. For since B is equal to D, C will be to B as C is to D [Margin: (n) — *Elements* V, 11]; but A is also to B as C is to D. Therefore A is to B as C is to B as well [Margin: (o) — *Elements* V, 9]; and consequently A is equal to C. Which is what was proposed.

THIRD, let B be less than D, as in the third figure. I say that A too is less than C. For since B is less than D, the ratio of C to D will be less than the ratio of C to B [Margin: (p) — *Elements* V, 8]. Now since A, the first, is to B, the second, as C, the third, is to D, the fourth — and the ratio of C, the third, to D, the fourth, has been shown to be less than the ratio of C, the fifth, to B, the sixth [Margin: (q) — *Elements* V, 13] — the ratio of A, the first, to B, the second, will also be less than

the ratio of C, the fifth, to B, the sixth [Margin: (r) — *Elements* V, 10]. Therefore C will be greater than A, and consequently A will be less than C. Which is what was proposed.

MORE BRIEFLY: If B is greater than D, and A is said to be not greater than C but either less than or equal to it, then B too will be less than or equal to D [Margin: (s) — *Elements* V, 14], which is contrary to the hypothesis. And the same reasoning holds in the other cases.

OR THUS: If A is to B as C is to D, then inversely [convertendo] B will be to A as D is to C. Therefore if B is greater than, less than, or equal to D, A too will be greater than, less than, or equal to C [Margin: (t) — *Elements* V, 14].

Euclid, however, did not demonstrate that if the first is greater than, equal to, or less than the second, the third is likewise greater than, equal to, or less than the fourth — though most geometers, both ancient and modern, do argue in this way — because it is evident from the similarity of the ratios. For it follows that if both ratios are of greater inequality, each antecedent magnitude (that is, the first and the third) is greater than each consequent (that is, the second and the fourth); if both ratios are of equality, each antecedent magnitude is equal to each consequent; and finally, if both ratios are of less inequality, each antecedent magnitude is less than each consequent.

For example, if A is to B as C is to D, then each ratio will be of greater inequality, or of equality, or of less inequality. Hence if A, the first, is greater than B, the second, then C, the third, will also be greater than D, the fourth; if equal, equal; and if less, less. Which is what was proposed. This, however, we shall demonstrate geometrically, along with Federico Commandino [Federico Commandino], at Proposition 16 of this book — though it is not necessary.

Diagram. The figure for the scholium, at the right margin. Four magnitudes are drawn as line-segments and paired by brackets: A over C on the left, B over D on the right, representing the four magnitudes A, B, C, D whose ratios $A : B$ and $C : D$ are compared. Visible labels: A, B, C, D.

- A (upper left): first magnitude
- B (upper right): second magnitude
- C (lower left): third magnitude
- D (lower right): fourth magnitude

[Margin: xv.]

THEOR. 15. PROPOS. 15.

Parts have the same ratio as their equimultiples, provided they are taken as they correspond to one another.

Let CD and EF be equimultiples of the parts A and B. I say that CD is to EF as A is to B. For since CD and EF are equimultiples of A and B, A will be contained in CD as many times as B is contained in EF. Divide CD, then, into the parts CG, GH, HD equal to A, and EF into the parts EI, IK, KF equal to B; then CG will be to EI as A is to B [Margin: (a) — *Elements* V, 7], since CG and A are equal to one another, as are EI and B. By the same reasoning GH will be to IK, and HD to KF, as A is to B; and therefore CG, GH, HD will have the same ratio to EI, IK, KF [Margin: (b) — *Elements* V, 11]. Hence, as CG is to EI — that is, as A is to B — so CD will be to EF [Margin: (c) — *Elements* V, 12], namely all of CG, GH, HD together to all of EI, IK, KF together, which is what was proposed. Parts, therefore, have the same ratio as their equimultiples, and so on. Which was to be demonstrated.

Diagram. Two vertical magnitude-lines at the right margin. The taller line is CD, running down from the top endpoint D and marked off by the intermediate points into the segments CG, GH, HD; clearly legible labels on it are D, H, G (the foot-label C is faint). Beside it stands the shorter line EF, divided into the parts EI, IK, KF; the labels E, I, K, F are only partly resolvable in the scan.

- D (top of taller line): endpoint of CD
- H, G (division points on CD): marking the parts CG, GH, HD
- E, I, K, F (on the shorter line): endpoints and division points of EF, marking EI, IK, KF [partly legible]

[Margin: xvj.]

THEOR. 16. PROPOS. 16.

If four magnitudes are proportional, they will also be proportional alternately.

Here Euclid demonstrates the alternate, or interchanged, proportion — the ratio explained in Definition 12. Let A be to B as C is to D. I say that alternately [vicissim], or by permutation [permutando], A is also to C as B is to D. For let E, F be taken as equimultiples of A, B, the first and second; and likewise G, H as equimultiples of C, D, the third and fourth. Then E will be to F as A is to B [Margin: (a) — *Elements* V, 15], since E and F are equimultiples of the parts A and

B. By the same reasoning G will be to H as C is to D. Now since the ratios $E : F$ and $G : H$ are the same as the ratio $A : B$, they will also be the same as one another [Margin: (b) — *Elements* V, 11]. Again, since the ratios $E : F$ and $G : H$ are the same as the ratio $C : D$, they too will be the same as one another [Margin: (c) — *Elements* V, 11]; that is, as E, the first, is to F, the second, so G, the third, will be to H, the fourth. Hence if E, the first, is greater than G, the third, or equal to it, or less than it, F, the second, will also be greater than H, the fourth, or equal, or less [Margin: (d) — *Elements* V, 14], in whatever multiplication the equimultiples E, F and the equimultiples G, H have been taken. Therefore A, the first, is to C, the second, as B, the third, is to D, the fourth [Margin: (e) — *Elements* V, def. 6] (since E and F are equimultiples of the first A and the third B, while G and H are equimultiples of the second C and the fourth D, and the former fall short of, are equal to, or exceed the latter all together, and so on) — which is what was proposed. Therefore if four magnitudes are proportional, they will also be proportional alternately. Which was to be shown.

Diagram. The figure for Proposition 16, at the lower right. It shows the four magnitudes A, B, C, D together with their equimultiples E, F, G, H, drawn partly as bracketed vertical segments (A and C above, B and E beside them, with I, K, F below) and partly as a stack of short horizontal magnitude-lines whose left-hand labels read, top to bottom, E, A, B, F, G, C, D, H. The thin lines and small labels do not all resolve individually in this scan.

- Vertical group: A, C (upper), B, E (lower), and I, K, F below
- Horizontal magnitude-lines (labels, top to bottom): E, A, B, F, G, C, D, H

[— several of the small segment-labels in this figure are not individually resolvable]

(Continuation of the SCHOLIVM to Proposition 16.)

Moreover, the demonstration of this proposition holds only when the four magnitudes are of the same kind. For if two, A and B, were of one kind and two, C and D, of another, then the multiples E, F would also be of one kind (namely that in which A, B are), and the multiples G, H of another (namely that in which C, D are). Hence it could not be said that E is greater than, equal to, or less than G; and consequently nothing could be inferred from Definition 6 of this book. Therefore alternate proportion is to be employed only among four magnitudes of the same kind. Some philosophers, failing to notice this, fall into grave errors when they apply it to things of different kinds.

From this that too will be demonstrated which, at the end of the scholium to Proposition 14, we showed from the mere similarity of the ratios, and which we undertook not to demonstrate at that place — namely:

If a first has to a second the same ratio as a third to a fourth, and the first is greater than the second, then the third will also be greater than the fourth; if equal, equal; and if less, less.

Although what is here proposed is self-evident, as we said at Proposition 14, we shall nonetheless demonstrate it, along with Federico Commandino, in this way. Let A, the first, be to B, the second, as C, the third, is to D, the fourth. I say that if A, the first, is greater than B, the second, then C, the third, is greater than the fourth D; if equal, equal; and if less, less. For alternately [permutando] A will be to C as B is to D [Margin: (f) — *Elements* V, 16]. Therefore if A, the first, is greater than B, the third, then C, the second, will also be greater than D, the fourth [Margin: (g) — *Elements* V, 14]; and if equal, equal; and if less, less. Which is what was proposed.

But this demonstration too holds only when the four magnitudes are of the same kind. Hence it is preferable to prove the point from the nature of ratios, as we did at Proposition 14. For in that way what is proposed will always be true, even if the magnitudes A, B are contained in one kind and C, D in another — indeed, even if A, B are continuous quantities and C, D are numbers, and so on.

[Margin: xvij.]

THEOR. 17. PROPOS. 17.

If magnitudes taken jointly are proportional, they will also be proportional when taken separately.

Here Euclid demonstrates the separation of a ratio [divisio rationis], which he set out in Definition 15. Let the composite magnitudes AB, CB and DE, FE be proportional — that is, let AB be to CB as DE is to FE. I say that, when separated, they too are proportional; that is, that AC is to CB as DF is to FE, in the sense we explained in Definition 6. For let equimultiples GH, HI, KL, LM of AC, CB, DF, FE be taken in the same order; then GI will be the same multiple of AB as GH is of AC [Margin: (a) — *Elements* V, 1] — that is, as KL is of DF — and likewise KM will be the same multiple of DE [Margin: (b) — *Elements* V, 1]. Therefore GI, KM are equimultiples of AB, DE. Again, let IN, MO be taken as equimultiples of CB, FE. Now since HI, the multiple of the second CB, is the same multiple as LM, [the multiple] of the fourth FE, and likewise IN, the fifth, is as great a multiple of the

second CB as MO, the sixth, is of the fourth FE, then HN will be the same multiple of the second CB as LO is of the fourth FE [Margin: (c) — *Elements* V, 2]. And so, since AB, the first, is to CB, the second, as DE, the third, is to FE, the fourth, and equimultiples GI, KM have been taken of the first and third, and equimultiples HN, LO of the second and fourth, it follows [Margin: (d) — *Elements* V, def. 6] that if GI, the multiple of the first AB, falls short of HN, the multiple of the second CB, then KM, the multiple of the third DE, likewise falls short of LO, the multiple of the fourth FE; if equal, equal; and if it exceeds, it exceeds. But if both GI falls short of HN and KM of LO, then, the common parts being taken away, GH will also fall short of IN, and KL of MO. And if GI is equal to HN and KM to LO, then, the common parts HI, LM being taken away, GH will be equal to IN and KL to MO. And finally, if GI exceeds HN and KM exceeds LO, then, the common parts HI, LM being taken away, GH will also exceed IN and KL will exceed MO. For this reason, since GH, KL have been taken as equimultiples of the first and third AC, DF, and IN, MO as equimultiples of the second and fourth CB, FE, and it has been shown that (in whatever multiplication those equimultiples were taken) the equimultiples of the first and third alike fall short of, are equal to, or exceed the equimultiples of the second and fourth by one and the same amount — AC, the first, will be to CB, the second, as DF, the third, is to FE, the fourth [Margin: (e) — *Elements* V, def. 6]. Therefore if composite magnitudes are proportional, and so on. Which was to be demonstrated.

Diagram. The figure for the demonstration of Proposition 17, at the left of the column. It consists of several parallel vertical magnitude-lines, each divided by tick-marks into the segments named in the proof (the magnitudes AC, CB, DF, FE and their equimultiples GH, HI, KL, LM, IN, MO, and the composite multiples GI, KM, HN, LO). Legible point-labels, reading down the several lines, include N, O, I, M, H, L, B, C, F, G, A, D, K (the letter E is also present); the thin rules and small italic labels do not all resolve cleanly.

- Vertical lines carrying (across the several columns) the labels N, O, I, M, H, L, B, C, F, G, A, D, K, E

[— more than two labels in this dense line-figure are not individually resolvable]

SCHOLIUM.

From these things we shall easily demonstrate that mode of arguing which, at Definition 15, we called the converse separation of a ratio [divisio rationis conversa]: namely, that if AB is to CB as DE is to FE, then also CB is to AC as FE is to DF. This is evident as follows. Since AB is to CB as DE is to FE, by separation

[dividendo] AC will be to CB as DF is to FE [Margin: (f) — *Elements* V, 17]. Therefore by conversion [convertendo] CB will also be to AC as FE is to DF. Which is what was proposed.

With no trouble at all, that mode of arguing will also be demonstrated which we called the contrary [mode], and in which the antecedent magnitude is less than the consequent — not greater, as in the separation of a ratio which Euclid defined — like the one we have just demonstrated. Let AC be to CB as DF is to FE. Since AB is to AC as DE is to DF, then by separation [dividendo] CB will be to AC as FE is to DF [Margin: (g) — *Elements* V, 17]; and consequently, by conversion, AC will be to CB as DF is to FE. Which is what was proposed.

Diagram. A numeric line-figure for the scholium. Two horizontal lines, each divided by a point into two segments bearing numerals. The upper line runs A—C—B, with the segment AC marked **12** and the segment CB marked **4**. The lower line runs D—F—E, with the segment DF marked **6** and the segment FE marked **2**.

- Upper line: A ... [12] ... C ... [4] ... B
- Lower line: D ... [6] ... F ... [2] ... E

THEOR. 18. PROPOS. 18.

If separated magnitudes are proportional, they will also be proportional when taken jointly.

Here Euclid demonstrates the composition of a ratio [compositio rationis], which he described in Definition 14. For let the separated magnitudes AB, BC and DE, EF be proportional — that is, AB is to BC as DE is to EF. I say that, taken jointly, they too are proportional; that is, that AC is to BC as DF is to EF. For if AC is not to BC as DF is to EF, then DF will have to some magnitude...

(Continuation of the demonstration of Proposition 18.)

smaller than EF, or to some larger one, the same ratio which AC has to BC. First let DF have to GF — smaller than EF, if that be possible — the same ratio which AC has to BC. Since, then, AC is to BC as DF is to GF, by separation [dividendo] AB will also be to BC as DG is to GF [Margin: (a) — *Elements* V, 17]. But AB is to BC as DE, which was assumed, is to EF. Therefore DG, the first, will also be to GF, the second, as DE, the third, is to EF, the fourth [Margin: (b) — *Elements* V, 11]. Since, then, DG, the first, is greater than DE, the third, GF, the second, will also be greater than EF, the fourth [Margin: (c) — *Elements* V, 14] — the part greater than the whole. Which is absurd.

Next let DF have to HF — greater than EF, if that be possible — the same ratio which AC has to BC. Since, then, AC is to BC as DF is to HF, by separation [dividendo] AB will also be to BC as DH is to HF [Margin: (d) — *Elements* V, 17]. But AB is to BC as DE, which was likewise assumed, is to EF. Therefore DH, the first, will also be to HF, the second, as DE, the third, is to EF, the fourth [Margin: (e) — *Elements* V, 11]. Since, then, DH, the first, is less than DE, the third, HF, the second, will also be less than EF, the fourth — the whole less than the part. Which is absurd. Therefore DF will have, to a magnitude neither smaller than EF nor greater, the same ratio which AC has to BC. Hence DF will be to EF itself as AC is to BC, which is what was proposed. Therefore if separated magnitudes are proportional, and so on. Which was to be demonstrated.

SCHOLIUM.

Some, along with Campanus [Campanus], demonstrate this proposition by almost the same reasoning by which Euclid demonstrated the preceding one — in this way, namely. Let the separated magnitudes AC, CB, DF, FE be proportional — that is, AC to CB as DF to FE. I say that, taken jointly, they too are proportional, so that AB is to CB as DE is to FE. For let there be taken, as in the preceding proposition, equimultiples GH, HI, KL, LM of AC, CB, DF, FE; and likewise other equimultiples IN, MO of CB, FE. Then again GI, KM will be equimultiples of AB, DE [Margin: (f) — *Elements* V, 1], and HN, LO equimultiples of CB, FE [Margin: (g) — *Elements* V, 2], as was shown in the preceding theorem. Now since AC, the first, is assumed to be to CB, the second, as DF, the third, is to FE, the fourth, and GH, KL have been taken as equimultiples of the first and third AC, DF, and IN, MO as equimultiples of the second and fourth CB, FE, it follows [Margin: (h) — *Elements* V, def. 6] that if GH, the multiple of the first AC, falls short of IN, the multiple of the second CB, then KL, the multiple of the third DF, likewise falls short of MO, the multiple of the fourth FE; if equal, equal; and if it exceeds, it exceeds. But if both GH falls short of IN and KL of MO, then, adding the common parts HI, LM, GI will also fall short of HN, and KM of LO. And if GH is equal to IN and KL to MO, then, adding the common parts HI, LM, GI will also be equal to HN, and KM to LO. And finally, if GH exceeds IN and KL exceeds MO, then, adding the common parts HI, LM, GI will also exceed HN, and KM will exceed LO. Since, therefore, if GI, the multiple of the first AB, falls short of HN, the multiple of the second CB, then KM, the multiple of the third DE, also falls short of LO, the multiple of the fourth FE; and if equal, equal; and if it exceeds, it exceeds — AB, the first, will be to CB, the second, as DE, the third, is to FE, the fourth [Margin: (i) — *Elements* V, def. 6]. Which is what was proposed. Therefore if separated magnitudes are proportional, and so on. Which was to be shown.

But this demonstration does not correctly infer what is proposed from Definition 6, because HN, LO are not multiples of CB, FE in the same way that the multiples IN, MO of those same CB, FE were taken. Hence one might justly doubt whether, under any multiplication whatever, the equimultiples preserve that condition of falling short of, being equal to, and exceeding, which Euclid required in Definition 6 — since in this demonstration one is not free to assume any equimultiples whatever of CB, FE, but only such as arise from the multiples HI, IN and LM, MO already taken. This objection cannot be raised against the demonstration of the preceding proposition, since there IN, MO were taken as any equimultiples whatever of CB, FE, and they remain the same equimultiples of those same CB, FE in the separated proportionality. For this reason Euclid's demonstration is to be preferred to this one of Campanus. Yet I have chosen to explain it too, lest the studious reader, abandoning Euclid's, should seize upon it as a good one — especially since it is direct, whereas Euclid's leads us to what cannot be [i.e., proceeds by reduction to the impossible].

Diagram. The figure for the Campanus demonstration in the scholium, at the left of the column. As in the Proposition 17 figure, it is a set of parallel vertical magnitude-lines divided by tick-marks (the magnitudes AC, CB, DF, FE and their equimultiples GH, HI, KL, LM, IN, MO, with the composite multiples GI, KM, HN, LO). Legible point-labels down the several lines include N, O, I, M, H, L, B, C, E, F, G, A, D, K; the thin rules and small italic labels do not all resolve cleanly.

- Vertical lines carrying (across the several columns) the labels N, O, I, M, H, L, B, C, E, F, G, A, D, K

[— more than two labels in this dense line-figure are not individually resolvable]

From these things we shall also easily confirm the two modes of arguing which we described at Definition 14. The former we called the converse composition of a ratio. Let AB be to BC as DE is to EF. I say that, by the converse composition of a ratio, AC is also to AB as DF is to DE. For since AB is to BC as DE is to EF, by conversion [convertendo] BC will be to AB as EF is to DE. Therefore, by composition [componendo], AC will be to AB as DF is to DE [Margin: (k) — *Elements* V, 18]. Which is what was proposed.

The latter mode we called the contrary composition of a ratio. Let it again be that AB is to BC as DE is to EF. I say that, by the contrary composition of a ratio, AB is also to AC as DE is to DF. For since AB is to BC as DE is to EF, by conversion BC will be to AB as EF is to DE. Therefore, by composition, AC will be to AB as DF is to DE

[Margin: (l) — *Elements* V, 18]; and consequently, by conversion once more, AB will be to AC as DE is to DF. Which is what was proposed.

Diagram. Two numeric line-figures for the scholium (one for each of the two argument-modes; both carry the same lettering and numerals). Each has an upper line A—B—C, with the segment AB marked **12** and the segment BC marked **8**, and a lower line D—E—F, with the segment DE marked **6** and the segment EF marked **4**.

- Upper line: A ... [12] ... B ... [8] ... C
- Lower line: D ... [6] ... E ... [4] ... F

THEOR. 19. PROPOS. 19.

If, as a whole is to a whole, so a part taken away is to a part taken away, then the remainder will also be to the remainder as the whole is to the whole.

What was demonstrated at Proposition 5 for multiple proportion is here demonstrated for every proportion, even an irrational one. Let the whole AB be to the whole CD as the part taken away AE is to the part taken away CF. I say that the remainder EB is also to the remainder FD as the whole AB is to the whole CD. For since AB is to CD as AE is to CF, then alternately [permutando] AB will also be to AE as CD is to CF [Margin: (a) — *Elements* V, 16]. Therefore, by separation [dividendo], EB will be to AE as FD is to CF [Margin: (b) — *Elements* V, 17]. Hence, alternately once more, EB will be to FD as AE is to CF [Margin: (c) — *Elements* V, 16] — that is, as the whole AB is to the whole CD, since AB was assumed to be to CD as AE is to CF. Therefore if, as a whole is to a whole, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 19. Two horizontal lines, each divided by an interior point. The upper line runs A—E—B (whole AB, part taken away AE, remainder EB). The lower line runs C—F—D (whole CD, part taken away CF, remainder FD).

- Upper line: A (start) — E (division point) — B (end)
- Lower line: C (start) — F (division point) — D (end)

COROLLARIVM [Corollary — to Proposition 19]

From this, that method of arguing in proportions which is drawn from the conversion of ratio [*convertendo*] can easily be demonstrated, in accordance with definition 16.

Let AB be to CB as DE is to FE. I say that, by conversion of ratio, it is likewise the case that AB is to AC as DE is to DF. For since AB is to CB as DE is to FE, then by separation [*dividendo*] AC will also be to CB as DF is to FE [Margin: (d) — V.17]. Therefore also by conversion, CB is to AC as FE is to DF; and consequently by composition [*componendo*] as well, AB is to AC as DE is to DF [Margin: (e) — V.18]. Which was to be demonstrated.

Diagram. Two horizontal straight lines representing the magnitudes of the corollary, drawn one above the other and subdivided by tick-marks.

- Upper line: points **A, C, B** in order (A at the left end, B at the right). The number **4** is printed over the segment CB.
- Lower line: points **D, F, E** in order (D at the left end, E at the right). The number **12** is printed over the segment DF, and **8** over the segment FE.

SCHOLIVM [Scholium]

All the interpreters of Euclid demonstrate the conversion of ratio in this way. Since AB is to CB as DE is to FE, then by alternation the whole AB will be to the whole DE as CB, the part taken away, is to FE, the part taken away [Margin: (f) — V.16]. Therefore, as the whole AB is to the whole DE, so too the remainder AC will be to the remainder DF [Margin: (g) — V.19]; and consequently, by alternation once more, AB is to AC as DE is to DF. Which was to be demonstrated.

But who does not see that this demonstration holds only for magnitudes of the same kind? For it employs the alternate or permuted proportion, which has force only among magnitudes of the same kind — as we noted both in definition 12 and in proposition 19. Therefore, since Euclid and the other geometers apply this method of arguing from the conversion of ratio to all magnitudes, even those not of the same kind, we have rejected this common demonstration of the interpreters and devised another of our own that fits all magnitudes. For it holds even if the first two quantities, AB and CB, are of one kind — namely lines — while the latter two, DE and FE, are of another kind — namely surfaces, or angles, or solids, or finally numbers — because in it the alternate or permuted proportion was not assumed.

[Margin: xx.]

THEOR. 20. PROPOS. 20.

If there are three magnitudes, and others equal to them in number, taken two by two and in the same ratio, then, *ex aequali*, if the first is greater than the third, the fourth will also be greater than the sixth. But if the first is equal to the third, the fourth will also be equal to the sixth; and if the first is less, the fourth too will be less.

Let there be three magnitudes A, B, C, and as many others D, E, F, and let A be to B as D is to E, and B to C as E is to F. Suppose first that A, the first, is greater than C, the third. I say that D, the fourth, is also greater than F, the sixth. For since A is greater than C, the ratio of A to B is greater than that of C to B [Margin: (a) — V.8]. But A is to B as D is to E; therefore the ratio of D to E is likewise greater than that of C to B [Margin: (b) — V.13]. Now since B is to C as D is to E, by conversion C is to B as F is to E. The ratio of D to E is therefore greater than that of F to E as well; and hence D is greater than F [Margin: (c) — V.10]. Which was to be demonstrated.

Next, let A be equal to C. I say that D is also equal to F. For since A is equal to C, A will be to B as C is to B [Margin: (d) — V.7]. But A is to B as D is to E; therefore D is to E as C is to B [Margin: (e) — V.11]. Now C is to B as F is to E, by inverse ratio, as before. Therefore D is to E as F is to E; and hence D and F are equal [Margin: (f) — V.9]. Which was to be demonstrated.

Third, let A be less than C. I say that D is also less than F. For since A is less than C, the ratio of A to B is less than that of C to B [Margin: (g) — V.8]. But A is to B as D is to E; therefore the ratio of D to E is likewise less than that of C to B [Margin: (h) — V.13]. Now by conversion, as before, C is to B as F is to E. Therefore the ratio of D to E is also less than that of F to E; and for that reason D is less than F [Margin: (i) — V.10]. Which was to be demonstrated. And so, if there are three magnitudes and others equal to them in number, and the rest as stated.

Diagram. In the left column, three stacked groups of six parallel horizontal line-segments (magnitudes), illustrating the three cases of the demonstration (A greater than, equal to, and less than C). Each group is labelled, from top to bottom, A, B, C, D, E, F; the segments are of differing lengths and are subdivided by tick-marks. The marginal citation letters a–i beside them belong to the demonstration text, not to the figure.

SCHOLIUM [Scholium]

Moreover, in proposition 22 Euclid will show that the magnitudes A and D are not only greater than, equal to, or less than the two magnitudes C and E — as he has demonstrated here — but also that they have the same ratio to them *ex aequali*; and this he could not demonstrate unless he had first established the present theorem, as will be clear from that proposition 22. [?]

[Margin: xxj.]

THEOR. 21. PROPOS. 21.

If there are three magnitudes, and others equal to them in number, taken two by two and in the same ratio, but their proportion is perturbed, then, *ex aequali*, if the first is greater than the third, the fourth will also be greater than the sixth. But if the first is equal to the third, the fourth will also be equal to the sixth; and if the first is less, this too will be less.

Let there be three magnitudes A, B, C, and as many others D, E, F, taken two by two and in the same ratio, and let their proportion be perturbed — that is, let A be to B as E is to F, and B to C as D is to E. Suppose first that A, the first, is greater than C, the third. I say that D, the fourth, is also greater than F, the sixth. For since A is greater than C, the ratio of A to B is greater than that of C to B [Margin: (a) — V.8]. But A is to B as E is to F; therefore the ratio of E to F is greater than that of C to B [Margin: (b) — V.13]. Now since B is to C as D is to E, by conversion C is to B as E is to D. The ratio of E to F is therefore greater than that of E to D as well; and hence D is greater than F [Margin: (c) — V.10]. Which was to be demonstrated.

Next, let A be equal to C. I say that D is likewise equal to F. For since A is equal to C, A will be to B as C is to B [Margin: (d) — V.7]. But A is to B as E is to F; therefore C is to B as E is to F [Margin: (e) — V.11]. Now by inverse ratio C is to B as E is to D, as before. Therefore E is to F as E is to D; and for that reason D is equal to F [Margin: (f) — V.9]. Which was to be demonstrated.

Third, let A be less than C. I say that D is also less than F. For since A is less than C, the ratio of A to B is less than that of C to B [Margin: (g) — V.8]. But A is to B as E is to F; therefore the ratio of E to F is less than that of C to B [Margin: (h) — V.13]. Now, as before, by inverse ratio C is to B as E is to D; therefore the ratio of E to F is also less than that of E to D; and hence D is less than F. Which was to be demonstrated [Margin: (i) — V.10]. And so, if there are three magnitudes and others equal to them in number, and the rest as stated. Which was to be shown.

Diagram. In the right-hand column, stacked groups of six parallel vertical line-segments (magnitudes) for the three cases of this demonstration. Each group is labelled **A, B, C, D, E, F**; the segments are of differing lengths and subdivided by tick-marks.

SCHOLIVM [Scholium]

Moreover, in proposition 23 Euclid will show that the two magnitudes A and D are not only greater than, equal to, or less than the two magnitudes C and F, but also that they have the same ratio to them *ex aequali*; and this he could not demonstrate without the aid of the present theorem, as will be evident from that proposition 23.

[Margin: xxij.]

THEOR. 22. PROPOS. 22.

If there are any number of magnitudes whatever, and others equal to them in number, taken two by two in the same ratio, then, *ex aequali*, they too will be in the same ratio.

Here Euclid demonstrates the method of arguing in proportions *ex aequali*, when the proportion is ordered. Let there first be three magnitudes A, B, C and three others D, E, F, and let A be to B as D is to E, and B to C as E is to F. I say that, *ex aequali* as well, A is to C as D is to F. For let G, H be taken as equimultiples of A, D; likewise I, K as equimultiples of B, E; likewise L, M as equimultiples of C, F. Then, since A, the first, is to B, the second, as D, the third, is to E, the fourth, G, the multiple of the first A, will be to I, the multiple of the second B, as H, the multiple of the third D, is to K, the multiple of the fourth E [Margin: (a) — V.4]. By the same reasoning, since B, the first, is to C, the second, as E, the third, is to F, the fourth, I, the multiple of the first B, will be to L, the multiple of the second C, as K, the multiple of the third E, is to M, the multiple of the fourth F [Margin: (b) — V.4]. Since, therefore, there are three magnitudes G, I, L and three others H, K, M, taken two by two in the same proportion, it follows that if G, the first, exceeds L, the third, then H, the fourth, necessarily also exceeds M, the sixth; and if equal, equal; and if it falls short, it falls short [Margin: (c) — V.10]. And so, since G and H, the equimultiples of the first A and the third D, either both fall short of L and M, the equimultiples of the second C and the fourth F, or are both equal to them, or both exceed them — whatever multiplication be taken in forming these multiples — A, the first, will be to C, the second, as D, the third, is to F, the fourth [Margin: (d) — V def. 6]. Which was to be demonstrated.

Next, let there be more magnitudes than three, so that also C is to N as F is to O. I say that it still holds that A is to

N as D is to O. For since it has already been shown, among three magnitudes, that A is to C as D is to F, and it is now posited that C is to N as F is to O, there will be three magnitudes A, C, N and three others D, F, O, taken two by two in the same ratio. Therefore, from what was shown *ex aequali* among three magnitudes, it again follows that A is to N as D is to O. And in the same way the same thing will be shown among five magnitudes by means of four, just as it was demonstrated among four by means of three; and so for more. And so, if there are any number of magnitudes whatever, and the rest as stated. Which was to be shown.

SCHOLIVM [Scholium]

Moreover, it does not seem right to pass over in this place a certain theorem very familiar to the ancient mathematicians, although — so far as I know — no one has yet demonstrated it. It is of the following kind.

If the first has the same ratio to the second as the third has to the fourth, then equimultiples of the first and third will have the same ratio to the second and fourth; likewise equimultiples of the second and fourth will have the same ratio to the first and third. And conversely, the second and fourth will have the same ratio to equimultiples of the first and third; likewise the first and third will have the same ratio to equimultiples of the second and fourth.

Let A, the first, be to B, the second, as C, the third, is to D, the fourth; and let E, F be taken as equimultiples of A, C, and G, H as equimultiples of B, D. I say that E is to B as F is to D; likewise that G is to A as H is to C. And conversely, that B is to E as D is to F; likewise that A is to G as C is to H.

For since E is to A as F is to C, by construction (the multiple ratio being the same in each case), and it is posited that A is to B as C is to D, then *ex aequali* E will be to B as F is to D [Margin: (e) — V.22]. Again, since G is to B as H is to D — because in each case, by construction, the multiple ratio is the same — and B is to A as D is to C (for since it is posited that A is to B as C is to D, by conversion B is to A as D is to C), then *ex aequali* G will be to A as H is to C [Margin: (f) — V.22]. Next, since B is to A as D is to C, by inverse ratio, and A is to E as C is to F — because by construction the submultiple ratio is the same in each case — then *ex aequali* B will be to E as D is to F [Margin: (g) — V.22]. Again, since it is posited that A is to B as C is to D, and B is to G as D is to H [?], because by construction the submultiple

ratio is the same in each case, then *ex aequali* A will be to G as C is to H [Margin: (h) — V.22]. Which was to be demonstrated.

Diagram. Four parallel horizontal line-segments (magnitudes), one above the other and subdivided by tick-marks. From top to bottom the lines carry the labels **E F, A C, B D, G H** — E, F being equimultiples of A, C, and G, H equimultiples of B, D.

From this is evident the mode of argument that geometers use most frequently — above all Archimedes, Apollonius of Perga [Apollonius Pergaeus], Theon, and others. Namely: A is to B as C is to D. Therefore, as E — the double, or triple, or quadruple, etc., of A — is to B, so also will F — the double, or triple, or quadruple, etc., of C — be to D. Likewise, A is to B as C is to D. Therefore, as A is to the double, or triple, or quadruple, etc., of B — namely to G — so also will C be to the double, or triple, or quadruple, etc., of D — namely to H.

[Margin: xxii.]

THEOR. 23. PROPOS. 23.

If there are three magnitudes, and others equal to them in number, taken two by two in the same ratio, but their proportion is perturbed, then, *ex aequali*, they too will be in the same ratio.

Here the ratio is demonstrated *ex aequali*, when the proportion is perturbed. Let there be three magnitudes A, B, C and three others D, E, F, and let their proportion be perturbed — that is, let A be to B as E is to F, and B to C as D is to E. I say that, *ex aequali* as well, A is to C as D is to F. For let G, H, I be taken as equimultiples of A, B, D; likewise K, L, M as equimultiples of C, E, F. Then A will be to B as G is to H, since G, H are equimultiples of A, B [Margin: (a) — V.15]. But A is to B as E is to F; therefore G is to H as E is to F as well [Margin: (b) — V.11]. But E is to F as L is to M, since L, M are equimultiples of E, F [Margin: (c) — V.15]. Therefore G is to H as L is to M [Margin: (d) — V.11]. Again, since B, the first, is to C, the second, as D, the third, is to E, the fourth, H, the multiple of the first B, will be to K, the multiple of the second C, as I, the multiple of the third D, is to L, the multiple of the fourth E [Margin: (e) — V.4]. Since, therefore, there are three magnitudes G, H, K and three others I, L, M, taken two by two in the same ratio, and their proportion is perturbed — it having been shown that G is to H as L is to M, and that H is to K as I is to L — it follows that if G, the first, exceeds K, the third, then I, the fourth, also exceeds M, the sixth; and if equal, equal; and if it falls short, it falls short [Margin: (f) — V.21]. And so, since G and I, the equimultiples of the first A and the third D, either both fall short of K and M, the

equimultiples of the second C and the fourth F, or are both equal to them, or both exceed them, A, the first, will be to C, the second, as D, the third, is to F, the fourth [Margin: (g) — V def. 6]. Which was to be demonstrated. And so, if there are three magnitudes, and the rest as stated. Which was to be shown.

Diagram. In the left column, two rows of parallel vertical line-segments (magnitudes), subdivided by tick-marks. The upper row is labelled **A, B, C, N, D, E, F, O**; the lower row **G, H, K, I, L, M** — G, H, I being equimultiples of A, B, D, and K, L, M equimultiples of C, E, F.

SCHOLIVM [Scholium]

But if there are more than three magnitudes and their proportion is perturbed — that is, if A is to B as F is to O, and B to C as E is to F, and C to N as D is to E — I say that it still holds that A is to N as D is to O. And although, among geometers, the *ex aequali* proportion is not in use for more magnitudes than three — which was the reason why Euclid framed the preceding proposition [22] for any number of magnitudes, but this one for three only, even though it is true for more as well — it is proved thus. Since it has already been shown, among three magnitudes, that A is to C as F is to E, there will be three magnitudes A, C, N and three others D, E, O, taken two by two in the same proportion, and their proportion is perturbed. Therefore, again from what was shown *ex aequali* among three magnitudes, A will be to N as D is to O. And in the same way the same thing will be shown among five magnitudes by means of four, just as it was demonstrated among four by means of three; and so for more. Which was to be demonstrated.

Euclid, *Elements* — Book V (continued)

THEOR. 24. PROPOS. 24. [Margin: xxiv.]

If a first has the same ratio to a second as a third has to a fourth, and a fifth also has the same ratio to the second as a sixth has to the fourth: then the first together with the fifth will also have the same ratio to the second as the third together with the sixth has to the fourth.

What Euclid demonstrated in Proposition 2 for multiple proportion alone, he here demonstrates for every proportion, even the irrational. For let AB be the first, standing to C the second as DE the third stands to F the fourth; likewise let BG be the fifth, standing to C the second as EH the sixth stands to F the fourth. I say that AG, composed of the first and the fifth, stands to the second C as DH, composed of the third and the sixth, stands to the fourth F. For since BG is to C as

EH is to F, then by conversion [convertendo] C will be to BG as F is to EH. Therefore, since AB is to C as DE is to F, and C is to BG as F is to EH, [Margin: a — *Elements* V.22] there will be, ex aequali, AB to BG as DE to EH. [Margin: b — *Elements* V.18] By composition [componendo], then, as the whole AG is to BG, so the whole DH is to EH. And so, since again AG is to BG as DH is to EH, and BG is to C as EH is to F, [Margin: c — *Elements* V.22] there will be, ex aequali, AG to C as DH to F. Which is the thing proposed. Therefore, if a first has the same ratio to a second, etc. Which was to be demonstrated.

Diagram. A single long vertical line at the left, subdivided by tick marks, with two short vertical bars set off to its right. The long line represents the composed magnitudes AG (= AB + BG) and DH (= DE + EH), drawn continuously; the short bars are the second and fourth magnitudes.

- G (top of the long line): endpoint of AG
- B (below G): division point; BG = the fifth magnitude, AB = the first
- A (below B): shared point (AG runs from A up to G)
- D (below A): endpoint of DH
- E (below D): division point; DE = the third magnitude, EH = the sixth
- H (bottom of the long line): endpoint of DH
- C (short bar, upper right): the second magnitude
- F (short bar, lower right): the fourth magnitude

SCHOLIUM

This proposition is true whether or not the magnitudes AB, BG, and C are of the same kind as the magnitudes DE, EH, and F — as is clear from the demonstration.

In almost the same way there will be shown, for every kind of proportion, what was demonstrated in Theorem 6 of this book for multiple magnitudes only.

Namely:

If two magnitudes have the same ratio to two magnitudes, and certain magnitudes taken away from them have the same ratio to the same two: then the remainders also will have the same ratio to the same two.

For let AG, DH have the same ratio to C and F — that is, let AG be to C as DH is to F — and let the magnitudes taken away, AB and DE, have the same ratio to the same C, F — that is, let AB be to C as DE is to F. I say that the remainders BG, EH also have the same ratio to the same C, F — that is, that BG is to C as EH is to F. For since AB is to C as DE is to F, then by conversion C will be to AB as F is to DE.

[Margin: d — *Elements* V.22] There will therefore be, ex aequali, AG to AB as DH to DE. [Margin: e — *Elements* V.17] By division [dividendo], then, BG will be to AB as EH is to DE. And so, since again BG is to AB as EH is to DE, and AB is to C as DE is to F, [Margin: f — *Elements* V.22] there will be, ex aequali, BG to C as EH to F. Which is the thing proposed.

THEOR. 25. PROPOS. 25. [Margin: xxv.]

If four magnitudes are proportional: the greatest and the least together will be greater than the remaining two together.

For let AB be to CD as E is to F, and let AB be the greatest of all and F the least. I say that the two AB and F together are greater than the two CD and E together. For let there be taken from AB a magnitude AG equal to E, and from CD another, CH, equal to F. Then AG will be to CH as E is to F — that is, as AB is to CD. Therefore, since the whole AB is to the whole CD as the part taken away AG is to the part taken away CH, [Margin: a — *Elements* V.19] it will also be that as the whole AB is to the whole CD, so the remainder GB is to the remainder HD. But AB (since it is the greatest of all) is greater than CD. Therefore GB too will be greater than HD. Now since AG and E are equal, if to them be added the equals F and CH — namely F to AG, and CH to E — then AG and F together will be equal to E and CH together. When, therefore, the unequals GB and HD are added, AB and F together will become greater than E and CD together, since GB is greater than HD. Which is the thing proposed. Therefore, if four magnitudes are proportional, etc. Which was to be demonstrated.

Diagram. Two vertical lines with tick-mark subdivisions, and two short vertical bars set alongside. The left line is AB; the right line is CD; the two short bars are the third and fourth magnitudes E and F.

- B (top of left line): endpoint of AB [reading of this topmost letter as B rather than E is slightly uncertain]
- G (below B on the left line): division point; AG (from A up to G) = E
- A (bottom of left line): endpoint of AB
- D (top of right line): endpoint of CD
- H (below D on the right line): division point; CH (from C up to H) = F
- C (bottom of right line): endpoint of CD
- E (short bar): the third magnitude
- F (short bar): the fourth magnitude

SCHOLIUM

It necessarily follows that, if the antecedent magnitude of one proportion is the greatest of all, the consequent of the other is the least of all — as may be seen in the example proposed. For since AB is to CD as E is to F, and AB the first is greater than E the third, [Margin: b — *Elements* V.14] CD the second will also be greater than F the fourth. Likewise, because AB is greater than CD, E too will be greater than F, on account of the same proportion of AB to CD and of E to F, as we showed in the scholium to Proposition 14. But if, on the contrary, the antecedent of one proportion is the least of all, the consequent of the other will be the greatest of all — as is evident, if one states that F is to E as CD is to AB. All four magnitudes must also be of the same kind; otherwise one magnitude could not be composed from the greatest and the least — indeed, not even from the remaining two. Federicus Commandinus [Federico Commandino] adds here another theorem not much unlike this twenty-fifth, namely:

If three magnitudes are proportional: the greatest and the least together will be greater than double the remaining one.

Let A be to B as B is to C, and let A be the greatest and C the least. I say that A and C together are greater than double B. For, taking D equal to B, we shall have A to B as D to C. Therefore A and C together will be greater than B and D together, [Margin: b — *Elements* V.25] as was just now demonstrated — that is, than double B. Which is the thing proposed.

Diagram. Four vertical bars of decreasing length, standing side by side; A is the longest and C the shortest, with B and D (equal) between.

- A: the greatest magnitude
- B: the middle (remaining) magnitude
- D: magnitude taken equal to B
- C: the least magnitude

Here Euclid puts an end to the fifth book. But since Campanus [Campanus of Novara] and some others append certain further propositions — which the weightiest writers, such as Archimedes, Apollonius [of Perga], Johannes Regiomontanus [Regiomontanus], and others, very often use, and cite as though they were Euclid's — I have thought it well to attach them to this fifth book, to demonstrate them with the greatest brevity possible, and also to bring them into the number and series of Euclid's propositions. They are all set forth concerning

magnitudes not in proportion [magnitudinibus impropotionalibus], of which the first is this:

THEOR. 26. PROPOS. 26. [Margin: xxvj.]

If a first has to a second a greater ratio than a third has to a fourth: then, by conversion [convertendo], the second will have to the first a smaller ratio than the fourth has to the third.

For let A have to B a greater ratio than C has to D. I say that the ratio of B to A is smaller than the ratio of D to C. For let E be conceived such that E is to B as C is to D; then the ratio of A to B will also be greater than the ratio of E to B, [Margin: a — *Elements* V.10] and on that account A will be greater than E. [Margin: b — *Elements* V.8] Hence the ratio of B to A (the greater) will be less than the ratio of B to E (the less). But as B is to E, so, by conversion, is D to C. Therefore the ratio of B to A is also smaller than the ratio of D to C. Which is the thing proposed.

Diagram. Five short vertical bars with tick marks, arranged as an upper row (A, B, E) with two bars (C, D) set below A and B. They represent the magnitudes of the two given ratios $A : B$ and $C : D$, together with the conceived magnitude E.

- A (upper left): first magnitude
- B (upper middle): second magnitude
- E (upper right): the conceived magnitude, $E : B = C : D$
- C (below A): third magnitude
- D (below B): fourth magnitude

SCHOLIVM

In almost the same way we shall demonstrate that, if a first has to a second a smaller ratio than a third has to a fourth, then by conversion the ratio of the second to the first is greater than that of the fourth to the third — provided we change the word "greater" into the word "less," and conversely.

For let the ratio of A to B be smaller than that of C to D. I say that, by conversion, B to A has a greater ratio than D to C. For let E be conceived such that E is to B as C is to D; then the ratio of A to B will also be smaller than that of E to B, [Margin: c — *Elements* V.10] and on that account A will be less than E. [Margin: d — *Elements* V.8] Hence the ratio of B to A (A being the less) will be greater than the ratio of B to E (E being the greater). But as B is to E, so, by conversion, is D to C. Therefore the ratio of B to A is also greater than that of D to C. Which is the thing proposed.

Alternatively. Since the ratio of A to B is smaller than that of C to D, the ratio of C to D will be greater than that of A to B. [Margin: e — *Elements* V.26] Therefore, by conversion, the ratio of D to C will be smaller than that of B to A; and consequently the ratio of B to A is greater than that of D to C. Which is the thing proposed.

Diagram. The same schematic arrangement as the preceding figure: an upper row of bars (A, B, E) with two bars (C, D) beneath A and B, serving the scholium's case in which $A : B$ is the smaller ratio.

- A (upper left): first magnitude
- B (upper middle): second magnitude
- E (upper right): the conceived magnitude, $E : B = C : D$
- C (below A): third magnitude
- D (below B): fourth magnitude

THEOR. 27. PROPOS. 27. [Margin: xxvij.]

If a first has to a second a greater ratio than a third has to a fourth: then it will also, alternately, have to the third a greater ratio than the second has to the fourth.

For let A have to B a greater ratio than C has to D. I say that, alternately [permutando], the ratio of A to C is also greater than that of B to D. For let E be conceived such that E is to B as C is to D; then the ratio of A to B will be greater even than that of E to B. [Margin: a — *Elements* V.10] And so A will be greater than E. [Margin: b — *Elements* V.8] Hence the ratio of A to C will be greater than that of E to C. [Margin: c — *Elements* V.16] But since, alternately, E is to C as B is to D (because E was set to be to B as C is to D), the ratio of A to C will therefore also be greater than that of B to D. Which is the thing proposed.

Diagram. Three vertical lines with tick subdivisions; C is set below A, and D below B, with E standing to the right. They represent the ratios $A : B$ and $C : D$ and the conceived magnitude E.

- A (upper left): first magnitude
- C (below A): third magnitude
- B (middle): second magnitude
- D (below B): fourth magnitude
- E (right): the conceived magnitude, $E : B = C : D$

SCHOLIUM

Similarly we shall show that, if a first has to a second a smaller ratio than a third has to a fourth, then alternately the first has to the third a smaller ratio than the second has to the fourth. For let the ratio of A to B be smaller than that of C to D. I say that, alternately, the ratio of A to C is also smaller than that of B to D. For let E be conceived such that E is to B as C is to D; then the ratio of A to B will also be smaller than that of E to B, [Margin: d — *Elements* V.10] and on that account A will be less than E. [Margin: e — *Elements* V.8] Hence the ratio of A to C will be smaller than that of E to C. [Margin: f — *Elements* V.16] But, alternately, E is to C as B is to D (because E was set to be to B as C is to D). Therefore the ratio of A to C will also be smaller than that of B to D. Which is the thing proposed.

Alternatively. Since the ratio of A to B is smaller than that of C to D, the ratio of C to D will be greater than that of A to B. [Margin: g — *Elements* V.27] Therefore, alternately, the ratio of C to A will also be greater than that of D to B; [Margin: h — *Elements* V.26] and consequently, by conversion, the ratio of A to C will be smaller than that of B to D. Which is the thing proposed.

Diagram. The same schematic arrangement as the preceding figure: vertical lines for A (with C below) and B (with D below), and E to the right, serving the scholium's case in which $A : B$ is the smaller ratio.

- A (upper left): first magnitude
- C (below A): third magnitude
- B (middle): second magnitude
- D (below B): fourth magnitude
- E (right): the conceived magnitude, $E : B = C : D$

THEOR. 28. PROPOS. 28. [Margin: xxvii.]

If a first has to a second a greater ratio than a third has to a fourth: then also, by composition [componendo], the first together with the second will have to the second a greater ratio than the third together with the fourth has to the fourth.

Let the ratio of AB to BC be greater than that of DE to EF. I say that, by composition, the ratio of AC to BC is also greater than that of DF to EF. For let GB be conceived such that GB is to BC as DE is to EF; then the ratio of AB to BC will also be greater than that of GB to BC. [Margin: a — *Elements* V.10] And so AB is greater than GB. Adding, therefore, the common BC, AC will become greater than GC; [Margin: b — *Elements* V.8] and on that account the ratio of AC to BC will be

greater than that of GC to BC. But, by composition, GC is to BC as DF is to EF (because GB was set to be to BC as DE is to EF). [Margin: c — *Elements* V.18] Therefore the ratio of AC to BC will also be greater than that of DF to EF. Which is the thing proposed.

Diagram. A composite figure of two straight lines. On the left, a vertical line runs from C (top) through B down to A (bottom), with a second line slanting from the upper part down to G at the lower left (representing GB, and $GC = GB + BC$). On the right, a parallel vertical line runs from F (top) through E down to D (bottom), representing DF (= DE + EF).

- C (top of left line): endpoint of AC (AB runs from A up to B, BC from B to C)
- B (on left line): division point of AC; AB above, BC below
- G (lower left): endpoint of GB, so that $GB : BC = DE : EF$
- A (bottom of left line): endpoint of AC
- F (top of right line): endpoint of DF
- E (on right line): division point; DE above, EF below
- D (bottom of right line): endpoint of DF

SCHOLIUM

By the same reasoning we shall show that, if the ratio of the first to the second is smaller than that of the third to the fourth, then the ratio of the first and second together to the second is also smaller than that of the third and fourth together to the fourth.

These pages continue Euclid's **Book V** with Clavius's annexed propositions (the "greater/smaller ratio" and *ex aequali* theorems, Props 28–32). The Book V→VI transition does **not** occur here; the running header remains "LIBER V." throughout. The magnitudes are represented by the labelled straight-line schematics standard to Clavius's Book V. Enunciations are set as blockquotes; Clavius's demonstrations and scholia follow as prose. Marginal citation letters key to *Elements* Book V propositions and are rendered as [Margin: ...].

[Conclusion of the Scholium to Prop. 28]

(continued from the previous page; catchword "SIT")

For let AB have a smaller ratio to BC than DE has to EF. I say that *componendo* as well, AC has a smaller ratio to BC than DF has to EF. For let GB be to BC as DE is to EF. Then AB will also have a smaller ratio to BC than GB has to BC,[Margin: a — *Elements* V.10] and so AB will be smaller than GB. Therefore, when the common

BC is added, AC becomes smaller than GC,[Margin: b — Elements V.8] and for that reason AC has a smaller ratio to BC than GC has to BC. But *componendo*, as GC is to BC, so is DF to EF — since GB was assumed to be to BC as DE is to EF. Therefore AC will also have a smaller ratio to BC than DF has to EF. Which was to be proved.

Alternatively. Since AB has a smaller ratio to BC than DE has to EF, DE will have a greater ratio to EF than AB has to BC.[Margin: c — Elements V.28] Therefore *componendo*, DF will also have a greater ratio to EF than AC has to BC, and for that reason AC will have a smaller ratio to BC than DF has to EF. Which was to be proved.

Diagram. A pair of adjacent vertical magnitude-lines with division points marked by ticks.

- Right line (top to bottom): F, E, D

THEOR. 29. PROPOS. 29.

[Margin: xxix.]

If the first compounded with the second has a greater ratio to the second than the third compounded with the fourth has to the fourth: then *dividendo* the first will also have a greater ratio to the second than the third has to the fourth.

Let AC have a greater ratio to BC than DF to EF. I say that *dividendo* AB too has a greater ratio to BC than DE to EF. For let GC be to BC as DF to EF; then AC has a greater ratio to BC than GC has to BC,[Margin: a — Elements V.10] and so AC is greater than GC. Therefore, when the common BC is taken away, AB is greater than GB,[Margin: b — Elements V.8] and for that reason AB has a greater ratio to BC than GB has to BC.[Margin: c — Elements V.17] But *dividendo*, as GB is to BC, so is DE to EF (since GC was assumed to be to BC as DF to EF). Therefore AB also has a greater ratio to BC than DE to EF. Which was to be proved.

Diagram. Two adjacent vertical magnitude-lines with tick-marked division points.

- Left line (top to bottom): C, B, G, A
- Right line (top to bottom): F, E, D

SCHOLIUM

But if the first compounded with the second has a smaller ratio to the second than the third compounded with the fourth has to the fourth, then *dividendo* the first will also have a smaller ratio to the second than the third has to the fourth.

For let AC have a smaller ratio to BC than DF to EF. I say that *dividendo* AB too has a smaller ratio to BC than DE to EF. For let GC be to BC as DF to EF; then AC has a smaller ratio to BC than GC has to BC,[Margin: d — Elements V.10] and so AC is smaller than GC. Therefore, when the common BC is taken away, AB is smaller than GB,[Margin: e — Elements V.8] and for that reason AB has a smaller ratio to BC than GB has to BC.[Margin: f — Elements V.17] But *dividendo*, as GB is to BC, so is DE to EF (since GC was assumed to be to BC as DF to EF). Therefore AB also has a smaller ratio to BC than DE to EF. Which was to be proved.

Alternatively. Since AC has a smaller ratio to BC than DF to EF, DF will have a greater ratio to EF than AC to BC.[Margin: g — Elements V.29] Therefore *dividendo* too, DE has a greater ratio to EF than AB to BC; and consequently AB has a smaller ratio to BC than DE to EF. Which was to be proved.

Diagram. Two adjacent vertical magnitude-lines with tick-marked division points.

- Left line (top to bottom): C, B, A, G
- Right line (top to bottom): F, E, D

THEOR. 30. PROPOSITIO 30.

[Margin: xxx.]

(Heading verbatim: "PROPOSITIO" is spelled out here, unlike the abbreviated "PROPOS." of the neighbouring theorems.)

If the first compounded with the second has a greater ratio to the second than the third compounded with the fourth has to the fourth: then, by conversion of ratio, the first-and-second together will have a smaller ratio to the first than the third-and-fourth together has to the third.

Let AC have a greater ratio to BC than DF to EF. I say that, by conversion of ratio, AC has a smaller ratio to AB than DF to DE. For since AC has a greater ratio to BC than DF to EF,[Margin: a — Elements V.29] *dividendo* AB will also have a greater ratio to BC than DE to EF.[Margin: b — Elements V.26] Therefore *convertendo*, BC

has a smaller ratio to AB than EF to DE;[Margin: c — Elements V.28] and for that reason *componendo* too, the whole AC has a smaller ratio to AB than the whole DF has to DE. Which was to be proved.

Diagram. Two adjacent vertical magnitude-lines with tick-marked division points.

- Left line (top to bottom): C, B, A
- Right line (top to bottom): F, E, D

SCHOLIVM (to Prop. 30)

By a not dissimilar argument we shall show that, if the first compounded with the second has a smaller ratio to the second than the third compounded with the fourth has to the fourth, then, by conversion of ratio, the ratio of the first-and-second together to the first is greater than that of the third-and-fourth together to the third.

For let AC have a smaller ratio to BC than DF to EF. I say that, by conversion of ratio, AC has a greater ratio to AB than DF to DE. For since AC has a smaller ratio to BC than DF to EF,[Margin: d — Elements V.29] *dividendo* AB will also have a smaller ratio to BC than DE to EF.[Margin: e — Elements V.26] Therefore *convertendo*, BC has a greater ratio to AB than EF to DE;[Margin: f — Elements V.28] and hence *componendo* too, AC has a greater ratio to AB than DF to DE. Which was to be proved.

Alternatively. Since AC has a smaller ratio to BC than DF to EF, DF will have a greater ratio to EF than AC to BC.[Margin: g — Elements V.30] Therefore, by conversion of ratio, DF has a smaller ratio to DE than AC to AB — that is, AC has a greater ratio to AB than DF to DE. Which was to be proved.

Diagram. Two adjacent vertical magnitude-lines with tick-marked division points.

- Right line (top to bottom): F, E, D

THEOR. 31. PROPOS. 31.

[Margin: xxxj.]

If there are three magnitudes, and others equal to them in number, and the ratio of the first of the first set to the second is greater than the ratio

of the first of the latter set to the second; and likewise the ratio of the second of the first set to the third is greater than the ratio of the second of the latter set to the third: then also, *ex aequali*, the ratio of the first of the first set to the third will be greater than the ratio of the first of the latter set to the third.

Let there be three magnitudes A, B, C, and three others D, E, F, and let A have a greater ratio to B than D to E, and likewise B a greater ratio to C than E to F. I say that *ex aequali* A also has a greater ratio to C than D to F. For let G be to C as E to F; then B has a greater ratio to C than G to C,[Margin: a — Elements V.10] and so B is greater than G. Therefore[Margin: b — Elements V.8] the ratio of A to the smaller G is greater than the ratio of A to the greater B; but A to B is posited greater than D to E. Much more, then, is A to G greater than D to E. Again, let H be to G as D to E; then A has a greater ratio to G than H to G,[Margin: c — Elements V.10] and so A is greater than H.[Margin: d — Elements V.8] Therefore the greater magnitude A will have a greater ratio to C than the smaller magnitude H has to the same C.[Margin: e — Elements V.22] But H to C is, *ex aequali*, as D to F (since $D:E = H:G$ and $E:F = G:C$). Therefore A also has a greater ratio to C than D to F. Which was to be proved.

Diagram. A row of five vertical magnitude-lines with tick-marked division points; the first three carry a second label at their foot.

- Line 1: A (over D)
- Line 2: B (over E)
- Line 3: C (over F)
- Line 4: G
- Line 5: H

SCHOLIVM

By the same reasoning we shall show that, if the ratio of A to B is the same as that of D to E, while B to C is greater than E to F; or conversely, if the ratio of A to B is greater than that of D to E, while B to C is the same as E to F — then *ex aequali* the ratio of A to C is likewise greater than that of D to F.

For let A first be to B as D to E, but let B have a greater ratio to C than E to F. Let G be to C as E to F; then B has a greater ratio to C than G to C,[Margin: f — Elements V.10] and therefore A has a greater ratio to G than to B.[Margin: g — Elements V.8] But A to B is posited as D to E; therefore A to G is also greater than D to E. Again, let H be to G as D to E; then A has a greater ratio to G than H to G,[Margin:

h — Elements V.10] and so A is greater than H.[Margin: i — Elements V.8]
Therefore A has a greater ratio to C than H to C.[Margin: k — Elements V.22] But
H to C is, *ex aequali*, as D to F (since $D:E = H:G$ and $E:F = G:C$). Therefore A too has
a greater ratio to C than D to F. Which was to be proved.

Next, let A have a greater ratio to B than D to E, but B to C as E to F. Let G be to C
as E to F; then B to C is also as G to C,[Margin: l — Elements V.9] and so B is equal
to G.[Margin: m — Elements V.7] Therefore A to G is as A to B. But A to B is posited
greater than D to E; therefore A to G is also greater than D to E. Again, let H be to
G as D to E; then A has a greater ratio to G than H to G,[Margin: n — Elements
V.10] and so A is greater than H.[Margin: o — Elements V.8] Therefore A has a
greater ratio to C than H to C.[Margin: p — Elements V.22] But H to C is, *ex aequali*,
as D to F (since $D:E = H:G$ and $E:F = G:C$). Therefore A too has a greater ratio to C
than D to F. Which was to be proved.

By a like demonstration we shall show that, if the ratios of the first magnitudes
are smaller, the ratio of the outermost terms is also smaller.

Diagram. A row of five vertical magnitude-lines with tick-marked division points;
the first three carry a second label at their foot.

- Line 1: A (over D)
- Line 2: B (over E)
- Line 3: C (over F)
- Line 4: G
- Line 5: H

(scholium to Prop. 31, continued)

The same will also result if A is to B as D to E, but the ratio of B to C is smaller
than that of E to F; or, conversely, if A to B is smaller than D to E, while B to C is as
E to F. For the demonstration will always be the same, provided only that you
everywhere change the word "greater" into the word "smaller," as is clear.

But if there are more magnitudes than three — whether all the ratios in one set of
magnitudes are greater (or smaller) than all the ratios in the other set, or only
one is greater than one, or two, and so on — we shall show that the ratio of the
first of the first set to the last is likewise greater (or smaller) than that of the first
of the latter set to the last, by the method we set out in Proposition 22: using
Proposition 22 in place of the present Proposition 31 whenever three magnitudes
of one set are proportional to three magnitudes of the other set, and using this

scholium whenever just one ratio among three magnitudes is equal to just one ratio among the three magnitudes of the other set.

Diagram. A boxed list of two ordered sets of four magnitudes, in two columns.

- Left column: A, B, C, D
- Right column: E, F, G, H

For if A has a greater ratio to B than E to F, and B a greater ratio to C than F to G, and C a greater ratio to D than G to H,[Margin: a — Elements V.31] then *ex aequali* A has a greater ratio to C than E to G. And since, again, A has a greater ratio to C than E to G, and C a greater ratio to D than G to H,[Margin: b — Elements V.31] then *ex aequali* A also has a greater ratio to D than E to H.

But if the three magnitudes A, B, C are proportional to the three E, F, G, while C has a greater ratio to D than G to H,[Margin: c — Elements V.22] then *ex aequali* A is to C as E to G. Hence, by this scholium, A will have a greater ratio to D than E to H.

But if A has a greater ratio to B than E to F, while the three B, C, D are proportional to the three F, G, H, then by this scholium A will have a greater ratio to C than E to G; and again, A a greater ratio to D than E to H.

Diagram. A boxed list of two ordered sets of four magnitudes, in two columns.

- Left column: A, B, C, D
- Right column: E, F, G, H

But if A has a greater ratio to B than E to F, while B to C is as F to G, and C has a greater ratio to D than G to H; or if A to B is as E to F, while B has a greater ratio to C than F to G, and C to D is as G to H — then in every case, by this scholium, A will have a greater ratio to C than E to G, and consequently again a greater ratio to D than E to H, and so on.

You will conclude the same if all the ratios of one set are smaller than all those of the other, whether one or two of them; and likewise if there are more magnitudes, as we said in Proposition 22.

THEOR. 32. PROPOS. 32.

[Margin: xxxij.]

If there are three magnitudes, and others equal to them in number, and the ratio of the first of the first set to the second is greater than the ratio

of the second of the latter set to the third; and likewise the ratio of the second of the first set to the third is greater than the ratio of the first of the latter set to the second: then also, *ex aequali*, the ratio of the first of the first set to the third will be greater than the ratio of the first of the latter set to the third.

Let there be three magnitudes A, B, C, and three others D, E, F, and let A have a greater ratio to B than E to F, and likewise B a greater ratio to C than D to E. I say that *ex aequali* A also has a greater ratio to C than D to F. For let G be to C as D to E; then B has a greater ratio to C than G to C, [Margin: a — Elements V.10] and so B is greater than G. [Margin: b — Elements V.8] Therefore the ratio of A to the smaller G is greater than the ratio of the same A to the greater B; but A to B is greater than E to F. Much more, then, is A to G greater than E to F. Again, let H be to G as E to F; then A has a greater ratio to G than H to G, [Margin: c — Elements V.10] and so A is greater than H. [Margin: d — Elements V.8] For this reason the greater A will have a greater ratio to C than the smaller H has to the same C. [Margin: e — Elements V.23] But H to C is, *ex aequali*, as D to F (since $D:E = G:C$ and $E:F = H:G$). Therefore A also has a greater ratio to C than D to F. Which was to be proved.

Diagram. A row of five vertical magnitude-lines with tick-marked division points; the first three carry a second label at their foot.

- Line 1: A (over D)
- Line 2: B (over E)
- Line 3: C (over F)
- Line 4: G
- Line 5: H

SCHOLIVM

By the same reasoning — if A to B is as E to F, while B to C is greater than D to E; or conversely, if A to B is greater than E to F, while B to C is as D to E — we shall show that *ex aequali* A has a greater ratio to C than D to F, as is seen in the figure set out here.

Not otherwise shall we show that, if the ratios of the first magnitudes are smaller, the ratio of the extremes is also smaller, and so on.

And if there are more magnitudes than three, we shall prove that the ratio of the first [of the first set to the last is likewise greater or smaller...]

Diagram. A stack of five horizontal magnitude-lines (the "figure set out here" cited in the scholium); the third and lowest two lines carry paired end-labels.

- Line 1 (top): H
- Line 2: G
- Line 3: C, F
- Line 4: B, E
- Line 5 (bottom): A, D

the first of the antecedents has to the last a greater ratio than the first of the consequents has to the last — by the same method we employed at Proposition 23, and so on. All of this is clear, provided the demonstrations of the scholium to the preceding proposition are examined with care.

THEOR. 33. PROPOS. 33.

[Margin: xxxii.]

If the ratio of a whole to a whole is greater than that of a part taken away to a part taken away, then the ratio of the remainder to the remainder will also be greater than that of the whole to the whole.

Let the ratio of the whole AB to the whole CD be greater than that of the part removed, AE, to the part removed, CF. I say that the ratio of the remainder EB to the remainder FD is also greater than that of the whole AB to the whole CD.

For since AB has to CD a greater ratio than AE to CF, [a] [Margin: a — *Elements* V.27] by alternation the ratio of AB to AE will also be greater than that of CD to CF. [b] [Margin: b — *Elements* V.30] Therefore, by conversion of the ratio, the ratio of AB to EB will be smaller than that of CD to FD. [c] [Margin: c — *Elements* V.27] By alternation, then, the ratio of AB to CD will likewise be smaller than that of EB to FD; that is, the remainder EB will have to the remainder FD a greater ratio than the whole AB has to the whole CD. Which was what was proposed.

Diagram. Two stacked horizontal magnitude-lines with tick divisions, illustrating the proposition. The upper line is the whole AB, divided at E into the removed part AE and the remainder EB; the lower line is the whole CD, divided at F into the removed part CF and the remainder FD.

- Upper line, left end: A
- Upper line, interior division point: E
- Upper line, right end: B

- Lower line, left end: C
- Lower line, interior division point: F
- Lower line, right end: D

SCHOLIUM

But if the whole has to the whole a smaller ratio than the part removed has to the part removed, then the remainder will also have to the remainder a smaller ratio than the whole has to the whole — as is evident from the manner of demonstration, provided one everywhere substitutes the word "smaller" for the word "greater," and the word "greater" for the word "smaller."

THEOR. 34. PROPOS. 34.

[Margin: xxxiv.]

If there are any number of magnitudes, and others equal to them in number, and the ratio of the first of the first set to the first of the second is greater than that of the second to the second, and this in turn greater than that of the third to the third, and so on: then all the first magnitudes taken together will have to all the second taken together a greater ratio than all the first, the first omitted, have to all the second, the first likewise omitted; but a smaller ratio than the first of the first set has to the first of the second; and finally a greater ratio than the last of the first set has to the last of the second.

Let there first be three magnitudes A, B, C, and three others D, E, F. Let the ratio of A to D be greater than that of B to E, and likewise the ratio of B to E greater than that of C to F. I say that the ratio of A, B, C together to D, E, F together is greater than that of B, C together to E, F together; smaller, however, than the ratio of A to D; and, lastly, greater than the ratio of C to F.

For since A has to D a greater ratio than B to E, [a] [Margin: a — *Elements* V.27] by alternation A will have to B a greater ratio than D to E. [b] [Margin: b — *Elements* V.28] Therefore, by composition, the ratio of A, B together to B will be greater than that of D, E together to E. [c] [Margin: c — *Elements* V.27] By alternation again, then, the ratio of A, B together to D, E together will be greater than that of B to E. And so, since the whole A, B has to the whole D, E a greater ratio than the removed part B has to the removed part E, [d] [Margin: d — *Elements* V.33] the remainder A will also have to the remainder D a greater ratio than the whole A, B has to the whole D, E. By the same reasoning, the ratio of B to E is greater than

that of the whole B, C to the whole E, F; therefore the ratio of A to D is much greater than that of the whole B, C to the whole E, F. [e] [Margin: e — *Elements* V.27] By alternation, then, the ratio of A to B, C is greater than that of D to E, F; [f] [Margin: f — *Elements* V.28] and therefore, by composition, the ratio of the whole A, B, C to B, C is greater than that of the whole D, E, F to E, F. [g] [Margin: g — *Elements* V.27] And again, by alternation, the ratio of all of A, B, C together to all of D, E, F together is greater than that of B, C to E, F. Which is the first point.

And so, since the whole A, B, C has to the whole D, E, F a greater ratio than the removed part B, C has to the removed part E, F, [h] [Margin: h — *Elements* V.33] the ratio of the remainder A to the remainder D will also be greater than that of the whole A, B, C to the whole D, E, F. Which is the second point.

Since, moreover, the ratio of B to E is greater than that of C to F, [i] [Margin: i — *Elements* V.27] by alternation the ratio of B to C will also be greater than that of E to F; [k] [Margin: k — *Elements* V.28] and, by composition, the ratio of the whole BC to C is greater than that of the whole E, F to F; [l] [Margin: l — *Elements* V.27] and again, by alternation, the ratio of B, C to E, F is greater than that of C to F. But the ratio of A, B, C to D, E, F is greater than that of B, C to E, F, as we have shown; therefore the ratio of all of A, B, C to all of D, E, F is much greater than that of the last, C, to the last, F. Which is the third point.

Next, let there be four magnitudes on each side, under the same hypothesis — that is, let the ratio of the first, A, to D be greater than that of the second, B, to E; and this greater than the ratio of the third, C, to F; and this in turn greater than the ratio of the fourth, G, to H. I say that the same results follow. For, just as has now been shown for three, the ratio of B, C, G to E, F, H is greater [than that of G to H]; therefore the ratio of A to D will be much greater than that of B, C, G to E, F, H. [m] [Margin: m — *Elements* V.27] By alternation, then, the ratio of A to B, C, G will be greater than that of D to E, F, H; [n] [Margin: n — *Elements* V.28] and, by composition, the ratio of A, B, C, G to B, C, G is greater than that of D, E, F, H to E, F, H; [o] [Margin: o — *Elements* V.27] and, by alternation, the ratio of A, B, C, G to D, E, F, H is greater than that of B, C, G to E, F, H. Which is the first point.

And so, since the whole A, B, C, G has to the whole D, E, F, H a greater ratio than the removed part B, C, G has to the removed part E, F, H, [p] [Margin: p — *Elements* V.33] the ratio of the remainder A to the remainder D will also be greater than that of the whole A, B, C, G to the whole D, E, F, H. Which is the second point.

Since, moreover, as was demonstrated for three, the ratio of B, C, G to E, F, H is greater than that of G to H, and the ratio of A, B, C, G to D, E, F, H is greater than that of B, C, G to E, F, H, as was shown: the ratio of A, B, C, G to D, E, F, H will be much greater than that of the last, G, to the last, H. Which is the third point.

By the same method you will conclude that the same follows for five magnitudes taken by fours, for six taken by fives, for seven taken by sixes, and so on — just as we have shown for four taken by threes. The whole theorem, therefore, is established, and so on.

EVCLIDIS ELEMENTVM SEXTVM

Euclid's Elements, Book Six

DEFINITIONES · Definitions

I.

Rectilinear figures are **similar** when they have their several angles equal, each to each, and also have the sides about the equal angles proportional.

Thus triangles ABC and DEF are said to be similar if they are equiangular — that is, if angle A is equal to angle D, B to E, and C to F — and if, moreover, the sides about the equal angles are proportional, that is: as AB is to AC, so is DE to DF; and as AB is to BC, so is DE to EF; and as AC is to CB, so is DF to FE.

But if the angles of the one are equal to the angles of the other, each to each, while the sides about the equal angles are not proportional — or the reverse — such figures will not be called similar. Of this sort are the square and the oblong (the figure longer on one side). For these figures do indeed have their angles equal, being right angles, yet the sides of the one are not proportional to the sides of the other, since the sides of the square about any right angle stand in a ratio of equality, whereas the sides of the oblong about any right angle stand in a ratio of inequality. From this it is clear that all equiangular and equilateral rectilinear figures which have their angles and sides equal in number are similar, however unequal in size they may be among themselves. Of this sort are the equilateral triangles GHI and KLM. For, on account of the equality of their sides, GH will be to GI as KL to KM; likewise GH to HI as KL to LM, and GI to IH as KM to ML, since the ratio is always one of equality. The same is to be said of squares, pentagons,

hexagons, heptagons, octagons, and other figures of that kind — rectilinear, equiangular, and equilateral.

Diagram. Two similar right triangles illustrating the definition of similar figures. Each has its right angle at the lower-left vertex; the two are of different size but the same shape.

- A (apex, upper left of first triangle)
- B (lower-left vertex, right angle, first triangle)
- C (lower-right vertex, first triangle)
- D (apex, upper part of second triangle)
- E (lower-left vertex, right angle, second triangle)
- F (lower-right vertex, second triangle)

Diagram. Two equilateral triangles of unequal size (the "similar though unequal" example).

- G (apex, first triangle)
- H (lower-left vertex, first triangle)

- K (apex, second triangle)
- L (lower-left vertex, second triangle)
- M (lower-right vertex, second triangle)

II.

Figures are **reciprocally related** when in each figure there are antecedent and consequent terms of the ratios.

Thus, if in the parallelograms ABCD and EFGH the sides AB and BC are proportional to the sides EF and FG in such a way that in each figure there is both an antecedent and a consequent of different ratios — that is, so that the ratio of AB to EF is the same as that of FG to BC, or, equivalently, that AB is to FG as EF is to BC (for in either way AB is the antecedent of one ratio and BC the consequent of another in the figure ABCD, just as, in the first way, EF is the consequent of one and FG the antecedent of another; or, in the second way, FG is the consequent and EF the antecedent, in the figure EFGH) — such parallelograms will be called reciprocally related, even though they are not similar. Likewise the triangles IKL and MNO will be reciprocally related if IK is to MN as MO is to IL, or if IK is to MO as MN is to IL. Nor do I recall having found among the geometers any use of reciprocally related figures other than in parallelograms and triangles.

Diagram. Two upright parallelograms and two triangles set in a row, illustrating reciprocally related figures.

- A (upper-left, first parallelogram); B (upper-right, first parallelogram); C (lower-right, first parallelogram); D (lower-left, first parallelogram)
- E (upper-left, second parallelogram); F (upper-right, second parallelogram); G (lower-right, second parallelogram); H (lower-left, second parallelogram)
- I (apex, first triangle); K (lower-left vertex, first triangle); L (lower-right vertex, first triangle)
- M (apex, second triangle); O (lower-left vertex, second triangle); N (lower-right vertex, second triangle)

III.

A straight line is said to be cut in **extreme and mean ratio** when, as the whole is to the greater segment, so the greater is to the less.

If any straight line AB is divided at C unequally, so that, as the whole AB is to the greater segment AC, so the greater segment AC is to the lesser segment CB, it will be said to be cut in extreme and mean ratio. Euclid will teach this division at Proposition 30 of the present book, and he has already taught it in other words at Book 2, Proposition 11, as will become clear at Proposition 30 of this book. There are almost countless valuable properties and uses of a line divided in this way, as will appear from the books of solid geometry, especially Book 13 — so that not without reason has it been called by some the **divine proportion**, the proportion into which a line is divided in this manner.

Diagram. A single straight line divided at an interior point.

- A (left end)
- C (interior point of division)
- B (right end)

IIII.

The **altitude** of any figure is the perpendicular line drawn from the vertex to the base.

If from the vertex A of triangle ABC a perpendicular AG is drawn to the base BC, this perpendicular will be called the altitude of triangle ABC; so that the triangle is said to have an altitude as great as the perpendicular AG. In the same way, the perpendicular DH, drawn from D, the vertex of triangle DEF, to the base EF produced toward E, will be called the altitude of triangle DEF. And so, if the

perpendiculars dropped from the vertices of two figures to their bases (whether these are produced or not) are equal, such figures will be said to have the same altitude. Now these perpendiculars will be equal when the bases of the figures, and their vertices, are set upon the same parallels — as are the perpendiculars AG, DH of triangles ABC, DEF, set upon the same parallels. For since the angles AGH and DHG, the interior angles on the same side, are equal to two right angles — indeed are two right angles — [a] [Margin: a — *Elements* I.28] the straight lines AG and DH will be parallel; and AD and GH are also parallel, since the triangles are supposed to be set upon the same parallels. Therefore ADHG will be a parallelogram; [b] [Margin: b — *Elements* I.34] and consequently the opposite sides AG and DH will be equal. These triangles will therefore be said to have the same altitude. But if in the same triangles the vertices are taken to be C and F, and the bases AB and DE, they will not have the same altitude; for the perpendicular drawn from F to the base DE produced is not equal to the perpendicular drawn from C to the base AB, since the triangles themselves cannot in that case be set upon the same parallels, as is manifest.

Diagram. Two triangles standing on a common baseline, with their apexes on an upper line parallel to it, each with its altitude drawn. The construction shows the parallelogram ADHG formed by the two apexes and the two perpendicular feet.

- A (apex of first triangle, on the upper parallel)
- D (apex of second triangle, on the upper parallel)
- Baseline, left to right: B (foot of first triangle) — G (foot of perpendicular AG) — C (foot of first triangle) — H (foot of perpendicular DH, on EF produced) — E (base vertex of second triangle) — F (base vertex of second triangle)
- AG (perpendicular altitude of triangle ABC)
- DH (perpendicular altitude of triangle DEF, dropped to base EF produced to H)

Euclid has rightly defined the altitude of any figure by means of the perpendicular line drawn from the vertex to the base — because, as Ptolemy [Ptolemæus] writes in his little treatise *On the Analemma*, and as Simplicius [Simplicio] reports in his book *On Measurement*, the measure of anything ought to be fixed and determinate, not indefinite; and among all straight lines, by which geometers, like ordinary people, rightly measure everything, the perpendicular alone is fixed and determinate, while all the others are uncertain and indeterminate. On this matter we have written more fully at the beginning of the

commentaries which we published on the *Sphere* of Johannes de Sacrobosco [Ioan. de sacro bosco].

V.

A ratio is said to be compounded of ratios when the quantities of the ratios, multiplied together, produce some ratio.

Since the denominator of any ratio expresses how great the antecedent magnitude is with respect to the consequent — as the denominator of the quadruple ratio, namely 4, shows that in any quadruple ratio the antecedent magnitude contains the consequent four times; while the denominator of the subquadruple ratio, namely $\frac{1}{4}$, indicates that the antecedent is the fourth part of the consequent, and so on — the denominator is therefore usually called by geometers the "quantity of the ratio," so that "quantity of a ratio" signifies the same as "denominator." This definition, then, means that some ratio is compounded of two or more ratios when the denominators of these, that is, their quantities, multiplied together (or, as Zamberti [Zambertus] renders it, when they have produced the quantity of that ratio, that is, its denominator).

Thus the duodecuple ratio (12:1) is said to be compounded of the double (2:1) and the sextuple (6:1); for the denominator of the duodecuple ratio, namely 12, is produced by multiplying the denominator of the double ratio, namely 2, into the denominator of the sextuple, that is, into 6. In the same way the same duodecuple ratio is said to be compounded of the triple (3:1) and the quadruple (4:1); for from the multiplication of 3 into 4 the same denominator 12 of the duodecuple ratio is produced. By the same reasoning the thirty-fold ratio (30:1) is said to be compounded of the double, the triple, and the quintuple (5:1); for the denominators of these, 2, 3, and 5, multiplied together, produce 30, its denominator. So too the double ratio (2:1) will be said to be compounded of the sesquialterate (3:2) and the sesquitertian (4:3); because the denominator of the sesquialterate, $1\frac{1}{2}$, multiplied into $1\frac{1}{3}$, the denominator of the sesquitertian, produces 2, the denominator of the double. Likewise the same double ratio will be compounded of the sesquiseptimal (8:7) and the supertripartient-of-fourths (7:4); for the denominators of these ratios, $1\frac{1}{7}$ and $1\frac{3}{4}$, multiplied together, produce 2, the denominator of the double. Again, the same double ratio will be said to be compounded of the subsesquiquartan (4:5) and the double-sesquialterate (5:2), because the denominators of these, $\frac{4}{5}$ and $2\frac{1}{2}$, multiplied together, likewise produce the same denominator 2 of the double ratio. And so the double ratio will be said to be compounded of infinitely many other ratios — which may be said of any other ratio as well, as will appear a little later.

Furthermore, just as, among magnitudes continuously proportional, the ratio of the first to the last is said to be compounded of the ratio of the first to the second, of the second to the third, of the third to the fourth, and so on — since that ratio is composed of these intermediate ones, and its denominator is produced from their denominators multiplied together, as we set out in Book 5, Definition 10 — so that, if there are two equal intermediate ratios out of which it is said to be compounded, the ratio of the first magnitude to the last is called the duplicate of the ratio of the first to the second; if three, the triplicate, and so on. Likewise, among any magnitudes whatever, set in any order, the ratio of the first to the last will be said to be compounded of the ratio of the first to the second, of the second to the third, of the third to the fourth, and so on, until the ratio is complete; because the denominator of the ratio of the first magnitude to the last arises from the denominators of the intermediate ratios multiplied together. This first point we shall confirm by a certain induction of Theon of Alexandria [Theonis Alexā[n]drini], which he adduces in this place; and then we shall establish the same by two demonstrations, one of which is handed down by Eutocius of Ascalon [Eutocio Ascalonita] in his commentary on Book 2 of Archimedes, *On the Sphere and Cylinder*, Theorem 4, and in Book 1 of Apollonius of Perga [Apollonij Pergæi], *On the Elements of Conics*, Proposition 11; the other we shall confirm from Witelo [Vitellione], Book 1, Proposition 13, of his *Perspective*.

(Continuation of Clavius's commentary on Euclid, Book VI, Definition V — the ratio compounded of ratios. Theon's induction, followed by the demonstrations of Eutocius and Witelo.)

THEON therefore attempts to settle the matter as follows.

Let AB have to CD a given ratio — say double, or triple, or any other whatever — and let CD likewise have to EF a given ratio. I say that the ratio of AB to EF is made up of the ratio of AB to CD and of CD to EF; or that the size [*quantitas*] of the ratio of AB to CD, multiplied into the size of the ratio of CD to EF, produces the size of the ratio of AB to EF.

First, let AB be greater than CD, and CD greater than EF; and let AB be double CD, and CD triple EF. Since, then, CD is triple EF, while AB is double CD, AB will be sextuple EF — for if we double the triple of something, sextuple results, and this is precisely the compounding. Or thus: since AB is double CD, divide AB into parts equal to CD, that is, into AG and GB. Now since CD is triple EF, and AG is equal to CD, AG too is triple EF; and for the same reason GB is also triple EF. Therefore the whole AB is sextuple EF. Hence the ratio of AB to EF is compounded,

through the middle term CD, out of the ratio of AB to CD and that of CD to EF.

Diagram. Three vertical line-segments illustrating the double/triple case. The leftmost and tallest, AB, is divided at G into two equal parts AG and GB; the middle segment is CD; the rightmost and shortest is EF.

- A (top of first segment)
- G (division point of AB)
- B (foot of first segment)
- C (top of second segment)
- D (foot of second segment)
- E (top of third segment)
- F (foot of third segment)

In like manner the same conclusion is gathered even if CD is less than each of AB and EF. For again let AB be triple CD, but let CD be half of EF. Since CD is half EF, while AB is triple CD, AB will be sesquialterate to EF [3:2] — for if we triple the half of something, it will contain that thing once and a half. And since AB is triple CD, and CD is half EF: of such parts as AB contains three, equal to CD, EF contains two. Therefore AB is sesquialterate to EF. So the ratio of AB to EF is connected, through the middle term CD, and compounded out of the ratio of AB to CD and of CD to EF.

Diagram. Three vertical line-segments illustrating the case where CD is less than both : AB (tall), CD (short), EF (medium).

- A (top), B (foot) — first segment
- C (?) (top), D (foot) — second segment
- E (top), F (foot) — third segment

But now again let CD be greater than each of AB and EF, and let AB be half of CD, and CD sesquitercian [4:3] to EF. Since, then, of such parts as AB is two, CD is four, and of such as CD is four, EF is three, therefore of such as AB is two, EF is three. So again the ratio of AB to EF is connected through the middle term CD, and it is that of two to three. And likewise with more terms and in the remaining cases. It is also evident that if, from any given compound ratio, one of the composing ratios is taken away — one of the simple ratios being cast out — what remains will be the ratio compounded of the rest.

These things we have taken word for word from Theon, following the translation of Zambertus [Bartolomeo Zamberti].

Diagram. Three vertical line-segments illustrating the case where CD is the greatest ($AB = 2$, $CD = 4$, $EF = 3$) : CD tallest, EF of middle height, AB shortest.

- A (top), B (foot) — first segment
- C (top), D (foot) — second segment
- E (top), F (foot) — third segment

The demonstration of Eutocius runs as follows.

Let there be three magnitudes A, B, C. I say that the ratio of A to C is compounded of the ratios of A to B and of B to C. This will be easily demonstrated once the following principle is assumed: that the size, or denominator, of any ratio, multiplied into the consequent magnitude of the same ratio, produces the antecedent. For since the denominator indicates the relation of the antecedent to the consequent, the consequent taken according to the denominator — that is, multiplied by the denominator — must necessarily restore the antecedent. Thus, because 12 to 3 has a quadruple ratio, 3 multiplied by 4 produces 12. Likewise, because 4 to 20 has a subquintuple ratio, whose denominator is $\frac{1}{5}$, it comes about that $\frac{1}{5}$ taken into the consequent 20 yields 4; and so on.

Let, then, the denominator of the ratio of A to B be D, and let the denominator of the ratio of B to C be E, and let D multiplying E produce F. I say that F is the size, or denominator, of the ratio of A to C — that is, that if F is multiplied into C, A is produced. For let G be produced by the multiplication of F into C; I say that G is equal to A, and hence that A too arises from F into C. For since D is the denominator of the ratio of A to B, if D is multiplied into B, A will be produced. By the same reasoning, if E is multiplied into C, B will be produced. Since, then, F and E, multiplying C, produce G and B (for from F into C comes G, and from E into C comes B, as was said), [Margin: Elements VII.18] it will be, as F is to E, so G is to B. Again, since D, multiplying E and B, produces F and A, [Margin: Elements VII.17] it will be, as E is to B, so F is to A; and by alternation, as E is to B, so F is to A; and inversely again, as F is to E, so A is to B. But it was shown that as F is to E, so is G to B. Therefore, as A is to B, so is G to B; and hence the magnitudes A and G are equal. Therefore, since G is produced from F into C, A too will be produced from F into C; and consequently F will be the size of the ratio of A to C. Which was to be proved.

Diagram. Eutocius's construction. A row of vertical line-segments labelled, along the foot, A B C D E F G (the three magnitudes A, B, C; the denominators D, E, F; and

the product G), together with taller construction lines at the far left and toward the right. Numeric annotations 4, 3, and 6 stand beside individual segments, and two segments carry a small mark I read as $Z [?] / 2 [?]$. The tall left-hand line's apex bears a bold letter that reads as K [?], not referenced in the text. **

The illustrative values keyed to this figure are:

A	B	C	D	E	F	G
100	20	5	5	4	20	100

(Here $A:B = 100:20 = 5$, denominator $D = 5$; $B:C = 20:5 = 4$, denominator $E = 4$; $A:C = 100:5 = 20$, denominator $F = D \times E = 20$; and $G = F \times C = 20 \times 5 = 100 = A$.)

The like reasoning holds for more magnitudes. For the ratio of the first to the last will always be compounded of the ratios of the first to the second, of the second to the third, of the third to the fourth, and so on. Thus, if there are four magnitudes A, B, C, D, the ratio of A to D will be compounded of the ratios A to B, B to C, and C to D. For if three magnitudes A, C, D are considered, the ratio of A to D will be compounded of the ratios A to C and C to D, as has been shown. But by the same reasoning the ratio of A to C is compounded of the ratios A to B and B to C. Therefore the ratio of A to D is likewise compounded of the ratios A to B, B to C, and C to D. Which was to be proved. You will see the same in 5, 6, 7, or however many magnitudes.

Diagram. Four vertical line-segments labelled A B C D along the foot, illustrating the generalization to more magnitudes, with a taller construction line whose apex reads as K [?] and numeric annotations 4 and 8 beside the segments. **

Finally, Witelo [Vitellio] offers a demonstration of the following kind.

Let there be three magnitudes A, B, C. I say that the ratio of A to C is compounded of the ratios of A to B and of B to C. This will be demonstrated by assuming the same principle of Eutocius — namely, that the denominator of a ratio, multiplied into the consequent magnitude of the ratio, produces the antecedent magnitude. For let D be the denominator of the ratio of A to B, and E the denominator of the ratio of B to C; and let F be the denominator of the ratio of A to C. It must then be shown that F is produced from D into E, which will come about thus. Since what is produced from F, the first quantity, into C, the fourth, is equal to what is generated from D, the second, into B, the third — because A is always produced (for from F, the denominator, into C, the consequent, the antecedent A is produced; and likewise from D, the denominator, into B, the consequent, the antecedent A is produced) — [Margin: Elements VII.19] it will be, as F, the first, is

to D, the second, so B, the third, is to C, the fourth. Since, then, E is the denominator of the ratio of B to C, E will also be the denominator of the ratio of F to D. Therefore E, multiplying the consequent D, will produce the antecedent F. Which was to be proved. So Witelo.

The illustrative values for this demonstration are:

A	B	C	D	E	F
100	20	5	5	4	20

The same will be shown for more magnitudes, as before from Eutocius. For instance, given six magnitudes A, B, C, D, E, F, the ratio of A to F will be compounded of the ratios A to B, B to C, C to D, D to E, and E to F. For, as has been shown, the ratio of A to F is compounded of the ratio A to B and the ratio B to F. But this ratio B to F is compounded of the ratios B to C and C to F; and this ratio C to F of the ratios C to D and D to F; and finally this ratio D to F is compounded of the ratios D to E and E to F. Therefore the ratio of A to F is generated from all the intermediate ratios; that is, the denominator of the ratio of A to F is generated from the five denominators of the five intermediate ratios multiplied among themselves.

Diagram. Six vertical line-segments labelled A B C D E F along the foot, for the six-magnitude compound, their heights proportional to the values listed alongside.

A	B	C	D	E	F
12	6	3	2	1	4

(A:B = 2, B:C = 2, C:D = 3:2, D:E = 2, E:F = 1:4; the compound A:F = 12:4 = 3.)

From these things there is clearly established what we taught with respect to Definition 10 of Book 5: namely, that when any number of quantities are continued in continued proportion, the ratio of the first to the last is compounded of all the equal intermediate ratios. That is, the denominator of the ratio which the first has to the last is produced from the denominator of the ratio which the first has to the second, multiplied into itself, and then this into the number so produced, and so on, until as many multiplications are made as — less one — there are ratios interposed between the first quantity and the last. So that the duplicate ratio of some ratio arises when the denominator of that ratio is set down twice (on account of the two equal ratios placed between the first quantity and the third) and is thus multiplied into itself; and the triplicate, when the

denominator is likewise set down three times (on account of the three equal ratios placed between the first quantity and the fourth) and is thus multiplied, first into itself, then again into the product. And so it must be said of the quadruplicate, quintuplicate, and the rest, without end. For the demonstration is the same in magnitudes that are in continued proportion and in magnitudes not proportional: only, in the former the denominators will be equal. Thus, if A, B, C are set down in continued proportion, the denominators D and E will be equal, and F will be the denominator of the duplicate ratio, and so on.

Although the demonstration both of Eutocius and of Witelo strictly fits only rational ratios — since each rests on the propositions of Book 7 of Euclid — nevertheless, because what is demonstrated concerning ratios of numbers holds also for incommensurable magnitudes, that is, for irrational ratios, either demonstration may be said to apply to all ratios.

But even if it were not established — given several magnitudes — that the denominator of the ratio which the first has to the last is produced from the multiplication of the denominators of the intermediate ratios among themselves (as we have demonstrated), the demonstrations in which the compounding of ratios is employed would nonetheless be no less certain, since in them this multiplication of denominators is not used. For just as Euclid said, in Definition 10 of Book 5, that when several magnitudes are set out in continued proportion, the first has to the third the duplicate ratio of that which the first has to the second — that is, one compounded of two equal intermediate ratios — and that the first has to the fourth the triplicate ratio of that which the first has to the second, i.e. one compounded of three equal intermediate ratios, and so on, with no mention made of any multiplication of denominators: so too, if several magnitudes of the same kind are set out in order but not in continued proportion, the first will be said to have to the last a ratio compounded of all the intermediate ratios — even though these are not all equal to one another (whether some be of greater inequality, some of equality, and some of lesser inequality, or whether all be of the same kind) — for this reason alone: that those intermediate ratios are interposed between the two extreme magnitudes. It is just as, in Definition 10 of Book 5, the ratio of the first to the third was called duplicate for this reason alone, that two equal ratios are interposed between the two extreme magnitudes. So that there is no other difference between this compounding of ratios and that duplication, triplication, etc. explained in Book 5, than this: that in the duplication, triplication, etc. of ratios the interposed ratios are all equal, whereas in the compounding of ratios the interposed ratios need not be equal. The multiplication of denominators is nonetheless useful, so that we may know what

that ratio is which is called the duplicate, triplicate, etc. of another, or which is said to be compounded of given ratios.

For example. To know what ratio is called the duplicate of the decuple ratio, we set down 10, the denominator of the decuple ratio, twice, thus: 10, 10, and multiply one into the other. For the number generated, 100, is the denominator of the ratio that is the duplicate of the decuple. And to have the denominator of the ratio that is called the triplicate of the same decuple, we set down the denominator 10 three times, thus: 10, 10, 10, and multiply the first into the second, and the product 100 into the third. For the number thus produced, 1000, is the denominator of the triplicate of the decuple ratio. The same must be said of other ratios as well. But we shall learn this also without multiplying denominators. For if three numbers are continued in a given ratio — as we taught in the treatise on ratios, when dealing with geometric proportionality — the two extreme numbers will have the duplicate of the given ratio; and if four numbers are continued, the two extremes will have the triplicate of the given ratio. But the greater must be compared with the lesser when the given ratio is one of greater inequality, and the lesser with the greater when the given ratio is one of lesser inequality. For instance, if the duplicate of the decuple ratio is sought, we shall

continue three numbers in decuple ratio, thus: 1, 10, 100; or 3, 30, 300. For the ratio of 100 to 1, or of 300 to 3, which is centuple, will be called the duplicate of the decuple. In the same way, the ratio of 1 to 100, or of 3 to 300, which is subcentuple, is called the duplicate of the subdecuple ratio, 1 to 10, or 3 to 30.

By the same method, to learn what ratio it is that is said, for example, to be compounded of the triple, double, sesquialterate, and sesquitertian, we set down their denominators in order, thus: 3, 2, $1\frac{1}{2}$, $1\frac{1}{3}$, and multiply them among themselves: first 3 into 2; then the product 6 into $1\frac{1}{2}$; and this number produced, 9, again into $1\frac{1}{3}$; and so on, if there were more denominators. The last number produced, 12, is the denominator of the ratio that is said to be compounded of the given ratios; so that the duodecuple ratio is said to be compounded of the triple, double, sesquialterate, and sesquitertian.

But we shall understand this even without such multiplication of denominators. For if the component ratios are continued in numbers, so that the first is to the second in the first component ratio, the second to the third in the second, the third to the fourth in the third, the fourth to the fifth in the fourth, and so on, then the ratio which the first number has to the last will be compounded of the given ratios. As in the preceding example the given ratios — namely the triple, double,

sesquialterate, and sesquitercian — are continued in these numbers: 36, 12, 6, 4, 3; or in these: 108, 36, 18, 12, 9; or in these: 12, 4, 2, $1\frac{1}{3}$, 1. For in every case the first number has to the second a triple ratio, the second to the third a double, the third to the fourth a sesquialterate, and the fourth to the fifth a sesquitercian. Therefore the ratio of the first to the last, which is duodecuple, is said to be compounded of those four ratios, as before. And in what way any number of ratios are to be continued in the least whole numbers, Euclid teaches in Book 8, Proposition 4.

Therefore, when Euclid demonstrates, in Proposition 23 of this book, that equiangular parallelograms have a ratio compounded of the two ratios which the two sides about one angle of the one bear to the two sides about the equal angle of the other, he means nothing else than this: that if those two ratios of the sides are continued in three quantities, the parallelograms have between themselves the ratio which the first quantity has to the third. Thus, if the ratio of one side of the first parallelogram to one side of the second is as 8 to 3, and the ratio of the other side to the other side is as 1 to 2, nothing else is to be understood than this: if three numbers are taken, say 24, 9, 18, of which the first is to the second as 8 to 3 and the second to the third as 1 to 2, then the ratio of the first parallelogram to the second is the same as that which the first number, 24, has to the third, 18 — which is sesquitercian. For the ratio of 24 to 18 is compounded, as has been said, of the ratios of 24 to 9 and of 9 to 18 — that is, of the ratios 8 to 3 and 1 to 2, which we said obtained between the sides.

Furthermore, just as certain interpreters of Euclid wished, at Definition 10 of Book 5, that the duplicate, triplicate ratio, etc. be truly greater than that of which it is called the duplicate or triplicate — namely double or triple it, etc. — and therefore that this definition should be understood of magnitudes in continued proportion in a ratio of greater inequality (which, however, we there showed to be false): so the same men wish, in this compounding of ratios too, that the ratio of the extremes, which is said to be compounded of the intermediate ratios, be truly greater than any of the intermediate components — as being formed from the addition of all the intermediate ratios together — and consequently that all the intermediate ratios must be less than the ratio of the extremes. But this is false, and altogether contrary to Euclid, as is clear from the preceding example, which we drew from Proposition 23 of this book. For, given these three numbers, 24, 9, 18, which have among themselves in order the same ratios which the sides of one parallelogram have to the sides of the other, the ratio of parallelogram to parallelogram will be the same as that of 24 to 18, as Euclid demonstrates. But who does not see that the ratio of 24 to 18, which is sesquitercian, is much less

than the ratio of 24 to 9, which is double-and-two-thirds [*dupla superbipartiens tertias*, i.e. 8:3]? But on this matter we shall write more at the end of Book 9.

Since this is so, if someone wishes to have any number of ratios composing a given ratio — that is, whose denominators, multiplied among themselves, generate the denominator of the given ratio — then between two numbers of the given ratio (whatever they be) there must be set as many middle numbers (whatever they be) as there are component ratios desired, less one. For instance, if someone wants three ratios out of which the centuple ratio is compounded, the question is satisfied by placing two middle numbers between 100 and 1, thus: 100, 50, 10, 1. For the ratio of the extremes, 100 to 1, is compounded of the three intermediate ratios — that is, of the double, quintuple, and decuple. Likewise, if you set other middle numbers, thus: 100, 10, 3, 1, the same ratio 100 to 1 will be compounded of the decuple, the triple-sesquitercian, and the triple. So too you see here, in 2, 3, 1, 10, 1, that the double ratio is compounded of four — namely of the subsesquialterate, the triple, the subdecuple, and the decuple.

But if someone asks for any number of ratios composing a given ratio, all of which are also given except one, we shall continue from one extreme of the given ratio all the given component ratios in order. For these, together with the ratio which the last middle number has to the other extreme of the given ratio, will compose the given ratio. For example, if someone says: give me five ratios, four of which are the double, triple, sesquialterate, and quintuple-sesquitercian, composing the sesquialterate ratio between 9 and 6 — we shall set these four middle numbers, giving 9, $4\frac{1}{2}$, $1\frac{1}{2}$, 1, $\frac{3}{16}$ [?], 6, so that 9 to $4\frac{1}{2}$ has the double ratio, $4\frac{1}{2}$ to $1\frac{1}{2}$ the triple, $1\frac{1}{2}$ to 1 the sesquialterate, and 1 to $\frac{3}{16}$ [?] the quintuple-sesquitercian. For out of these four, together with the ratio of $\frac{3}{16}$ [?] to 6 — which is the same as 1 to 32 — the sesquialterate ratio 9 to 6 is compounded. The same will result if the four given ratios are continued from the lesser extreme, 6, thus: 6, 12, 36, 54, 288, 9, so that 12 to 6 has the double ratio, 36 to 12 the triple, 54 to 36 the sesquialterate, and 288 to 54 the quintuple-sesquitercian. For the fifth ratio, 9 to 288, is the same as the earlier $\frac{3}{16}$ [?] to 6, which is as 1 to 32.

From these things we shall, with no trouble, satisfy the question in which someone demands to be given any number of numbers which, multiplied among themselves, produce some given number. For if two numbers are taken having a ratio denominated by the given number, and between them are placed as many numbers (whatever they be), less one, as the numbers desired, then the denominators of the intermediate ratios will be the numbers sought. For these,

multiplied among themselves, produce the denominator of the ratio of the extremes, as has been demonstrated — that is, the given number. For instance, if someone asks for three numbers from whose mutual multiplication 100 is generated, we shall place, between two numbers having a centuple ratio (500 and 5), two middle numbers whatever they be, thus: 500, 250, 50, 5. And the three numbers sought will be 2, 5, 10 — namely the denominators of the ratios 500 to 250, 250 to 50, and 50 to 5. For from 2 into 5 comes 10, and from 10 into 10 comes 100.

But if someone demands a single number which, together with any number of others already given, when they are multiplied among themselves, produces some given number: again two numbers must be taken whose ratio is denominated by the given number that is to be produced, and from one of the two the ratios denominated by the other given numbers must be continued. For the denominator of the ratio between the other number and the last of those continued will be the number we seek. Thus, if these four numbers are given — 2, 3, $1\frac{1}{2}$, $5\frac{1}{3}$ — and a fifth is sought which, multiplied into the number produced from their mutual multiplication, generates this given number, $1\frac{1}{2}$: we shall take two numbers, 9 and 6, having the sesquialterate ratio denominated by the given number $1\frac{1}{2}$; and from 9 we shall continue the four ratios denominated by 2, 3, $1\frac{1}{2}$, $5\frac{1}{3}$, thus: 9, $4\frac{1}{2}$, $1\frac{1}{2}$, 1, $\frac{3}{16}$ [?], 6. For the fifth number sought will be the denominator of the ratio of $\frac{3}{16}$ [?] to 6 — namely $\frac{1}{32}$. For these five numbers — 2, 3, $1\frac{1}{2}$, $5\frac{1}{3}$, $\frac{1}{32}$ — of which the first four are given and the fifth is found, when multiplied among themselves produce the given number $1\frac{1}{2}$. The same fifth number, $\frac{1}{32}$, will be found if the four ratios denominated by the given numbers are continued from the number 6, thus: 6, 12, 36,

54.

288.

9. The denominator of the ratio of 9 to 288 is $\frac{1}{32}$, as before.

The same holds too if four numbers are sought which, multiplied together, produce 1. We set down, between any two equal numbers whose ratio of equality is denominated by 1, any three middle numbers we please — as you see here: 4, 2, 1, 3, 4. For the denominators of the ratios 4 to 2, 2 to 1, 1 to 3, and 3 to 4 — namely 2, 2, $\frac{1}{3}$, $\frac{3}{4}$ [?] — are the four numbers sought, since when multiplied together they generate 1.

Such problems are solved **more easily** if you multiply together as many arbitrary numbers, less one, as are required, and then divide the given number that is to be generated by the last number produced. For the quotient, together with the

numbers assumed and multiplied among themselves, will be the numbers we are looking for. Thus in the previous problem: if these three numbers, for example, 4, 5, 6, are multiplied together, and 1 (which is to be produced) is divided by the number they yield, 120, the quotient will be $1/120$. The four numbers sought are therefore 4, 5, 6, and $1/120$. For 4 into 5 makes 20, and 20 into 6 makes 120, and 120 into $1/120$ makes 1.

Finally, this too must not be passed over — namely: just as, when any number of terms are set down in order, the denominator of the ratio of the extremes is produced from all the denominators of the intermediate ratios (as we have shown), so also, when any number of terms are set down in order, yet in such a way that each following term is greater than the one before it, the difference of the extremes is accumulated from all the differences of the intermediate terms. For example, here: 3, 7, 12, 20, 30, 100, 713. The difference between 3 and 713 is 710. But the difference between 3 and 7 is 4; between 7 and 12 is 5; between 12 and 20 is 8; between 20 and 30 is 10; between 30 and 100 is 70; and finally between 100 and 713 is 613. All these differences — 4, 5, 8, 10, 70, 613 — together make up 710, the difference of the extremes.

And let this be what we have to say about the five definitions set down by Euclid in this sixth book. To them we judge that the following sixth should be added, which will do much to make propositions 27, 28, 29, and 30 of this book — and a great many others of the tenth book — more easily understood. It is as follows:

VI.

A parallelogram applied to a certain straight line is said to *fall short of* [deficere] a parallelogram when it does not occupy the whole line; and to *exceed* [excedere] when it occupies a greater line than the one to which it is applied — yet in such a way that the deficient or exceeding parallelogram has the same altitude as the parallelogram applied, and together with it constitutes one whole parallelogram.

Let there be a given straight line AB, upon which the parallelogram ACDE is constructed, which does not occupy the whole of AB but falls short by CB. Draw BF parallel to CD until, meeting ED extended, it reaches F, so that the whole parallelogram ABFE is completed. The parallelogram AD, applied along the straight line AB, is then said to fall short of the parallelogram DB — so that DB is called the *defect* [defectus].

Again, let there be a given straight line AC, upon which the parallelogram ABFE is constructed, having a side AB greater than the given straight line AC; and let CD

be drawn parallel to BF. The parallelogram AF, applied along the straight line AC, is then said to exceed by the parallelogram DB — so that DB is called the *excess* [excessus].

Now this defect or excess DB may, in the case of right-angled figures, be either a square or an oblong [figure longer on one side]; and in the case of non-right-angled figures, either a rhombus or a rhomboid, as is plain.

Diagram. A leaning parallelogram (rhomboid) illustrating the applied, deficient, and exceeding parallelograms of Definition VI. The base runs left to right; the top is parallel to it, and an internal vertical divides the whole into two parts.

- A (bottom-left corner): start of the base line
- C (bottom, middle): division point on the base
- B (bottom-right corner): end of the base line
- E [?] (top-left corner): above A
- D (top, middle): above C, foot of the internal dividing line
- F (top-right corner): above B
- (Whole figure ABFE; ACDE is the applied parallelogram, CBFD the defect/excess.)

THEOR. 1. PROPOS. 1.

Triangles and parallelograms which have the same altitude are to one another as their bases.

Let there be two triangles ABC and DEF having the same altitude, whose bases are BC and EF; likewise two parallelograms CG and EH of the same altitude, whose bases are the same BC and EF. I say that triangle ABC is to triangle DEF, and parallelogram CG is to parallelogram EH, as the base BC is to the base EF. That is: if the base BC is set as the first magnitude and the base EF as the second, while triangle ABC (or parallelogram CG) is the third and triangle DEF (or parallelogram EH) the fourth, then equimultiples of the first and third must, together, either fall short of, or be equal to, or exceed the equimultiples of the second and fourth — as definition 6 of Book 5 requires.

For let the triangles and the parallelograms alike be placed between the same parallels GH and LN. (For, as was said in definition 4, triangles and parallelograms will have the same altitude only when they are constructed between the same parallels, since the perpendiculars dropped from the vertices to the bases will then be equal.) On BL take any number of straight lines BI, IK, KL

equal to BC; likewise on FN mark off any number of straight lines FM, MN equal to EF. Then from A and from D draw the straight lines AI, AK, AL and DM, DN.

[Margin: a — I.38] The triangles AIB, AKI, ALK, constructed upon equal bases and between the same parallels, are equal to one another; and by the same reasoning the triangles DEF, DFM, DMN will be equal. Therefore, whatever multiple the straight line CL is of the straight line BC, the triangle ACL will be the same multiple of the triangle ABC; and whatever multiple the straight line EN is of the straight line EF, the triangle DEN will likewise be that multiple of the triangle DEF — since the whole triangles ACL and DEN are divided into just as many equal triangles as the whole straight lines CL and EN were cut into equal parts. [Margin: b — I.38] Now if the base CL is equal to the base EN, the triangle ACL is necessarily equal to the triangle DEN; and accordingly, if CL is greater than EN, then necessarily ACL is greater...

is greater than DEN; and if less, less. Therefore the equimultiples of the first magnitude BC and the third ABC — namely the straight line CL and the triangle ACL — will, together with the equimultiples of the second EF and the fourth DEF — namely the straight line EN and the triangle DEN — either be equal, or the one exceed the other, if those are taken which correspond to each other. [Margin: a — V, def. 6] Therefore the ratio that the first magnitude BC has to the second EF (base to base) is the same as that which the third ABC has to the fourth DEF (triangle to triangle). And so, as base is to base, so is triangle to triangle. Which was what was proposed.

Now [Margin: b — V.15] since triangle ABC is to triangle DEF as parallelogram CG [Margin: c — I.34] (which is double triangle ABC) is to parallelogram EH [Margin: d — I.34] (which is double triangle DEF), it is clear [Margin: e — V.11] that parallelogram is likewise to parallelogram as base is to base. This too can be confirmed by the same argument we used for the triangles, if first, from the points I, K, L, straight lines are drawn parallel to BG, and likewise from the points M, N, parallels to FH, and so on. Therefore triangles and parallelograms which have the same altitude are to one another as their bases. Which was to be demonstrated.

Diagram. The equimultiples figure for Proposition 1: a horizontal base line with equal segments marked off on either side, and two apex points from which lines fan down to the division points, all set between two parallels. (The same figure is repeated at the top of the following page.)

- Top line (left to right): G, A, D, H

- A (upper): common vertex of triangles ALK, AKI, AIB, ABC (over the left base)
- D (upper): common vertex of triangles DEF, DFM, DMN (over the right base)
- Base line (left to right): L, K, I, B, C, E, F, M, N
- BI, IK, KL equal to BC; FM, MN equal to EF

Diagram. The same equimultiples figure for Proposition 1, repeated at the top of this page.

- Top line (left to right): G, A, D, H
- A (upper): vertex over the left base (triangles ALK, AKI, AIB, ABC)
- D (upper): vertex over the right base (triangles DEF, DFM, DMN)
- Base line (left to right): L, K, I, B, C, E, F, M, N

SCHOLIUM.

But we shall also demonstrate the converse of this. Namely:

Triangles and parallelograms which are to one another as their bases have equal altitudes, or the same altitude.

Let triangle ABC be to triangle DEF, and parallelogram AGBC to parallelogram DEFH, as the base BC is to the base EF. I say that their altitudes — namely the perpendiculars AI and DK — are equal. For if they are not equal, let AI, if possible, be greater than DK. Cut off IL equal to DK, draw LM parallel to BC, cutting the side AC at N, and join the straight line BN. [Margin: a — VI.1] Then triangle NBC will be to triangle DEF as the base BC is to the base EF, since the altitudes LI and DK are assumed equal. But it was also the case that ABC is to DEF as BC is to EF. [Margin: b — V.11] Therefore the triangles NBC and ABC have the same ratio to triangle DEF; [Margin: c — V.9] and accordingly they are equal to one another — the part and the whole. Which is absurd. The altitudes AI and DK are therefore not unequal, but equal. The same reasoning holds for parallelograms: for by a similar argument we shall show that the parallelograms NMBC and AGBC are equal, if the altitudes AI and DK are said to be unequal while LI and DK are equal.

Here Federico Commandino [Federicus Commandinus] adds another theorem, which we shall demonstrate more briefly. Namely:

Diagram. Two figures for the scholium's first converse: on the left a parallelogram AGBC with the inscribed triangle NBC and the construction lines of

the altitude; on the right a parallelogram DEFH with its altitude DK. Several small interior labels are hard to resolve. []

- Left figure — G (top-left), A (top-right), B (bottom-left), C (bottom-right)
- I [?] (base, foot of perpendicular AI)
- M [?], L [?], N [?] (interior points of the construction LM/IL/N)
- Right figure — D (top-left), H (top-right), K (bottom-left, foot of DK), E, F (base)

Triangles and parallelograms whose bases are equal, or the same, are to one another as their altitudes.

Let there be two triangles ABC and DEF, and parallelograms AGBC and DEFH, having equal bases BC and EF. I say that triangle ABC is to triangle DEF, and parallelogram AGBC to parallelogram DEFH, as the altitude AI is to the altitude DK. For if the straight lines IL and KM are taken equal to the bases BC and EF, and the straight lines LA and MD are drawn, [Margin: d — I.38] then triangle ALI will be equal to triangle ABC, since they stand on equal bases LI and BC and between the same parallels AG and IB. In the same way triangle DKM will be equal to triangle DEF. [Margin: e — V.7] Therefore, as ABC is to DEF, so will ALI be to DKM. [Margin: f — VI.1] But as ALI is to DKM, so is AI to DK. (For if AI and DK are set as the bases, the equal straight lines LI and KM will be the altitudes.) Therefore ABC will be to DEF as AI is to DK. Which was what was proposed.

And [Margin: g — V.15] since ABC is to DEF as parallelogram AGBC [Margin: a — I.34] (which is double triangle ABC) is to parallelogram DEFH [Margin: b — I.34] (which is double triangle DEF), [Margin: c — V.11] AGBC will also be to DEFH as AI is to DK. This too can be confirmed in the same way if the straight lines LG and MH are drawn. The same will follow if the triangles and parallelograms have the same base.

This too we shall convert, in the following manner.

Diagram. Two figures for the scholium's second converse: on the left a triangle ABC with the parallelogram AGBC and its equal-base construction; on the right a triangle DEF with the parallelogram DEFH.

- Left figure — G (top-left), A (top-right), B (bottom-left), L, C, I (base, left to right)
- Right figure — D (top-left), H (top-right), K, F, M (base, left to right)

Triangles and parallelograms which are to one another as their altitudes have equal bases, provided they do not have one and the same base.

Let triangle ABC be to triangle DEF, and parallelogram AGBC to parallelogram DEFH, as the altitude AI is to the altitude DK. I say that their bases BC and EF are equal. For if they are not equal, let BC, if possible, be greater than EF. Cut off BL equal to EF and draw the straight line LA. Then, as we have just demonstrated, ABL will be to DEF as AI is to DK. But AI is to DK, by hypothesis, as ABC is to DEF. [Margin: d — V.11] Therefore ABL and ABC have the same ratio to DEF; [Margin: e — V.9] and accordingly they are equal to one another — the part and the whole. Which is absurd. The bases BC and EF are therefore not unequal, but equal. The same reasoning applies to parallelograms: for by a similar argument, drawing LM parallel to GF, we shall show that the parallelograms MGBI and AGBC are equal, if the bases BC and EF are said to be unequal while BL and EF are equal.

In all these cases the demonstration will not vary even if the triangles and parallelograms are right-angled — so that their sides are the altitudes — or if one is right-angled and the other not. We have taken the more difficult case, namely when neither is right-angled; for in that case the demonstration sometimes requires a larger construction.

Diagram. Two figures for the scholium's third converse: on the left a parallelogram AGBC with the inscribed parallelogram MGBI on the reduced base; on the right the parallelogram DEFH.

- Left figure — G (top-left), M (top), A (top-right); B, L, C (base, left to right); I (?) (base, foot of the altitude)
- Right figure — D (top-left), H (top-right); K, E, F (base, left to right)

THEOR. 2. PROPOS. 2.

[Margin: ij.]

If a straight line is drawn parallel to one side of a triangle, it will cut the sides of the triangle proportionally. And if the sides of a triangle are cut proportionally, then the straight line joined to the points of section will be parallel to the remaining side of the triangle.

In the triangle ABC let there first be drawn the straight line DE parallel to the side BC. I say that the sides AB and AC are cut proportionally at D and E — that is, that AD is to DB as AE is to EC. For when the straight lines CD and BE are drawn, [Margin: a — I.37] the triangles DEB and DEC, constructed on the same base DE and between the same parallels DE and BC, are equal to one another. [Margin: b — V.7] Therefore, as triangle ADE is to triangle DEB, so is the same triangle ADE to triangle DEC. [Margin: c — VI.1] But as triangle ADE is to triangle DEB, so is the

base AD to the base DB (since these triangles are of the same altitude, as is evident if a straight line parallel to AB is drawn through E); and by the same reasoning, as triangle ADE is to triangle DEC, so is the base AE to the base EC. [Margin: d — V.11] Therefore AD is to DB as AE is to EC (since these two ratios are the same as the ratio of triangle ADE to triangle DEB, and of the same triangle ADE to triangle DEC). Which was what was proposed.

Next, let the straight line DE cut the sides AB and AC proportionally. I say that DE is parallel to the remaining side BC. For when the straight lines CD and BE are drawn again, [Margin: e — VI.1] the base AD will be to the base DB as triangle ADE is to triangle DEB, since they are of the same altitude. But it is assumed that AD is to DB as AE is to EC. [Margin: f — V.11] Therefore triangle ADE will be to triangle DEB as AE is to EC. But again [Margin: g — VI.1] the base AE is to the base EC as triangle ADE is to triangle DEC, since they are of the same altitude. [Margin: h — V.11] Therefore triangle ADE is to triangle DEB as the same triangle ADE is to triangle DEC. [Margin: i — V.9] The triangles DEB and DEC are therefore equal; and consequently, since they have the same base DE, [Margin: k — I.39] they will be placed between the same parallels. Therefore DE is parallel to BC. Which was what was proposed. And so, if a straight line is drawn parallel to one side of a triangle, and so on. Which was to be shown.

Diagram. Triangle ABC with DE drawn parallel to the base BC, and the two cross-diagonals CD and BE drawn (crossing inside the triangle).

- A (apex, top): vertex of the triangle
- E (left, mid-height): point on side AC
- D (right, mid-height): point on side AB, on line DE
- C (bottom-left): base vertex
- B (bottom-right): base vertex

THEOR. 3. PROPOS. 3.

[Margin: iij.]

If an angle of a triangle is bisected, and the straight line bisecting the angle also cuts the base, the segments of the base will have the same ratio as the remaining sides of the triangle. And if the segments of the base have the same ratio as the remaining sides of the triangle, then the straight line drawn from the vertex to the point of section bisects the angle of the triangle itself.

In the triangle ABC let the straight line AD first bisect the angle BAC. I say that BA is to AC as BD is to DC. For through B draw the straight line BE parallel to AD, until it meets CA extended at E. (BE and CA will certainly meet, because the angles C and CBE are less than two right angles. For since C and CDA [Margin: a — I.17] are less than two right angles, [Margin: b — I.29] and the angle CDA is equal to the angle CBE, exterior to interior, the angles C and CBE will also be less than two right angles.) [Margin: c — I.29] And the angle EBA will be equal to the alternate angle BAD, and the angle E to the exterior angle DAC. Since, then, the two angles BAD and DAC are assumed equal, the angles EBA and E will also be equal to one another; [Margin: d — I.6] and therefore the straight lines BA and EA are equal to one another. [Margin: e — V.7] Therefore EA is to AC as BA is to the same AC. [Margin: f — VI.2] But EA is to AC as BD is to DC, since in the triangle BCE the straight line AD is parallel to the side BE. [Margin: g — V.11] Therefore BA is to AC as BD is to DC. Which was what was proposed.

Next, let BA be to AC as BD is to DC. I say that the straight line AD bisects the angle BAC. For again, through B, draw the straight line BE parallel to AD, meeting CA extended at E. Since, then, BA is to AC as...

Diagram. Triangle for Proposition 3: the bisector AD from the vertex to the base, with BE drawn from B parallel to AD meeting CA extended at E.

- E (apex, top): meeting point of BE with CA extended
- A (right, mid-height): vertex whose angle BAC is bisected
- B (bottom-left): base vertex
- D (bottom, middle): point where the bisector meets the base
- C (bottom-right): base vertex

THEOR. 3. PROPOS. 3. — conclusion of the demonstration

as AC, so is BD placed to DC. [Margin: Elements VI.2] But BD is to DC as EA is to AC — for in triangle BCE the line AD is drawn parallel to side BE. [Margin: Elements V.11] Therefore BA is to AC as EA is to the same AC; [Margin: Elements V.9] and so BA and EA [printed: "EB"; recte EA] are equal to one another. [Margin: Elements I.5] Consequently the angles ABE and E [that is, AEB] will also be equal. [Margin: Elements I.29] Since, then, angle ABE equals the alternate angle BAD, and angle E equals the exterior angle DAC, the two angles BAD and DAC will likewise be equal to one another — which is the proposition. And so, if an angle of a triangle is bisected, and so on. Which was to be demonstrated.

THEOR. 4. PROPOS. 4.

[Margin: iij.]

In equiangular triangles the sides about the equal angles are proportional, and those are the corresponding (homologous) sides which subtend the equal angles.

Let ABC and DCE be equiangular triangles, with angle ABC equal to angle DCE, angle ACB equal to angle DEC, and angle BAC equal to angle CDE. I say that AB is to BC as DC is to CE; that BC is to CA as CE is to ED; and finally that AB is to AC as DC is to DE. For this is what it means for the sides about the equal angles to be proportional, and for the corresponding sides to be those which subtend the equal angles — that is, all the antecedents look toward equal angles, and the consequents likewise.

Let the sides BC and CE be set along a single straight line, so that the exterior angle DCE is equal to the interior angle ABC, and likewise the exterior angle ACB to the interior angle DEC. Since the two angles ABC and ACB [Margin: Elements I.17] are less than two right angles, and angle DEC is equal to angle ACB, the angles B and E will also be less than two right angles. [Margin: 13. prop.] Therefore the straight lines BA and ED, produced toward the sides A and D, will meet. Let them be produced, then, and let them meet at F.

Now since the exterior angle DCE is equal to the interior and opposite angle ABC, [Margin: Elements I.28] the lines CD and BF will be parallel; [Margin: Elements I.34] and by the same reasoning CA and EF will be parallel, because the exterior angle ACB is equal to the interior angle DEC. ACDF is therefore a parallelogram, and consequently AF equals CD, and CA equals DF.

Since, then, in triangle BEF the line AC is parallel to side EF, [Margin: Elements VI.2] AB will be to AF — that is, to DC (which is equal to AF) — as BC is to CE. [Margin: Elements V.16] Therefore, alternately, AB is to BC as DC is to CE. Again, since in the same triangle BEF the line CD is parallel to side BF, [Margin: Elements VI.2] BC will be to CE as FD — that is, as CA (which is equal to FD) — is to ED. [Margin: Elements V.16] Therefore, alternately, BC is to CA as CE is to ED. Since, then, AB is to BC as DC is to CE, and BC is to CA as CE is to ED, [Margin: Elements V.22] it will follow, ex aequali, that AB is to CA as DC is to ED. Which is the proposition. Therefore in equiangular triangles the sides are proportional, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 4. Along the base lie B (left), C (middle), and E (right) on one straight line. From B the left side rises through A to the apex F; from E the right side rises through D to F. The segment AD is joined across; CA and CD are drawn, forming the parallelogram ACDF.

- F (apex): meeting-point of the produced sides BA and ED
- A (on BF): vertex of triangle ABC
- D (on FE): vertex of triangle DCE
- B (base, left): endpoint
- C (base, middle): shared vertex of the two triangles
- E (base, right): endpoint

COROLLARIUM.

From this it follows that a straight line drawn parallel to one side of a triangle cuts off a triangle similar to the whole. For in triangle ABC let DE be drawn parallel to side BC. I say that triangle ADE is similar to triangle ABC. They are equiangular, [Margin: Elements I.29] since the angles ADE and AED are equal to the exterior angles ABC and ACB, and angle A is common. Therefore, as has been demonstrated, [Margin: Elements VI.4] they have the sides about the equal angles proportional; and consequently, by the definition, they are similar.

Diagram. The figure for the corollary. Triangle ABC with apex A at the top; B at the lower left and C at the lower right form the base BC. The line DE is drawn parallel to BC, with D on side AB and E on side AC, cutting off the similar triangle ADE.

- A (apex): common vertex
- D (on AB): left end of the parallel
- E (on AC): right end of the parallel
- B (base, left): endpoint
- C (base, right): endpoint

SCHOLIUM.

I think it not foreign to our purpose to demonstrate here two theorems. The first of these Federico Commandino [Federico Commandino] proves in his little book on Archimedes' *On Floating Bodies* [Archimedes, *De iis quae vehuntur in aqua*]; the second, in his commentary on Apollonius's *Conics* [Apollonius, *Conica*]. The first is as follows.

If from two points of any straight line — one of them an endpoint, the other lying within the line — two mutually parallel lines are drawn toward the same side, so that they have the same ratio as the segments of the straight line enclosed between them and the other endpoint, then the straight line joining the extremity of the one to the endpoint of the original line will pass through the extremity of the other line.

Let AB be a straight line, and from the points A and C let two parallels AD and CE be drawn, having the same ratio as AB has to BC — so that AD is to CE as AB is to BC; or CE is to AD as BC is to AB. I say that the straight line joining the extremities B and E passes through the point D. Likewise that the straight line joining the extremities B and D passes through the point E. For if the straight line BE does not pass through D, let it meet AD at the point F, which will be either above D or below it, as in the first figure. Since, then, by the corollary of this proposition the triangles BAF and BCE are similar, [Margin: Elements VI.4] AB will be to AF as BC is to CE; and, alternately, [Margin: Elements V.16] AB is to BC as AF is to CE. But AB is to BC as AD is to CE. [Margin: Elements V.11] Therefore AF is to CE as AD is to CE, [Margin: Elements V.9] and consequently the lines AF and AD will be equal — the part and the whole. Which is absurd. Therefore the straight line BE passes through the point D. Which was the first point.

Diagram. The first case ("prima figura") of the scholium's first theorem. Along the base lie A (left), C (middle) and B (right). From A the line AD rises; from C the parallel CE rises. Lines are drawn from B to D and from B to E; where BE meets AD (produced) the auxiliary point F is marked above D. Labels legibly read: A, B, C, D, E, F. The precise placement of the two interior labels (E and the auxiliary F) is hard to resolve at this resolution.

- A (base, left): endpoint of AB
- C (base, middle): interior point of AB
- B (base, right): endpoint
- D (top of AD): extremity of the first parallel
- E (on CE): extremity of the second parallel [?]
- F (above D): intersection of BE with AD produced [?]

[\[continuation on the following page\]](#)

Again, if the straight line BD does not pass through E, let it pass through F, a point either above E or below it, as in the second figure. Since, then, by the corollary of this proposition the triangles BAD and BCF are similar, [Margin: Elements VI.4] AB will be to AD as BC is to CF; and, alternately, [Margin: Elements V.16] AB is to BC

as AD is to CF. But AB was to BC also as AD is to CE. [Margin: Elements V.11] Therefore AD is to CF as AD is to CE; [Margin: Elements V.9] and consequently the lines CF and CE will be equal — the part and the whole. Which is absurd. Therefore the straight line BD passes through E. Which was the second point.

Diagram. The second case ("secunda figura") of the scholium's first theorem. Along the base lie A (left), C (middle) and B (right). From A rises AD (with D at the top), from C rises the parallel CE; lines BD and BE are drawn, and the auxiliary point F falls below D on the line AD. Labels legibly read: A, B, C, D, E, F; the two interior labels (E and the auxiliary F) are hard to resolve.

- A (base, left): endpoint
- C (base, middle): interior point
- B (base, right): endpoint
- D (top of AD): extremity of the first parallel
- E (on CE): extremity of the second parallel [?]
- F (below D): intersection point [?]

This also holds when the two parallels are drawn to opposite sides, having the same ratio as the segments of the straight line lying between the neighbouring parallels and one and the same point within the given line. Thus, as in the figure of Problem 7 of the scholium to Proposition 17: if the parallels AE and FC are drawn to opposite sides, and AE is to CF as AG is to CG, then the straight line EF will pass through G — that is, the two lines EG and FG will form a single straight line. For since AE is to CF as AG is to CG, then, alternately, AE is to AG as CF is to CG. And since the alternate angles A and C are equal, [Margin: Elements VI.6] the angles AGE and CGF will also be equal. Therefore, since AC is a straight line, EG and FG will likewise form one straight line — by what we demonstrated from Proclus [Proclus] on Proposition 15 of Book 1. That was the first theorem; the second is as follows.

Diagram. A crowded construction borrowed from the figure of Problem 7 of the scholium to Proposition 17. Around a central region are grouped many lettered points; those legibly read are D (top), K (below D, left), F (upper middle), H (below F), I (below H), A (left), M (right of A), G (below M), C (right of G), B (far right), L (below A), E (bottom). The dotted and solid lines form several overlapping triangles and parallels.

- D (top): vertex
- K (upper left): vertex [?]
- F (upper middle): vertex

- H (below F): interior point [?]
- I (below H): interior point [?]
- A (left): vertex
- M (right of A): interior point [?]
- G (lower middle): interior point
- C (right of G): vertex
- B (right): vertex
- L (lower left): vertex [?]
- E (bottom): vertex

If in any triangle a straight line is drawn parallel to one side, and from any point of that side a straight line is drawn to the opposite angle, then the parallel line and that side will be divided in the same ratios.

In triangle ABC let DE be drawn parallel to side BC, and from any point F let the straight line FA be extended to angle A, cutting DE at G. I say that BF is to FC as DG is to GE. For since triangles AFB and AGD are similar (by the corollary of this proposition), [Margin: Elements VI.4] AF will be to BF as AG is to DG; [Margin: Elements V.16] and, alternately, AF is to AG as BF is to DG. By the same argument we shall conclude that AF is to AG as FC is to GE. [Margin: Elements V.11] Therefore BF is to DG as FC is to GE; and, alternately, BF is to FC as DG is to GE. Which was the proposition.

Alternatively: since triangles ABF and ADG are similar, and likewise triangles AFC and AGE (by the corollary of this proposition), [Margin: Elements VI.4] BF will be to FA as DG is to GA; likewise FA is to FC as GA is to GE. [Margin: Elements V.22] Therefore, ex aequali, BF is to FC as DG is to GE. Which was to be demonstrated.

Diagram. The figure for Clavius's added theorem. Triangle ABC with apex A; the base runs B (left) — F (middle) — C (right). The line DE is drawn parallel to BC, with D on side AB and E on side AC; the line FA rises from F to the apex A, cutting DE at G.

- A (apex): opposite angle
- D (on AB): left end of the parallel
- G (on DE): point of section on the parallel
- E (on AC): right end of the parallel
- B (base, left): endpoint
- F (base, middle): point of section on the side
- C (base, right): endpoint

THEOR. 5. PROPOS. 5.

[Margin: v.]

If two triangles have their sides proportional, the triangles will be equiangular, and will have equal those angles under which the corresponding sides are subtended.

Let triangles ABC and DEF have their sides proportional, so that AB is to BC as DE is to EF, BC is to CA as EF is to FD, and finally AB is to AC as DE is to DF. I say that the triangles are equiangular — namely that angle A equals angle D, angle B equals angle E, and angle C equals angle F; for in this way equal angles subtend the corresponding sides.

On EF construct angle FEG equal to angle B, and angle EFG equal to angle C, with the lines EG and FG meeting at G. [Margin: Elements I.32] Then the remaining angle G will be equal to the remaining angle A. Triangles ABC and GEF are therefore equiangular. [Margin: Elements VI.4] Hence AB is to BC as GE is to EF; but AB is to BC as DE is to EF (by assumption). [Margin: Elements V.11] Therefore GE is to EF as DE is to EF; [Margin: Elements V.9] and consequently GE and DE will be equal. Again, [Margin: Elements VI.4] since BC is to CA as EF is to FG — but BC is to CA as EF is to FD (by assumption) — [Margin: Elements V.11] EF is to FG as the same EF is to FD; [Margin: Elements V.9] and therefore FG and FD will be equal.

And so, since the sides EG and FG are equal to the sides DE and DF, each to each, and the base EF is common, [Margin: Elements I.8] the angles G and D will be equal; [Margin: Elements I.4] and consequently the remaining angles GEF and GFE will also equal the remaining angles DEF and DFE. Therefore, since angle G equals angle A, angle D too will equal the same angle A; and in the same way angle DEF will equal angle B, and angle DFE will equal angle C. Which is the proposition. If, then, two triangles have their sides proportional, and so on. Which was to be shown.

Diagram. The figure for Proposition 5. On the left, triangle ABC (A apex, B lower left, C lower right). On the right, the constructed figure: D at the top, E at the left and F at the right (with EF horizontal), and G below, forming triangle GEF beneath DEF.

- A (apex, left triangle): vertex
- B (lower left): vertex
- C (lower right): vertex

- D (top, right figure): vertex
- E (left): vertex of the base EF
- F (right): vertex of the base EF
- G (below EF): apex of the constructed triangle GEF

THEOR. 6. PROPOSITIO 6.

[Margin: vj.]

If two triangles have one angle equal to one angle, and the sides about the equal angles proportional, the triangles will be equiangular, and will have those angles equal under which the corresponding sides are subtended.

Let angle B of triangle ABC be equal to angle E of triangle DEF, and let the sides AB, BC be proportional to the sides DE, EF — that is, let AB be to BC as DE is to EF. I say that the remaining angles are equal to the remaining angles: namely angle A to angle D, and angle C to angle F; for in this way the equal angles subtend corresponding sides.

On EF construct angle FEG equal to angle B, and angle EFG equal to angle C; then, as was stated in the preceding proposition, triangle GEF will be equiangular with triangle ABC. [Margin: Elements VI.4] Hence AB is to BC as GE is to EF; but AB is to BC as DE is to EF (by assumption). [Margin: Elements V.11] Therefore DE is to EF as GE is to the same EF; [Margin: Elements V.9] and so DE and GE will be equal.

And so, since the sides DE, EF are equal to the sides GE, EF, and the angles contained by them are also equal — for angle DEF is set equal to angle B, to which angle FEG was made equal, and therefore the angles DEF and GEF are equal to one another — [Margin: Elements I.4] the remaining angles D and EFD will be equal to the remaining angles G and EFG. Then, since angle G equals angle A and angle EFG equals angle C, the angles D and EFD will also equal angles A and C; and for that reason triangles ABC and DEF are equiangular. Which is the proposition. If, then, two triangles have one angle equal to one angle, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 6. On the left, triangle ABC (A apex, B lower left, C lower right). On the right, the constructed figure: D at the top, E at the left and F at the right (EF horizontal), and G below, forming triangle GEF beneath triangle DEF.

- B (lower left): vertex
- C (lower right): vertex
- D (top, right figure): vertex
- E (left): vertex of base EF
- F (right): vertex of base EF
- G (below EF): apex of the constructed triangle GEF

THEOR. 7. PROPOSITIO 7.

If two triangles have one angle equal to one angle, the sides about other angles proportional, and each of the remaining angles either both less than a right angle or both not less than a right angle, the triangles will be equiangular and will have equal those angles about which the sides are proportional.

Let angle A of triangle ABC be equal to angle D of triangle DEF, and let the sides AC, CB about angle ACB be proportional to the sides DF, FE about angle F — that is, let AC be to CB as DF is to FE — yet under this condition, that each of the remaining angles B and E is either less than a right angle or not less than a right angle. I say that the triangles are equiangular: that the angles ACB and F, about which the sides are proportional, and the angles B and E, are equal.

First let both B and E be less than a right angle. On this supposition, if the angles ACB and F are not equal, let ACB be the greater; and construct angle ACG equal to F. Then, since angle A is also assumed equal to angle D, [Margin: Elements I.32] the remaining angle AGC will equal the remaining angle E, and so triangles AGC and DEF will be equiangular. [Margin: Elements VI.4] Hence AC is to CG as DF is to EF; but DF is to FE as AC is to CB (by assumption). [Margin: Elements V.11] Therefore AC is to CG as the same AC is to CB; [Margin: Elements V.9] and consequently CG and CB will be equal, [Margin: Elements I.5] and the angles CBG and CGB equal. Now since angle B is assumed less than a right angle, CGB too will be less than a right angle, and therefore its adjacent angle AGC will be greater than a right angle, [Margin: Elements I.13] since AGC and CGB together equal two right angles. But angle AGC was shown to equal angle E. Angle E therefore is also greater than a right angle; yet it was assumed to be less than a right angle. Which is absurd.

Next let both B and E be not less than a right angle. Then, as before, angle B will equal angle CGB; and consequently the angles CBG and CGB in triangle BCG will not be less than two right angles, but either greater than or equal to two right angles. Which is absurd, [Margin: Elements I.17] for they are less than two right

angles. Therefore the angles ACB and F are not unequal, but will be equal — which is the proposition — and [Margin: Elements I.32] consequently the remaining angles B and E will also be equal. If, then, two triangles have one angle equal to one angle, and so on. Which was to be demonstrated.

Diagram. The figure for Proposition 7. On the left, triangle ABC (A apex, B lower left, C lower right); from a point G on the left side a line is drawn to C, marking off the auxiliary triangle used in the reductio. On the right, triangle DEF (D apex, E lower left, F lower right).

- A (apex, left triangle): vertex, equal angle
- G (on side AB, lower): auxiliary point
- B (lower left): vertex
- C (lower right): vertex about which the sides are proportional
- D (apex, right triangle): vertex
- E (lower left): vertex
- F (lower right): vertex

SCHOLIVM.

Euclid added that each of the remaining angles B and E must be either less than a right angle or not less than a right angle. For otherwise, with the whole hypothesis remaining, it would not follow that the triangles are equiangular. Suppose, in the same triangle ABC, that CG is made equal to CB [Margin: Elements I.19] — which can happen when angle B is acute and greater than angle A, for then side CA will be greater than side CB. If, then, a circle is described with center C and radius CB, it will cut the straight line AB before it cuts AC, which is longer than CB. And this circle will necessarily cut AB, because, owing to the acute angle B, the line AB falls within it — since it is drawn below the tangent, which at B makes a right angle with CB, as is clear from Proposition 16 of Book 3 (Elements III.16). In that case the two triangles ABC and AGC will have one angle equal to one angle — indeed angle A in common — and about the other angles ACB and ACG the sides proportional; that is, [Margin: Elements V.7] AC is to CB as the same AC is to CG, since the lines CB and CG are assumed equal — and yet the triangles ABC and AGC are in no way equiangular, as is evident. This happens because it is not the case that both angles ABC and AGC are less than a right angle, or both not less. On the contrary, ABC is indeed less than a right angle, whereas AGC is greater than a right angle. For since CG and CB are equal sides, [Margin: Elements I.5] and therefore the angles CBG and CGB equal, [Margin: Elements I.17 (or I.32)]

each of them will be less than a right angle, [Margin: Elements I.13] and consequently AGC will be greater than a right angle.

[Margin: viij.]

THEOR. 8. PROPOS. 8.

If in a right-angled triangle a perpendicular is drawn from the right angle to the base, the triangles adjoining the perpendicular are similar both to the whole triangle and to one another.

In triangle ABC let angle BAC be a right angle, and from it let the perpendicular AD be drawn to the base. I say that the triangles ADB and ADC are similar both to the whole triangle ABC and to one another. For since in triangles ABC and DBA the angles BAC and ADB are right angles, and angle B is common, [Margin: Elements I.32] the remaining angles ACB and DAB [printed: "DAE"; recte DAB] will also be equal. Triangle DBA is therefore equiangular with triangle ABC, [Margin: Elements VI.4] and consequently they will have the sides about the equal angles proportional, and so on; that is, CB is to BA as BA is to BD; BA is to AC as BD is to DA; and BC is to CA as BA is to AD. For in this way the corresponding sides are set opposite the equal angles, as Proposition 4 of this book requires. Hence triangle ADB is similar to the whole triangle ABC.

In the same way it is shown that triangle ADC is similar to the same triangle ABC. For the angles BAC and ADC are right angles, and angle C is common, [Margin: Elements I.32] and consequently the remaining angles ABC and CAD are equal. Hence [Margin: Elements VI.4] BC is to CA as CA is to CD; CA is to AB as CD is to DA; and CB is to BA as CA is to AD. For thus too the corresponding sides are set opposite the equal angles, as prescribed by Proposition 4 of this book. In just the same way it will be demonstrated that triangles ADB...

Diagram. The figure for Proposition 8. A right-angled triangle with the right angle at the apex A. The base runs C (lower left) — D (lower middle) — B (lower right); AD is the perpendicular dropped from A to the base, dividing the triangle into ADC (left) and ADB (right).

- A (apex): the right angle BAC
- C (base, left): vertex
- D (base, middle): foot of the perpendicular AD
- B (base, right): vertex

Book VI (continued)

Proposition 8 — demonstration concluded

[triangles] ADB and ADC [are similar to one another], since the angles ADB and ADC are right, the angles ABD and CAD have been shown equal, and likewise the angles BAD and ACD. And therefore [Margin: c. *Elements* VI.4] BD is to CA as DA is to DC; DA is to AB as DC is to CA; and AB is to BD as CA is to AD. If, then, in a right-angled triangle a perpendicular is drawn from the right angle to the base, and so on. Which was to be demonstrated. [Margin: d. *Elements* VI.4]

COROLLARIUM (Corollary)

From this it is evident that the perpendicular dropped in a right triangle from the right angle to the base is the mean proportional [*media proportionalis*] between the two segments of the base; and likewise that each of the sides containing the right angle is the mean proportional between the whole base and that segment of the base which is adjacent to that side.

For it has been shown that BD is to DA as DA is to DC, and therefore that DA is the mean proportional between BD and CD. Likewise, that CB is to BA as BA is to BD, and therefore that BA is the mean proportional between CB and BD. Finally, that BC is to CA as CA is to CD, and therefore that CA is the mean proportional between BC and CD. Which was proposed.

PROBL. 1. PROPOS. 9. (Problem 1, Proposition 9)

[Margin: ix. [?]]

To cut off a prescribed part from a given straight line.

Suppose we are required to cut off a third part from the line AB. From A draw a straight line AC at any angle, forming the angle CAB. On AC mark off as many equal parts, of any size whatever, as is the number of the part to be taken from AB — in the present example three: AD, DE, EF. Then from F to B draw the straight line FB, and through D draw DG parallel to it. I say that AG is the required third part of the straight line AB.

For since in the triangle ABF the straight line DG is parallel to the side FB, [Margin: a. *Elements* VI.2] FD is to DA as BG is to GA. Therefore, by composition [*componendo*], [Margin: b. *Elements* V.18] FA is to DA as BA is to GA. But FA is triple AD by construction; therefore BA is also triple AG, and so AG is the third

part of AB, which was required. We have therefore cut off from a given straight line the prescribed part. Which was to be done.

Diagram. The figure for Proposition 9: a triangle with the base AB running along the bottom and an oblique upper side AC.

- A (bottom-left vertex): apex of the angle CAB.
- G (on base AB, between A and B): the point marking off the required third part AG.
- B (bottom-right vertex): far end of the base.
- D (on AC, first division from A): AD is the first equal part.
- E (on AC, second division): DE is the second equal part.
- F (on AC, third division, near C): EF is the third equal part.
- C (top-right vertex): far end of the oblique side.
- FB is drawn, and DG is drawn parallel to it.

SCHOLIUM (Scholium)

But if the part to be cut off from AB is not an aliquot part, but one comprising several aliquot parts that do not make up a single one — for instance, one containing four elevenths of AB — then eleven equal parts must be marked off along AC as far as the point D; from D draw the straight line DB to B, and parallel to it draw EF from E, the end of the fourth part. Then AF will be the required part.

For again, DA is to AE as BA is to AF. Therefore, by conversion [*convertendo*], AE is to AD as AF is to AB. But AE, by construction, is the part containing four elevenths of AD; therefore AF will be the same part of the straight line AB. Which was proposed. In just the same way there may be cut off from AB any part comprising any number of aliquot parts of the line that do not make up a single one.

Diagram. The figure for the Scholium: a long, shallow triangle with base AB and an oblique upper side AD marked off into eleven equal parts (indicated by tick marks).

- A (bottom-left vertex): apex of the angle.
- F (on base AB): foot of the parallel EF.
- B (bottom-right vertex): far end of the base.
- E (on AD, at the end of the fourth part from A): from E the line EF is drawn parallel to DB.
- D (upper-right, end of the eleven divisions): from D the line DB is drawn.

- A short mark labelled "q" [?] appears just beyond D at the upper right (uncertain — possibly a reference letter or line-extension).

PROBL. 2. PROPOS. 10. (Problem 2, Proposition 10)

[Margin: x. [?]]

To divide a given undivided straight line in the same way as another given straight line has already been divided.

Let AB be the straight line to be cut in the same way as the straight line AC has been cut at D and E — that is, into parts proportional to the parts AD, DE, EC. Join the two given lines at A, forming any angle BAC, and draw the connecting straight line BC. Then from D and E draw DF and EG parallel to BC. I say that the straight line AB is cut at F and G in the same way as AC is cut at D and E.

[Margin: a. *Elements* VI.2] For AD is to DE as AF is to FG; therefore the parts AF, FG are proportional to the parts AD, DE. And if DH is drawn parallel to FB, cutting EG at I, then again [Margin: b. *Elements* VI.2] DE is to EC as DI is to IH — that is, as FG is to GB — [Margin: c. *Elements* I.34] since FG is equal to DI, and GB to IH. Therefore the parts FG, GB will also be proportional to the parts DE, EC. And the same reasoning holds for more parts, if from E and C lines are drawn parallel to AB, and so on. Thus we have cut the given undivided straight line in the same way as the other given straight line was cut. Which was to be done.

Diagram. The figure for Proposition 10: a triangle with base AB, apex above, formed by the two given lines meeting at A.

- A (bottom-left vertex): apex of the angle BAC.
- F (on base AB): first division point.
- G (on base AB): second division point.
- B (bottom-right vertex): far end of the base.
- D (on the upper side): division point, from which DF is drawn parallel to BC.
- I (interior): intersection of DH with EG.
- H (upper right): endpoint of the line DH drawn parallel to FB.
- C (apex) [?] and E (further division on the upper side) [?]: named in the construction but not clearly resolved on the leaf.

(*Scholium to Proposition 10, continued.*) ...as is evident from the demonstration of this problem. And since AH has been divided into five equal parts, AB too will be

divided into the same number of equal parts. In just the same way the same straight line AB may be divided into more equal parts.

[The preceding scholium had run:] From this problem one can derive a very easy method and procedure for dividing a given straight line into any number of equal parts — which we undertook to do at proposition 10 of Book I, and which we have also demonstrated by another route at proposition 40 of Book I. For let AB be the straight line to be divided into five equal parts. Draw AC making any angle CAB with AB, and mark off along it five equal parts AD, DE, EF, FG, GH. Now since the straight line AH has been divided in this manner, if from H to B the line HB is drawn, and parallel to it, from the points D, E, F, G, the lines DI, EK, FL, GM are drawn, then AB will be divided in the same way as AH.

To this method of dividing a straight line into any number of equal parts, others, not unpleasing, may be added — as we promised at proposition 10 of Book I, and demonstrated at proposition 40 of Book I. For let AB again be the given straight line, to be divided into five equal parts. From B draw the straight line BC at any angle to AB. Then, from an assumed point D — whether above B or below it — draw DE parallel to AB, and mark off along it five equal parts DF, FG, GH, HI, IE, subject to this condition: that if D is above B, the line DE, made up of the five equal parts, is less than AB; but greater, if D lies below B. Finally, from A through E draw the straight line AC, meeting BC at the point C; and from C, through the points F, G, H, I, draw the lines CK, CL, CM, CN, which I say divide the straight line AB into five equal parts.

For since DE is parallel to AB, the lines EH and AM in the triangle CAM will be divided proportionally, by the scholium to proposition 4 of this book. Therefore, since EH is bisected at I, AM too will be bisected at N. By the same reasoning the line NL in triangle CNL, the line MK in triangle CMK, and the line LB in triangle CLB will each be bisected. Therefore AN is equal to NM, NM to ML, ML to LK, and LK to KB; and consequently AB is divided into five equal parts. Which was proposed.

Diagram. A large triangle with its apex at the top, from which lines fan down to the base. Two horizontal lines cross it.

- Apex (top): the meeting point C [?] (label not clearly resolved).
- Base row (bottom): A, N, M, L, K, B — the line AB divided at N, M, L, K.
- Middle row (a chord parallel to the base): E, I, H, G, F, D (left to right) — the line DE divided at I, H, G, F.
- A further row of labels A, N, M, L, K, B appears higher in the figure [?].

ALITER (Another method)

From the extreme points A and B draw two straight lines BC and AD parallel to one another — that is, make the angles A and B equal. From BC mark off four equal parts BE, EF, FG, GH, so that there are as many parts, less one, as the number into which the line is to be divided; and from AD cut off the same number of equal parts, AI, IK, KL, LM. Then, drawing the straight lines EM, FL, GK, HI, which cut AB at N, O, P, Q, I say that AB is divided into five equal parts.

For since GH, IK are equal and parallel, [Margin: d. *Elements* I.33] HI and GK will also be parallel; and by the same reasoning GK, FL, EM will be parallel. Therefore, since AM is divided into four equal parts, AQ too will be divided into four equal parts, as is evident from the demonstration of this Proposition 10. By the same reasoning BN will be divided into four equal parts, because BH is divided into the same number of equal parts. Therefore, since both AN and BQ are each equal to the individual parts NO, OP, PQ, all five parts AN, NO, OP, PQ, QB will be equal to one another. Which was proposed.

Diagram. A lattice figure: two oblique lines AD and BC parallel to one another, with the line AB crossed by the connecting lines to form a network of parallelograms.

- H, G, F, E (along BC, descending toward B): the divisions BE, EF, FG, GH.
- A, I, K, L, M (along AD): the divisions AI, IK, KL, LM.
- N, O, P, Q (on AB): the intersection points where EM, FL, GK, HI cross AB.
- B (right end of AB).

[Margin: d. *Elements* I.33]

ALITER (Another method — by an instrument)

First prepare an instrument suited to this purpose in the following way. Draw two straight lines CD, EF parallel to one another at any distance; from each mark off any number of equal parts — at least as many as the number of parts into which the line is to be divided — and join the corresponding pairs of points by straight lines. Then, with a compass, take the length of the line AB to be divided, and from some point of the line CE — say from E — transfer it onto the instrument to the point I, that is, to that transverse line which bounds as many spaces as the number of parts into which the line is to be divided; in the example this is the line GH, for it encloses five spaces. Finally, from E to I draw the straight line EI, which I say is divided into five equal parts.

For since GK, HL are equal and parallel, [Margin: e. *Elements* I.33] GH and KL will also be parallel; and in the same way all the lines between CD and EF will be shown parallel to one another. Therefore, as is clear from the demonstration of this Proposition 10, just as EG is divided into five equal parts, so likewise EI will be divided into the same number. For if the point taken is not the same as E or C, IE must be produced until it meets EF or DC; for then, as was proved in this Proposition 10, the lines EI, EG will be similarly divided. But if perhaps IE meets neither FE nor DC, but is parallel to both, [Margin: f. *Elements* I.34] the individual parts of the line EI will be equal to the individual parts of the line EG, because of the parallelograms enclosed between the parallels. Therefore, since all the parts of EG are equal, all the parts of EI will also be equal. If, then, by means of the compass the individual parts of the line EI are transferred onto the proposed line AB, equal to EI, then AB too will be divided into five equal parts. Which was proposed.

It is sometimes necessary to extend the parallel lines beyond the instrument. Thus, if the same length is transferred from M as far as N, a point on the line GH when it is produced, then MN too will be divided into five equal parts — as is clear, if from M a line is drawn parallel to EG as far as the line GH, or if NM is produced until it meets GE produced. If the line to be divided is very short, smaller portions of the parallels CD, EF should be taken, and so on. But if the line is somewhat long and is to be divided into few parts, it may be transferred across twice as many spaces, or three times, or four times as many, and so on — for two, three, or four spaces will then give one part. For instance, if it is to be divided into three parts and is transferred across six spaces, two spaces will give one part; if it is transferred across fifteen spaces, five spaces will give one part, because five spaces make a third of fifteen. Likewise, if a line to be divided into two equal parts is transferred across eighteen spaces, nine spaces will give one part, since nine spaces make half of eighteen; and so with the rest.

Diagram. The dividing instrument: two long, nearly parallel lines CD and EF, connected by a series of transverse "rungs" that enclose equal spaces (a ladder-like lattice).

- C, A (top): ends of the upper transverse line region.
- M (upper, on the top rung).
- L, K (on an intermediate rung).
- N, H, I, G, B (along the lower part): division points and the endpoints of the segments used.
- E, F, G, D: the frame lines CD, EF and the working line EG / EI.

[Margin: e. *Elements* I.33] [Margin: f. *Elements* I.34]

In the same way, on the analogy of this proposition, we may easily demonstrate the following problem, which is not seldom employed by geometers, and which is of this kind:

To cut a given straight line into two parts having any given ratio.

Let AB be the straight line to be cut into two parts having between them the ratio that the lines C and D have. From A draw a line AE making any angle A, and on it mark off AF equal to C, and FG equal to D. Then draw GB, and through F draw FH parallel to it. I say that AB is cut at H according to the ratio of C to D. This is manifest, [Margin: g. *Elements* VI.7 [?]] since, as AF is to FG — and therefore as C is to D — so is AH to HB.

Diagram. A triangle with two short reference segments (C and D) at the left, and the oblique construction line AE.

- A (top): apex of the angle.
- C, D (two short vertical segments at the left): the two given lines whose ratio is prescribed.
- H (on AB): the point of section.
- B (bottom-left): lower end of the line AB being cut.
- F (on AE): with AF equal to C.
- G (on AE, lower right): with FG equal to D; GB is drawn, and FH is drawn parallel to GB.
- E (bottom-right): far end of the oblique line AE.

Finally, we insert here a certain theorem, also bearing on the sections of lines, taken from Federico Commandino[’s commentary] on Archimedes’s little book on the things carried in water [Archimedes, *On Floating Bodies*]. Namely:

If two straight lines are each cut at two points proportionally, then the intermediate sections will also be in the same ratio as any two of the segments.

(*Commandino’s theorem, demonstration.*) Let the straight lines AB and CD be cut proportionally, each at two points, E, F and G, H, so that AE is to EB as CG is to GD, and likewise AF is to FB as CH is to HD. I say that the intermediate sections EF, GH are also proportional to any two of the segments FB, HD — or to the two AE, CG — that is, that FB is to EF as HD is to GH, and likewise that AE is to EF as CG is to GH.

For since AE is to EB as CG is to GD, by composition AB will be to EB as CD is to GD. Likewise, since AF is to FB as CH is to HD, by composition AB will be to FB as CD is to HD, and by conversion FB will be to AB as HD is to CD. Therefore, since FB is to AB as HD is to CD, and AB is to EB as CD is to GD, [Margin: h. *Elements* V.22] *ex aequali* FB will be to EB as HD is to GD; and by conversion EB will be to FB as GD is to HD; and by conversion of the ratio [*per conversionem rationis*] EB will be to EF as GD is to GH; and by division [*dividendo*] FB will be to EF as HD is to GH. Which was the first point.

Again, since AE is to EB as CD [recte: CG] is to GD, and EB is to EF as GD is to GH, as has been shown, *ex aequali* AE will be to EF as CG is to GH. Which was the second point.

The same will be shown more briefly in this way. Let the two points A and C be brought together, and let the straight lines DB, HF, GE be joined. Now since it is assumed that AE is to EB as CG is to GD, [Margin: i. *Elements* VI.2] GE will be parallel to DB. Again, since it is assumed that AF is to FB as CH is to HD, [Margin: k. *Elements* VI.2] HF too will be parallel to DB. [Margin: l. *Elements* I.30] Therefore GE and HF will be parallel to one another; and on that account [Margin: m. *Elements* VI.2] AE will be to EF as CG is to GH. Which was the second point.

In the same way, if the extreme points B, D are brought together into one, and so on, we shall show that BF is to EF as HD is to GH; and, by conversion, that EF is to FB as GH is to HD. Which was the first point.

The same holds even if the magnitudes AB, CD are of different kinds — as, for example, if AB is a surface and CD a line or a solid — as is clear from the earlier demonstration.

Diagram. Two related figures. First, two horizontal straight lines set one above the other; second, a triangle version (with A and C brought together).

Two parallel lines:

- Upper line: A — E — F — B, cut at E and F.
- Lower line: C — G — H — D, cut at G and H.

Triangle (A and C coincident):

- D (apex, top): from which DB descends.
- H, G (on the side AD, descending): with HF and GE drawn.
- A / C (bottom-left, coincident): apex of the triangle.
- E, F (on the base AB): the section points.

- B (bottom-right): far end of the base.

[Margin: h. *Elements* V.22]

Nor does it seem right to omit here the theorem that follows:

If a straight line is cut into any number of arithmetically proportional parts, and another straight line is cut into the same number of parts having the same ratios among themselves as those parts, then the parts of this [second] line too will be arithmetically proportional.

Let the straight line AB be cut into arithmetically proportional parts AC, CD, DB — that is, into parts having the same excess [*excessus*, i.e. common difference].

[Margin: n. *Elements* VI.10] Let another straight line EF be cut into parts EG, GH, HF proportional to those. I say that these parts too have the same excess — that is, that they are arithmetically proportional.

For let CI be equal to AC, and DK equal to CD, so that ID is the excess between CD and AC, and KB the excess between DB and CD, and therefore equal to ID. Let GL likewise be equal to EG, and HM equal to GH, so that LH is the excess between GH and EG, and MF the excess between HF and GH. It must be proved that the excesses LH, MF are equal.

Now since AC is to CD as EG is to GH, then by alternation AC is to EG as CD is to GH. Likewise, since CD is to DB as GH is to HF, then also by alternation CD is to GH as DB is to HF. And so, however many the parts, the parts of line AB will always have to the parts of line EF, each to each, the same ratio — even though the parts of a single line are not continuously proportional. Since, then, CD is to GH as AC is to EG — that is, as CI is to GL — [Margin: o. *Elements* V.19] the remainder ID will also be to the remainder LH as the whole CD is to the whole GH. Again, since DB is to HF as CD is to GH — that is, as DK is to HM — [Margin: p. *Elements* V.19] the remainder KB will also be to the remainder MF as the whole DB is to the whole HF, or as the subtracted DK is to the subtracted HM; that is, ID is to LH as CD is to GH. [Margin: q. *Elements* V.11] Therefore ID is to LH as KB is to MF. But ID is equal to KB; [Margin: r. *Elements* V.14] therefore LH will also be equal to MF. And on that account EG, GH, HF are arithmetically proportional, since they have equal excesses. Which was proposed.

Diagram. Two vertical scaled lines, side by side, marking the parts and their excesses.

- Left line (bottom to top): A, C, I, D, K, B — the line AB with parts AC, CD, DB, and the auxiliary points I (with CI = AC) and K (with DK = CD).

- Right line (bottom to top): E, G, L, H, M, F — the line EF with parts EG, GH, HF, and the auxiliary points L (with GL = EG) and M (with HM = GH).

[Margin: o. *Elements* V.19] [Margin: p. *Elements* V.19] [Margin: q. *Elements* V.11]
[Margin: r. *Elements* V.14]

This theorem cannot be converted in any way. For it does not follow, if two lines are arithmetically proportional, that the parts of the one have the same ratios as the parts of the other. For suppose that in line EF the second part is set as GM, so that the excess between EG and GM is LM; then, beyond M, take a portion equal to GM and add to it the same excess LM — three arithmetically proportional parts will be formed in the line EF, and yet they will not have the same ratios among themselves as the parts of line AB have: [Margin: s. *Elements* V.8] since the ratio of EG to GM is less than that of EG to GH — that is, than that of AC to CD.

From this another theorem is inferred:

If two unequal lines have the same ratio to two others — the greater to the greater — then the excess of the first pair will also be to the excess of the second pair as one of the first is to one of the second.

As in the figure above: since AC was to EG — that is, CI to GL — so was the excess ID to the excess LH, as CD is to GH. Therefore, if AC, CD are double (or half) the parts EG, GH, then ID too will be double (or half) of LH, and so on.

From these results we shall also solve this problem:

To cut a given straight line into any number of arithmetically proportional parts.

Let the straight line EF be cut into three arithmetically proportional parts. Take three lines AC, CD, DB, arithmetically proportional in any way, composing the straight line AB. Then if the given line EF is [Margin: t. *Elements* VI.10] cut similarly at G, H, as AB is cut at C, D, the parts EG, GH, HF will be arithmetically proportional, as has been demonstrated.

All of this is true also for numbers, and for any other magnitudes whatsoever, since the demonstration is always the same. And from these results we derived, in the tenth rule of arithmetical proportionality, the final method of distributing a given number into any number of arithmetically proportional parts. For by it a given number is divided into parts having the same ratios as the assumed numbers of the arithmetical proportion, since it is always arranged that, as the sum of the assumed numbers is to the given number, so each of the assumed

numbers is to another [i.e. to the corresponding part]. From this it follows that the assumed numbers have the same ratio to the parts of the given number that are found. Therefore, as has been shown here, the parts found are arithmetically proportional.

PROBL. 3. PROPOSITIO 11. (Problem 3, Proposition 11)

[Margin: xi. [?]]

Given two straight lines, to find a third proportional.

PROBL. 3. PROPOS. 11. (construction and demonstration, continued)

(The enunciation — "Given two straight lines, to find a third proportional" — was set out at the end of the preceding pages; the construction opens here.)

Let AB and AC be two straight lines so arranged as to form any angle A, and let a third proportional to them be sought, such that as AB is to AC, so AC is to the third. Extend AB — which we wish to be the antecedent — and take BD equal to AC, which is to be the consequent, that is, the mean. Then, having drawn the straight line BC, from D draw DE parallel to it, meeting AC extended at E. I say that CE is the third proportional; that is, that as AB is to AC, so AC is to CE. For since in triangle ADE the straight line BC is drawn parallel to the side DE, [Margin: a — 2. sexti (*Elements* VI.2)] it follows that as AB is to BD, so AC is to CE. [Margin: b — 7. quinti (*Elements* V.7)] But as AB is to BD, so is the same AB to AC, since BD is equal to AC. Therefore as AB is to AC, so AC is to CE — which was what was proposed. So, given two straight lines, we have found a third proportional. Which was to be done.

Diagram. The construction figure for Proposition 11. On the horizontal base lie A (left), B (middle), and D (right); E is the apex above, and C lies on the slanting line AE.

- A (bottom-left): vertex of the given angle
- B (base, between A and D): endpoint marking $BD = AC$ laid off along the extended base
- D (bottom-right): terminus of the extended line AB
- E (apex): where DE (parallel to BC) meets AC extended
- C (on line A–E): the given point; CE is the third proportional found
- Lines drawn: AE (with C on it), ED, and BC (with $BC \parallel DE$)

SCHOLIUM

We shall prove the same thing another way, as follows. Let the two given straight lines AB and BC be set at a right angle ABC, and let the straight line AC be joined. Then, with AB extended as the antecedent, draw from C the perpendicular CD to AC, meeting AB extended at D. I say that BD is the third proportional. For since in triangle ACD the angle ACD is right, and from it the perpendicular CB is dropped to the base AD, then by the corollary to Proposition 8 of this book, BC will be the mean proportional between AB and BD; that is, as AB is to BC, so will BC be to BD. Which was what was proposed.

Diagram. The alternative (Scholium) figure. A right triangle standing on base AD with its right angle at the apex C.

- A (bottom-left): endpoint of base AD
- B (base, between A and D): foot of the perpendicular CB
- D (bottom-right): where the perpendicular CD (from C to AC) meets AB extended
- C (apex): right angle ACD; $CB \perp AD$
- Lines drawn: AC, CD, and the perpendicular CB

Once the third continuously-proportional line has been found, if you drop the first and find a third to the other two, you will have four continuously proportional lines. For example, if to the lines A and B a third proportional C is found, and to the two lines B and C a third proportional D, then A, B, C, D will be four continuously proportional lines. By the same technique a fifth proportional will be obtained — a sixth, a seventh, an eighth — and so on without limit.

Diagram. Four separate straight-line segments of decreasing length are drawn one above another and labelled A, B, C, D — the sample lines of the continued proportion just described.

- A, B, C, D: four line segments in continued proportion

A more expeditious method. We shall find any number of lines continuously proportional in a given ratio, in the following way. Let the given ratio first be that of the larger line A to the smaller B. About the straight line CD, taken equal to A, describe the circle CEDF, and in it fit the chords DE and DF, each equal to B. With a ruler applied to the points E and F, draw the straight line EG, which will be perpendicular to CD. For since the straight line DC, passing through the centre, bisects the arc ECF (indeed, when the equal arcs DE and DF are removed from the equal semicircles DEC and DFG, the remaining arcs CE and CF will be equal), the

same line will also bisect the drawn straight line EF, by what we showed in the scholium to Proposition 27 of Book 3; [Margin: c — 3. tertij (*Elements* III.3)] and therefore it does so at right angles. And since, if the straight line EC were drawn, [Margin: d — 31. tertij (*Elements* III.31)] the angle at E would be right, being in a semicircle, it follows from the corollary to Proposition 8 of this book that DE is the mean proportional between CD and DG; and hence DG will be the third proportional to CD and DE — that is, to the two given lines A and B. Now if from D, through G, an arc is described cutting the straight lines DE and DF at H and I, and a ruler is applied to the points H and I and the straight line HK is drawn, then DK will be the fourth proportional. For on account of the angles HDG and IDG (which are equal, [Margin: e — 27. tertij (*Elements* III.27)] because the arcs EC and FC are equal), [Margin: f — 26. tertij (*Elements* III.26)] the arcs HC and IG will be equal; and therefore, by the scholium to Proposition 27 of Book 3, the drawn straight line HI will be bisected at K, [Margin: g — 3. tertij (*Elements* III.3)] and hence at right angles. [Margin: h — 28. primi (*Elements* I.28)] Therefore EG and HK are parallel. [Margin: i — 2. vel 4. sexti (*Elements* VI.2 or VI.4)] So then, as the straight line ED is to DG, so will DH — that is, DG — be to DK. Therefore the four lines CD, DE, DG, DK are continuously proportional. And if from D, through K, another arc is described cutting the straight lines DE and DF, a fifth proportional will be found by the same technique, and so on without limit.

Diagram. A composite construction figure serving the two "expeditious" methods. A circle (CEDF) stands on a horizontal diameter running to D at the right; a straight line slants down from the upper left through the points T, R, P, E toward the circle, and several chords, arcs, and perpendiculars are drawn. At the far left are short vertical reference segments labelled A and B (the two given lines); a baseline below carries the marks M, Q, O and I.

- On the slanting upper line (top to bottom): T, R, P, E, H
- On the horizontal diameter: S, C, N, G, K, and D (right endpoint)
- Circle passing through C, E, D, F, with F at the bottom
- I: point within the lower part of the figure
- A, B (far left): the two given reference segments; I: a taller vertical reference line
- M, Q, O (lower baseline): division/tick marks
- [Several small peripheral vertex-letters on the outer margin are at the resolution floor — this figure]

Next, let the given ratio be that of the smaller line B to the larger A. Having drawn the two straight lines DC and LM perpendicular to DL, cut off from them

the straight lines DN and LO, each equal to the smaller line B; and with a ruler applied to the points O and N, draw the straight line NP, [Margin: k — 29. primi (*Elements* I.29)] which will be perpendicular to DC, [Margin: l — 33. primi (*Elements* I.33)] since it is parallel to DL. Then, taking the straight line DC equal to the larger line A, describe from D, through C, an arc cutting the straight line NP at P; and extend from D, through P, the straight line DPT; then DP will be equal to DC — that is, to A. Cut off also LQ equal to DC, and with the ruler applied to the points Q and C, draw the straight line CR, which by the same reasoning will be perpendicular to DC and parallel to NP. [Margin: m — 2. vel 4. sexti (*Elements* VI.2 or VI.4)] And since, as ND is to DP — that is, as B is to A (because ND and DP have been taken equal to B and A) — so is CD to DR, that is, so is DP to DR; the three straight lines ND, DP, DR will be continuously proportional, and hence DR will be the third proportional to B and A. And if from D, and the straight line DS equal to LM being cut off, a ruler is applied to the points M and S and the straight line ST is drawn, then DT will be the fourth proportional. For by the same reasoning ST will be parallel to CR and perpendicular to DC. [Margin: n — 2. vel 4. sexti (*Elements* VI.2 or VI.4)] Therefore it will follow that, as CD is to DR — that is, as A is to DR — so is SD, that is, DR, to DT. So then the four lines ND, DP, DR, DT are continuously proportional. And if from D, through T, another arc is described cutting the straight line DC produced, a fifth proportional will be found by the same technique, and so on without limit.

From these methods we shall, without great labour, find two mean proportionals between two given straight lines — not indeed by a strictly geometrical procedure, but as it were by trial, repeating the practical operation again and again until we attain what we seek. For instance, if two mean proportionals are to be found between CD and DK, then, having described about the larger line CD the circle CEDF, we erect from K the perpendicular KH to CD, and draw DH under this condition: that from the point E (where DH meets the circumference) a perpendicular EG dropped to DC cuts off the line DG equal to the line DH — that is, so that the arc described from D through H passes through the point G. When this is done, DE and DH will be the two mean proportionals between CD and DK. For, as we have shown, as CD

is to DE, so is DE to DG, by the corollary to Proposition 8 of this book. [Margin: a — 2. vel 4. sexti (*Elements* VI.2 or VI.4)] And as DE is to DG, so is DH — that is, DG — to DK. Therefore the four straight lines CD, DE, DH, DK are continuously proportional, and hence DE and DH are the two mean proportionals between CD and DK. But if the straight lines DH and DG are found not to be equal, then, if DH

turns out to be the smaller, DH must be raised higher; whereas if it is the larger, it must be lowered further, until DH and DG are found equal.

PROBL. 4. PROPOS. 12. [Margin: xj. [?]]

Given three straight lines, to find a fourth proportional.

Let AB, BC, AD be three straight lines to which a fourth proportional is to be found, namely such that as AB is to BC, so AD is to the fourth. Arrange the first two, AB and BC, along one straight line, which is AC; and let the third, AD, make with the first line AB any angle A whatever. Then from B to D draw the straight line BD, and through C draw CE parallel to it, meeting AD extended at the point E. I say that DE is the fourth proportional. For since in triangle ACE the line BD is drawn parallel to the side CE, [Margin: a — 2. sexti (*Elements* VI.2)] it follows that as AB is to BC, so AD is to DE. Therefore DE is the fourth proportional; and consequently, given three straight lines, we have found a fourth proportional. Which was to be done.

Diagram. The construction figure for Proposition 12. Along the base lie A (left), B (middle), C (right); D is on the slanting line above, and E is the apex at upper right.

- A (bottom-left): vertex of the angle
- B (base, between A and C): junction of AB and BC along the straight line AC
- C (bottom-right): endpoint of AC
- D (on the slant A–E): endpoint of the third given line AD
- E (apex, upper right): where CE (parallel to BD) meets AD extended
- Lines drawn: AE (with D on it), BD, and CE (with $CE \parallel BD$)

SCHOLIVM

From this we readily gather how, given two straight lines, two others may be found in the same ratio with them. For if two straight lines A and B are given in any ratio, and any third line C is taken and a fourth proportional D is found to it, so that as A is to B, so C is to D, then what is proposed will have been accomplished. By the same technique six lines will be found, or eight, ten, twelve, and so on, of which every consecutive pair keeps the same ratio.

Diagram. Four separate straight-line segments of decreasing length, drawn one above another and labelled A, B, C, D — the sample lines of the scholium.

- A, B, C, D: four line segments in the same continued ratio

We shall also demonstrate, with Pappus, the following problem. Namely:

Given three straight lines, to find a fourth, which is to the third as the first is to the second.

Let AB, BC, CD be three straight lines, and let it be required to find a fourth which is to the third, CD, as AB, the first, is to BC, the second. Arrange the first two, AB and BC, in a straight line so that they make the line AC; and let the third, CD, make with the second, BC, any angle C whatever. Then from B to D draw the straight line BD, and through A draw AE parallel to it, meeting CD extended at E. I say that ED is the fourth — that is, that ED is to DC, the third, as AB, the first, is to BC, the second. This is manifest, [Margin: b — 2. sexti (*Elements* VI.2)] since AC and EC are cut proportionally at the points B and D.

ALTERNATIVELY: Let the second, CB, be made the first, and the first, AB, be made the second. [Margin: c — 12. sexti (*Elements* VI.12)] Then let a fourth proportional DE be found to the three lines CB, BA, CD, so that as the second CB is to the first BA, so the third CD is to the fourth DE. For then, by conversion, as AB, the first, is to BC, the second, so DE, the fourth, is to CD, the third.

Diagram. The figure for the Pappus problem. Along the base lie C (left), B (middle), A (right); D is on the slanting line above, and E is the apex at upper right.

- C (bottom-left): endpoint of CA
- B (base, between C and A): junction of the first two lines
- A (bottom-right): vertex of the angle
- D (on the slant C–E): endpoint of the third given line CD
- E (apex): where AE (parallel to BD) meets CD extended
- Lines drawn: CE (with D on it), BD, and AE (with AE $\parallel$ BD)

PROBL. 5. PROPOS. 13. [Margin: xij. [?]]

Given two straight lines, to find a mean proportional.

Let AB and BC be two straight lines to which a mean proportional is to be found, set along the straight line AC. Bisect AC at E, and from E as centre, with radius EA or EC, describe the semicircle ADC. Then from B erect the perpendicular BD to AC, up to the circumference. I say that BD is the mean proportional between AB and BC. For, the straight lines AD and CD being drawn, [Margin: a — 31. tertij (*Elements* III.31)] the angle ADC will be right, being in a semicircle. Since, then, from the right angle ADC of the right-angled triangle ADC the perpendicular DB is dropped to the base AC, it follows, by the corollary to Proposition 8 of this book,

that BD is the mean proportional between AB and BC. So, given two straight lines, we have found a mean proportional. Which was to be done.

Diagram. The construction figure for Proposition 13. A semicircle on the diameter AC, with apex D above.

- A (bottom-left): endpoint of the diameter
- E (base, centre): midpoint of AC, centre of the semicircle
- B (base, between E and C): the division point of AC into AB and BC; foot of the perpendicular
- C (bottom-right): endpoint of the diameter
- D (apex, on the circumference): the perpendicular DB meets the arc here
- Lines drawn: the semicircle ADC, the chords AD and DC, and the perpendicular DB

SCHOLIUM

From this it becomes clear that a straight line drawn within a circle, from any point of the diameter, perpendicular to that diameter as far as the circumference, is the mean proportional between the two segments of the diameter made by the perpendicular. For let a semicircle ABC be given, and from the point D of the diameter AC let the straight line DB be drawn to the circumference, perpendicular to AC. I say that DB is the mean proportional between AD and DC — which is plainly established by the demonstration of this problem. For if the straight lines AB and CB are drawn, [Margin: b — 31. tertij (*Elements* III.31)] the angle ABC will be right. Therefore, by the corollary to Proposition 8, the proposition is established. By the same reasoning the perpendicular EF will be the mean proportional between AE and CE; likewise GH between AG and GC; and the same is to be said of any others whatever that are drawn perpendicular to the diameter from any points of the diameter.

Diagram. The scholium figure. A semicircle on the diameter AC, with three perpendiculars rising to the circumference.

- A (bottom-left): endpoint of the diameter
- D (base): foot of the perpendicular DB
- E (base): foot of the perpendicular EF
- G (base): foot of the perpendicular GH
- C (bottom-right): endpoint of the diameter
- B (circumference, over D): top of perpendicular BD
- F (circumference, over E): top of perpendicular FE

- H (circumference, over G): top of perpendicular HG
- Lines drawn: the semicircle, the chords AB and CB, and the three perpendiculars BD, FE, HG

(*Scholium, continued.*) When the smaller given line is very small, the perpendicular BD will cut the circumference at D too obliquely. Therefore, so that the point D may then be found more precisely, we shall multiply the smaller line BC as many times as we please. For example, we shall take BE as the quadruple of BC, and shall cut the larger line AB into as many equal parts as BE contains multiples of BC, letting one part be BF, so that AB has the same ratio to BF as BE has to BC. And at length, about EE let a circle be described cutting BD at D: then BD will be the mean proportional between BF and BE, as we have demonstrated in this scholium. I say that the same line is the mean proportional between [AB and BC]. For since, as the first AB is to the second BF, so the third BE is to the fourth BC, [Margin: c — 16. sexti (*Elements* VI.16)] the rectangle contained by AB, the first, and BC, the fourth, will be equal to the rectangle contained by BF, the second, and BE, the third. [Margin: d — 17. sexti (*Elements* VI.17)] But this is equal to the square on BD. Therefore so is the former. [Margin: e — 17. sexti (*Elements* VI.17) [?]] Hence BD is the mean proportional between AB and BC.

But you need not be troubled that we have cited Propositions 16 and 17 of this book, which have not yet been demonstrated; for this demonstration, together with its construction, can be deferred until after Proposition 17 of this book, so that there is no danger of "begging the question," as the philosophers put it.

FROM PELETIER [Jacques Peletier]

Given a straight line, to cut another straight line — one that is not smaller than double the former — in such a way that the given straight line is the mean proportional between the segments of this one.

Let AC be the given straight line, and let the straight line AB be proposed for division (one that is not smaller than double AC itself, but either double or larger), in such a way that AC is the mean proportional between its segments. Set the straight lines AB and AC at a right angle BAC, and, having bisected AB at D, describe from D as centre, with radius DA or DB, the semicircle AEB. Then through C draw CE parallel to AB, cutting or touching the circumference at the point E. (Now CE will necessarily either cut or touch the circumference. For if it is less than half of AB — that is, less than the semidiameter erected at right angles from D — it will cut the circumference; whereas it will touch that same circumference if it is equal to half of AB, that is, equal to the semidiameter drawn

at right angles from D; and if it is less than half of AB, it will necessarily cut the circumference, or touch it.) From E drop the perpendicular EF to AB. I say that AC is the mean proportional between the segments AF and FB. For, the straight lines AE and BE being drawn, it will follow — as has already been demonstrated, from the corollary to Proposition 8 of this book — that EF is the mean proportional between AF and FB. [Margin: f — 34. primi (*Elements* I.34) [?]] Since, then, EF is equal to AC, because ACEF is a parallelogram (for CE is parallel to AF by construction, [Margin: g — 28. primi (*Elements* I.28)] and AC is parallel to EF on account of the right angles CAF and EFA), AC too will be the mean proportional between AF and FB. Which was what was proposed.

Diagram. The figure for the continuation of the Proposition-13 scholium (the "when the smaller line is very small" construction). A large semicircle on the diameter A...E, with apex D, overlapped by a smaller semicircle sharing the apex D.

- A (bottom-left): endpoint of the larger diameter
- F (base): endpoint of the part BF cut off on AB
- B (base): division point
- C (base): endpoint of the smaller line

THEOR. 9. PROPOS. 14. [Margin: xiiij.]

In equal parallelograms which have one angle equal to one angle, the sides about the equal angles are reciprocally proportional. And parallelograms which have one angle equal to one angle, and whose sides about the equal angles are reciprocally proportional, are equal.

Let ABCD and BEFG be two equal parallelograms having the angles ABC and EBG equal. I say that the sides about these angles are reciprocally proportional — that is, that as AB is to BG, so EB is to BC. For let the parallelograms be joined at the equal angles, so that AB and BG make one straight line. When this is done, since the angles ABC and EBG are equal, EB and BC will also form one straight line, as we demonstrated from Proclus at Proposition 15 of Book 1. Now let DC and FG be extended until they meet at H. Since, then, the parallelograms DB and BF are equal, [Margin: a — 7. quinti (*Elements* V.7)] it follows that as DB is to BH, so BF is to the same BH. But as DB is to BH, [Margin: b — 1. sexti (*Elements* VI.1)] so is AB, the base, to the base BG, because the parallelograms are of the same altitude; and likewise as BF is to BH, so is EB to BC. Therefore as AB is to BG, so is EB to BC. Which was what was proposed.

CONVERSELY, let the sides about the equal angles ABC and EBG now be reciprocally proportional — that is, as AB is to BG, so EB is to BC. I say that the parallelograms DB and BF are equal. For, the same construction being made, since as AB is to BG, so DE is to BH, [Margin: c — 1. sexti (*Elements* VI.1)] and as EB is to BC, so BF is to the same BH, it will also follow that as DB is to BH, so BF is to the same BH. [Margin: d — 9. quinti (*Elements* V.9)] And therefore the parallelograms DB and BF will be equal. So then, of equal parallelograms which have one angle equal to one angle, etc. Which was to be demonstrated.

Diagram. The figure for Proposition 14. Two parallelograms joined at B, the first (ABCD) lying above and the second (BEFG) below.

- D (top-left): corner of parallelogram ABCD
- C (top, middle): corner of ABCD
- H (top-right): where DC and FG extended meet
- A (middle row, left): corner of ABCD
- B (middle row, centre): the shared vertex at the equal angles
- G (middle row, right): corner of BEFG
- E (bottom-left): corner of BEFG
- F (bottom, middle): corner of BEFG

- Lines drawn: parallelogram A–B–C–D, parallelogram B–E–F–G, and DC, FG extended to H

THEOR. 10. PROPOS. 15. [Margin: xiv.]

In equal triangles which have one angle equal to one angle, the sides about the equal angles are reciprocally proportional. And triangles which have one angle equal to one angle, and whose sides about the equal angles are reciprocally proportional, are equal.

Let ABC and DBE be two equal triangles having the angles at B equal. I say that the sides about these angles are reciprocally proportional — that is, that as AB is to BE, so DB is to BC. For let the triangles be joined at the equal angles, so that AB and BE make one straight line. When this is done, since the angles ABC and DBE are equal, DB and BC will also form one straight line, as was demonstrated from Proclus at Proposition 15 of Book 1. Now, the straight line CE being drawn, since the triangles ABC and DBE are equal, [Margin: a — 7. quinti (*Elements* V.7)] it follows that as ABC is to BCE, so DBE is to the same BCE. But as triangle ABC is to triangle BCE, [Margin: b — 1. sexti (*Elements* VI.1)] so is the base AB to the base BE, because these triangles are of the same altitude; and likewise as DBE is to BCE, so is the base DB to BC. Therefore as AB is to BE, so is DB to BC. Which was what was proposed.

Diagram. The figure for Proposition 15. Two triangles, ABC and DBE, meeting at the common vertex B.

- A (top-left): vertex of triangle ABC
- D (top-right): vertex of triangle DBE
- B (centre): the shared vertex at the equal angles

LIBER VI (continued)

THEOR. 11. PROPOS. 16. [Margin prop-no.: XV.]

(Conclusion of the converse of Prop. 15, begun in the preceding pages.)

Now conversely, let the sides about the equal angles at B be reciprocally proportional — that is, let AB be to BE as DB is to BC. I say that the triangles ABC

and DBE are equal. For, the same construction having been made, since AB is to BE as DB is to BC; and since AB is to BE as triangle ABC is to triangle BCE [a]; and DB is to BC as triangle DBE is to the same triangle BCE; it will follow that ABC is to BCE as DBE is to that same BCE, and therefore the triangles ABC and DBE will be equal [b]. So, of triangles that are equal and have one angle equal to one angle, and so on. Which was to be shown.

[Margin: a — *Elements* VI.1] [Margin: b — *Elements* V.9]

THEOR. 11. PROPOS. 16. [Margin prop-no.: XV.]

If four straight lines are proportional, the rectangle contained by the extremes is equal to the rectangle contained by the means. And if the rectangle contained by the extremes is equal to the rectangle contained by the means, then those four straight lines will be proportional.

Let the four proportional lines be AB, FG, EF, BC — so that AB is to FG as EF is to BC. Let ABCD be the rectangle contained by the extremes AB and BC, and EFGH the rectangle contained by the means EF and FG. I say that the rectangles AC and EG are equal. For since the right angles B and F are equal, and AB is to FG as EF is to BC, the sides about the equal angles B and F are reciprocally proportional. Therefore the parallelograms AC and EG will be equal [a]. Which is what was proposed.

[Margin: a — *Elements* VI.14]

Conversely, let the rectangles AC and EG now be equal. I say that the four straight lines AB, FG, EF, BC are proportional — that is, that AB is to FG as EF is to BC. For since the rectangles AC and EG are equal and have equal angles (namely the right angles B and F), the sides about these angles will be reciprocally proportional [b]: AB will be to FG as EF is to BC. And so, if four straight lines are proportional, and so on. Which was to be shown.

[Margin: b — *Elements* VI.14]

Diagram. At the left, four line segments representing the four proportional lines are drawn one above another; at the right, two rectangles.

- Line segments (left column): A—B; F—G; E—F; B—C.
- Upper rectangle (right): A (top-left), B (top-right), C (bottom-right), D (bottom-left) — the rectangle AC contained by the extremes.
- Lower rectangle (right): E (top-left), F (top-right), G (bottom-right), H (bottom-left) — the rectangle EG contained by the means.

SCHOLIUM.

The same is true even if the parallelograms AC and EG are not right-angled, provided only that they are equiangular — that is, provided the angles contained by the said straight lines are equal. This is evident from the figure, for the demonstration is exactly the same.

Diagram. The same four line segments at the left; at the right, two oblique (equiangular) parallelograms in place of the rectangles.

- Line segments (left): A—B; F—G; E—F; B—C.
- Upper parallelogram: A (top-left), B (top-right), C (bottom-right), D (bottom-left).
- Lower parallelogram: E (top-left), F (top-right), G (bottom-right), H (bottom-left).

THEOR. 12. PROPOS. 17. [Margin prop-no.: xvj.]

If three straight lines are proportional, the rectangle contained by the extremes is equal to the square described on the mean. And if the rectangle contained by the extremes is equal to the square described on the mean, then those three straight lines will be proportional.

Let the three straight lines AB, EF, and BC be proportional — so that AB is to EF as EF is to BC. Let ABCD be the rectangle contained by the extremes AB and BC, and let EFGH be the square on the mean EF. I say that the rectangle AC and the square EG are equal. For, taking a line FG equal to EF itself, the four lines AB, EF, FG, BC will be proportional — AB being to EF as FG is to BC; and the square EG will be the rectangle contained by the means EF and FG, because EF and FG are equal. Therefore the rectangle AC, contained by the extremes AB and BC, is equal to the square EG — that is, to the rectangle contained by the means EF and FG [a]. Which is what was proposed.

[Margin: a — *Elements* VI.16]

But now let the rectangle AC and the square EG be equal. I say that AB is to EF as EF is to BC. For since the rectangles AC and EG are equal, AB will be to EF as FG is to BC [b]; and as FG is to BC, so is EF — which equals FG — to the same BC [c]. Therefore AB is to EF as EF is to BC. So, if three straight lines are proportional, and so on. Which was to be demonstrated.

[Margin: b — *Elements* VI.16] [Margin: c — *Elements* V.7]

Diagram. At the left, three line segments (the three proportional lines); at the right, a rectangle above and a square below.

- Line segments (left): $A-B$; $E-F$; $B-C$.
- Upper rectangle: A (top-left), B (top-right), C (bottom-right), D (bottom-left) — the rectangle AC.
- Lower square: E (top-left), F (top-right), G (bottom-right), H (bottom-left) — the square EG on the mean.

COROLLARIVM.

From the latter part of this theorem it follows that any straight line is the mean proportional between any two other straight lines that contain a rectangle equal to the square on it. For from the fact that the lines AB and BC contain a rectangle equal to the square on the line EF, it was shown that AB is to EF as EF is to BC. Therefore EF is the mean proportional between AB and BC.

SCHOLIVM.

The same conclusions follow entirely even if the parallelograms are not right-angled, provided they are equiangular — so that EG is a rhombus and AC a rhomboid. For the demonstration in these cases will not be different, as the figure shows.

Diagram. At the top, line segments; at the right, two oblique parallelograms — one a rhombus (EG), the other a rhomboid (AC).

- Line segments: $A-B$; $F-G$; $E-F$; $B-C$.
- Upper parallelogram: A (top-left), B (top-right), C (bottom-right), D (bottom-left).
- Lower parallelogram: E (top-left), F (top-right), G (bottom-right), H (bottom-left).

I should like, at this point, to demonstrate together with Peletier [Jacques Peletier du Mans] a problem not without use, bearing on proportional lines. It is of this kind:

A straight line having been cut into two parts in any way, to divide one of them again into two parts, so that all three parts are in continued proportion.

Let AB be cut at C in any way, and suppose the part CB is to be so divided into two further parts that all three parts are in continued proportion. Let AC be bisected

at F, and FC again bisected at I, so that CI is a quarter of the first part AC. From B and I erect two perpendiculars BE and IK equal to the first part AC, and draw the line EK, so that the rectangle IE is contained by AC (the first part) and the line IB (made up of the other part BC together with CI, the quarter of the first part). Now since AC is bisected at F, and CB is added to it in a straight line, the rectangle contained by AB, BC together with the square on CF is equal to the square on BF [c].

[Margin: c — *Elements* II.6]

But the rectangle IE is less than the rectangle contained by AB, BC together with the square on CF. (For, CD being drawn perpendicular to AB, the rectangle CE contained by AC, CB will be less than the rectangle contained by AB, BC; while the rectangle CK is equal to the square on CF, since each is a quarter of the square on AC — the rectangle CK because CK is to the square on AC (that is, to the rectangle contained by AC, CD) as CI is to CA [d]; and so, since CI is a quarter of the line AC, CK will also be a quarter of the square on AC. And the square on CF is a quarter of the same square on AC, by the scholium to Prop. 4 of Book II.) The rectangle IE will therefore also be less than the square on BF.

[Margin: d — *Elements* VI.1]

If, then, a square is made equal to the rectangle IE [e], its side will be less than FB but greater than FC — since the square on FC has been shown equal to the rectangle CK, and hence less than the rectangle IE. Let that side be FL. I say that the part CB is so cut at L that the three parts AC, CL, LB are in continued proportion.

[Margin: e — *Elements* II.14]

For let the square FM be described on FL, and let the line DC be extended to O and the side ML to P; and, taking two lines FG and LQ each equal to CF, draw the line GQ cutting CO at H. Then CG will be the square on the line CF, because CF and FG are equal. And since, when the equals FC and FG are taken from the equals FL and FN, the remainders CL and GN are equal [f]; and CL is equal to HQ and GN to HO; the remainders HQ and HO will also be equal, and therefore HM will be the square on CL.

[Margin: f — *Elements* I.34]

Again, since the rectangle CQ is contained by CL and CH (that is, CF, the half of AC), and the rectangle GO by GN (that is, CL) and GH (that is, CF, the half of the same AC, that is CD), the two rectangles CQ and GO together will be equal to the

rectangle CP contained by the same CL and CD (which equals CH and GH together) [g]. And so, since the rectangle IE is equal to the square FM, and the rectangle CK to the square CG, and the rectangle CP to the two rectangles CQ, GO together, the remaining rectangle LE — contained by BE (that is, AC) and BL — will be equal to the remaining square HM. Therefore, since with the three given lines AC, CL, LB the rectangle LE, contained by the extremes AC and BL, is equal to the square HM on the mean CL [h], the three lines AC, CL, LB will be in continued proportion. Which is what was proposed.

[Margin: g — *Elements* II.1] [Margin: h — *Elements* VI.17]

Diagram. A compound square-and-rectangle construction on the base line AB, gridded by the perpendiculars and the squares FM, CG, HM.

- Base line AB: A (left), I (between F and C, the quarter-point mark), B (right).
- Top edge: K, D, P, E.
- Upper band: F, C, L.
- Lower band: G, H, Q.
- Bottom edge: N, O, M.

The same problem will be carried out in numbers as follows. To the latter part of the proposed number add a quarter of the first part, and multiply the number so formed into the first part. Then extract the square root of the resulting product. For if from the root found you subtract half the first part, the remainder will be the second proportional part; and if you subtract this from the latter part of the given number, the remainder will be the third part.

For example, let the line AB be set at 76, the part AC at 36, and CB at 40. We add CI — that is, 9, a quarter of the first part 36 — to CB, that is to the latter part 40, and multiply the number so formed, 49 (namely the line IB), into the first part 36 (that is, into the line AC). From the product 1764 (that is, the rectangle IE) we extract the square root, 42, for the line FL. If from this we subtract CF, half of the part AC (namely 18), the remaining part CL will be 24. This, taken from the whole latter part CB, 40, leaves the third part LB, 16. So the three parts AC, CL, LB of the number AB, 76 — these three, 36, 24, 16 — are in continued proportion. From this it is clear that when the square root cannot be extracted from that product, the problem cannot be carried out in numbers. And from this too will be understood what we wrote near the end of Book V, in the treatment of proportions, where we dealt with the origin of geometric proportionality out of arithmetic proportionality.

But since so far we have discussed proportional lines with Euclid, it will not be foreign to our purpose to treat of them also with Pappus of Alexandria [Pappus], who, given two of the three terms of any mediety whatever — arithmetic, geometric, or harmonic — seeks the third; and, in the case of geometric proportionality, does so otherwise than Euclid did. We shall carry this out in the following propositions, of which let this be the first.

I.

Given two straight lines, to find the mean proportional in arithmetic proportionality.

Let there be two given lines AB and C (here represented by units set out lengthwise), between which the mean in arithmetic proportionality is to be found. Set FH equal to the lesser, C, and from the greater, AB, cut off another part AD equal to it. Bisecting the segment BD at E, take HG equal to DE itself. I say that FG is the arithmetic mean proportional between AB and C. For AB exceeds FG by the excess BE, and FG exceeds C by the excess GH (that is, DE). Since, then, the two excesses BE and DE are equal by construction, it plainly follows that the lines AB, FG, and C are in arithmetic proportion.

Diagram. Three vertical dotted segments representing the lines AB, FG, and C.

- Line AB (left): A (bottom), D, E, B (top).
- Line FG (middle): F (bottom), H, G (top).
- Line C (right): C (bottom point of the short segment).

(*Conclusion of Prop. I.*) Hence it follows that the mean line FG is half of the sum formed from the extremes. For since both AD and C are equal to FH, the sum of AD and C is double FH; and DB is likewise double HG [a]. Therefore the sum of AB and C is double the whole FG; and consequently FG is half the sum of the extremes. Which is what was proposed.

[Margin: a — *Elements* V.1]

II.

Given two straight lines, to find the lesser extreme in arithmetic proportionality.

In the same figure, let the two given lines be AB and FG, for which the lesser third term in the arithmetic mediety is to be found. From the lesser, FG, cut off a line GH equal to the excess BE by which AB exceeds FG; and set C equal to FH. I say that C is the lesser third proportional. For AB exceeds FG by the excess BE, and FG

exceeds C by the excess GH — which two excesses BE and GH are equal by construction.

III.

Given two straight lines, to find the greater extreme in arithmetic proportionality.

In the same figure, let the two given lines be C and FG, for which the greater third term in the arithmetic mediety is to be found. Take AE equal to FG, and to it add EB equal to the excess GH by which FG exceeds C; so that the three lines AB, FG, and C are in arithmetic proportion. For AB exceeds FG by the excess BE, and FG exceeds C by the excess GH. Since, then, the two excesses BE and GH are equal by construction, the proposition is evident.

And so, given two unequal numbers 30 and 16: if half of the excess — namely 7 — is added to the lesser, 16, the arithmetic mean proportional 23 is produced, as here appears: 30, 23, 16. Or the middle term is obtained by taking half the sum of the extremes, as is evident in the same example — for the sum of the extremes is 46, and its half, 23, constitutes the middle term.

But if from the lesser, 16, the excess 14 is subtracted, the remainder will be the lesser extreme, 2, in the arithmetic mediety, as you see here: 30, 16, 2.

And finally, if to the greater, 30, the excess 14 is added, the greater extreme 44 is produced, in arithmetic proportionality, as is evident here: 44, 30, 16.

IIII.

Given two straight lines, to find the mean proportional in geometric proportionality.

Let the given lines be AB and BC, having the same endpoint B, between which the geometric mean proportional is to be found. Describing the semicircle ADB on the greater line AB, erect from C the perpendicular CD to AB; and from B, through D, describe an arc cutting AB at E. I say that BE is the mean proportional between AB and BC in geometric proportionality. For, the lines AD and BD being drawn, the angle ABD [recte: ADB — angle in a semicircle] will be right [a]. Therefore, by the corollary of Prop. 8 of this book, the line BD — that is, BE, which is equal to it — will be the mean proportional between AB and BC. Which is what was proposed.

[Margin: a — *Elements* III.31]

Diagram. A semicircle described on the diameter AB, with the perpendicular CD and the arc from B cutting AB at E.

- Diameter (left to right): A, E, C, B.
- Apex on the semicircle: D.
- Chords/lines drawn: AD, DB, DC (perpendicular to AB at C), DE.

V.

Given two straight lines, to find the lesser extreme in geometric proportionality.

In the same figure, let the given lines be AB and BE, possessing the same endpoint B, for which the lesser third geometric proportional is to be found. Describing the semicircle ADB on the greater line AB, describe from B, through E, an arc cutting the circumference ADB at D — the point from which the perpendicular DC is dropped to AB. I say that BC is the third proportional to AB and BE. For, the lines AD and BD being drawn, the angle ADB will be right [a]. Therefore, by the corollary of Prop. 8 of this book, BD — that is, BE, which is equal to it — will be the mean proportional between AB and BC; that is, AB will be to BE as BE is to BC. Which is what was proposed.

[Margin: a — *Elements* III.31 [?] (printed digit at the outer-margin resolution floor; reads "21", but the geometry and Prop. III require III.31)]

VI.

Given two straight lines, to find the greater extreme in geometric proportionality.

In the same figure, let the given lines be CB and BE, possessing the same endpoint B, for which the greater third geometric proportional is to be found. From C, the endpoint of the lesser, erect the perpendicular CD to EB, and let the arc described from B through E cut it at D. Then, the line BD being drawn, erect to it at D the perpendicular DA, cutting BE produced at A. I say that AB is the third proportional to CB and BE. For since the angle ADB is right, by the corollary of Prop. 8 of this book, BD — that is, BE, which is equal to it — will be the mean proportional between BC and AB; that is, CB will be to BE as BE is to AB. Which is what was proposed.

VII.

Given two straight lines, to find the mean proportional in harmonic proportionality.

VII.

(Construction and demonstration of the added proposition whose enunciation — "Given two straight lines, to find the harmonic mean proportional" — ended the previous section.)

Let there be given two straight lines AB and BC sharing the same endpoint B, between which the harmonic mean proportional is to be found. Through A, draw a perpendicular DE to AB, and mark off on it equal segments AD and AE of any length whatever. From C also raise a perpendicular CF to AB, cutting the line BD (once drawn) at the point F; and from F draw a line FE to E, cutting AB at G. I say that BG is the harmonic mean proportional between AB and BC — that is, that AB, the first term, is to BC, the third, as AG (the excess between the first term AB and the mean BG) is to GC (the excess between the mean BG and the third term BC). [Margin: m — Elements V.28]

For since CF is parallel to DE, on account of the right angles at A and C, by the scholium to Proposition 4 of this book the triangle BCF is similar to the triangle BAD. Hence AB is to AD as BC is to CF; and by alternation, AB is to BC as AD is to CF, that is, as AE is to CF. Again, because of the similarity of the triangles AEG and CFG, [Margin: n — Elements VI.4] AE is to AG as CF is to CG; and by alternation, AE is to CF as AG is to GC. But it was shown that AE is to CF as AB is to BC. Therefore AB is also to BC — the first line to the third — as AG (the excess between the first term AB and the mean BG) is to GC (the excess between the mean BG and the third term BC). Which is what was proposed.

Diagram. The construction for the harmonic mean. A horizontal base line runs from A (left) to B (right). Through A a vertical line DE is drawn, with D above and E below A. A point C lies on the base between A and B, and the perpendicular CF rises from C to F. The line from B to D and the line FE from F down to E cross the base at the interior points; G lies on the base. Additional equal marks (AK = AL) with K above-left and L below-left support the "these magnitudes are not determined" argument, in which BK meets CF at H and the line LH is drawn; M is an alternative point on the base.

- D (top, above A): upper endpoint of the perpendicular at A
- E (bottom, below A): lower endpoint of the perpendicular at A
- A (left end of base): foot of the perpendicular DE
- B (right end of base): shared endpoint of the two given lines
- C (on base, between G and B): foot of the perpendicular CF

- F (upper region, right of centre): top of the perpendicular CF / intersection of BD produced with CF
- G (on base, centre): point where FE cuts AB; foot of the mean BG
- K (upper left): endpoint of the alternative equal segment AK
- L (lower left): endpoint of the alternative equal segment AL
- H (centre): intersection of BK with the perpendicular CF
- M (on base, right of A): the alternative interior point used in the reductio
- I (centre, below H): interior intersection point [?]

These magnitudes are not determined. The magnitudes of the straight lines AD and AE are not fixed: whether they are taken larger or smaller, the same mean BG is found. For let there be other equal segments AK and AL. Draw the line BK, cutting the perpendicular CF at H, and join the line LH — which I claim passes through G. For if it were to pass through some other point, say through M, between A and G, we would show in the same way that AB is to BC as AM is to MC. For the triangles ALM and MHC would again be equiangular, provided HML is a straight line. But AB is to BC as AG is to GC, as was shown. Therefore AM would also be to MC as AG is to GC [printed "AC"] — which is absurd. [Margin: o — Elements V.8] For the ratio of AM to GC is less than that of AG to GC; and the ratio of AM to MC is still less than that to GC. Much less, therefore, will the ratio of AM to MC equal that of AG to GC. So AM is not to MC as AG is to GC; and consequently HL will not cut AG at M. In the same way it will not cut GC. It therefore passes through G; and for that reason the same mean BG is found by way of the equal lines AK and AL.

VIII.

Given two straight lines, to find the lesser extreme in the harmonic mean.

Let there be given, in the same figure, two straight lines AB and BG sharing the same endpoint B, for which the lesser third harmonic proportional is to be found. Draw DE perpendicular to AB, and mark off equal segments AD and AE of any length whatever. Then, having joined the line BD, draw from E through G a line cutting BD at the point F, and from F let a perpendicular FC be dropped to AB. I say that BC is the harmonic proportional to AB and BG — that is, that AB, the first term, is to BC, the third, as AG (the excess between the first and the second) is to GC (the excess between the second and the third). This will indeed be demonstrated just as in the preceding proposition.

These magnitudes are not determined here either. The magnitudes of AD and AE are not fixed here either, for whether they are taken larger or smaller, the same third term BC is found. For let there be other equal segments AK and AL. Draw the line BK, cutting the perpendicular CF at H, and join the line LG, which I claim falls at H. For if it should fall below, say at I, we would show in the same way that AB is to BC as AK is to CH, that is, as AL is to CH. But AB was to BC as AG is to GC. Therefore AG is to GC as AL is to CH. And since, if LGI is a straight line, [Margin: p — Elements VI.4] by the similarity of the triangles ALG and CIG, AL is to AG as CI is to GC, then by alternation AL is to CI as AG is to GC. [Margin: q — Elements V.9] Since, then, it has been shown that AG is to GC as AL is to CH, AL will be to CH as it is to CI. Therefore CH and CI are equal — a whole and its part — which is absurd. So LG will not fall below H; and in the same way we shall show that it does not fall above. It therefore falls at H, where BK cuts the perpendicular CF; and consequently the perpendicular HC dropped from H to AB will exhibit the same lesser third term BC, the harmonic proportional.

Corollary. From this it follows that, given three straight lines in harmonic proportion, the least is greater than the excess by which the mean exceeds the least. For since AB is to BC as AG is to GC, and since AB, the first, is greater than AG (the excess between the first term AB and the mean BG), [Margin: r — Elements V.14] BC too, the third, will be greater than GC (the excess between the mean BG and the least term BC).

IX.

Given two straight lines, to find the greater extreme in harmonic proportionality.

Let there be given two straight lines AB and BC sharing the same endpoint B, for which the greater third harmonic proportional is to be found. Through A, draw a perpendicular DE to BC, mark off equal segments AD and AE of any length whatever, and draw the line BD; let EC, produced, cut this line produced at the point F (that BD and EC do in fact meet we shall prove shortly). From F let a perpendicular FG be dropped to BC produced. I say that GB is the harmonic proportional to CB and BA — that is, that GB, the first term, is to BA, the third, as GC (the excess between the first term GB and the mean BC) is to CA (the excess between the mean CB and the third term BA). [Margin: s — Elements I.28]

For since GF is parallel to AD, on account of the right angles at G and A, by the scholium to Proposition 4 of this book the triangle BAD is similar to the triangle BGF. Hence GB is to GF as BA is to AD; and by alternation, GB is to BA as GF is to

AD, that is, as GF is to AE. Again, because of the similarity of the triangles FGC and EAC, [Margin: t — Elements VI.4] FG is to GC as EA is to CA; and by alternation, FG is to AE as GC is to CA. But it was shown that FG is to AE as GB is to BA. Therefore GB, the first term, is also to BA, the third, as GC (the excess between the first term GB and the mean BC) is to CA (the excess between the mean BC and the third term BA). Which is what was proposed.

Diagram. The construction for the greater harmonic extreme. From an apex F at the top, lines descend to a base line that runs (left to right) through G, C, A, and B, with H just to the right of A; K lies below the base and E at the bottom. The line BD rises to D at the upper right, and EC produced meets BD produced at F; the perpendicular FG falls to G. L (upper left), M (mid-left), and I (centre) support the "these magnitudes are not determined" argument.

- F (apex, top): meeting point of BD produced and EC produced
- D (upper right): endpoint of the perpendicular through A (with E below)
- E (bottom): lower endpoint of the perpendicular through A
- G (base, left): foot of the perpendicular FG
- C (base, left of centre): foot of the mean
- A (base, centre): foot of the perpendicular DE
- H (base, just right of A): the point AH cut off equal to AC
- B (base, right end): shared endpoint of the given lines
- L (upper left): endpoint of the alternative equal segment (AI = AK version)
- M (mid-left): the alternative interior point used in the reductio
- I (centre): interior intersection point [?]
- K (below base): endpoint of the alternative equal segment

That BD and EC do meet is proved as follows. Since BC is set as the mean and BA as the third or least term, BA (the third) will be greater than CA — the excess by which the mean BC exceeds the least BA — as we showed at the end of the preceding problem. For unless AB were greater than AC, no greater third term could be found in harmonic proportionality, because EC would not meet BD. Cut off, then, AH equal to AC, and join the line HD. Since, therefore, the sides AE and AC are equal to the sides AD and AH, [Margin: u — Elements I.4] and they contain equal angles (right angles, or vertical angles at A), the angles ACE and AHD will also be equal; and since these are alternate angles, [Margin: b — Elements I.27] the lines EC and HD will be parallel. [Margin: c — Elements I.29] Consequently the interior angles DHC and HCF are equal to two right angles. Since, then, [Margin: d — Elements I.16] the angle DHC is greater than the interior angle B, the two

angles BCF and CBF will be less than two right angles. [Margin: e — Axiom 13 (13. pronunciatum; Clavius's form of Euclid's parallel postulate — that lines meet when the interior angles are less than two right angles)] Therefore BD and EC will meet, as was proposed.

These magnitudes are not determined here either. The magnitudes of AD and AE are not fixed here either, for whether they are taken larger or smaller, the same third term BG is found. For let there be other equal segments AI and AK. Draw the line BI, which, produced, cuts the perpendicular FG at L, and draw KC, which I claim, when produced, falls at L. For if it should fall below, say at M, we would show in the same way that GB is to BA as GL is to AI, that is, as GL is to AK. But GB was to BA as GC is to CA. Therefore GC is to CA as GL is to AK. And since, if KCM is a straight line, [Margin: f — Elements VI.4] by the similarity of the triangles GMC and AKC, GM is to GC as KA is to AC, then by alternation GM is to AK as GC is to CA. Since, then, it has been shown that GL is to AK as GC is to CA, GM too will be to AK as GL is to AK. [Margin: g — Elements V.9] Therefore GM and GL are equal — a part and the whole — which is absurd. So KC will not fall below L; and by the same reasoning it will not fall above. It therefore falls at L, where BI produced cuts the perpendicular FG; and consequently the perpendicular LG dropped from L to GB falls at G and exhibits the same greater third term BG, the harmonic proportional.

From this it is clear that when two numbers have a double ratio, or one greater than double, no greater third term can be added to them in harmonic proportionality, as we stated in the treatment of proportions, in the third rule of harmonic proportionality. For since we showed that the least line BA is greater than the excess AC by which the mean BC exceeds the least AB, AB will be greater than half of BC; and consequently BC to AB — the mean to the least — will have a ratio less than double. But if BC to AB were double, or greater than double, then AB would be either equal to AC or less than it. Therefore, as was shown, no greater third term could be found in harmonic proportionality, because EC would not meet BD.

But let us also demonstrate, following Giovanni Battista Benedetti [Io. Baptista Benedictus], by what method the same terms of harmonic proportionality may be found among numbers. For from this the rationale of certain procedures will become clear which we set out in the treatment of proportions in Book 5. We shall use several propositions of Book 7, since they do not depend on Books 5 and 6 and can therefore be demonstrated before those books. Here, then, we shall take our beginning.

X.

From any two given numbers, to find three numbers in harmonic proportion whose extremes have the same ratio as the two given numbers.

On any straight line AB describe the square ABCD; and having taken two equal parts BE and EF on the side AB, draw EG and FH parallel to AD and BC. Likewise, having taken a segment AI equal to BE (or EF), draw IK parallel to AB and DC, cutting FH at L. The rectangle AG will be contained by AB (that is, by the sum of the lines AE and EB, [Margin: a — Elements I.34] since EG is equal to BC and therefore to AB) and by AE (namely the greater part of the sum AB). The rectangle EC, however, will be contained by AB (that is, by the same sum of the lines AE and EB) and by EB (namely the lesser part of the same sum AB). Finally, both the rectangle AK and the rectangle GL will be contained under the parts AE and EB, because AI has been taken equal to EB, and HL, LK are equal to AE, EB. [Margin: b — Elements I.34] For since FH is equal to AD, that is, to AB, and FL is equal to AI, that is, to EB, the remainder HL will be equal to the remainder AE; [Margin: c — Elements I.34] and KL is equal to EF, that is, to EB. From this it follows that the two rectangles AK and KH together contain twice the rectangle contained under the parts AE and EB.

I say that the rectangle AG, the sum of the two rectangles AK and KH, and the rectangle EC constitute a harmonic proportionality — that is, that as AG (the first) is to EC (the third), so IH (the excess between the first, AG, and the second, HLIAEG) is to AL (the excess between the second, HLIAEG, and the third, EC, or FG, [Margin: d — Elements I.36] which is equal to EC). For since HL is equal to AE and LF is equal to EB, as we showed, [Margin: e — Elements V.7] AE will be to EB as HL is to LF. But AE is to EB [Margin: f — Elements VI.1] as AG is to EC; and HL is to LF as HI is to HL. Therefore AG, the first, is also to EC, the third, as HI (the excess between the first and the middle term) is to AL (the excess between the middle term and the third). Which is what was proposed.

Diagram. The square ABCD, arranged for the numerical harmonic construction. The square has D at the top-left, C at the top-right, A at the bottom-left, B at the bottom-right. Along the top edge lie H and G (between D and C); along the bottom edge lie F and E (between A and B). The verticals EG and FH run from the bottom edge to the top edge. A horizontal line IK crosses from the left edge (at I) to the right edge (at K), cutting FH at the central point L. These lines partition the square into the rectangles AG, EC, AK, KH, and GL discussed in the proof.

- D (top-left corner)
- C (top-right corner)
- A (bottom-left corner)
- B (bottom-right corner)
- H (top edge): top of the vertical FH
- G (top edge, right of H): top of the vertical EG
- F (bottom edge): foot of the vertical FH
- E (bottom edge, right of F): foot of the vertical EG
- I (left edge): left end of the horizontal IK
- K (right edge): right end of the horizontal IK
- L (centre): intersection of IK with FH

Thus, if AE is set as 6 and EB as 4, the sum AB will be 10; and if we multiply this into AE and EB separately, AG becomes 60 and EC becomes 40. And twice the product of AE by EB — that is, HLIAEG — becomes 48, the harmonic mean. Therefore the three numbers in harmonic proportion will be 60, 48, 40, whose extremes have the same ratio as the given numbers 6 and 4. For since the same sum 10, gathered from 6 and 4, multiplying each of 6 and 4 has produced the extremes 60 and 40, [Margin: g — Elements VII.17] 60 will be to 40 as 6 is to 4. This is also evident from the figure: [Margin: h — Elements VI.1] for AG, that is 60, is to EC, that is 40, as AE, that is 6, is to EB, that is 4.

By this technique, if the sum of any two given numbers is multiplied into each of them separately, the extreme terms of a harmonic proportionality will be generated having the same ratio as the two given numbers; while the middle term will be the number that is double the product of the two given numbers multiplied together.

From this we shall also easily find three numbers in harmonic proportion whose extremes have a given ratio, and whose middle term equals a given number. For example, if the extremes are to have a quintuple ratio and the middle is to be 30: take 5 and 1 in the given ratio, and their sum 6 is to be multiplied into each, so as to make 30 and 6, between which the middle term 10 is set — which is double the product of the given numbers 5 and 1 multiplied one into the other. And 30, 10, 6 will be in harmonic proportion, as has been said. Then let the given middle 30 be divided by the found middle 10, and let the quotient 3 be multiplied into the three found numbers 30, 10, 6. In this way the three required numbers 90, 30, 18 will result.

Another method.

Between the two given numbers 6 and 4, let the arithmetic mean proportional be set — namely 5, half of their sum — thus: 6, 5, 4. Then let the middle term 5, multiplied into the extremes 6 and 4, produce 30 and 20; and between these let the middle term 24 be set, which the extremes produce when multiplied together, thus: 30, 24, 20. I say that these three are in harmonic proportion. For the three numbers 60, 48, 40 — which arise from the sum 10 of the given numbers 6 and 4 taken into the given numbers 6 and 4, and from 4 into 6 — are the doubles of the three numbers here found (since these were produced from half the sum of the given numbers into the given numbers, and from 4 into 6 once), as is clear. Therefore the excess between 60 and 48 is double the excess between 30 and 24, just as the excess between 48 and 40 is double the excess between 24 and 20, as we showed at Proposition 10. Since, then, the three numbers 60, 48, 40 are in harmonic proportion, as we demonstrated in the preceding problem, their halves too, 30, 24, 20, [Margin: i — Elements V.15] which have the same ratios, will be in harmonic proportion — inasmuch as their excesses also have the same ratio as the excesses of the numbers 60, 48, 40, seeing that the excesses of the numbers 30, 24, 20 are the halves of the excesses of these numbers 60, 48, 40, as has been said. [Margin: 60. 48. 40 / 30. 24. 20]

XI.

Given two numbers, to find the harmonic mean proportional.

Let there be two given numbers AB, 15, and BC, 10, between which the harmonic mean proportional is to be found. From the greater, AB, 15, subtract the number BD equal to the lesser BC, 10; and let the remaining number AD, 5 — namely the difference of the given numbers — be multiplied into the lesser BC, 10; and let the product, 50, divided by AC, 25, the sum of the given numbers, yield the quotient DE, 2.

[Number line: A ····· E · D ····· B ····· C]

Let this, added to the lesser BD, 10, make BE, 12. I say that BE is the harmonic mean proportional between AB and BC, thus: 15, 12, 10. For since the number arising from AD into BC, divided by AC, gives the quotient DE, the same number will be reproduced by multiplying the quotient DE into the divisor AC, as is clear from the definition of division. Since, then, the same number arises from AC (the first) into DE (the fourth) as from BC (the second) into AD (the third), [Margin: b — Elements VII.19 or VI.16] AC (the first) will be to BC (the second) as AD (the third) is to DE (the fourth); and by separation, AB is to BC (the first given to the

third given) as AE (the excess between the first term AB and the found middle BE) is to DE (the excess between the middle BE and BD, that is, the third term BC). Therefore AB, BE, BC — namely 15, 12, 10 — are in harmonic proportion. Which is what was proposed.

And so, if the difference of the given numbers is multiplied into the lesser, and the product divided by the sum of the given numbers, and finally the quotient added to the lesser, the middle term of the harmonic proportionality will be formed.

XII.

Given two numbers, to find the lesser extreme in harmonic proportionality.

Let there be two given numbers AB, 15, and AC, 12, for which the lesser harmonic proportional is to be found. Add BD equal to BC, the excess between the given numbers. By this sum AD, 18 — gathered from the greater number and the difference of the given numbers — divide the number 36 (made from the lesser given number AC into BC, the difference of the given numbers); and let the quotient CE be subtracted from the lesser given number AC. I say that the remainder AE, 10, is the required lesser third term, thus: 15, 12, 10.

[Number line: A ······· E · C ··· B ··· D]

For since the number arising from AC into BC, divided by AD, gives the quotient CE, the same number will be reproduced by multiplying the quotient CE into the divisor AD, as is clear from the definition of division. Since, then, the same number is generated from AD (the first) into CE (the fourth) as from BC (the second) into AC (the third), [Margin: a — Elements VII.19 or VI.16] AD (the first) will be to BC (the second) — that is, to BD — as AC (the third) is to CE (the fourth). And by separation, AB is to BD, that is to BC, as AE is to CE; and by alternation, AB (the first given) is to AE (the third, found) as BC (the excess between the first term AB and the middle AC) is to CE (the excess between the middle AC and the third term AE). Therefore the three numbers AB, AC, AE — that is, 15, 12, 10 — are in harmonic proportion. Which is what was proposed.

And so, if the number produced from the lesser number into the difference of the given numbers is divided by the sum gathered from the greater number and the difference of the given numbers, and the quotient is subtracted from the lesser given number, the remainder will be the lesser extreme in harmonic proportionality.

Another method.

Again let there be two given numbers AB, 15, and AC, 12, for which the lesser is to be found in the harmonic mean. To the greater, AB, add BD equal to the difference BC, 3, of the given numbers. And by the sum AD, 18, divide the number 180 produced from the multiplication of the given numbers AB, AC — that is, 15 and 12 — into each other, and let the quotient be AE, 10. I say that AE is the lesser extreme in the harmonic mean.

[Number line: A ······· E ·· C ··· B ··· D]

For since the number generated from AB into AC, divided by AD, gives the quotient AE, the same number will be reproduced by multiplying the quotient AE into the divisor AD, as is clear from the definition of division. Since, then, the same number arises from AD (the first) into AE (the fourth) as from AB (the second) into AC (the third), [Margin: b — Elements VII.19 or VI.16] AD (the first) will be to AB (the second) as AC (the third) is to AE (the fourth); and consequently, since AD is greater than AB, AC too will be greater than AE. Hence also, by separation, BD — that is, BC — is to AB as CE is to AE; and by conversion, AB is to BC as AE is to CE; and by alternation, AB (the first) is to AE (the third, found) as BC (the excess between the first term AB and the middle AC) is to CE (the excess between the middle AC and the third term AE). Therefore the three numbers AB, AC, AE — that is, 15, 12, 10 — are in harmonic proportion. Which is what was proposed.

And so, if the number produced from the multiplication of the given numbers into each other is divided by the sum gathered from the greater number and the difference of the given numbers, the quotient will be the lesser extreme term of the harmonic mean.

Euclid, *Elements*, Book VI — Clavius's added propositions on means; Euclid Prop. 18

(Continuation of Clavius's inserted series of propositions on the arithmetic, geometric, and harmonic means, following Euclid VI.15–17; then Euclid's own Proposition 18.)

XIII.

Given two numbers, to find the greater extreme in harmonic proportionality.

Let there be two given numbers, $AB = 10$ and $AC = 12$, for which a third and greater term in the harmonic mean is to be found. From the lesser number AB cut off BD , equal to the difference $BC = 2$ of the given numbers. Then, by the remaining number $AD = 8$, divide the number 24, which is produced by multiplying the greater number $AC = 12$ into the difference $BC = 2$ (that is, BD) of the given numbers. Let the quotient $CE = 3$ be added to the greater number $AC = 12$. I say that the sum $AE = 15$ is the greater term in the proportionality, or harmonic mean — that is, that the three numbers AE , AC , AB , namely 15, 12, 10, are harmonically proportional.

Diagram. A number-line laying out the five points in order from left to right, with their computed positions:

- A: left end (0)
- D: at 8 ($AD = 8$, the remainder after cutting off $BD = 2$ from B)
- B: at 10 (the given number AB)
- C: at 12 (the given number AC ; $BC = 2$)
- E: right end, at 15 ($CE = 3$ added to C)

For when the number produced from AC into BD is divided by AD and the quotient is CE , the same number will be reproduced by multiplying the quotient CE into the divisor AD . Since, then, the same number is generated from AC (the first) into BD (the fourth) as from CE (the second) into AD (the third), AC (the first) will be to CE (the second) as AD (the third) is to BD (the fourth). [Margin: a. Elements VII.19; or VI.16] And by composition, AE is to CE as AB is to BD , that is, to BC . And by alternation, AE (the first) is to AB (the third) as CE — the excess between the first term AE and the mean AC — is to BC , the excess between the mean AC and the third term AB . Therefore the three numbers AE , AC , AB , namely 15, 12, 10, are harmonically proportional. Which is what was proposed.

And so, given two numbers: if their difference is subtracted from the lesser, and the number produced from the greater number into the difference of the given numbers is divided by the remainder, and the quotient is added to the greater number, the greater extreme term of the harmonic mean will be formed.

ALITER.

Again, let there be two given numbers, $AB = 10$ and $AC = 12$, for which the greater term in the harmonic mean is to be found.

From the lesser AB take away BD , equal to the excess BC of the given numbers. Then, by the remaining number $AD = 8$, divide the number 120, produced by

multiplying the given numbers $AB = 10$ and $AC = 12$ together; and let the quotient be $AE = 15$. I say that AE is the greater term in harmonic proportionality.

Diagram. The same number-line as above, points in order A, D, B, C, E (positions 0, 8, 10, 12, 15).

For when the number produced from AB into AC is divided by AD and the quotient is AE , the same number will be reproduced by multiplying the quotient AE into the divisor AD , by the definition of division. Since, then, the same number is generated from AB (the first) into AC (the fourth) as from AD (the second) into AE (the third), AB (the first) will be to AD (the second) as AE (the third) is to AC (the fourth). [Margin: b. Elements VII.19; or VI.16] Consequently, since AB is greater than AD , AE will also be greater than AC . And since AE is to AC as AB is to AD , then by conversion of the ratio AE will be to CE as AB is to BD , that is, to BC . And by alternation, AE — the first term found — is to AB (the third) as CE , the excess between the first term AE and the mean AC , is to BC , the excess between the mean AC and the third term AB . Therefore the three numbers $AE = 15$, $AC = 12$, $AB = 10$ are harmonically proportional. Which is what was proposed.

And so, given two numbers: if their difference is subtracted from the lesser, and the number generated by multiplying the given numbers together is divided by the remainder, the quotient will give the greater extreme term of the harmonic mean.

Finally, following Pappus, I wish also to demonstrate those procedures by which, at the end of the treatment of proportions, we showed that from a proportion of equality all rational proportions arise, and conversely that from a proportion of inequality any equality arises; and finally that from any geometric proportionality there arise a geometric, an arithmetic, and a harmonic proportionality. Thus from a geometric proportionality — whether of equal or of unequal terms — there is generated another geometric proportionality of unequal terms.

XIV.

Given three terms in geometric proportion, whether equal or unequal:
the sum made up of the first once, the second twice, and the third once;
the sum composed of the second and third once each; and the third taken once — are geometrically proportional.

Let A, B, C be three terms continuously proportional in the geometric sense, and let D be the sum collected from A once, B twice, and C once; let E be the sum

composed of B and C once each; and finally let F be equal to C. I say that D, E, F are likewise geometrically proportional. For since A is to B as B is to C, then by composition A + B together is to B as B + C together is to C. [Margin: a. Elements V.12] Therefore, as all the antecedents together — that is, the term D — are to all the consequents together, namely B + C, so is one antecedent, that is B + C, to one consequent, C. But D equals A + B and B + C together, E equals B + C, and F equals C. Therefore D is to E as E is to F; and consequently D, E, F are geometrically proportional. Which is what was proposed.

	first	second	third	first	second	third
A B C	1	1	1	12	6	3
D E F	4	2	1	27	6 [?]	3

From this it is clear that if the terms A, B, C are equal, then D, E, F are doubles [i.e. in continued double proportion]. For B and C together are double C, and therefore E is double F, since E equals B + C and F equals C. Since, then, D, E, F are continuously proportional, they will be in double proportion. And if the equal terms A, B, C are units, a double proportionality D, E, F is generated in the least terms 4, 2, 1, because F is equal to C, that is, to unity.

But if A, B, C are doubles [in double proportion], the resulting D, E, F are triples. For if B is double C, the sum of B and C — that is, E — is triple C, that is, triple F; and so D, E, F will have a continued triple proportion. In the same way, from triples arise quadruples, from quadruples quintuples, and so on without end.

But if the terms A, B, C are doubles in reverse order, the resulting D, E, F are sesquialterate [3 : 2]. For since B is half of C, the sum of B and C — that is, E — is sesquialterate to C, that is, to F. In the same way, if A, B, C are triples in reverse order, the resulting D, E, F are sesquitertian [4 : 3]. For B will be a third part of C; therefore the sum of B and C — that is, E — contains C (or F) once and, in addition, a third part of it; and so D, E, F will have a continued sesquitertian proportion. By the same reasoning, from inverse quadruples arise sesquiquartans [5 : 4], and from inverse quintuples sesquiquintans [6 : 5], and so on to infinity. In the same manner we shall show that the generations of other proportions from other proportions have been correctly prescribed in the treatment of proportions; and likewise that any proportion of inequality can rightly be brought back to equality — since in that reduction we in some way retrace the operation by which we showed a proportion of inequality to be generated from equality.

(The third example — 3, 20, 1 — shows terms that are not geometrically proportional, yet still yield an arithmetic mean 47, 24, 1.)

XVI.

Given three terms, whether equal or unequal, in geometric proportion: the sum collected from the first twice, the second three times, and the third once; the sum composed of the second twice and the third once; and, finally, the sum gathered from the second once and the third once — are harmonically proportional.

Let A, B, C be three geometrically proportional terms, and let D be the sum collected from A twice, B three times, and C once; let E be the sum composed of B twice and C once; and finally let F be the sum gathered from B once and C once. I say that D, E, F constitute a proportionality, or harmonic mean. For since A is to B as B is to C, then, by the scholium to Proposition 22 of Book V, twice A is to B as twice B is to C. Therefore by composition, twice A plus once B is to B as twice B plus once C is to C. [Margin: a. Elements V.12] Hence, as all the antecedents together — namely twice A, three times B, and once C, that is, the term D — are to all the consequents together, namely to the sum of B and C, that is, to F, so is one antecedent, namely twice A plus once B, to B. Now twice A plus once B is the excess by which twice A, three times B, and once C — that is, the term D — exceeds the mean E [twice B plus once C]; while B is the excess by which E [twice B plus once C] exceeds the third term F. Therefore D, the first, will be to F, the third, as the excess between the first and the mean is to the excess between the mean and the third; and so D, E, F will be harmonically proportional. Which is what was proposed.

	first	second	third
A B C	12	6	3
D E F	45	15	9

The least terms D, E, F are always produced when the given terms A, B, C are units, as is clear in the examples set out. When, however, A, B, C are not units — even if they are the least terms in their proportion — the least terms D, E, F are not always produced. This is plainly established by the following examples. For in the first example, from the least terms of the sesquialterate proportion; in the second, from the least terms of the subquadruple proportion; and in the third, from the least terms of the subsesquitertian proportion, there are generated three terms in harmonic proportionality that are not the least. But if the terms

are inverted, then at last — remarkably — the least terms of the harmonic mean are produced, as these examples show.

Terms **not** least (given terms not units):

	first	second	third	first	second	third	first	second	third
A B C	9	6	4	1	4	16	9	12	16
D E F	40	16	10	30	24	20	70	40	28

The same terms inverted, now yielding the **least** harmonic terms:

	first	second	third	first	second	third	first	second	third
A B C	4	6	9	16	4	1	16	12	9
D E F	35	21	15	45	9	5	77	33	21

PROBL. 6. PROPOS 18.

[Margin: xix.]

On a given straight line, to describe a rectilinear figure similar and similarly situated to a given rectilinear figure.

Let AB be the given straight line, on which a rectilinear figure similar and similarly situated to the rectilinear figure CDEFG is to be described. From any one angle — say from F — draw lines to each of the opposite angles, resolving the figure into the triangles CDF, DEF, FGC. Next, on AB make angle BAI equal to angle DCF, and angle ABI equal to angle CDF, so that the lines AI and BI meet at the point I. (They will certainly meet, because the two angles IAB and IBA are less than two right angles, being equal to the two angles FCD and FDC, which [Margin: a. Elements I.17] are less than two right angles.) [Margin: b. Elements I.32] Then the remaining angle AIB will be equal to the remaining angle CFD, and the whole triangle AIB will be equiangular with the whole triangle CFD. Again, make angle IBH equal to angle FDE, and angle BIH equal to angle DFE. And since [Margin: c. Elements I.17] the two angles EDF and EFD are less than two right angles, the two angles HBI and HIB will also be less than two right angles; and therefore the lines

BH and IH will meet. Let them meet at the point H; and by the same reasoning triangle BHI will be equiangular with triangle DEF. Furthermore, make angle AIK equal to angle CFG, and angle IAK equal to angle FCG. And since [Margin: d. Elements I.17] the two angles GCF and GFC are less than two right angles, the two angles KAI and KIA will also be less than two right angles; and therefore the lines AK and IK will meet at some point. Let them meet at K; and triangle AKI will likewise be equiangular with triangle CGF. Proceed in this way until all the triangles of the proposed figure are exhausted, if there are more of them. I say, then, that the rectilinear figure ABHIK is similar and similarly situated to the rectilinear figure CDEFG.

Diagram. Two pentagons side by side. On the left is the constructed figure ABHIK; on the right is the given figure CDEFG, each triangulated by lines drawn from an apex to the base corners.

- Left pentagon (constructed, ABHIK):
- A: lower-left vertex (base left)
- B: lower-right vertex (base right)
- H: right vertex
- I: apex (top) — printed faint [?]
- K: upper-left vertex
- Right pentagon (given, CDEFG):
- C: lower-left vertex (base left)
- D: lower-right vertex (base right)
- E: upper-right vertex
- F: apex (top)
- G: upper-left vertex

For since angle IAB has been made equal to angle FCD, and angle IAK equal to angle FCG, the whole angle BAK will be equal to the whole angle DCG. By the same reasoning angle ABH will be equal to angle CDE, and the remaining angles equal to the remaining ones, as is clear from the construction, since the several parts of the one have been made equal to the several parts of the other. The rectilinear figure ABHIK will therefore be equiangular with the rectilinear figure CDEFG. And since [Margin: e. Elements VI.4] AB is to BI as CD is to DF, and BI is to BH as DF is to DE, the sides about the equal angles ABH and CDE are proportional, [Margin: f. Elements V.22] just as the sides about the equal angles H and E are proportional, because the triangles BHI and DEF are equiangular. [Margin: g. Elements VI.4] Again, HI is to IB as EF is to FD, and IB is to IA as FD is to FC, and IA

is to IK as FC is to FG; [Margin: h. Elements VI.4] and so, *ex aequali*, HI is to IK as EF is to FG, [Margin: i. Elements V.22] and therefore the sides about the equal angles HIK and EFG will also be proportional, and so on for the rest. Since, then, the figures are equiangular and have the sides about their equal angles proportional, they are similar and similarly described. Thus on the given straight line we have described a rectilinear figure similar and similarly situated to the given rectilinear figure. Which was to be done.

SCHOLIUM.

Rectilinear figures described upon straight lines are said to be similar and similarly situated when equal angles are set up upon those straight lines, and both the remaining angles are equal and the sides are proportional, following one another always in the same order. For example, the triangles ABC and DEF will not only be similar but also similarly described upon the straight lines BC and EF, if angles B and C are equal to angles E and F, and AB is to BC as DE is to EF, and so on. But upon the straight lines BC and DE they will not be said to be similarly described (although they are similar), since angles B and C are not equal to angles D and E. Likewise the rectangles AC and EG, being similar, will be said to be similarly described upon the straight lines DC and HG, because as AD is to DC, so is EH to HG, and so on. But the rectangles AC and IG will not be said to be similarly described upon the straight lines DC and HG, although they are similar, as is evident. They will, however, be similarly described upon the straight lines DC and IH, or upon the straight lines AD and GH.

Diagram. Two similar triangles. On the left the smaller triangle ABC (A at the apex, B at lower-left, C at lower-right); on the right the larger triangle DEF (D at the apex, E at lower-left, F at lower-right).

- A: apex of left triangle
- B: lower-left of left triangle
- C: lower-right of left triangle
- D: apex of right triangle
- E: lower-left of right triangle
- F: lower-right of right triangle

Diagram. Three rectangles illustrating similar and similarly-situated placement. A wide rectangle EFGH (E top-left, F top-right, G bottom-right, H bottom-left); beside it a tall rectangle IKGH (I top-left, K top-right, G bottom-right, H bottom-left) standing on the same base HG; and below, a wide rectangle ABCD (A top-left, B top-right, C bottom-right, D bottom-left).

- Rectangle "AC": vertices A (top-left), B (top-right), C (bottom-right), D (bottom-left); base DC, left side AD
- Rectangle "EG": vertices E (top-left), F (top-right), G (bottom-right), H (bottom-left); base HG, left side EH
- Rectangle "IG": vertices I (top-left), K (top-right), G (bottom-right), H (bottom-left); the tall rectangle on base HG

Moreover, all figures described according to the construction of this problem are necessarily similarly situated, as is clear in the rectilinear figures ABHIK and CDEFG described upon the lines AB and CD. Likewise all equilateral and equiangular figures are similarly situated upon any of their sides.

Perhaps, however, we shall accomplish the proposed problem more expeditiously in the following way. Let a rectilinear figure similar and similarly situated be described upon the given straight line G (or another equal to it), on the model of the given rectilinear figure ABCDEF. Producing the two sides AB and AF about angle A, draw from A through all the other angles the lines AC, AD, AE, extended as far as you like. Then from AB cut off AH equal to the given line G — or from AB itself, further produced, if G happens to be greater than AB. After this, through H draw the line HI parallel to the side BC, and through I the line IK parallel to the side CD, and so on in succession, until all the sides have their parallels, except the two produced sides AB and AF. What is proposed will then be accomplished: that is, the figure AHIKLM upon the straight line AH...

SCHOLIVM (to Prop. 18, continued)

Diagram. A composite construction figure illustrating the "more expeditious" method of the preceding scholium: the model figure ABCDEF and the similar figure AHIKLM constructed upon the line AH, sharing the common apex A, with the diagonals drawn from A through the several angles and the given line G marked (as short vertical segments) along the right of the figure. Many lines radiate from the shared apex to the successive vertices of the two overlapping figures. Legible vertex-labels, with approximate positions:

- L (top peak): apex vertex of the constructed/model outline
- K (upper right): vertex
- E (upper centre-left): model-figure vertex
- D (upper right, below K): model-figure vertex
- N (left): vertex/endpoint on a produced side
- F (left, below N): model-figure vertex

- M (lower left): constructed-figure vertex
- I (centre-right): constructed-figure vertex
- H (lower centre): constructed-figure vertex on the base
- B (lower right): model-figure vertex on the base
- G (vertical segments, right side): the given line, marked at several points
- [?] interior label near centre (reads as a second "L" or "K") — unresolved
- [?] label at centre-right (reads as "Q" or "G") — unresolved
- [?] label at far-right foot (reads as "II", possibly a doubled point) — unresolved
- A (shared apex): expected at the lower convergence of the radiating lines, not clearly lettered on the tile [?]

[Margin: k. *Elements* I.29] [Margin: l. *Elements* VI.4]

[the figure AHIKLM] will be similar to the proposed figure ABCDEF and similarly situated, being constructed upon the straight line AB — that is, upon AH, equal to the given straight line G. For the angle HAM is common to both; and since the angles AHI, AML are equal to the angles ABC, AFE [Margin: k. *Elements* I.29], and likewise the angles AIH, AIK are equal to the angles ACB, ACD — that is, the whole angle HIK is equal to the whole angle BCD — and in the same way the angles IKL, KLM are equal to the angles CDE, DEF: the rectilinear figures ABCDEF, AHIKLM will be equiangular. Moreover, the sides about the equal angles are proportional. For since the triangles AHI, AIK, AKL, ALM are similar, by the corollary of Prop. 4 of this book, to the triangles AEC [recte: ABC?], ACD, ADE, AEF, it follows [Margin: l. *Elements* VI.4] that as AB is to BC, so is AH to HI; again, as BC is to CA, so is HI to IA; and as CA is to CD, so is IA to IK; and consequently, *ex aequali*, as BC is to CD, so is HI to IK, and so on. Therefore, by the definition, the rectilinear figures ABCDEF and AHIKLM are similar, and indeed similarly situated, by the very method we described just above in this scholium.

THEOR. 13. PROPOS. 19.

[Margin: xvij.]

Similar triangles are to one another in the duplicate ratio of their corresponding [homologous] sides.

Clavius's demonstration. Let ABC, DEF be similar triangles, having the angles at B and E equal, likewise those at C and F, and so on; and let AB be to BC as DE is to EF, and so forth. I say that the triangles have to one another a ratio that is the duplicate of the ratio which the corresponding sides BC and EF have — or AB and

DE, or AC and DF. That is: if a third proportional BG be found to the corresponding sides BC, EF, then the triangle ABC is to the triangle DEF as the straight line BC is to the straight line BG. Consequently, since by Definition 10 of Book 5 the ratio of BC to BG is called the duplicate of the ratio of BC to EF, the ratio of triangle to triangle is likewise said to be the duplicate of the ratio of the corresponding sides BC, EF.
