Translator Version 2

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: "What do I need this new instrument for?" — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBris HaShalem* (1797)

A note on the work

Tomus III holds Clavius's astronomy. The first and larger part is his commentary on Sacrobosco's *De sphaera* — the most influential Renaissance astronomy textbook — reprinting Sacrobosco's brief text and surrounding it with a vast commentary on spherical astronomy: the celestial and terrestrial spheres, the circles of the sphere, risings and settings, the climes, the motions of the Sun and planets, eclipses, and the computus. The second part, the *Astrolabium*, is a comprehensive treatise on the construction and use of the astrolabe, with its projection geometry and tables. Both are richly illustrated with woodcut diagrams.

A note on the translation process

This translation was produced with the [translation-pipeline](#). See the linked repository for details on the process.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Opera Mathematica, Tomus III — Front Matter

Binding and endpapers

This opening covers the volume's binding cover and its front endpapers; no printed text of the work appears yet.

Upper cover. Blind-tooled leather binding with a densely worked ornamental panel design: an outer floral roll border enclosing concentric rectangular frames of scrollwork and foliate tooling, with a central oval cartouche containing an armorial device (a quartered shield). The tooling is worn and no lettering is legible.

Front flyleaf. Blank leaf carrying two handwritten notations in the upper portion:

- [Margin: Upper left, ink shelfmark:] "2 Math. u. 10 / 3" [?] — an early library pressmark (partly written as a fraction, "2 Math. u. 10" over "3").
- [Margin: Center, ink:] "Clavius" — the author's name, written as an identifying note.

The remainder of the leaf is blank, with staining, show-through, and edge damage.

Front paste-down / endpaper. Blank leaf showing faint mirror-image offset (show-through) of the printed title page from the facing recto — a few reversed capitals are visible but not reliably transcribable. Applied at the lower center is the modern Bayerische Staatsbibliothek barcode label:

- "<36613880450015" (printed twice)
- "Bayer. Staatsbibliothek"
- A red inked shelf/serial number "5" [?] beside the barcode, and a pencilled "33" below.

Blank front endpaper. No printed text. A handwritten shelfmark appears at the top in ink: "2 Math. u. 10 - 3" [the Bavarian State Library call-number "2 Math. u. 10-3"]. The lower part of the leaf is blank, with a faint show-through of the woodcut on the following title page.

CHRISTOPHORI CLAVII BAMBERGENSIS E SOCIETATE IESV OPERVM MATHEMATICORVM TOMVS TERTIVS

The Mathematical Works of Christoph Clavius [Christoph Clavius] of Bamberg, of the Society of Jesus: Volume Three.

Comprising the *Commentary on the Sphere of Johannes de Sacro Bosco* [Sacrobosco], and the *Astrolabe*.

Diagram. The title-page device is a woodcut armillary sphere shown in oblique perspective, seen slightly from the front and above. A graduated meridian ring encircles the whole, marked off in tens of degrees; running down each quadrant the numbers read 10, 20, 30, 40, 50, 60, 70, 80, 90, then back 80, 70, 60, 50, 40, 30, 20, 10 toward the opposite pole. Within it are set the principal circles of the sphere — the two polar (Arctic and Antarctic) circles, the two tropics, the equator (equinoctial), the horizon, and the oblique zodiac band bearing its signs — with the earth shown as a small globe at the centre. The poles are marked by small star-shaped figures at upper left and lower right.

- POLVS SEPTENTRIONALIS (upper left, at a star): North Pole
- [meridian ring, both quadrants]: 10 · 20 · 30 · 40 · 50 · 60 · 70 · 80 · 90 · 80 · 70 · 60 · 50 · 40 · 30 · 20 · 10 (degree graduation)
- ARCTICVS (upper left interior): the Arctic Circle [Circulus Arcticus]
- TROPICVS ÆSTIVVS (upper interior, printed "TROPICVS... ESTIVVS"): the Summer Tropic (Tropic of Cancer)
- ÆQVINOCTIALIS (mid-right interior, printed "EQVINOCTIALIS"): the Equinoctial (celestial equator)
- ORIZON (across the middle): the Horizon
- ARIES ♈ · TAVRVS ♉ · GEMINI ♊ (on the zodiac band, upper right, with degree subdivisions 10 · 20 · 30): the zodiac signs Aries, Taurus, Gemini
- AQVARIVS ♒ · PISCES ♓ (on the zodiac band, lower interior, with degree subdivisions 10 · 20 · 30): the zodiac signs Aquarius, Pisces
- TROPICVS HIEMALIS (lower interior): the Winter Tropic (Tropic of Capricorn)
- ANTARCTICVS (lower interior): the Antarctic Circle [Circulus Antarcticus]
- POLVS AVSTRALIS (lower right, at a star): South Pole

MOGVNTIÆ, — At Mainz [Moguntia]:

At the expense of Antonius Hierat [Anton Hierat]; printed by Reinhard Eltz [Reinhardus Eltz].

Cum gratia & privilegio sacræ Cæsar. Maiest. — With the grace and privilege of His Sacred Imperial Majesty.

ANNO M. DC. XI. — In the year 1611.

[Handwritten ownership marks on the title page: a large pen flourish (a signature) across the centre, over the printer's device [?]; a cursive signature to the right of "Complectens," reading approximately "de Berennis" [?]; and, below the woodcut above "MOGVNTIÆ," a monastic ownership inscription reading approximately "Monast[erii]... senis" [?]. All are illegible manuscript hands.]

Blank verso of the title leaf. No printed text of its own; the whole title-page setting shows through in mirror image. The leaf carries the ownership stamp of the Bavarian State Library:

[Ownership stamp: **BIBLIOTHECA REGIA MONACENSIS** — Royal Library of Munich]

A handwritten cursive signature also appears on this side, illegible [?].

Dedicatory Epistle

TO THE MOST REVEREND AND MOST ILLUSTRIOUS PRINCE AND LORD, LORD JOHANN GOTTFRIED [Johann Gottfried von Aschhausen], Bishop of Bamberg [Episcopo Bambergensi], and Provost of the Metropolitan Church of Würzburg [Ecclesiæ Metropolitanæ Herbipolensis Præposito], etc., his own Most Gracious Lord: CHRISTOPHORUS CLAVIUS [Christoph Clavius] OF BAMBERG, OF THE SOCIETY OF JESUS.

I have been especially glad, Most Reverend and Most Illustrious Prince, that at the very time when this third volume of my mathematical studies, brought to completion by my later revisions, was pressing to be released by me and made public, you — not long after you had taken up the governance of the Church of Bamberg — set all your affairs at home swiftly in order and, in the harshest season of the year and by arduous journeys, went off to Carinthia [Carinthia]. Your aim was to carry out the duty of a diligent shepherd: to visit kindly, and see for yourself, your sheep that lay far removed from the fold, and to learn what

dangers they were exposed to, or what hardships oppressed them, and with what help of yours above all they stood in need.

For when I came to understand the extraordinary devotion of those who are subject to your rule — how they first awaited you in your absence, then welcomed you on your arrival, honored you in your presence with every kind of service, as was fitting for subjects to do, and at last, when you departed, accompanied you with no gifts so much as with sighs and tears — I was very glad that I could take part in it, and could join my own reverence toward you to their acts of homage. The service they once rendered to the Emperor Henry [Henry II], who first founded the Church of Bamberg, when he was passing through those regions on his way into Lombardy, they now rendered to you with as much greater zeal as their reason was the better one. [Margin: Baronius [Cesare Baronio], *Annales Ecclesiastici*, vol. II.] Him, under arms, they had perhaps feared; you, in the civilian's gown and in no way to be feared, more renowned for the fame of your virtues than he for the terror of war, they could only love. Him, the most powerful monarch of Germany, they deservedly revered; but you — their lord, their bishop, and their most kindly shepherd, and (to come nearer to their own feeling, and indeed to the truth of the matter) their most beloved father — they were bound to embrace with their whole heart.

As for me, I am inclined to think that my own reasons for love and reverence are weightier still — the very ones I already recounted earlier, in the first volume. Receive, therefore, Most Reverend and Most Illustrious Prince, this my third gift, which I offer to you on your return to your homeland in the same spirit in which the Carinthians offered you their loyalty and homage as you came to them, and the people of Bamberg rejoiced with you over your safe journey as you returned — rejoicing no more on your account than on their own.

Farewell, both for your own sake and for that of the orthodox religion. Rome, in the year of the Lord 1611.

In Sphæram Ioannis de Sacro Bosco Commentarius

**A COMMENTARY BY CHRISTOPHORUS CLAVIUS [Christoph Clavius] OF
BAMBERG, OF THE SOCIETY OF JESUS, ON THE SPHERE OF JOANNES DE
SACRO BOSCO [Sacrobosco].**

[The remainder of this half-title leaf is otherwise blank; heavy show-through from the verso (an index/preface *Ad Lectorem*) is visible but belongs to the following page.]

To the Reader

AD LECTOREM. [To the Reader]

So that greater profit might be drawn from our Commentary on the *Sphere*, we have added — for the benefit of students, over and above the Author's own exposition, along with much else — these items in particular, which follow.

I.

A most useful disputation on the fourfold motion of the eighth sphere, according to the periods discovered by Nicolaus Copernicus; in which the emptiness of the motion of trepidation [motus trepidationis] is refuted by the most compelling arguments, and an eleventh heaven, the *Primum Mobile*, is established. Page 33.

II.

By what technique the declinations of the stars are to be computed by means of sines, once their longitudes and latitudes are known. Page 99.

III.

The history and my own view concerning the new star [*stella nova*] that appeared in Cassiopeia in the year of the Lord 1572; and concerning two others, likewise new, one of which was seen in Cygnus in the year 1600, and the other in Sagittarius near the ecliptic in the year 1604. Page 103.

IV.

By what means the distances of the heavens, their thickness, and their circumference may be investigated, together with the magnitudes of the stars. Page 117.

V.

A digression on the number of the sand, drawn from Archimedes. Page 120.

VI.

By what method the declination of any given point is to be investigated from the doctrine of sines. Page 149.

VII.

By what device the place of the Sun in the zodiac, and its entry into the twelve signs, may be found from memory, more or less. Page 158.

VIII.

By what means the interval between any two cities whose longitude and latitude are known may be found, both geometrically by lines and from the sines. Page 177.

IX.

Likewise, how the latitudes of rising and of setting [Latitudines ortivae atque occiduae] are to be computed by sines. Page 182.

X.

Next, by what way the right and oblique ascensions of all points, or of the arcs of the ecliptic, are found from the doctrine of sines. Pages 198 and 203.

XI.

Again, in what manner the lengths of the days and nights throughout the whole year, in every clime, may be inquired into by sines. Page 238.

XII.

Besides these, tables most necessary to astronomical work: namely, a table of all the fixed stars, with the longitude, latitude, magnitude, and position within the constellations of each. In which matter we have followed the order of all the asterisms, or constellations, as they were observed by the most ancient astronomers. Page 76.

A table for reducing degrees to hours, and the reverse. Page 128.

A table for converting degrees, minutes, seconds, thirds, and so on of the equator into minutes, seconds, thirds, and so on of days, and the reverse. Pages 130 and 131.

A table of the declinations of the points of the ecliptic, far fuller than any published by others, inasmuch as it proceeds by five-minute steps. Page 150.

A table of right ascensions. Page 199.

A table of ascensional differences for all elevations of the pole. Page 203.

A table of oblique ascensions for various altitudes of the pole. Page 209.

A table of semidiurnal arcs computed for all elevations of the pole. Page 288.

XIII.

A geometric digression on the twilights [de Crepusculis]. Page 256.

XIV.

A demonstration of why the more northerly climes are the narrower. Page 286.

XV.

A most useful disputation on eccentric orbs and epicycles, against certain philosophers. Page 290.

XVI.

Finally, the *Theorics* of the planets arranged into tables. Page 308.

[The lower half of this page carries a large, faint mirror-image ghost of a set of concentric circles — offset/show-through from the woodcut cosmological figure printed on the facing page; not an independent figure.]

Diagram. A new figure and series of the twelve heavens — a full-page geocentric woodcut of concentric spheres. The heading above reads: "A NEW FIGURE AND SERIES OF THE TWELVE HEAVENS; being one that until nearly the present day was unknown, but is explained in this Commentary. Page 42 and following." The circles are labelled, reading from the outermost inward, with the seven planetary spheres each flanked on both sides by the planet's astronomical symbol. Small star-figures (asterisks) are scattered through the firmament and the outer rings; at the very center is a small woodcut of the terrestrial globe (the elemental Earth).

- Outermost ring: *Caelum Empyreum* (the Empyrean Heaven)
- *Primum mobile* (the First Movable)
- *Decimum caelum* (the Tenth Heaven)

- *Nonum coelum* (the Ninth Heaven)
- *Firmamentum* (the Firmament)
- ♄ *Saturnus* ♄ (Saturn)
- ♃ *Iuppiter* ♃ (Jupiter)
- ♂ *Mars* ♂ (Mars)
- ☉ *Sol* ☉ (the Sun)
- ♀ *Venus* ♀ (Venus)
- ☿ *Mercurius* ☿ (Mercury)
- ☾ *Luna* ☾ (the Moon)
- Center: the terrestrial globe (Earth)

Christoph Clavius of Bamberg, of the Society of Jesus, on the Sphere of John of Sacrobosco

Preface

In various ways — as Proclus Diadochus [Proclus] reports in the Commentary he wrote on the first book of Euclid — the ancient philosophers divided up the mathematical disciplines. Among all their divisions, the one ascribed to the Pythagoreans, and followed by Plato, Aristotle, Boethius, and other philosophers of the greatest weight, both ancient and more recent, has always been the most celebrated. By it all the mathematical disciplines are distributed into four principal kinds, namely Arithmetic, Geometry, Music, and Astronomy; and this was not done without reason. For since all the mathematical sciences are concerned with quantity, and quantity is twofold — discrete and continuous — and since, again, discrete quantity can be considered either absolutely and in itself, or in comparison with another, and likewise continuous quantity falls under our understanding either as immobile or as mobile, it was entirely right that four principal mathematical disciplines should be established, treating of the twofold quantity under the twofold consideration of each. Such are the four just enumerated.

Arithmetic, then, deals with discrete quantity — that is, with number considered absolutely and in itself — investigating and setting out at length and with care its properties and the whole force of numbers, together with the art of counting. Geometry next treats of continuous immobile quantity, and teaches how to measure the magnitudes of the earth and of other things. Music, for its part, deals with discrete quantity — that is, number — considered in comparison with another, and studies the concord and harmony of sounds. Astronomy, finally,

undertakes the discussion of continuous quantity, of mobile magnitude, and scrutinizes the heavens and the unchanging motions of the stars.

[Margin: The division of the mathematical disciplines.]

Of these four mathematical disciplines — from which, indeed, all the others that deal with quantity in any way flow and are propagated — Astronomy is the most far-reaching, and for that reason at once the most worthy and the most delightful. On account of the multitude of things it considers, it has always been held in such esteem that the ancient philosophers devoted more study, labor, and diligence to no other science than to this one Astronomy. But since, as time went on, very many shrank back from this excellent discipline, daunted by the length of its books and the difficulty of the subject, so that it nearly collapsed, therefore John of Sacrobosco, an Englishman by birth, an outstanding philosopher and mathematician of his day, who flourished around the year of the Lord 1232, wishing to remedy this evil, composed for the common benefit of students — drawing on the most approved and choicest astronomers, Ptolemy, Alfraganus [al-Farghānī], al-Battānī [Albategnius], and very many others — a certain small compendium of the whole of Astronomy, to serve as a kind of introduction to the weightier writers on Astronomy, with all the care he could; and this work has indeed always held a great name in all the schools right up to our own times.

This little work, therefore, we have thought good to illustrate, for the benefit of students, with fuller annotations. In them we have tried, so far as possible, first to explain the author's meaning in a plain account; then to supply what he himself seems to have omitted; and to clarify at greater length what he taught too briefly — always keeping to the footsteps of the ancient astronomers, while adding besides a number of observations of more recent writers, so that what has been obscurely stated by others concerning the motions of the heavens and the form of the whole universe may be more perfectly understood.

But before we approach the author himself to interpret him, it will be worthwhile to say a few things first about Astronomy in general, so that students may come to this science with a better-prepared and more eager mind. These we shall divide into four chapters. In the first we shall briefly teach who were the first inventors of this discipline, and who were its most eminent authorities. In the second we shall make clear what parts this whole science of Astronomy comprises. In the third we shall discuss the excellence and dignity of Astronomy. And in the fourth, finally, we shall bring forward some remarks about its usefulness and necessity.

[Margin: When John of Sacrobosco flourished, and why he wrote this compendium of Astronomy.]

Commentary on the First Chapter of the Sphere

On the Inventors of Astronomy

[Margin: Who were the first inventors of Astronomy.]

No one ought to doubt that the first inventors of Astronomy were the forefathers and propagators of the human race — I mean Adam, Noah, Abraham, and others of this kind — from whom, as the most ancient histories testify, all the other honorable disciplines also drew their origin. For as Josephus writes in the *Antiquities of the Jews* I.4, when Adam had foretold to his sons the destruction of all things — one coming by the force of fire, the other by the might and mass of waters — they, fearing that the science of celestial things which they had first discovered might slip away from among men, or might die out before it came to their knowledge, made two columns, one of brick and the other of stone, and inscribed on both the things they had discovered, so that if the one built of brick should be destroyed by the rains, the stone one, remaining, might furnish men with the writings concerning celestial matters. This stone column, Josephus reports, survives to this day in Syria; and if the stone column were consumed by fire, the brick one would remain unharmed and would present the science of the stars to mortals. The same Josephus, in chapter 8 of the same book, affirms that those ancient fathers were granted so long a life precisely so that they might have leisure for matters astronomical and geometrical; and his very words are these:

[Margin: The two columns, on which the sons of Adam inscribed the sciences lest they perish in the flood, and what they were.]

"Let no one, comparing modern life and the brevity of the years in which we now live with those of the ancients, suppose false what is said of them; nor, because life is now not prolonged to so great a length, let him believe that they in no way reached that length of life. For they, being religious and made by God himself, and having more suitable nourishment provided for a longer span of time, rightly lived through the cycles of so many years. Moreover, on account of the virtues and glorious benefits which they continually investigated — that is, Astrology and Geometry — God granted them ampler spaces of life, which they could not have learned thoroughly unless they lived six hundred years. For it is through so many years' courses that the Great Year is completed."

[Margin: Why God prolonged so long a life for the first parents, according to Josephus's opinion.]

Again, in the same book he names him [Abraham] as experienced in celestial matters; and in chapter 16 he testifies that Abraham was the first to instruct the Egyptians in Arithmetic and the science of the stars. For thus he writes of him: "Arithmetic too he imparted to them (that is, to the Egyptians), and he himself conveyed to them what pertains to Astrology. For before Abraham's coming into Egypt, the Egyptians were entirely ignorant of these things." For these things are known to have passed from the Chaldeans to the Greeks.

It is established, therefore, that Astronomy existed even at the very beginning of the world, so that with the fullest right it may contend with all the other arts and disciplines in point of antiquity, since we read of none more ancient. Hence it comes about that those authors who are read of in the histories as having been the first inventors of Astronomy should be judged rather to have illustrated it — a science already discovered long ago, indeed sprung from the very beginnings of the world — and to have enriched it with new additions, than to have first discovered it; and that they are called the first authors of this discipline only in that sense.

[Margin: Who are said by writers to be the first inventors of Astronomy.]

As to whom this invention — or rather amplification — of Astronomy is chiefly to be ascribed, there has always been great controversy among authors, and the case is still before the judge. For some attribute it to the Egyptians, some to the Assyrians, some to the Babylonians; while others assert that it was first discovered by the Ethiopians, on the ground that, living under the equinoctial circle, they always enjoy a most serene sky, from which they can easily observe the courses of the stars. These authors, however, do not deny that the Egyptians afterward rendered it more perspicuous and more illustrious. Nor, indeed, are there wanting those who make Atlas the first inventor of this discipline, and who would have it that from this arose that famous fable — namely, that he bore the heaven on his shoulders — because he was the first to take care, by the vigor of his mind and his skill, to hand on to men the courses of the Sun and Moon and the revolutions and principles of all the stars. Concerning this Diodorus Siculus writes thus in Book 4: "They say that Atlas was most skilled in Astrology, and was the first among men to dispute about the sphere; from which circumstance he was thought to bear the heaven on his shoulders, the invention of the sphere giving occasion to the fables." Concerning the same, St. Augustine [Augustine] in Book 18 of the *City of God* [*De Civitate Dei* XVIII] says thus: "Atlas is said to have

been a great astrologer, from which the fable took its occasion, so that he was feigned to bear the heaven." Eusebius of Caesarea, too, in his *Preparation for the Gospel*, would have Enoch and Atlas to be one and the same man; but from the histories it is established that Atlas is younger by at least seven hundred years. Caelius Rhodiginus [Lodovico Ricchieri], in Book 18 of his *Ancient Readings* [*Lectiones Antiquae* XVIII], thinks that Astronomy was first discovered by the Sidonians on account of the practice of navigation. For just as the Egyptians laid the first foundations of Geometry on account of the measuring of fields, which they could not do without Geometry, and the Phoenicians, on account of their frequent trade and commerce, are thought to have handed down the first rudiments of Arithmetic, so too the Sidonians, on account of the constant navigation they practiced, are believed to have first discovered Astronomy, since the practice of navigation cannot in the least subsist without this science. This, however, was afterward increased in a wonderful manner by the Chaldeans, Persians, Indians, Egyptians, Greeks, and very many Arabs.

[Margin: Various authors who flourished in Astronomy.]

Whatever, then, may finally be certain and clear about the first inventors of Astronomy, many distinguished authors excelled in it, of whom I shall review only the more eminent. In the first place there flourished in it Atlas, the brother of Prometheus, king of Mauretania, born in Egypt, who handed it on to Hercules; and Hercules is said to have made such progress in this discipline that, on account of the knowledge of celestial matters with which he was endowed, he is reported to have borne on his shoulders the heaven taken over from Atlas, and to have attained great glory — as the histories testify — because he was the first to bring the sphere of the stars into Greece. After these, very many distinguished astrologers followed in succession, such as Anaximander of Miletus, Thales of Miletus, Pythagoras of Samos, Eudoxus of Cnidus (in Plato's time, a pupil of the Egyptians and Chaldeans), Callippus, Archytas of Tarentum, Euclid of Megara, Aratus of Soli, Timocharis of Alexandria, Abrachis — who by another name is called Hipparchus, although very many think Abrachis different from Hipparchus — Eratosthenes of Athens, Archimedes of Syracuse, Sosigenes, Julius Caesar (who by the work of Sosigenes adapted the year to the Sun's course), Andromachus of Crete, who is said to be the inventor of the Theorics, Proclus Diadochus, Menelaus the Roman (also called Mileus the Geometer), Theodosius of Tripoli, author of the three books on spherical elements, Ptolemy the most skilled of all, Theon of Alexandria, Pappus of Alexandria, Albumasar [Abū Ma'shar], Almeon the Arab, Abraham Avenezra [Abraham ibn Ezra], al-Battānī [Albategnius], Thabit [Thābit ibn Qurra], the discoverer of the motion of

trepidation in the eighth sphere, who flourished 1140 years after Ptolemy, Haly [‘Alī], Geber of Seville [Jābir ibn Aflāḥ], Alfraganus [al-Farghānī], Alphonsus king of Spain (in the year of the Lord 1250), from whom the Alphonsine Tables took their name, George Peurbach [Georg Peuerbach], John of Königsberg [Regiomontanus], John Werner of Nuremberg, John Bianchini of Ferrara (who also composed astronomical tables), Johannes Stöffler [Stoflerinus], Nicolaus Copernicus, Francesco Maurolico the Sicilian abbot, Pedro Nunes of Alcácer [Petrus Nonius Salaciensis], the Portuguese, and Giovanni Antonio Magini of Padua, and others almost without number.

On the Parts of Astronomy

[Margin: What Astronomy is.]

In order that we may more correctly gather what parts Astronomy comprises under itself, we shall not inappropriately take our beginning from the explanation of the name. This science concerning celestial things, then, which is called Astronomy, according to the meaning of the name and its etymology seems to signify nothing else than the reckoning and law of the stars, so that Astronomy is the same as the science of the stars. For it treats of the motions of the stars, and of the fixed and perpetual alternations and laws of those motions; of the order of the stars and heavens, their site and position, rising and setting, multitude and magnitude, distance from the earth and from one another, their mutual conjunction, eclipses, and other things of this kind. This is by others usually called Astrology. For in our age Astronomy and Astrology are used almost interchangeably for the same science; and therefore we too shall use these names without distinction in these our commentaries, although some mathematicians would have some distinction established between these terms — that Astronomy should signify that doctrine which considers the motions of the heavens and stars, while Astrology should be applied to that art which, from the revolutions of the heavens and the conjunctions or oppositions of the stars, predicts future events and certain presentiments and significations bearing on the safeguarding of health and of the household.

[Margin: Astronomy and Astrology — in what way they differ from each other.]

Astronomy is divided into Theoretical — that is, contemplative — and Practical, that is, working and active. Theoretical astronomy considers the whole machine of the world as it is in itself, describing the constitution of the world and dividing the whole framework of the world into the ethereal and the elementary region. Then it investigates the number, magnitude, and motion of all the celestial bodies,

and speculates on the risings and settings of all the stars and planets. In like manner it considers the figures and images of all the constellations and signs, and teaches how to compute by calculation of numbers the true places both of the fixed stars and of the wandering ones, which they call Planets. Likewise it most diligently inquires into the progressions, stations, retrogradations, conjunctions, and oppositions of the planets, together with the eclipses of the luminaries — namely the Sun and Moon — and other such things almost infinite in number. And this Astronomy is expounded partly in the *Almagest*, or Great Construction of Ptolemy, or also in the *Epitome* of Regiomontanus, in the astronomical work of al-Battānī [Albategnius], in the little work of al-Farghānī [Alfraganus], in the *Theorics of the Planets* of George Peurbach, in the *Celestial Revolutions* of Nicolaus Copernicus [*De Revolutionibus*], and in the volumes of almost countless other authors; partly by very many instruments devised for this purpose by astronomers with the greatest industry, to set the celestial motions before our eyes — such as the common Astrolabe, or planisphere of Ptolemy, the Astrolabe of Gemma Frisius, the Catholicon or universal instrument, the universal Planisphere of Johannes de Royas, the Astronomical Ring, the Quadrant, the Torquetum, the Astronomical Radius [cross-staff], and other things of the kind; and partly, finally, Theoretical Astronomy is taught in that part which is usually called tabular, because through numbers arranged into tables astronomers scrutinize the motions of the heavens — such as the tables of Alphonsus king of Spain [Alphonsine Tables], of Regiomontanus, of Bianchini of Ferrara, and of Nicolaus Copernicus (which tables are usually called Prutenic [Prutenicae]), and of many others.

[Margin: The division of Astronomy into Theoretical and Practical.]

Practical Astronomy, however — which others call Judiciary, or Prognostic, that is, Divinatory — accommodates all these things to the use of human life. For it contemplates the complexions and natures both of the signs and constellations, and also of the Planets and the other stars, and explains which signs are hot, which cold, which temperate, which masculine, which feminine, and other such things. Again, from the motions of the orbs and stars it predicts future events in these lower regions. But since many have rashly and wrongly dared to add many things to this part of Astronomy, and have so amplified this prognostic part that it has now become an altogether superstitious and hateful matter, and is deservedly held suspect by the Church, and wonderfully condemned by St. Augustine in his books *On Christian Doctrine* [*De Doctrina Christiana*], therefore I judge that nothing at all should be said of it by us — except that it is utterly overthrown by John Pico della Mirandola [Giovanni Pico della Mirandola] in his

twelve books written against the astrologers; by Francesco Pico, his nephew, in his books *On Foreknowledge* [*De Praenotione*]; by Antonio Bernardi della Mirandola, Bishop of Caserta, in books 22, 23, and 24 of the *Monomachia*; by Michael Medina in Book 2 *On the Right Faith in God*, chapter 1; and by Julius Syrenus in his books *On Fate*.

[Margin: Judiciary Astrology is a superstitious matter.]

On the Excellence of Astronomy

Since the nobility of any science, on the authority of Aristotle, ought to be derived from two things — namely, from the excellence of the subject with which it deals, and from the certainty of the demonstrations by which it confirms what it considers (for he says that that science is the more excellent and noble which either deals with more excellent things or is more certain) — how great the dignity and excellence of Astronomy is can be recognized without obscurity from both heads. For if we look to the subject or matter of Astronomy, it must be granted, and we are compelled to confess, that almost the supreme place among all the other human disciplines, or those acquired by the natural light, is to be conceded to it. For this science treats of the celestial bodies, which are the most noble of all, for many reasons. First, because, according to the philosophers, they are ungenerable and incorruptible, free from all corrupting alteration, and, in short, unchangeable by any motion that in any way varies their substance — which is not the case with the other bodies of which the natural philosopher disputes. For although the elements, as Aristotle holds together with the philosophers, cannot as wholes be generated or corrupted, yet in respect of their parts they are subject to generation and corruption. Second, because the celestial bodies are the cause of all these lower things, as Aristotle holds in *Meteorologica* I, where he says that the lower world must necessarily be continuous with the higher motions, so that all virtue may be derived from them. Likewise in *Physics* VIII he asserts that all things are produced by means of the motion of the heaven, and on that account he did not hesitate to call the celestial motion the life of all beings. Again, in *On the Heavens* II [*De Caelo* II] he affirms that the heaven acts upon these lower things by means of light and motion. Finally, in *On Generation and Corruption* II he testifies that, on account of the motion of the Sun and of the other planets in the oblique circle — that is, in the Zodiac — generations and corruptions come about in these lower regions; and he affirms the same in very many other places, in which almost the whole assembly of philosophers agrees with him. Third, because the celestial bodies are nearer to the most noble and first being, namely to the glorious God; indeed, according to Averroes, the

celestial body is the mediator and bond of the higher things with the lower, and the place of things eternal and divine. For all philosophers and nations, however barbarous, place God in the heaven as in his proper seat. For although God is not bound to this or that place, but exists everywhere (which belongs to no other things), yet he is placed in the heaven as in the more noble part of the world, where he most manifests his omnipotence and goodness, as the Theologians assert. Fourth and last, because among all other bodies the celestial bodies possess the most noble place, namely the supreme; and the higher bodies are, the more noble they must be esteemed, as all philosophers confess. For just as the earth is the lowest of all the elements in site and place, so too it is the last in dignity; to it in nobility succeeds water, because it occupies a higher place; then follows air, because by its lightness it transcends water; and lastly fire obtains the primacy among all the elements, since it is set above them all. There accrues also to the dignity of the celestial bodies the fact that they possess most noble accidents — namely both motion and circular figure (as we shall show in its own place), light, and other things of this kind — so that not undeservedly does Aristotle seem to have called these bodies divine.

[Margin: The excellence of Astronomy from its subject.]

[Margin: The celestial bodies are the most noble of all.]

But if we consider the mode of demonstrating which Astronomy employs, no one will deny that all the natural disciplines are far surpassed by this science. For to confirm the matters of which it treats, it employs the most effective demonstrations — namely the Geometrical and Arithmetical — which, in the opinion of all philosophers, obtain the first degree of certainty. Wherefore not without reason...

[Margin: The dignity of Astronomy from its mode of demonstrating.]

(Continuing from the preceding page, on the nobility of astronomy from its mode of demonstration.)...on both counts — namely by the nobility of its subject and by the certainty of its demonstration — Ptolemy, at the beginning of the *Almagest*, held astronomy to be simply the first among all the other sciences. For he says that natural philosophy and metaphysics, if we consider their mode of demonstration, ought rather to be called conjectures than sciences, because of the multitude and disagreement of opinions about them.

DE VTILITATE ASTRONOMIAE.

(On the Usefulness of Astronomy)

[Margin: Astronomy is useful for theology.]

How great is the usefulness — indeed the necessity — of this most excellent science can scarcely be explained. For astronomy seems in some way to prepare the road to all the disciplines and to point out a safe approach to them. It is above all of the greatest service to sacred theology. For from the contemplation of the celestial orbs and of their motions, which always keep themselves in the same manner and unchangeably, the greatness and excellence of their Creator is made known. Hence Ptolemy, at the beginning of the *Almagest* and following the tradition of the Arabs, not without reason declared this one science to be the road and pathway to the knowledge of God most high.

From this opinion St. Paul does not differ, where he says (Romans 1) that "the invisible things of God are clearly seen, being understood from the creation of the world by the things that are made," and so on. In that passage, when he speaks of all created things, he seems most of all to have understood the celestial bodies. For these, by their beauty, their magnitude and multitude, by the wondrous variety of their motions and influences, and by their perpetual stability, commend in a marvellous way the goodness, wisdom, and providence of the glorious God, and most powerfully draw us to the knowledge, love, and admiration of Him. This the royal prophet David admirably testifies when he says: "The heavens declare the glory of God, and the firmament proclaims the work of his hands." And again: "For I will behold thy heavens, the works of thy fingers, the moon and the stars which thou hast founded." This opinion is supported by what is written in the book of Wisdom, chapter 13, where it reads thus concerning the celestial bodies: "Let those who, delighted by their beauty, supposed them to be gods, know how much more beautiful is the Lord of them; for by the greatness of the beauty and of the creature the creator of them may be seen so as to be known." From this it has come about that astronomy, which treats of these most excellent bodies, is by many called natural theology.

[Margin: Astronomy is useful for metaphysics, physics, medicine, poetry, and navigation.]

This discipline also serves metaphysics, since on the authority of the astronomer Aristotle, in Book 12 of the *Metaphysics*, gathered the number of the intelligences from the number of the orbs. By the same reasoning, from the motions of the

celestial orbs the power and substance of the intelligences that move them can best be investigated and grasped.

Nor does this science contribute a little to natural philosophy, since the philosopher borrows much from the discoveries and demonstrations of astronomy, as may be seen in the second book of *On the Heavens* and in other books of Aristotle. Moreover, from the unchanging celestial motion Aristotle, in the eighth book of the *Physics*, tracked down the first mover, eternal and free from all change.

To medicine, too, astronomy is so conducive that Galen, the prince of physicians, warns the sick not to entrust themselves to the hands of doctors ignorant of astrology. For, he says, medicines administered at unsuitable times profit little or nothing; indeed, they often do harm. But these seasons can be known only from the motions of the planets, which belong to the astronomer.

And what would the poets produce if they were entirely deprived of this splendid discipline? For what in their poems or writings is fine or excellent that is not filled with the motions of the stars, the rising and setting of the signs, and the constellations? Add to this that no one will understand the poems of the ancients unless he has first been thoroughly versed in the study of astronomy.

The art of navigation, too — so useful and necessary to the human race — can by no means worthily guard its own bounds without the aid of astronomy, as all writers on the nautical art frankly admit.

[Margin: Astronomy is necessary for churchmen.]

Astronomy is furthermore quite indispensable to men set in ecclesiastical dignity — as St. Augustine testifies — for calculating more exactly the conjunctions and oppositions of the two luminaries in relation to the movable feasts, and other matters of that kind that concern the honor and standing of the Church. It was through neglect of this astronomy that, right up to the year of our Lord 1583, we for the most part strayed so far from the true observance of the sacred Easter and of the other movable festivals that the Jews, the Turks, and other nations reproached us marvellously for our ignorance. This indeed the most numerous and weighty mathematicians very often, and very bitterly, lamented; although it is said that at an earlier time Nicholas V, Leo X [Popes Nicholas V and Leo X], and many other supreme pontiffs wished to apply a remedy, if only there had then been available to them an abundance of outstanding and excellent astronomers to whom they could safely have entrusted the task of correcting the calendar. Astronomy has, moreover, among its other almost infinite uses, this notable one

as well: that it demonstrates the fixed limits of the year and the true description of its parts, once the equinoxes and solstices have been carefully noted; it defines the measured intervals, measures out and distinguishes most accurately the alternations of days and nights, their intervals, and their lengths. But by divine goodness and providence it has at last come about that in our own times Gregory XIII [Pope Gregory XIII], best and greatest pontiff, put the final hand to the correction of the Roman calendar and brought the equinoxes and solstices back to the times of the Council of Nicaea. Hence it is that henceforth we shall always celebrate the most holy Easter, together with the other movable feasts, rightly and in accordance with the decrees of the holy Fathers and of the Roman pontiffs. In this matter I too, by command of the same supreme pontiff, expended no small effort and labor; and toward the explanation of the new calendar I published, by order of Clement VIII [Pope Clement VIII], supreme pontiff, a fairly large volume, in the year 1603.

[Margin: Astronomy is useful for cosmography.]

Astronomy is, besides, as it were the fountain and origin of cosmography, since without the aid of this science the description of the terrestrial globe, the doctrine of place and interval, the designation of regions, and other matters of this kind — which bring a wonderful adornment together with usefulness to all commonwealths — can in no way be perfectly obtained.

[Margin: Astronomy is useful for the governance of the state.]

I pass over the fact that this science is in the highest degree necessary to the administration of the commonwealth, to agriculture, to the waging of wars, and the like. Of this history sets before us many examples. Sulpicius [Gaius Sulpicius Gallus], on account of his knowledge of the lunar eclipse — which is taught only in astronomy — is reported to have freed a whole army from immense fear. Historians relate that Pericles [Pericles of Athens] did the same, as did Dion the Sicilian [Dion of Syracuse]. But Nicias, the general of the Athenians, through ignorance of this matter, was struck with fear and did not dare to lead his fleet out of harbor — to no small loss and injury of the Athenian commonwealth.

Nor should it be passed over that not so many years ago — as Juan de Rojas [Juan de Rojas Sarmiento] reports in the letter to the Emperor Charles V [Charles V] which he prefixed to his commentary on the universal planisphere — Columbus [Christopher Columbus], leader of the army of Ferdinand king of the Spains, in those earlier years in which the new world of the West Indies was discovered and explored, rescued his whole Christian army near the island of Jamaica from utter

want by the aid of this divine discipline. For when the entire Spanish army had been placed in the last extremity of life, and the commander could by no means obtain provisions from the people of Jamaica — for in this way the barbarians hoped easily to overcome the Christian army by hunger and by arms — it was announced to the rulers of the Jamaicans that, unless they supplied to him and to all his men the necessities for sustenance, very great and utmost evils threatened them: in proof of which they would, not long after, see the moon darkened, which he himself, being eminently versed in astronomy,

already knew was about to fail. At first the barbarians scorned the commands and threats of the Christian commander; but when, at the appointed time, they saw the moon gradually failing, and did not understand the cause of it, then for the first time giving credence to his words, they supplied the Christians with provisions in abundance, and, throwing themselves at the feet of the commander and of the rest of the soldiers, they earnestly begged forgiveness. I say nothing of many other similar examples — so that Ptolemy would seem not without reason to have declared that a good astrologer prevents much evil, and that a wise astronomer can procure much good for men.

[Margin: Among the ancients astronomy was held in great esteem.]

To all these praises this is added: that this science of celestial things — astronomy, that is — has always been held in great esteem. Thales of Miletus [Thales] took such delight in this art that he philosophized in complete poverty and seemed to have no care whatever for his household affairs. When, as often happens, he was mocked by idle men as though forgetful of his own advantage, he — having learned from astrology of the marvellous fertility of that coming year — is said to have bought up beforehand all the olives in the Milesian countryside before they had begun to blossom, and to have come out extremely rich. In this way he wished to show the Milesians that a prudent and wise man can make money if he chooses.

It should not be passed over in silence that among the Egyptians no priests and no pontiffs were appointed unless they were mathematicians (for so they called astrologers, by *antonomasia*); that among the Lacedaemonians none sat beside the kings unless they were mathematicians; that among the Persians none were saluted as kings unless they were mathematicians. Indeed, Alexander the Great [Alexander] is reported to have written thus (though this be far from a Christian): "O most merciful king, neither rise, nor sit, nor take food or drink, nor do absolutely anything without the counsel of a skilled mathematician, if it can possibly be done."

By this discipline, we read, Dionysius the Areopagite [Dionysius the Areopagite] recognized that the eclipse of the sun which occurred at the full moon — which could not then happen by the powers of nature — announced the Passion of the Lord, when he cried out: "Either the God of nature suffers, or the fabric of the world is being dissolved." A little later, by the preaching of the Apostle Paul, he was converted to the faith of Christ. This discipline, if we believe Josephus, Abraham first handed on to the Egyptian priests; in it Moses, that eminent leader of the people of God, excelled, as St. Stephen testifies in the Acts of the Apostles, saying that he was instructed in all the wisdom of the Egyptians — which indeed consisted chiefly in astronomy.

[Margin: Kings and emperors have always taken delight in astronomy.]

To all these praises add this: that there is no profession in which the greatest kings and emperors have taken more delight than in astronomy — as also in our own age. For this astronomical study was pursued with the greatest care by Julius Caesar [Julius Caesar], emperor of the Romans, who, as the histories relate, brought back with him from Egypt Sosigenes, a distinguished and skilled mathematician, whose services he used greatly in the ordering of the year and the course of the sun; and from that time the mathematical arts began to be more diligently cultivated in Italy. This Caesar took such delight in this study that of himself he said, in Lucan [Lucan]:

.....media inter praelia semper Stellarum, cœlique plagis, superisque
vacauit.

"...ever amid the midst of battle I have had leisure for the stars, for the tracts of heaven, and for the gods above."

Following him, the Emperor Hadrian [Hadrian] was so versed in the motions of the stars that, as the histories relate, he used to write out for himself each year his own prognostication.

What shall I say of Alfonso, king of the Spains [Alfonso X of Castile]? He was so learned in the science of the stars that he composed that notable work, the Astronomical Tables.

I pass over, among the more recent, the Emperor Charles V, ever Augustus, and Ferdinand his brother [Ferdinand I], who in a marvellous way found refreshment in these studies and in astronomical instruments; whose example was followed by Philip, king of the Spains [Philip II], the Emperor Maximilian

[Maximilian], Emmanuel Philibert, Duke of Savoy [Emmanuel Philibert], and very many others who are still living today.

[Margin: From no science is greater pleasure derived than from astronomy.]

To this it is further added that from no other human science is so much pleasure and delight taken as from astronomy. For what can be more agreeable, more charming, more sweet, and finally more delightful than to survey with the eyes that most lovely array of so many and so great lights? That there is nothing in this life which more delights the mind of man, very many weighty authors affirm — so that it ought not to seem so strange why some have spent twelve whole years, some forty, some more or fewer, on the mountaintops under the open sky, for the sake of observing the stars. Indeed, Plato [Plato] did not scruple to assert that eyes have been granted to us by God for the sake of astronomy alone. To this Ovid [Ovid], the most ingenious of poets, seems to allude when he sings thus:

Finxit in effigiem moderantum cuncta Deorum, Pronaque cum spectent
animalia cætera terram, Os homini sublime dedit, cœlumque videre
Iussit, & erectos ad sidera tollere vultus.

"He shaped [man] into the likeness of the gods who govern all things; and whereas the other animals look bent down toward the earth, he gave to man an uplifted countenance, and bade him look upon the sky and raise his upright face to the stars."

[Margin: And in another place.]

Felices animæ, quibus hæc cognoscere primum, Inque domos superas
scandere, cura fuit.

"Happy the souls whose first care it was to gain this knowledge, and to climb up to the mansions on high."

[Margin: And a little after.]

Admouere oculis distantia sidera nostris, Aetheraque ingenio supposuere
suo.

Sic petitur cœlum, non vt ferat Ossan Olympus, Summaque Peliacus
sidera tangat apex.

"They brought the distant stars near to our eyes, and subjected the heavens to their genius. Thus is heaven attained — not that Olympus should bear up Ossa, and the peak of Pelion touch the topmost stars."

For in this most beautiful art those things are made clear than which nothing greater or more beautiful can be conceived. By it the powers of our mind are seized and drawn away from the things of this earthly world, which never remain in the same state, to those things which lie subject to no corruption. In it, with contempt for the narrow confines of this earthly speck, the mind wanders with wondrous sweetness and delight through the spacious air, among the golden Suns, the silvery and changing Moons, and the shining stars. Let these few things, out of many that could be brought forward concerning the praises and usefulness of this excellent discipline, suffice to have been said. Now let us proceed to the exposition of the author of the *Sphere*.

PROOEMIUM IOANNIS DE SACRO BOSCO.

(The Prooemium of Johannes de Sacrobosco)

(Sacrobosco's base text — the lemma:)

[Margin: The order the author keeps in the treatment of the sphere.]

We divide the treatise on the sphere into four chapters. First we shall speak of the composition of the sphere: what the sphere is, what its center is, what the axis of the sphere is, what the pole of the world is, how many spheres there are, and what the shape of the world is.

In the second, of the circles from which the material sphere is composed, and from which the supercelestial sphere — which is represented by it — is understood to be composed.

In the third, of the rising and setting of the signs, of the diversity of days and nights, and of the division of the climes.

In the fourth, of the circles and motions of the planets, and of the causes of eclipses.

COMMENTARIUS.

(Commentary)

[Margin: The title of this work.]

This little book is entitled *On the Sphere* — that is, on a certain globular or round figure containing various and diverse circles, which is customarily called the *material sphere*, devised with marvellous artifice for this purpose: that we might be able to have some knowledge of celestial things. For since it is not in our power to ascend to the heavens whenever we please, so that we might there perceive by sight the degrees and circles once we have considered them, and revolve them from wherever and to wherever we wish; and since, again, the span of a man's life does not suffice to wait for all the things that are to be in the heaven, nor can any man, while he lives, behold all the things that are present; and further, since it is now day here and night there, and to some the Sun (or any other star you please) is now rising while to others it is setting, and some dwell under the oblique sphere and others under the right sphere; and since, finally, no one can dwell in all places at the same time — all of which, nevertheless, are required if we are to have any knowledge of the things that are in that celestial region — for this reason the craftsmen of this discipline, endowed with wondrous learning, with great industry and the highest ingenuity devised some material instrument which might set before our eyes all those things which we imagine in the heaven and desire to know. This instrument, then, is called the material sphere, about which the author here has entitled his little book — not that he wishes, as if by his own set purpose, to discourse about this sphere; for his principal intention in this book is to treat of that celestial sphere, for whose sake this material one was devised. But since, as we have said, knowledge of the things that appear in the heaven cannot at all be acquired without the use of the material sphere, he therefore entitled his little book *On this Sphere*, yet in such a way that all the things that are said about this sphere are to be referred to that celestial one.

[Margin: Why the material sphere was devised by astronomy. It is chiefly the celestial sphere that is treated in this book. The intention of the author. The subject of astronomy and of his book, and what it is.]

The whole aim of the author, then, is set in this: that through the material sphere he may make clear to us the constitution and figure of the whole world, and may teach how the celestial bodies are moved, by what reasoning the stars and signs rise and set, and finally what follows from this rising with respect to days and nights in the various climes — so that this treatise is almost a compendium of the whole of astronomy. Wherefore not inappropriately we lay down the same subject for this little book as for the whole of astronomy, namely the *movable celestial body about the center*. For according to the principles of the philosophers, the subject of any book ought to have three conditions. First, that the parts of the

subject and the properties of that which is called the subject be set forth in that book. Second, that all the things which are treated in that treatise be referred to the subject itself. Third, that that which is constituted the subject of that book distinguish the book — or that science — from all others. All these conditions belong to the movable celestial body about the center with respect to this little book. For in it the subject parts of the movable celestial body are investigated — namely how many particular ones there are in number — and its properties are most diligently explained, such as motion, position, figure, quantity, and the like. Next, all the things treated here are considered by attribution to the movable celestial body about the center, as that earth and water make up a round body, that the earth is situated immovable at the center of the world and is a point with respect to the firmament, and other things of that kind; for the account of the things that appear in the celestial bodies could not be assigned without this cause. And this was the reason why Ptolemy in the *Almagest*, and our own author, and Alphraganus [al-Farghānī], and all the other astronomers said much about the four elements, and especially about the earth — indeed, so that they might the more easily explain the celestial motions, which take place about the earth as about a center. Lastly, through the movable celestial body about the center this little book is distinguished from all other disciplines. For although Aristotle too treats of the heaven in the book *On the Heavens*, yet he does so on a different principle than the astronomer does. For the philosopher chiefly endeavors to investigate the nature and substance of the heaven, and whatever he asserts about the motion of the heaven in particular, all of it he begs from the astronomers; whereas the astronomer treats of the same celestial body on this precise principle: insofar as it is movable about the center of the universe — that is, so that he may assign the periods and varieties of all the motions, always understanding only local motion. For the celestial bodies, according to the philosophers, do not admit of other motions, or of alteration and the like: for they do not admit — according to the philosophers — of corruption, augmentation, diminution, generation, and corruption.

[Margin: What is contained in each of the chapters of this book.]

In this Prooemium, therefore, the author makes clear to us his intention and his manner of proceeding, dividing the whole treatise into four parts. In the first of these he declares that he will set forth the parts of the sphere and what the shape of the world is — which is indeed most worthy to be known. For how will it not be most delightful, as well as most useful, to know in what manner the fabric of this world, by which we are covered and in which we continually pass our life, is constructed and arranged? In the second he promises that he will speak of the

circles of the sphere. In the third and fourth he declares that he will discuss the motions of the stars — that is, the rising and setting of the signs and constellations. But since the treatment of the celestial motions can be twofold — one which inquires into and unfolds the *first motion*, which is proper and peculiar to the *primum mobile*, from east to west, and carries all the other orbs along with it in the space of twenty-four hours; the other which considers and explains the *second motion*, which is peculiar and proper to the other heavens below the first —

the *primum mobile*, and it proceeds from west to east. For the individual lower orbs strain, in a way, against that first motion—each of them also by its own proper motions—the first motion by which they are dragged from east to west. Therefore our author, wishing to touch briefly on both treatments, in the third chapter deals with that first motion and with everything that happens on its account in various regions: namely, the rising and setting of the signs, which are perpetually carried by the *primum mobile* from east to west; likewise the variation of days and nights, which differs from place to place because of the differing rising and setting of the signs; and finally the climes, in which such variation is found. In the fourth chapter he discusses the circles, orbs, and motions of the planets, the causes of eclipses of the Sun and Moon, and those things that come about by reason of the second motion. And so, in a kind of compendium, he seems in this little book to have embraced the whole science of celestial things.

CAPVT PRIMVM. [Chapter One]

The sphere, then, is described by Euclid as follows. A sphere is the passage of the circumference of a half-circle which, its diameter held fixed, is carried round until it returns to its own place. That is, a sphere is a round, solid figure of the kind that is described by the arc of a semicircle carried around.

[Margin: Definition of the sphere.]

COMMENTARIVS.

This first chapter contains the principles and foundations of the whole of Astronomy, on which Ptolemy [Ptolemy] too discourses most learnedly in the first Book of his *Great Composition* [*Almagest* I]. It may most conveniently be divided into four principal parts. The first part contains five definitions: two of the sphere, the third of the center of the sphere, the fourth of the axis of the world, and the fifth of the poles of the world.

[Margin: What is treated concerning the sphere in the first chapter.]

In the second part are contained certain divisions of the sphere. In the third, the author explains what the shape of the world is. In the fourth, finally, he demonstrates certain conclusions about the celestial and elemental regions.

Now, so that the two definitions of the sphere may be understood, it must be observed that among Mathematicians only three kinds of quantity are found. Under the first are contained all lines, whose extremities are points. Under the second are included all surfaces, which are bounded by lines. The third kind, finally, comprises bodies, or solids, whose boundaries are surfaces.

[Margin: There are only three kinds of quantity.]

A line is length without breadth, having only one dimension, along which it is divided lengthwise. A surface is breadth without depth, admitting only two dimensions, one according to length, the other according to breadth. A body, finally, or solid, is a magnitude admitting three dimensions: namely length, breadth, and thickness or depth.

[Margin: What a line is. — What a surface is. — What a body is.]

And no other magnitude or quantity, besides these three, is considered by the Mathematician, because no more can be given—since not even more than the three aforesaid dimensions can be found. Although Aristotle [Aristotle], at the beginning of his books *On the Heavens* [*De Caelo*], tries to confirm this by many probable arguments, the Mathematicians nonetheless demonstrate the same point most clearly by a single proof, which I have chosen to set down here, since it is found well explained by few.

It must be known, then, that all things are measured by Mathematicians by the perpendicular line, so that any magnitude is said to be as long as is the perpendicular drawn from one extremity of the figure to the other. Thus, in the parallelogram ABCD here proposed, the length will be the perpendicular line LM, drawn from point L on side AD to the opposite side BC (produced), or the perpendicular AF. In the same way they say that the breadth of any quantity is as great as the perpendicular drawn from one side to the other: thus the breadth of the proposed parallelogram will be the perpendicular BE, extended from side AB to side DC (produced). Depth, finally—that is, thickness or height of any body whatever—is judged to be as great as the perpendicular drawn from one part to the other. For which reason Euclid, most beautifully, at the beginning of the sixth

book, in defining the height of any figure, said that it is the perpendicular line drawn from the vertex to the base.

[Margin: Mathematicians measure everything by the perpendicular line.]

Diagram. A parallelogram construction illustrating measurement by perpendiculars, drawn with several internal and produced lines. The four corners of the parallelogram are labelled A (top left), B (top right), C (bottom right), and D (bottom left); several perpendiculars and their feet are marked within and below it. Labels read on the figure:

- A (top left corner)
- G (on the top side, between A and B)
- B (top right corner)
- L (on the left side / near AD)
- M (interior, foot of the perpendicular LM)
- F (interior toward the right side)
- D (bottom left corner)
- K (along the bottom, right of D) [?]
- I (along the bottom, right of K)
- C (bottom, center-right corner)
- E (bottom right)
- [?] (a further label set below C, near the base — possibly H) [?]

The perpendiculars discussed in the text are LM (from L on AD), AF, BE (from AB to DC), and GH, where GBEH forms a parallelogram; the non-perpendicular lines GI, GK are also referenced.

The reason why Mathematicians measure everything by the perpendicular line is the one Ptolemy adduces in the little book he wrote *On the Analemma*, and which Simplicius took from a book of the same Ptolemy *On Dimension*: namely, because the measure of anything ought to be settled and determinate, not indefinite. Now, among all the straight lines by which any measurement is taken, only the perpendicular line is of certain and determinate length; all the others are indeterminate. Thus, in the parallelogram above, the perpendicular line BE, by which we took the breadth of the figure, is—among all the lines that can be drawn from side AB to side DC, whether produced further or not—the only one of settled and invariable quantity. For from whatever point of side AB you draw a perpendicular to side DC, this will have exactly the same length as the perpendicular BE—such as is the perpendicular GH. For since GBEH is a

parallelogram (as is plainly established from the first book of Euclid), the opposite sides BE, GH will be equal; and so of the rest.

[Margin: Why Mathematicians measure everything by the perpendicular line. — a. Euclid I.34.]

This by no means happens with the other lines, which are not perpendicular. For from any point of side AB, to side DC, innumerable non-perpendicular lines can be drawn, of which one is greater than another, and the perpendicular drawn from the same point is smaller than all of them—as is evident in the lines GH, GI, GK. Since this is so, it is not without great design—nay, with Nature herself as guide—that the measures of quantities are taken by perpendicular lines, which alone are determinate and invariable, and not by the others, which can be drawn in infinite ways, now shorter, now longer. Just as, not only among Mathematicians but also among ordinary people, distances and the intervals of journeys are reckoned along straight lines, which are the shortest,

[Margin: b. Euclid I.19.]

and not along curved ones, which can be varied in six hundred ways. Thus the space lying between the two points A and B is defined to be only as great as the straight line ACB, and not as great as the circular line ADB, or AEB, or AFB; for these are not of the same length, but one is greater than another, whereas the straight line is always the same, and the shortest of all that can be drawn from point A to point B.

Diagram. A figure showing a straight base line with a series of nested arcs above it, illustrating that the straight line between two points is shorter than any arc joining them. Labels read on the figure:

- A (left end of the base)
- C (midpoint of the straight base line)
- B (right end of the base)
- D (lowest arc, ADB)
- E (middle arc, AEB)
- F (highest arc, AFB)

The straight line ACB is the shortest path from A to B; the successive circular arcs ADB, AEB, AFB are longer and unequal.

This, then, being shown—namely, that all things are measured by the perpendicular line—it will easily be demonstrated that there are, from the nature

of the thing, only three dimensions in every corporeal thing: one according to length, another according to breadth, and the third according to depth.

[Margin: Why there are only three dimensions.]

The reason for this is that at any point taken within a body, only three perpendicular lines can be set up—such that each of them is at right angles to the other two—and no more; of which any two, taken in any way, will lie in one and the same surface, while the remaining one lies in another, different surface. By one of these lines, then, the length of the body is measured, by another its breadth, and by the third its height or depth. From these things it is established why a body has only three dimensions. Hence some are not unfitting when they define a body thus: A body, or solid, is a magnitude in which three straight lines, intersecting one another at right angles, can be drawn through one and the same point; whereas in a surface only two can be drawn.

That at any point three lines can be drawn, each perpendicular to the other two, we shall demonstrate as follows. In the figure above, where the two straight lines AB, BE cut one another at right angles at B: if from B a straight line is understood to be raised at right angles to the plane in which those straight lines lie (for two intersecting straight lines are always in one plane), this line will be perpendicular to both AB and BE, by the third definition of the eleventh book of Euclid; and consequently each of them in turn will be perpendicular to it. From which it follows that any one of them is perpendicular to the other two.

[Margin: a. Euclid XI.2. — b. Euclid XI.12.]

That no other line, however, can be perpendicular to these three, we shall make clear in this way. Let there be drawn, if it can be done, a fourth line from B perpendicular to the straight lines AB, BE; this will necessarily be at right angles to the plane in which the straight lines AB, BE lie. Since, then, the third line too has been raised at right angles to the same plane, there will be drawn from point B two straight lines perpendicular to the same plane on the same side—which cannot happen.

[Margin: c. Euclid XI.4. — d. Euclid XI.14.]

These things being rightly understood, the two definitions of the sphere will easily be grasped. For the first definition runs thus (which the author testifies he took from Euclid): *A sphere is the passage of the circumference of a half-circle which, its diameter held fixed, is carried round until it returns to its own place—*

that is, as the author himself explains: *A sphere is a round, or solid, figure of the kind that is described by the arc of a semicircle carried around.*

[Margin: Explanation of the preceding definition of the sphere. — The definition of the sphere handed down by Euclid.]

For the sphere is not the passage or revolution itself, but is produced from such a passage or revolution—so that this predication, "a sphere is a passage," is causal, and by no means formal. For the sense is that a sphere is a solid of the kind understood to be circumscribed by the arc of a semicircle in one complete revolution, its diameter remaining immovable and fixed; and that Solid is understood to be circumscribed which is continuously touched by the arc as it is carried around. Thus, if one takes clay, or any other workable material, into which some diameter is inserted to serve as the material's thickness, and the circumference of the semicircle, applied at both ends of this diameter, is carried around until it returns to the place from which it began to move, all unevenness of the clay will be removed, and a spherical or round figure will be produced. Such a round body, then, described by the circumference of the semicircle, is called a sphere.

But someone will say: since the circumference of a semicircle is a certain curved line devoid of all breadth, and since—by the consensus of all Mathematicians—nothing but a surface is produced by the imaginary drawing or motion of any line, how can it be that a sphere, which is a solid thing (as the author himself asserted in explaining his definition, and as will presently be added again from Theodosius), is generated from the drawing, revolution, or turning-round of the circumference of a semicircle? For from such a carrying-round only the outermost surface of the sphere is produced.

[Margin: A difficulty against the author's preceding definition. — Solution of the difficulty.]

To this it must be answered that this definition of Euclid has not been faithfully reported by the author. For Euclid, in Book XI, definition 14, did not say that a sphere is produced from the turning of the *circumference* of a semicircle about the diameter, but from the drawing and revolution of the *whole* semicircle—which, indeed, is agreed to be a surface. Wherefore, just as from the revolution of a finite straight line about one fixed end a circle is described (so that the line itself makes the surface, while the other end—the point—marks out the circumference), so likewise from the turning-round of the surface of the semicircle the solidity of the sphere will be produced, and from the revolution of

the semicircumference the outermost round surface; and in this way the perfect spherical body arises.

[Margin: Another definition of the sphere handed down by Theodosius.]

A sphere is also described by Theodosius thus: A sphere is a certain solid contained by a single surface, in the middle of which is a point, from which all lines drawn to the circumference are equal.

COMMENTARIVS.

This is the second definition of the sphere, taken from Theodosius, *On the Elements of Spherics*; in it three parts are contained. The first is "solid"—that is, a body—and it is set down to distinguish it from plane figures, of which sort are the circle, the square, and so on. The second, "contained by a single surface," is added to exclude solid figures comprised by several surfaces, such as a cartwheel, a millstone, a pyramid, a cube, and so on. But since surface is of two kinds—one plane, which on every side can be measured exactly by a straight line, such as the surface of a well-leveled wall, or of a board, or of a well-stretched sheet of paper; the other curved, which cannot be measured on every side by a straight line, and this is either concave, as is the inner surface of some water-jar, or convex, of which sort is the outer surface of a water-jar or of a ball—the sphere is contained by a curved surface, and that a convex and single one. The third part, finally, is "in the middle of which," etc., and it is joined on to distinguish it from very many solids that are indeed contained by a single surface, but in which nevertheless no such point can be assigned: such as an egg-shaped body, a lentil-shaped body, and others of this kind.

[Margin: Explanation of the definition of the sphere handed down by Theodosius.]

But if we compare this definition with the former, we shall find that the former furnishes us with the manner and technique of fabricating a sphere, whereas this one explains the substance of a sphere already fabricated; and for that reason the former should rather be called a description, and this one a definition. This definition of Theodosius, taken from Plato's *Timaeus* [Tymæo], Cicero elegantly expressed in his book *On the Universe*, speaking of the world in these words: *Therefore it was made globe-shaped—what the Greeks call σφαιροειδές* [Greek: σφαιροειδές (sphairoeides, "spherical, sphere-shaped")]—*every extremity of which is reached by equal radii from the center.*

[Margin: Comparison of the two definitions of the sphere with each other.]

For this definition also fits the whole world; since the world is a solid sphere, there being no vacuum in it, but all things being filled with bodies from the convexity of the world right down to its center, as Aristotle proves in the fourth book of the *Physics* [Aristotle, *Physics* IV].

But if we look into the matter more carefully, both of the aforesaid definitions of the sphere can be fitted rather to any globe or ball than to that sphere about which the author wrote his little book, and about which our discussion is chiefly to be. Therefore we shall adduce another description, in this manner: The sphere (of which we are to treat) is a certain round instrument, in which various circles, or rings, are contained, by which the motions of the heavens and the situation of the whole world are most conveniently explained. Such, indeed, is the instrument they call a *material sphere*.

[Margin: Description of the material sphere, which is treated here.]

Who were the first and most excellent inventors of this instrument is not sufficiently established. For some think that Atlas first devised the sphere, and that it was afterward carried into Greece by Hercules, as Pliny reports. Some, however, as the same author testifies, make Anaximander of Miletus the first inventor. Diogenes Laertius ascribes this invention to Musaeus. Others, finally, name yet other inventors, among whom is also counted Archytas of Tarentum, a writer of no small distinction. Cicero, however, and Maternus testify that Archimedes of Syracuse, that most subtle Mathematician, was the first inventor of the instrumental sphere, which would represent to the life that celestial sphere.

[Margin: Who are said to be the first inventors of the material sphere.]

For, in order to set before our eyes the composition, arrangement, and motions of the heavens, he fashioned (they say) a certain glass sphere, wholly transparent, with such craftsmanship that in it the globes of the planets—especially of the Sun and Moon—moved by their own motions into the different regions of the world, exactly as they move in the heaven itself. So perfectly and precisely did this glass sphere, built by Archimedes with the utmost care and art, imitate the celestial sphere. Of this sphere the poet Claudian wrote a most elegant epigram, which I have chosen to set down here:

[Margin: The wonderful sphere of Archimedes.]

When Jupiter beheld the heavens in a little glass, he laughed, and to the gods above spoke thus: Has the power of mortal effort advanced this far?

Now in a fragile globe my labor is made sport of. The laws of the sky, the constancy of things, and the ordinances of the gods— behold, the old man of Syracuse has transferred them by his art. An enclosed spirit serves the various stars, and drives the living work by fixed motions. A counterfeit Zodiac runs through its own year, and a feigned Cynthia [the Moon] returns with each new month. And now bold industry, rolling its own world, rejoices, and governs the stars with human mind.

And that point is called the center of the sphere. A straight line passing through the center of the sphere, touching its ends to the circumference on either side, about which the sphere revolves, is called the axis of the sphere. And the two points bounding the axis are called the poles of the sphere.

[Margin: What the center, axis, and poles of the sphere are.]

COMMENTARIVS.

Here, by the three remaining definitions, he declares what the center is, what the axis is, and finally what the poles of the sphere are; all of which are clear in the author.

The center of the sphere Euclid describes thus in Book XI: The center of the sphere is the same as that of the semicircle, from whose revolution the sphere is understood to be produced.

[Margin: What the center and axis of the sphere are, according to Euclid.]

The axis he defines thus, in the place cited: The axis of the sphere is that motionless line about which the semicircle (from whose turning, of course, the sphere is made) is turned. Proclus Diadochus, however, defines it thus: The axis of the world—which we have already said to be a sphere—is called its diameter, about which it revolves. From all these definitions it is evident that not every line which, passing through the center of the sphere, touches its ends to the circumference on either side, is called an axis (although it is called a diameter), unless the sphere revolves about it. For the diameter embraces far more than the axis, since the axis is something inferior, and the diameter something superior: every axis, indeed, is a diameter, but not conversely. For in the celestial sphere only those diameters can be called axes about which some motion takes place—and these are few—and the principal axis is the one that stretches from the North through the middle of the earth toward the South. Yet innumerable diameters can be assigned—all the lines, that is, passing through the center of the sphere;

may, even plane figures have diameters, such as the circle and so on, but not an axis.

[Margin: The distinction between the diameter and the axis of the sphere.]

For an axis is found only in solid bodies. Yet any diameter can also be called an axis, because a sphere can be revolved about it—just as about the axis of the world—although in fact it does not itself move. So too, among Geometers and Astronomers, every circle in the sphere is said to have its own proper axis, about which it would move circularly and uniformly, if it had to move—although in actual fact it does not move. An axis of this kind is a diameter of the sphere drawn through the center of the circle and standing at right angles to the plane of that same circle. And that diameter about which the heaven, or sphere, is turned is called the axis, by a likeness taken from the wooden axle upon which the wheel of some cart is turned; and this name is derived from "acting"—that is, from moving—because, of course, the world is turned about it without ceasing. This axis the poet Manilius elegantly depicted for us in these verses:

A slender axis is drawn through the cold air, and holds the world
balanced upon its opposite pivots; the starry sphere revolves about its
middle, and, itself unmoved, wheels its eternal courses...

The ancients also imagined that heaven and earth are supported by an axis.
Hence Cicero says:

the earth, which is held up by the axis that runs through it. Lucan alludes to this when he points out to Caesar his seat in heaven, writing:

If you should press upon a single part of the boundless sky, the axis will
feel the burden — the weight of the balanced heavens.

[Margin: The poles of the world.]

On the poles. Now there are two poles of the world — that is, the two points that terminate the axis. The one that is always visible to us here, living in Europe, and stands plainly in view, is called the northern pole (*Borealis*, *Boreus*, *Septentrionalis*, or *Aquilonius*). The astronomers, however, call it the Arctic pole — that is, the "Bear pole" — from a certain notable constellation which in Greek is called ἄρκτοι [Greek: arktoi, "bears"], in Latin *ursa* ("the Bear"), and which revolves perpetually around this pole. Most nations also call it "North"; the Italians call it *Tramontana*. The other pole is called the southern pole (*Australis*, *Austrinus*, *Meridionalis*, or *Notius*). The astronomers call it the Antarctic, because it is diametrically opposite the Arctic pole. This one is never visible to us: it

always lies hidden below our horizon by just as much as the other rises above that same horizon — here at Rome, for instance, by roughly 42 degrees. Virgil describes both poles beautifully when he says:

This vertex is always high above us; but the other, beneath our feet,
black Styx and the deep shades behold.

[Margin: Why the pole is called the "sea-star."]

Sailors call each pole a "sea-star" (*stella maris*) or "sailors' star" — not because the poles themselves are stars, but because near them are certain stars so close by that they are scarcely seen to move (though near the Antarctic pole no notable star has been found that is less than 30 degrees from the pole itself). Of these, the one nearest the Arctic pole is at the tip of the tail of the Lesser Bear; the one observed to be nearer the Antarctic pole is set in the left foot of the Centaur. And since sailors, keeping their eyes on these stars, steer their courses across the open sea by them, each has customarily been called the "sea-star" or "sailors' star."

[Margin: Why they are called "poles."]

The poles take their name from the Greek verb πωλέω [Greek: pōlēō, "to turn" or "to revolve"], which means "to turn" or "to spin around"; for the whole machinery of the world revolves ceaselessly about these two points. Moreover, some call these two points the "vertices" or "hinges" (*cardines*) of the world. For just as a door turns on its hinges, so too the entire structure of the world turns about these said points, which alone are motionless.

DIVISION OF THE SPHERE OF THE WORLD

[Margin: Division of the sphere according to substance.]

[Lemma] The sphere of the world, moreover, is divided in two ways: according to substance, and according to accident. According to substance it is divided into nine spheres — namely, the ninth sphere, which is called the first motion or the primum mobile; and the sphere of the fixed stars, which is called the firmament; and the seven spheres of the seven planets, of which some are larger and some smaller, according as they approach nearer to, or recede farther from, the firmament. Hence among these spheres the sphere of Saturn is the largest, while the sphere of the Moon is the smallest.**

COMMENTARIUS

This is the second part of this chapter, in which two divisions of the sphere of the world are set forth: one according to substance, the other according to accident. According to substance, the author divides the sphere of the world into nine spheres.

[Margin: "Sphere" is here taken to mean the celestial sphere.]

In this division, "sphere" is not taken in the sense that embraces all the bodies that compose the entire universe — that is, the heavens together with the elements. For on that reckoning there would be more than nine spheres, as will soon be evident when we discuss the number of the heavens and the elements and their order. Rather, it is taken to mean the celestial sphere, which indeed consists of, or is bounded by, two surfaces: a convex outer surface and a concave inner one — and this is properly called an *orb*.

[Margin: The difference between an orb and a sphere.]

For an orb differs from a sphere in this: a sphere is solid all the way to its center and is enclosed by only a single surface, namely the convex outer one; an orb is not like this, but is bounded by two surfaces, one outer and one inner — such as all the heavens are.

[Margin: "Sphere," or celestial orb, is taken in two ways.]

But since "sphere," or celestial orb, can be taken in two ways: in one way, for any orb distinct from another, whether it be concentric with the world or eccentric — that is, whether it has the same center as the world or a different one. In this sense each planet is said to contain its own orbs, the treatment and study of which belong to the *Theories of the Planets*, although our author too attempts to touch on them very briefly in chapter 4. In the other way, the celestial sphere is taken for a total orb, distinct from the others, which is everywhere equidistant from the center of the world and is concentric with the world both on its convex and on its concave side; and it is sometimes conceived as made up of several partial orbs that are arranged to produce the motion of a planet. In this sense each planet is said to have its own proper and peculiar orb, containing other partial orbs, some concentric, some eccentric.

[Margin: In what sense "sphere" is taken in this division.]

as is clear in the *Theories of the Planets*. It is therefore in this latter sense that "sphere" is taken in the present division — namely, for the entire celestial orb

which contains (if we are speaking of the heavens of the planets) several other partial orbs arranged to produce the planet's motion, whether these be concentric or eccentric. And so the author divides the sphere, taken in this sense, into nine spheres: namely, the ninth sphere, which is called the first motion or *primum mobile*; the sphere of the fixed stars, which is called the firmament; and the seven spheres of the seven planets — that is, the sphere of Saturn, of Jupiter, of Mars, of the Sun, of Venus, of Mercury, and of the Moon. This division, however, we shall examine a little later, since the more recent astronomers posit more celestial spheres.

[Margin: The celestial orbs are contiguous with one another.]

Now all the celestial orbs are entirely contiguous and immediately adjacent to one another, so that the higher always encloses the lower, and there is nothing intermediate between any one and the next — just as we see in the coats of an onion, where the outer everywhere surrounds the one beneath it. This we shall demonstrate to be so when we discuss the order of the heavens. Therefore, since every containing body is, in its circumference, equal to the body it contains, the author rightly adds that some of the celestial spheres are larger and some smaller, according as they approach nearer to, or recede farther from, the firmament. For on this reckoning the ninth sphere will be the largest of all.

[Margin: Why the ninth sphere is called the sphere of the first motion, or first mover.]

Then the firmament will be larger than the sphere of Saturn, which comes next after it, and so on in turn, until we come down to the sphere of the Moon, which is the lowest. For this is the smallest of all the spheres.

The ninth sphere is called by the author, and by the other astronomers, the first motion or *primum mobile*, because, as they suppose, no other movable heaven exists above it, and by its own extremely swift motion — as we shall explain in its proper place — it

carries off with it all the lower spheres it surrounds, from east to west, in the space of twenty-four hours. Yet, although the author here holds the ninth sphere to be the highest and the *primum mobile*, we can without any difficulty call it both the first sphere and the ninth (or last). The first in the order of nature, because it is nearer to the First Being — in which sense the sphere of the Moon is last, since it is farthest from the First Being. But the ninth, or last, with respect to us, because it is the more remote from us — in which sense the sphere of the Moon, being nearer to us, will be called the first. Yet the astronomers have not

customarily called it the "last motion" or "last mover," but only the "first motion" or *primum mobile*, on account of the dignity and pre-eminence it has in carrying the lower spheres around with it by its own proper motion — in which respect it seems to hold the primacy.

[Margin: Why the eighth sphere is called the firmament and the sphere of the fixed stars.]

The author, with the astronomers, also calls the sphere that is eighth with respect to us the "firmament" and the "sphere of the fixed stars." The firmament, because just as a rampart, wall, and city walls set at the outermost boundaries encircle, fortify, and secure a city, so too the eighth sphere, which is called the firmament — and which all antiquity held to be the highest and outermost heaven — secures, contains, encompasses, and, as it were, fortifies not only all the remaining lower spheres but also everything whatsoever that exists in the whole universe. Or else it is called the firmament because it holds the stars fixed more firmly, as will presently be said.

[Margin: Why the stars of the firmament are called "fixed."]

He calls it the "sphere of the fixed stars" because it carries, conveys, and contains all the fixed stars. Now these stars are not called "fixed" because they do not move, or because they remain wholly stationary; for that is false, since experience has shown most clearly that they do move, as will be said in its proper place. Nor again are they called "fixed" in the sense that they move only with the motion of the orb in which they are set; for on that reckoning the planets too would have to be called "fixed," since they are carried around only by the motion of the orbs in which they exist, as we shall later show. Rather, they are called "fixed" because they always keep the same position, order, and distance among themselves — as the observations both of the ancient astronomers (Ptolemy [Ptolemy], al-Battānī [al-Battānī], and the rest) and of the more recent ones make most evident to us. For the stars of that brilliant constellation called Orion always keep the same position, order, and distance among themselves: the three stars that make up Orion's belt, for instance, perpetually form what is almost a straight line. The same has been observed in the stars of the Greater and Lesser Bear, and finally of the other constellations. On this matter, read Ptolemy in Book 7 of the *Almagest*, and Regiomontanus [Regiomontanus] in his epitome of the same Book, where very many observations of the stars are brought forward, from which it is clearly gathered that the stars of the firmament always keep the same order and position among themselves. For this same reason the eighth sphere was called by the Greeks ἀπλανής [Greek: aplanēs, "not wandering," "fixed"], as if to say "not

straying" and "not erring," because all the stars fixed in it proceed without any wandering or intermingling.

[Margin: Why the sphere of a planet is so called.]

Finally, the remaining seven spheres, each of which contains a single star, are called the "spheres of the planets," because they carry stars — or heavenly bodies — that are called planets, that is, "wandering stars" or "wanderers" (*Errones*). This is not because they stray about the heaven in the sense of being carried by no ordered, certain, and determinate motion — for on that reckoning there could be no science of them, which is not true, since they have fixed periods of their motions. Rather, they are called "wandering stars" because they neither keep always the same distance among themselves, nor keep the same order with respect to the fixed stars of the eighth orb. This we perceive more clearly than daylight, day by day, in the Sun and Moon. For at one time these two planets are wholly joined together, as happens at new moon; at another the one is opposite the other, and the one recedes as far as possible from the other, as happens at full moon; at another they are seen nearer to, or farther from, each other. Again, at one time they appear near a given fixed star of the eighth orb, or firmament, and at another near a different one; and exactly the same has been observed in the rest of the planets. For now they are seen to advance in a direct course, now to go backward and press in the contrary direction; now to be hidden and to lie concealed on account of their nearness to the Sun; then, when the Sun withdraws from them, or they from the Sun, to come forth again into the light, and to open and reveal themselves; now to go before the Sun, now to follow it; now to be hurried along, as it were, with the swiftest course; now, on the contrary, to slow down so much that they are not even thought to move, but to stand still in exactly the same place of the Zodiac; now, finally, to run off toward the north, now toward the south. On this matter more is set forth in the *Theories of the Planets*. For this reason, then, the stars appear to stray about the heaven in such a way that they seem to be driven by a kind of chance and fate; and this is why they are rightly called "planets" by the astronomers.

[Margin: Division of the sphere according to accident.]

[Lemma] According to accident, moreover, it is divided into the right sphere and the oblique sphere. Those are said to have a right sphere who dwell under the equator, if anyone could dwell there. And it is called "right" for them because neither of the poles is raised higher than the other for them; or because their horizon cuts the equator, and is cut by it, at right spherical angles. But those are said to have an oblique sphere who dwell on this side of the equator, or beyond it. For them, one of

the poles is always raised above the horizon while the other is always depressed; or because their artificial horizon cuts the equator, and is cut by it, at unequal and oblique angles.

COMMENTARIUS

He now divides the sphere according to accident into the right sphere and the oblique sphere. But since what is said in this division, and what follows next, cannot be understood unless certain circles of the sphere are first known — circles frequently mentioned in what follows — I think it worthwhile to explain the circles of the sphere briefly and in general, intending to discuss them more fully, along with their functions and names, in chapter 2, where the author himself treats of them. For now I shall only set out the names of the circles in a rough and ready way.

ON THE CIRCLES OF THE SPHERE

[Margin: The ten circles of the sphere. What a great circle and a lesser circle of the sphere are.]

The circles of the sphere are 10, whose names are these: the Equator (*Aequinoctialis*), the Zodiac, the Colure of the Solstices, the Colure of the Equinoxes, the Meridian, the Horizon, the Tropic of Cancer, the Tropic of Capricorn, the Arctic Circle, and the Antarctic Circle. The first six are called "greater," or "greatest" (great circles); the latter four are "lesser," or "not greatest." A great circle is one that has the same center as the sphere and divides

the sphere itself into two equal hemispheres. A lesser circle, on the other hand, is one that has a center different from the center of the sphere and divides the sphere into two unequal segments. For the rest, every circle

[Margin: What the pole of a circle in the sphere is.]

of the sphere, whether greater or lesser, is said to have two poles, about which, if it were to move, it would be carried uniformly. Indeed, it is from the poles themselves that all circles are described on the surface of the sphere. For the pole of any circle of the sphere is that point on the convex surface of the sphere from which all straight lines drawn to the circumference of the circle are equal. For since the circumference is described from the pole of the circle, it necessarily follows that the pole is equally distant from all points of that circumference.

[Margin: The Equator.]

The **Equator** is that great circle in the sphere which is described from the poles of the world, and which is equally distant, in all its parts, from each pole of the world.

[Margin: The Zodiac.]

The **Zodiac** is likewise a great circle, described from poles that are distant from the poles of the world by a fourth part plus a ninetieth of one quadrant — that is, by 47 of the 180 parts into which the quadrant is understood to be divided. It cuts the equator, and is cut by it in turn, into two halves, but obliquely; so that the Zodiac is inclined to the equator, one half slanting toward the north and the other toward the south. The midpoint of each half recedes from the equator by just as much as the poles of the Zodiac recede from the poles of the world — a distance that amounts to $23\frac{1}{2}$ degrees. And it calls a "degree" one part of any circle divided into 360 parts; for the astronomers divide every circle into that many parts. Now in the Zodiac four principal points are considered, of which two are called equinoctial and two solstitial. The equinoctial points are those at which the Zodiac cuts the equator; the two solstitial points are those which, as we said, are farthest removed from the equator. Again, of the equinoctial points, the one that lies to the right of the Arctic pole (assuming, that is, that the half of the Zodiac which slants toward the north is placed in the upper hemisphere) — or that is placed in the west — is called the vernal point, and is the beginning of Aries. The other, which lies to the left of the same pole (the sphere keeping the same position), or is placed in the east, is called the autumnal point, and is the beginning of Libra. Or, if you prefer: that point of the Zodiac belongs to the vernal equinox which is the beginning of the semicircle slanting toward the Arctic pole, proceeding from west to east; while the end-point of that same semicircle — that is, that point of the Zodiac — belongs to the autumnal equinox, which is the beginning of the other semicircle, slanting toward the Antarctic pole, likewise proceeding from west to east. Of the solstitial points, too, the one that recedes from the equator toward the north is called the summer point, and is the beginning of Cancer; the other, which withdraws toward the south, is called the winter point, and is the beginning of Capricorn. And these four points are to be carefully noted, so that the other circles of the sphere may be understood.

[Margin: The Colure of the Solstices.]

The **Colure of the Solstices** is that circle which passes through the poles of the world, the poles of the Zodiac, and the solstitial points.

[Margin: The Colure of the Equinoxes.]

The **Colure of the Equinoxes** is that circle which is drawn through the poles of the world and the equinoctial points, but not through the poles of the Zodiac.

Diagram. A woodcut armillary sphere showing the principal circles of the sphere set within a graduated meridian ring. The outer ring (the meridian) is graduated in degrees, marked in tens from 10 to 90 and back down (10, 20, 30, 40, 50, 60, 70, 80, 90, 80, 70...) around each quadrant. Four cardinal reference letters sit at the ends of the vertical and horizontal axes: **B** at top, **D** at bottom, **A** at the left. [A corresponding letter at the right (expected **C**) is not legibly resolved — [?].] The inner rings run from the upper-left pole to the lower-right pole, tilted, and carry the following labels:

- POLVS SEPTENTRIONALIS (upper left): "North Pole"
- ARCTICVS: the Arctic Circle
- TROPICVS AESTIVVS (upper): "Summer Tropic" (Tropic of Cancer)
- AEQVINOCTIALIS: the Equator
- ORIZON (horizontal band across the middle): "Horizon"
- TROPICVS HIEMALIS (lower): "Winter Tropic" (Tropic of Capricorn)
- ANTARCTICVS: the Antarctic Circle
- POLVS AVSTRALIS (lower right): "South Pole"

[Margin: The Meridian. The vertex of the place, or Zenith. The Nadir of the place. The Horizon.]

The **Meridian** is that circle which is drawn through the poles of the world and the vertex of the place, and which stands above the other great circles in a material sphere. Now the vertex of the place is a point in the heaven directly above that place — such as the point indicated by the summit of some tower, if it were extended all the way to the heaven; or the point that stands directly over the crown of any person's head. This point the Arabs call the **Zenith**; the point diametrically opposite — indicated by that same tower, if it be imagined to run through into the other part of the heaven — they call the **Nadir**.

The **Horizon** is a great circle described from the vertex of the place as if from a pole, which [also] with other circles in a material

it rises above the material sphere, divides the Meridian, and is itself divided by the same at right spherical angles; and it separates the visible hemisphere from the one not seen.

The **Tropic of Cancer** is that smaller circle which, on the side of the Arctic pole, lies equidistant from the Equator, and passes through that point of the Zodiac

most remote from the Equator — the point we said above is called the beginning of Cancer. [Margin: Tropic of Cancer]

The **Tropic of Capricorn** is that smaller circle which, on the side of the Antarctic pole, lies equidistant from the Equator, and passes through that point of the Zodiac which we noted above is called the beginning of Capricorn. [Margin: Tropic of Capricorn]

The **Arctic circle** is a smaller circle, described near the Arctic pole through the pole of the Zodiac, and lying parallel to the Equator. [Margin: Arctic circle]

The **Antarctic circle** is likewise a smaller circle, which runs near the Antarctic pole through the other pole of the Zodiac, also equidistant from the Equatorial circle. [Margin: Antarctic circle]

An **example** of all the circles we have explained you have, after a fashion, in the accompanying figure ABCD, in which E is the beginning of Cancer; F, the beginning of Capricorn; G, the beginning of Aries; H, the beginning of Libra. ABCD is the Meridian; B, the Zenith; D, the Nadir; AHCG, the Horizon; ABC, the visible hemisphere; ADC, the hemisphere not seen; K and L, the poles of the Zodiac, and so on. But all these things will be perceived more clearly by means of the material instrument.

Now that we have spoken of the circles of the sphere, it will not be out of place to indicate briefly in what manner the material sphere is to be composed out of them — if only for this one benefit, that we may be able to judge of any sphere whatever whether it has been rightly made and assembled. [Margin: The composition of the material sphere] First, then, let three circles be prepared out of some material, entirely equal to one another and each divided into 360 equal parts, which we have said are called degrees. Let two of them be so joined that they cut each other at equal angles — that is, at right spherical angles — in two points, through which the axis of the world is to be extended; and these two circles will be the Colures. Next, in each Colure let 90 degrees be counted from the poles of the world, and at the ninetieth degree of each let a third circle be applied, namely the Equator, which by this reckoning will be equally distant from both poles. After this, from the Equator toward each pole let $23\frac{1}{2}$ degrees be counted along the Colures, and at the limits of these numbers let the two Tropics be applied; you will readily have their size if you first take their diameters, by drawing a straight line from the end of the counting on one Colure to the end of the counting on the same Colure toward the same pole. In the same way, when the like number of parts has been counted from each pole toward the Equator

along the same Colures, the Polar circles will be established, namely the Arctic and the Antarctic, whose diameters you will find by a not dissimilar art. Again, let the circle of the Zodiac be prepared, equal indeed in circumference to the three greater circles already mentioned, but differing from them in breadth: for it must contain in breadth 12 degrees, in the middle of which is drawn the line called the Ecliptic, distant 6 degrees from the edges of the Zodiac, as we shall teach in chapter 2. This circle is to be applied and fitted so that the whole circle obliquely cuts the Equator in those two points where one of the Colures cuts the same Equator; and so that the ecliptic line touches each Tropic at two other points, where the remaining Colure cuts the Tropics — one of which is taken toward one pole, the other, diametrically opposite to it, toward the other. Finally, in this manner let the Meridian and the Horizon be established and fitted to each other, so that the whole sphere thus far constructed may turn freely within these fixed and immovable circles — yet on this condition: that these two circles cut each other mutually at right angles, and that the Meridian move about its own poles (which are the common intersections of the Horizon with the Equator) to this end, that the sphere may serve every elevation of the pole — that is, so that either pole may be depressed and raised, according to the altitude of the pole. On some spheres the Horizon is now depressed, now raised, for the same purpose, the Meridian remaining fixed; but the former arrangement pleases me more. And thus the whole material sphere will be finished and completed. For as to the circles of the Planets, which are usually set upon some spheres so that they always move under the Zodiac and about the poles of the Zodiac, anyone may easily set them upon the sphere by his own industry, since here we treat only of the principal circles of the sphere. Let these things be said in general concerning the circles which astronomers consider in the heavens. Now let us return to the author's division.

They are said, etc.) Having divided the sphere according to accident (in which division the sphere is taken for the whole sphere of the world) into the right sphere and the oblique, he now sets forth each part of the division. He says, then, that those have a right sphere who remain under the Equatorial circle — *if anyone could remain there*. He added this because many most weighty men — philosophers, astrologers, and also most of the theologians — doubted whether there was any habitation under the Equatorial circle; indeed the greater part, along with the ancients, affirmed as certain that under the Equatorial circle there is no habitation, on account of the excessive heat which the Sun, perpetually running there, produces. A similar doubt might be raised about the poles of the world; for not a few there have been, nor are there now lacking, who deny that men can dwell there, on account of the intolerable cold that persists there

through the great remoteness and perpetual absence of the Sun. On this matter we shall say something at the end of chapter 2. But for now let it be held certain and beyond doubt, established by the experience of many, that men dwell both under the Equatorial circle and under the poles — at least under the Arctic pole. [Margin: In what way the sphere is taken in the latter division] [Margin: Who are said to have a right sphere] [Margin: The earth under the Equator and the poles is habitable] [Margin: Why those dwelling under the Equator are said to have a right sphere]

And it is called right for them, etc.) For two reasons he says that the sphere of those who dwell under the Equator is called right: either because neither of the poles is raised above the Horizon more than the other for them; or because their Horizon cuts the Equator and is cut by it at right spherical angles.

Hence it has come about that some have defined the right sphere by saying: it is that in which each pole stands and rests upon the Horizon; or that in which the Equator (which holds exactly the middle place between the poles) makes right spherical angles with the Horizon; or that in which each pole lies on the Horizon and the Equator rises directly above the top of the head; or that in which each pole touches the Horizon. A right sphere has fallen to the lot of a great part of Africa and of the West Indies — namely that part which is called Peru; also the Molucca Islands, the island of Taprobana, and the island of St. Thomas. But no part of Europe is subject to a right sphere. [Margin: Various descriptions of the right sphere] [Margin: What regions have a right sphere]

But those are said, etc.) He says that they have an oblique sphere who dwell on this side of, or beyond, the Equator. He then adds the reason why theirs is called an oblique sphere: namely, because one of the poles is always raised above the Horizon, while the other is always depressed; whence the sphere seems to have an oblique position. Or, certainly, because their artificial Horizon cuts the Equator and is cut by it at oblique and unequal angles. [Margin: Who are said to have an oblique sphere, and why]

He calls the Horizon of the oblique sphere **artificial**, perhaps for this reason: that it is highly variable and does not divide the sphere naturally. For only the Horizon of the right sphere, since it passes through both poles of the world, seems of itself and in a certain way to divide the sphere naturally. For in this way the sphere obtains its proper and direct position, nor can such a Horizon ever be varied, so that some might have a more nearly right Horizon and others a less right one. But in the Horizon of the oblique sphere — since it does not pass through the poles of the world, and since above it one pole is always raised and

beneath it the other is depressed — the sphere seems to be set obliquely and not naturally. There is this further point: that the Horizon of the oblique sphere, according to the choice and will of the men dwelling on earth, is variable in almost infinitely many ways. For the nearer one draws to the pole, the more oblique a Horizon he must have. Not without reason, therefore, can the Horizon of the oblique sphere be called in a certain sense artificial, so as to be distinguished from the Horizon of the right sphere, which is as it were natural to the sphere itself. For since both poles of the world exist upon it, the sphere seems to move naturally within it. [Margin: Why the Horizon of the oblique sphere is called artificial by the author]

Others **define the oblique sphere** by saying that it is that in which one of the poles of the world stands raised and eminent above the Horizon, while the other lies down and sinks below the Horizon; or that in which the Equator makes and forms oblique angles with the Horizon — an obtuse angle, indeed, on the side that faces the exalted pole, but an acute one on the side that inclines toward the hidden pole. An oblique sphere has fallen to all the inhabitants of Europe — such as the Spaniards, French, Italians, Germans, Greeks, and Poles — and to the greater part of Africa and of the West Indies, and also to all of Asia. [Margin: Various descriptions of the oblique sphere]

Not only the sphere, but also the orb, or World, and likewise the Horizon or Bounder (Finitor), is commonly called by authors right and oblique. For they are accustomed to say that the Germans, Italians, French, and Spaniards dwell in an oblique orb; and by the same reasoning, that the Horizon, or Bounder, the world, or the sphere, is for them oblique, and so on. [Margin: What regions have an oblique sphere] [Margin: Those who dwell under the poles have an oblique sphere]

If anyone should ask what sort of sphere those are said to have who dwell directly under the poles, the answer must be that, according to the author's view, they have an oblique sphere. For although their Horizon, since it is one and the same with the Equator, cuts it in no way at all — and hence at neither right nor oblique angles — nevertheless one of the poles is raised to its highest for them, while the other is depressed to its lowest; whence, from this consideration, they are to be reckoned as having a most oblique sphere. There are, however, those who assert that they dwell in a right sphere, because their Horizon makes no oblique angles with the Equator. But by this same argument it is concluded that they do not dwell in a right sphere, since their Horizon does not make right angles with the Equator, but coincides with it entirely. Therefore, in my

judgment, it is more correct to say, with the author, that they dwell in an oblique sphere, since at least one of the reasons for an oblique sphere fits them, but none of those for a right one. This is also indicated by the definitions of the right and oblique sphere handed down by others. [Margin: Those who dwell under the poles have an oblique sphere]

The origin and cause of this division of the sphere into right and oblique is the roundness of the earth. For since, as we shall show in its proper place, the earth is round, it comes about that the position of the poles and of the whole sphere is changed in different parts of the earth; so that men advancing toward one of the poles always see it more and more elevated. This would not happen if the earth were flat. Moreover, since wherever a man is, and in whatever part of the terrestrial globe he stands, he always sees half of the heaven — the impediments of mountains and valleys set aside — as has been ascertained by Ptolemy, al-Farghānī, and other astronomers from various phenomena; and since the Horizon divides the seen half from the unseen: it follows that in whatever region one pole lies on the Horizon, the other also lies on the same. Likewise, by however much one of the poles is raised above the Horizon, by just so much the other is depressed beneath the same; otherwise we should behold more or less than half of the heaven — since the poles are distant from one another by half the heaven, being opposite through the diameter of the world. Hence it is necessary that a man set in some great level plain should have either both poles of the world (all impediments of mountains and valleys being removed) lying on the Horizon, when the Horizon passes through the poles of the world; or one raised and the other depressed, when the Horizon does not pass through the poles of the world. From all these things, therefore, the reasoning of the division of the sphere into right and oblique clearly stands established. [Margin: The roundness of the earth is the cause of the right and oblique sphere]

The earlier division made by the author — that by which the celestial sphere is distributed into nine spheres — **is said to be according to substance**, because it is a division of a superior into its inferiors, namely of the heaven into the particular heavens; just as if we were to divide "animal" into man, lion, horse, and the other animals. Or, certainly, because it is a division of the whole celestial region into the individual heavens out of which it is composed; no otherwise than if a man were divided into head, chest, legs, arms, and the other members out of which he is constituted. But this later division of the sphere into the right and the oblique sphere is called **according to accident**, because in it the sphere is not divided into things essential to itself, as in the former, but into things accidental — namely, those which befall it — regard being had to those who pass their life in

the sphere. For a sphere is called right or oblique in respect of those dwelling under it, which indeed is an accident of the sphere. For the sphere would exist just as much if no one dwelt in it as it does now; but it would not be right or oblique, since there would be no Horizon — which those living on the earth are alone accustomed to consider. This division, then, is like the one by which "animal" would be divided into white animal, black animal, and so on — which is agreed to be a division according to accident. [Margin: Why the earlier division is said to be according to substance, the later according to accident]

Diagram. Two circular woodcut diagrams side by side, illustrating the right sphere (left) and the oblique sphere (right). In each, the lower half is shaded dark (the region below the Horizon). Labels:

Left circle (right sphere):

- Top: ZENITH
- Vertical band through the center: AEQVINOCTIALIS (the Equator, drawn upright, passing through Zenith and Nadir)
- Horizontal band: HORIZON RECTVS ("right Horizon")
- Left edge and right edge: POLVS (the two poles, lying on the Horizon)
- Bottom: NADIR

Right circle (oblique sphere):

- Top-left: ZENITH
- Upper-right: POLVS (the elevated pole)
- Diagonal band across the center: AEQVINOCTIALIS (the Equator, drawn obliquely)
- Horizontal band: HORIZON OBLIQVVS ("oblique Horizon")
- Lower-left: POLVS (the depressed pole)
- Bottom: NADIR

In the accompanying prose Clavius refers to these as the "prior" (right) and "posterior" (oblique) figures.

In the earlier figure set here you have an example of the right sphere; in the latter, of the oblique sphere. You plainly see that in the right sphere the axis of the world coincides with the Horizon, since it does not differ from it; and consequently that each pole lies on the Horizon. But in the oblique sphere the axis of the world differs from the Horizon, and therefore one pole is exalted above the Horizon while the other is depressed beneath the same.

Now the universal machine of the world is divided into two — namely, into the aethereal and the elementary region. [Margin: The division of the world into the aethereal and the elementary region]

COMMENTARIVS.

Being about in this third part of the chapter **to set forth the form of the whole world**, the author first divides the entire machine of the world into two: namely, into the elementary and the aethereal region, out of which, as out of parts, the whole machine of the world is composed. In this division, the "machine" of the world is taken for the heap and compacting-together of all bodies, higher and lower. For the world is the perfect and complete assemblage and adornment of all things: whence by the Greeks it is called κόσμος [Greek: κόσμος (kosmos, "world"; literally "order/adornment")], from adornment. Aristotle, in the little book *On the World*, chapter 2 (if indeed the book is Aristotle's), describes it by two definitions, of which the first is this: "The world is a framework consisting of heaven, earth, and the other natures contained in them." The latter runs thus: "The world is the ordering and arrangement of bodies, which is preserved by God and for the sake of God." [Margin: What the world is]

Some philosophers have held **the world** to be eternal, without beginning and without end — as Aristotle and not a few of his followers. Pliny too, in book 1, chapter 1 of the *Natural History*, thinks the same, when he says: "*The world, and that which it has pleased us to call by another name, the heaven, by whose vault all things are covered, is rightly believed to be a divine power, eternal, immense, neither begotten nor ever to perish.*" The Catholic faith, however, teaches that the world had a beginning, was created and made, and was founded by God, the Best and Greatest, out of nothing, by his word alone, to be a dwelling for human nature, in which he willed to become known and to be beheld; as we read in Genesis, chapter 1. Indeed Plato too, in the *Timaeus*, teaches that God is the maker of the world. Again, some philosophers — among whom was Democritus — held that there are innumerable worlds, some outside our own, others like balls or globes. For the form of the world is round and globular, as will be said hereafter: and when Anaxarchus, a disciple of Democritus, reported this to Alexander the Great, Alexander is said to have groaned, saying, "Alas for me, wretch that I am, who have not yet made myself master even of one!" Aristotle, nevertheless, and our theologians hold that there is one world only, although God, the Best and Greatest, could by his absolute power — according to the theologians — produce infinitely many worlds. [Margin: The world is held by many philosophers to be eternal] [Margin: According to the Catholic faith the world was made]

Furthermore, the **ancient philosophers and the weightiest theologians** divided all things whatsoever that exist into three kinds, so that they asserted the world to be threefold — namely, the Supramundane, the Celestial, and the Sublunar. The Supramundane the theologians call the Angelic world, the philosophers the Intellectual, comprising God, the Best and Greatest, together with all the intelligences. The Celestial is composed of the orbs and celestial spheres, however many there are, and by common usage is called the heaven. The Sublunar, finally, which we inhabit, is that which comprises all things stored up within the concavity of the whole Lunar heaven — such as the elements, animals, inanimate things, and so on. [Margin: The world is threefold: Supramundane, Celestial, and Sublunar]

Our author, therefore, leaving aside the Supramundane world — since the consideration of it is foreign to the astronomer and belongs rather to the metaphysician or the theologian — divided the world, as it comprises the Celestial and the Sublunar, into these two members, out of which, as out of parts, it is made up: namely, into the Elementary and the Aethereal region. He called these two chief parts of the World "regions," perhaps because of the common manner of speaking by which we are accustomed to distribute this terrestrial globe, in which we live, into various regions. He will now set forth for us the form and figure of each region, both the Elementary and the Aethereal.

The elementary region, being pervious to continual alteration, is divided into four. For the earth stands as it were as the center of the world, set in the midst of all; around it, water; around the water, air; around the air, fire, there pure and untroubled, reaching to the orb of the Moon, as Aristotle says in the book of Meteorology. For thus did God, glorious and sublime, dispose them.

And these four are called elements, which in turn are altered by one another, corrupted, and generated.

The elements, moreover, are simple bodies, which cannot be divided into parts of diverse forms, and out of whose mingling arise the diverse species of things generated.

Any three of them surround the earth on all sides in a spherical manner, except in so far as the dryness of the earth resists the moisture of the water, for the preservation of the life of living creatures.

All of them too, except the earth, are movable, which — fleeing on all sides equally the motion of the extremities, as from the center of the world by its own heaviness

— *the earth possesses the middle of the round sphere.* [Margin: The form and figure of the elementary region]

COMMENTARIVS.

Here he begins to treat of the elementary region, or (what is the same) of the Sublunar world, and sets forth its form and disposition. And he goes through this region very briefly in six points.

First, he assigns a certain property of the elementary region: namely, that it stands pervious to continual alteration — that is, giving place and admission to the alterations that occur in it. By the name "alteration" understand every natural transmutation — such as generation, corruption, augmentation, diminution, local motion, and alteration properly so called (such as heating, cooling, and the like) — and finally every motion that in some way varies the substance of a thing. For the elementary region is that part of the universe in which continual transmutations of things occur. [Margin: The elementary region is subject to continual alteration]

Second, he divides the elementary region into four members, namely into Earth, Water, Air, and Fire, where he also shows the order these parts hold in the Universe, saying that the earth is set as it were as the center of the world, in the midst of all. He said "as it were the center," because, since the earth has a great quantity and mass — if considered absolutely — it cannot be the true center. For the center of any circle or sphere is an indivisible point, lacking all magnitude. But since the whole magnitude of the earth, however immense it appears to us, is, in respect of the whole heaven, but as a point (as will afterward be demonstrated), it deservedly [Margin: The order of the elements]

can be called the center.

Next [Sacrobosco] asserts that around the earth there is water — which must be understood of water's natural place, since it belongs to water's nature to surround the earth; but why it does not now surround it, we shall say shortly — and around the water, air; and finally around the air, fire, which exists there pure and untroubled, reaching the orb of the Moon. The philosophers hold that fire is pure and not turbid there for three reasons. The first is that vapors cannot rise there to make it impure and turbid. The second is the difference between that fire and this lower fire of ours, which is said to be not pure but mixed, because it is not in its natural place; for this lower fire is continually mingled with the air in which it exists, and it has its earthy nourishment, by which it is made turbid and

impure, whereas fire in its own sphere is unmixed, rare, and pure. A sign of this can be that, because of its very great rarity and purity, it does not shine there, and so is also not seen. The third reason is taken with respect to the other elements, which do not exist pure; for water is mingled indiscriminately with earth, and air is made impure and turbid by the continual rising of vapors from earth and water; but fire is mingled with none of these, especially near the concavity of the Moon. On this account Aristotle said in *Meteorologica* I: "Either the simple element exists nowhere, or, if it exists anywhere, it will be in the place of fire." And if you ask the author the cause of this order — namely, why earth is lowest, then water above it, and so on — he replies that the cause of this order is the glorious God, who so arranged them and willed this element to be above that one.

[Margin: The elements are in turn altered, corrupted, etc., by one another.]

Thirdly, he says that these four parts of the elementary region are called Elements, which are in turn altered, corrupted, and generated by one another. For now water comes to be from earth, air from water, and fire from air, and conversely, and this continually. For which reason the elementary region has been called by the philosophers the sphere of active and passive things [*sphaera activorum et passivorum*]. You should not understand this to mean that these elements so fight among themselves that one element corrupts another entirely — for that is false — but rather that a part of one sometimes alters and corrupts a part of another, and introduces the form of its own species into the other's matter.

[Margin: What the elements are.]

Fourthly, he defines the elements, saying that Elements are simple bodies [*corpora simplicia*] which can least of all be divided into parts of diverse forms, and from whose mixture the various species of generated things arise. He took this definition from Avicenna [Ibn Sīnā]. They are called elements ("bodies") to be distinguished from prime matter, which is not a body. They are called ("simple bodies") not because they lack composition of matter and form — for that would be false — but because they are not composed of other bodies (as mixed bodies are composed of elements), and are resolved into the same. What is added — ("which into parts of diverse forms," etc.) — is taken from *Metaphysics* book 5, chapter 3, and signifies that the elements are not resolved into things of diverse forms in the way that mixed bodies are resolved into elements. Or else it signifies that in the division of the elements one cannot assign dissimilar parts, since they are homogeneous bodies, that is, of similar kind or nature — whereas other

bodies are divided into dissimilar parts, since they are heterogeneous, that is, of another or diverse kind or nature.

[Margin: The five kinds of mixed bodies.]

Finally, as regards what follows — ("from whose mixture," etc.) — this alone must be known: that there are five kinds of mixed bodies, which arise from the various proportion and tempering of the miscible elements among themselves. In the first and lowest grade are those mixed bodies which may be called, and are called by the philosophers, imperfect mixtures, and are named Meteorological impressions [*impressiones Meteorologicae*], because they come to be aloft — such as rains, hail, snow, thunder, lightning, and the like. In the second grade are stones, minerals, and fossil bodies, which are called inanimate mixtures. In the third grade are vegetables, such as plants, which are called animate mixtures. In the fourth grade are comprised the brute animals. And in the fifth and highest grade, finally, are contained human beings.

[Margin: The figure of the elements.]

Fifthly [printed QVNTO; recte QVINTO], he shows the figures of the elements, saying that each of the three elements roundly surrounds another: fire surrounds air, air water, and water earth — the contrary of which we observe. For water does not surround the whole earth, but these two elements, namely earth and water, make one globe, as we shall show a little later. He adduces two causes why water does not surround the whole earth. The first is efficient and natural, namely the dryness of the earth, which (he says) continually, acting upon the moist watery [element], diminishes the water, or at least resists it, lest it cover the whole earth and complete its orb. But this cause is quite ineffective. For how can the dryness of the earth be so great that it can resist so great an element, and one by its own nature superior to it? Indeed it even conflicts with experience, for dryness rather seizes and draws in moisture, as we see in ashes and other such dry things. The second cause is final and supernatural, namely divine providence. For God, as we read in Genesis, separated the waters from the earth to preserve the life of certain animals. For before God, Most Good and Great, had said "Let the waters be gathered into one place" [etc.], the water surrounded the whole earth (according to the theologians); but by God's command the water withdrew, and dry land appeared. But in what manner this was done by God's command, various opinions exist.

[Margin: Various opinions as to how the water withdrew from the earth so that dry land might appear.]

For some say that the earth remained indeed in its own place, but the water was raised up above the earth, so that if it flowed down it would again cover the whole earth; and yet, as to why it does not now flow down and cover the earth, the agreed view among these [authors] is that it comes about by a miracle and the power of God, that the flowing water may not cover the globe of the earth. This opinion seems also to be that of Blessed Jerome [St. Jerome], moved by the authority of Scripture; for it is said in Proverbs 8 and Psalm 103 that God set a boundary for the waters which they would not cross. Others, unwilling to grant this continual miracle, adduce a ridiculous and worthless cause. For they say that around the arctic pole there are certain stars — namely in Ursa, Draco, etc. — of such efficacy and power upon these lower things that, from this habitable part of the earth, they drive toward the North the Ocean that inclines [there], and restrain it, lest it again overwhelm the earth. Others, judging the quantity of water to be much greater than that of the earth, say that the water, by the huge bulk of its mass, drives the earth out of its natural place by its own weight, and itself occupies the center of the world, so that the earth seems as it were to float in the sea. And all these authors think that this whole earth toward the Arctic pole is laid bare of waters, but the remaining part of the earth toward the Antarctic pole is entirely filled by the sea — which conflicts with the experience of today's navigators, as we shall say later. Others, finally, still granting that the water is much greater than the earth itself — indeed ten times greater — assert that the whole earth is like a kind of sponge (a sign of which, they say, can be that water is at once found in every place wherever the earth is dug), and that it is full of many caverns and hollows, so that the waters mingle with the whole earth and are received into those hollows. Hence a smaller part of the water than [the quantity of] earth will remain above the earth; and so it is no wonder that it cannot bury the earth any further. Into this opinion many Peripatetics try to draw Aristotle. But even if..

even if we grant that there are huge hollows in the earth, it is impossible that the water be ten times greater than the earth itself. For by this reasoning, even though the whole terrestrial globe were water, it could not fail that a greater portion of water than earth would exist above the earth, since even so nine parts of water out of ten would be left over. There is also the fact that the water is much less than the earth, as we shall show later. All these opinions, therefore, are in manifest conflict with reason and with experience — which will become plainer when we have treated of the roundness of the earth and water. For which reason, as to the manner in which, by God's command, the waters were separated so that dry land might appear, I prefer the one that St. John Damascene [John of Damascus] — a man of the highest authority among the theologians — sets out in

book 2 of *On the Orthodox Faith*, chapters 9 and 10, and which Jaime Pérez de Valencia [Jacobus de Valentia], Bishop, follows.

[Margin: The truer opinion, explaining in what way the water was separated from the earth.]

Namely, that the earth was created by God, Most Good and Great, perfectly round and globe-shaped, without any hollows, valleys, mountains, or eminences, and wholly surrounded by waters. But afterwards, when God said "(Let the waters be gathered into one place, etc.)," for the sake of the life of certain living creatures, hollows were made in the earth by divine command, and into them the whole force of the waters gathered, as into their own gathering-places; and various seas at once arose in different parts of the earth, and from those parts of the earth that were drawn out, mountains were made. To this opinion some add that the waters, in the beginning of the world, were very thin, but afterwards, by God's command, were condensed and received into the said hollows, so that it is no wonder they are not smaller than the earth. But in whatever way, finally, this was done, let us leave it to others to dispute. For us let it now be certain that earth and water make one globe — which will be demonstrated a little below from various experiences — and that this is the reason why water does not now surround the whole earth, indeed cannot surround it, since these two elements have one and the same convex surface, and both by their weight naturally tend toward the center of the whole universe.

[Margin: The earth is immovable; but the other elements are moved from East to West.]

Sixthly and lastly, he teaches that all the elements except the earth are movable — the earth being that (*which, as the center of the world, by its own heaviness, fleeing equally on every side the great motion of the extremes, namely of the heavens, [being] a round sphere, that is, possesses the middle of the world*). You should not understand this as if no earth is movable, for that is false, since, when placed outside its own place, it recurs with great force to its natural place. But [he means] that it is not moved circularly in its own place, as the other elements are. For fire indeed, and the upper part of the air — indeed, some affirm from experiment that a good part of the Ocean also — are carried by the motion of the *primum mobile* from East to West, on account of their lightness and mobility.

ON THE NUMBER AND ORDER OF THE ELEMENTS [DE NVMERO ET ORDINE ELEMENTORVM]

[Margin: That there are four elements is proved from the combinations of the primary qualities.]

Since our author has taught that there are four elements, it will not be out of place to open up briefly by what strongest arguments the philosophers gather that there are four elements, and then to say something about their order and position. The first argument, then, by which the philosophers prove that there are four elements is taken from the primary qualities, which Aristotle in *On Generation [and Corruption]* book 2 says are four — two active, namely heat and cold; and two passive, namely dryness and moisture. And the argument is of this sort. There are as many elements as there are possible combinations of these four primary qualities — that is, in as many ways as these four primary qualities can be joined among themselves and mutually endure one another, as Aristotle says in the passage cited. But there are only four possible combinations. Therefore there will be four elements also. The minor premise is evident, because among those four qualities, if we always take them two at a time, only six combinations can arise: namely, of heat with dryness, from which Fire is constituted, which is hot in the highest degree but dry in the remitted degree; of moisture with heat, from which we have air, which is supremely moist but exists remittedly hot; of cold with moisture, from which the philosophers gather water, which they say is cold in the highest [degree] but moist remittedly; of dryness with cold...

Diagram. A circular woodcut "wheel" (*rota*) of the four elements and the four primary qualities, set into the lower-left of the page. The outer ring is divided into segments alternately lettered **SVMMA** ("highest [degree]") and **REMISSA** ("remitted [degree]"). Four large roundels are placed at the cardinal points, each with a small emblematic image: **IGNIS** (Fire, top, shown as flames); **AER** (Air, right, shown as clouds); **AQVA** (Water, bottom, shown as waves); **TERRA** (Earth, left, shown as a walled town). Four smaller roundels stand at the diagonal points, each naming a quality: **CALIDITAS** (Heat, upper right, between Fire and Air); **SICCITAS** (Dryness, upper left, between Fire and Earth); **HVMIDITAS** (Moisture, lower right, between Air and Water); **FRIGIDITAS** (Cold, lower left, between Earth and Water). At the hub is a roundel bearing the **IHS** Christogram (the Jesuit device). Radiating spokes and cross-bars carry labels: **Combinatio** ("combination") on the spokes; **CONTRARIA** ("contrary," lettered CONTRA...RIA) along the two diameters joining opposite elements/qualities; and **possibilis** / **impossibilis** ("possible" / "impossible") on the connecting bars, marking which

quality-pairings can and cannot be joined. Additional fine italic words run along the thin diagonal bars near the hub (apparently "sym[bolizatio]" or the like) which do not resolve at this resolution [?]; a further small word on the lower diagonals reads [?]. (Uncaptioned; the surrounding text explains the figure's meaning.)

[of dryness with cold], from which earth is made, which is predicated as dry in the highest [degree] but cold remittedly; of heat with cold; and of moisture with dryness. But since these two last combinations are impossible, being combinations of contraries — whose nature is such that the one always expels the other, for one and the same thing cannot be numerically hot and cold, nor moist and dry at the same time — they are therefore reckoned useless, nor can anything be constituted from them. But all these combinations are seen more clearly than light in the figure set forth. That there is one quality in each element in the highest degree, and another in the remitted [degree], must be understood according to the opinion of certain philosophers; for many think that both qualities are in any element in the highest degree.

[Margin: A most beautiful digression on the combinations, or comparisons, of things.]

[Margin: How many combinations can be made among any number of things, if they are taken two at a time.]

Since we have said that among four things there cannot be more combinations than six, if they are always taken two at a time, it has seemed good to me to explain a little more fully how many combinations of this kind can be made among any number of proposed things; for the knowledge of this matter is conducive to many things, and is most delightful. Given, therefore, the number of some things, let it be multiplied by the number next smaller: for the half of the product will indicate the number of combinations that can be made among the proposed things. As in the proposed example: since there are four primary qualities, if 4 be multiplied by 3, 12 will result, whence six combinations can be made among them. And if there are five things to be combined, 5 must be multiplied by 4; for the half of the product, namely 10, will show the number of combinations — as many, namely, as Porphyry [Porphyry] established among the five predicables.

This rule as given can be split into two, according as the number of things is even or odd. For if the number of things is even, the number next smaller must be multiplied by the half of the number of things: for the product will directly show

the number of combinations. As, if you wish to know how many combinations can be made among 10 things, 9 will be multiplied by 5, to make 45 — as many combinations, namely, as can be made among ten things. But if the number of things is odd, it must be multiplied by the half of the number next smaller: for by this reasoning the number produced will indicate how many combinations can be made. As, if the things be 15: multiplying 15 by 7, the number of combinations among them will be produced, namely 105. Among 9 things, 36 combinations will be made; and so of the rest.

[Margin: How many combinations can be made among any number of things absolutely, if not only two, but also three, four, five, etc., are taken.]

But if it should please you to know how many conjunctions can simply be made from any number of proposed things — not only understanding it when they are taken two at a time, as in the preceding rule, but also when three, five, etc., that is, in how many distinct ways they can be compared among themselves — this will be accomplished by this art and rule. Let as many numbers be taken, beginning from unity in double proportion, as there are things proposed; and from the sum of them all let the number of things be subtracted: for the remaining number will indicate how many diverse comparisons can be made.

[Margin: How the sum of any number of numbers of double proportion beginning from 1 is found.]

Now the sum of any number of numbers in double proportion beginning from 1 will easily be had, if the last number be doubled and unity be cast off from the product. As, if you wish to know the sum of these numbers in double proportion 1. 2. 4. 8. 16. 32. 64., the last number, 64, must be doubled to make 128; from which, one being taken away, there remain 127, for the sum of all those numbers — that is, 127 units are contained in them. But we have written more on this matter in our *Practical Arithmetic* [*Epitome Arithmeticae Practicae*].

An example of the combinations in the aforesaid four qualities: the numbers in double proportion, according to the number of things, will be four, namely 1. 2. 4. 8., whose sum is 15. Four therefore being cast off, there remain 11. In so many diverse ways, then, the four primary qualities can be joined, namely these: heat, cold; heat, dryness; heat, moisture; cold, dryness; cold, moisture; dryness, moisture; heat, cold, dryness; heat, cold, moisture; heat, dryness, moisture; cold, dryness, moisture; and finally heat, cold, dryness, moisture. Nor can it be that any other comparison be made that differs from all these. For these two — heat, cold : cold, heat — are not reckoned to be distinct, since only the order is changed and

not the thing. By this reasoning, among five things — as among the five predicables — 26 diverse comparisons can be made. For the sum of these numbers 1. 2. 4. 8. 16. is 31; and 5 being taken away, there remain 26. This rule, moreover, is much conducive to the astrologers, that they may know all the diverse conjunctions which can be made among the seven planets; for by the aforesaid device they can be joined, or varied, in 120 ways, which it would be long to recount. In like manner it will be known how many words, whether useful or useless, can be constituted from the 23 letters of the alphabet — that is, in how many ways the said 23 letters can be joined among themselves, so that they are always diverse conjunctions, whether they can be pronounced or not. For from 23 letters there will be made words, or diverse conjunctions, to the number 8388584. For the last number, namely the twenty-third of double proportion, is 4174304, and so the sum of all the numbers will be 8388607. Therefore 23 being cast off, there remain 8388584, and so on. It is true that more words can be made, or combinations of letters, if the letters in any conjunction be permuted among themselves. As this aggregate, or conjunction, AVE can be varied in six ways, namely AVE, AEV, VAE, VEA, EVA, EAV — which modes, indeed, are taken by us in the rule as one conjunction only, since all these modes contain the same letters, though they change place among themselves.

[Margin: In how many ways any number of things can be interchanged among themselves, the same number of things always remaining.]

But if a number of things be proposed, and it be worth the labor to investigate in how many ways they can be interchanged, the same number of things always remaining, you will obtain it by this rule. Take as many numbers in the natural series as there are things, beginning from unity, and multiply them all among themselves: for the number produced will show what is sought. As two things — e.g. A, B — can be varied in two ways, thus: AB, BA — since these numbers 1. 2. multiplied among themselves make 2. But three things can be varied in six ways, for these numbers 1. 2. 3. multiplied among themselves make 6. The reason of this is that each thing will hold the first place once, and the remaining two twice, as we said, and so can be changed among themselves. So too four things can be varied in twenty-four ways [printed **vigintiquator**; recte **vigintiquatuor**], since these numbers 1. 2. 3. 4. multiplied among themselves make 24. The reason is that each thing will once occupy the first place, and the remaining three six times, as we said, and so can be varied among themselves. By the same way you will gather that 10 things can be arranged among themselves in 3628800 ways, since these numbers 1. 2. 3. 4. 5. 6. 7. 8. 9. 10. multiplied among themselves generate this number, 3628800. But eleven things [can be varied] in 39916800 ways among

themselves, since these numbers 1. 2. 3. 4. 5. 6. 7. 8. 9. 10. 11. multiplied among themselves procreate the aforesaid number. Since, therefore, by the preceding demonstration all the conjunctions of the twenty-three letters of the alphabet have become known, if it be inquired by this rule in how many ways the letters of each conjunction can be interchanged among themselves, there will be had the number of all words, useful and useless — provided that in one word no letter be taken twice, or three times, etc. For thus many more words still could be made.

By this reasoning, from the final combination of twenty-three letters among themselves, there arise 25,852,016,738,884,976,640,000 permutations — and this without any single letter being taken twice, which is scarcely credible. I decided to include these remarks on combinations here, since combinations had already been mentioned, and rules of this kind are usually explained by means of a few examples.

A second argument by which the fourfold number of the elements is proved, philosophers draw from lightness and heaviness. For every simple body — the kind into which mixed bodies are resolved, that is, an element — is either heavy or light. If heavy, it is either heavy without qualification, like earth, or heavy in a certain respect [*secundum quid*], like water; if light, it is either light without qualification, like fire, or light in a certain respect, like air. And in this way these four elements are gathered together. Water is said to be heavy in a certain respect because, although it is heavy relative to fire and air, it is nevertheless somehow light relative to earth, since earth is heavier than water. Yet it is called heavy rather than light, because it is called light only relative to one element, namely earth, whereas relative to the other two it is called heavy; and in reality it contains heaviness in itself, and not lightness. By the same reasoning air is called light in a certain respect: for although it is light relative to earth and water, it is nevertheless somehow heavy relative to fire, since fire is much lighter than it. But it is named light rather than heavy, because it is called heavy only relative to one element, namely fire, while relative to the other two it is light; and in reality it contains lightness in itself, and not heaviness at all, since — unless it is impeded — it always tends by its own motion toward a higher place.

[Margin: That there are four elements is confirmed from lightness and heaviness.]

[Margin: Why water is called heavy in a certain respect, and air light in a certain respect.]

A third argument is drawn from the simple local motions. For, on the authority of Aristotle in the book *On the Heavens* [*De Caelo*], there are only three simple local motions: the first takes place about the center, of the kind that is circular, which belongs to the celestial bodies; the second is away from the center; the third is toward the center — and these two latter motions are rectilinear. Now philosophers reason thus: there are as many simple bodies carried by rectilinear motion (excluding the heaven, which is not moved by rectilinear motion) as there are simple rectilinear motions — since every simple motion belongs to some simple body, and conversely every simple body is apt to be moved by a simple motion. But there are four such motions: two away from the center, that is, from the center of the world — of which one is away from the center without qualification, and is assigned to fire, the lightest of all; the other away from the center in a certain respect, which is granted to air, since it is not so light as fire, yet lighter than earth and water. And two toward the center, or toward the center of the world, of which the one that is toward the center without qualification belongs to earth, corresponding to its supreme heaviness; while the other, which is toward the center in a certain respect, is ascribed to water, inasmuch as it is not so heavy as earth, but heavier than fire and air. There are therefore these four elements. Let further arguments be sought from natural philosophy.

[Margin: That there are four elements is proved from the local motions.]

The order and position of the elements can likewise be gathered chiefly from three considerations. First, from their lightness and heaviness. For the lighter one thing is than another, the higher the place to which it ascends, and the heavier it is, the lower. Since, then, fire, on account of its very great rarity, is supremely light, the highest place is due to it — which indeed lies beneath the concave surface of the Moon. Air has obtained the place next to it, since it is lighter than the other two elements, yet less light than fire. Next after this comes water, for it is heavier than fire and air, but lighter than earth. Finally, the lowest place, which is near the center of the universe, earth by fullest right claims for itself, since it is the heaviest of all.

[Margin: The order of the elements is gathered from lightness and heaviness.]

Secondly, the order is gathered from the agreement of the elements in their properties. For the more any elements agree in their properties, the nearer and closer they are to one another in place. Hence, since we see that earth holds the lowest seat, and that water is more like earth than air is — because air is wholly opposed to earth and agrees with it in no quality, whereas water accords with earth in coldness — nature has, not without reason, placed water immediately

above earth. By the same reasoning we shall fittingly place air above water, since it agrees with water in moisture, whereas fire is like water in no quality, but is altogether contrary to it. Above air, lastly, we shall not unjustly set fire, since it agrees with air in heat. To this is added that, since fire and water possess wholly contrary qualities, they cannot be placed immediately next to each other; therefore most skillful nature interposed the middle elements, which in their qualities share with each of the two contraries — air, namely, between fire and water, and water between earth and air. And by this reasoning the elements stand in a symbolizing relation [symbolizantia] to one another.

[Margin: The order of the elements is gathered from their properties.]

But if anyone should ask why it is rather water that immediately follows earth, and not rather fire, then air, and lastly water — since in this order too the said agreements of the elements in their qualities would be preserved, because the middle elements are always interposed between the contraries — the answer is that this comes about for a twofold reason. First, since we see that earth, the heaviest of all, has occupied the lowest place, natural reason seems to require that fire, the lightest of all, should occupy the highest place; and so it was not fitting for earth to follow immediately upon it. Secondly, since water is exceedingly unstable and flowing, it cannot hold together unless it rests upon some hard body, such as earth is; therefore with the best right water is placed immediately above earth.

Thirdly, the order is gathered from sense and experience. For we see daily that fire is borne naturally above earth, water, and air, since its shape always forms a pyramid; therefore its natural place must be above all these. We also see that air naturally ascends above earth and water, as is evident in an earthquake. For an earthquake arises from the violence of air enclosed within the bowels of the earth, striving to ascend into its own place above earth and water. This is likewise established in the bubbles of air that well up in water, as may be seen in marshes if someone thrusts a stick into the bottom. Reason therefore requires that air be placed above earth and water, and beneath fire. We see, finally, that water placed in air descends, and that earth placed in water likewise tends downward. Therefore it will be concluded that, not without reason, the natural place of water is beneath air, and that of earth beneath water.

[Margin: The order of the elements is gathered from experience.]

There are, however, some — among whom is Cardano [Girolamo Cardano] — who deny that fire exists above air, on the ground that it is in no way perceived

by us; indeed, they say, if it were there, it would burn up these lower things. And so these men do not grant any elemental fire other than this lower one which we use. But let us leave this dispute to the philosophers. For the present it will be enough to know that the far more probable and more common opinion is that of those who, with Aristotle, place fire beneath the concave surface of the Moon as in its natural place. That it is not perceived arises from its excessive rarity; for since it is exceedingly pure and exists in matter rarer than air, it cannot be seen — indeed not even air itself, which is denser, can be seen. That it does not burn up these lower things happens from the same rarity: for fire, existing in the rarest matter, cannot have so great a power of burning; yet it does warm these lower things wonderfully by its heat.

[Margin: Cardano denies that the element of fire lies beneath the concave surface of the Moon.]

As for the shapes of these elements, there will be occasion to speak later; for the present it is only worth noting that air is divided by philosophers into three regions: namely the supreme, the middle, and the lowest. The supreme, in which we see comets carried, is always hot on account of its continuous motion — which it has from the *primum mobile* — and its nearness to fire, and the continuous emission of the sun's rays through it. Likewise the lowest region, being nearer to us, grows warm from the manifold reflection of the sun's rays. But the middle region, on account of its great distance from fire, and because the reflections of the sun's rays cannot reach it, is always cold, as the meteorological impressions generated there show — impressions that are cold, such as rains, snow, hail, and the like.

[Margin: Air is divided into three regions by philosophers.]

Diagram. A circular woodcut of the sublunary and elemental spheres, drawn as a set of concentric rings within a flame-hatched border (the sphere of fire). At the center is the terrestrial globe (a small landmass or figure representing earth and water); around it the three concentric bands of air are labeled, and the whole is set within an outer frame marked with celestial reference points. The labels read:

- Center: the globe of earth (and water), unlabeled.
- Inner band: **INFIMA REGIO** ("lowest region" — of air).
- Middle band: **MEDIA REGIO** ("middle region").
- Outer band: **SVPREMA REGIO** ("supreme region"), bordered by the wavy flame-hatching of the sphere of fire.
- Top (radial): **POLVS ARCTICVS** ("arctic pole").

- Bottom (radial): **POLVS ANTARCTICVS** ("antarctic pole").
- Left (vertical): **ZENITH**.
- Right (vertical): **NADIR**.
- Diameter line: **ÆQVINOCTIALIS** ("equinoctial [circle]"), lettered across the figure.

Moreover, granting that the whole airy orb is uniform, so that it has the same center as the world both according to its concave and according to its convex surface, it seems probable enough that the middle region of air is broader and denser near the poles of the world, on account of the weakness of the heat which the very great absence of the Sun produces there, and the excessive cold that perpetually exists there; and that the parts of that same middle region lying midway between each pole of the world — as under the equator — are compressed, on account of the abundance of heat which the perpetual presence of the Sun produces there; and conversely, that the parts of the supreme and lowest region near either pole of the world are compressed, while their parts lying midway between each pole are dilated. All this you may clearly draw out from the figure set beside the text, in which you will also observe the position and order of the elements. Indeed, perhaps fire itself is not uniform in density, since, on account of the speed of the motion by which it is swept from east to west, it can easily transmute into itself the air that lies beneath it.

But surrounding the elementary region is the aethereal region — luminous, exempt from all variation by its own immutable essence, and moving continuously in a circular fashion. And this is called by the philosophers the fifth essence.

[Margin: The aethereal region.]

COMMENTARY.

After treating the form of the elementary region, the author proceeds to a discussion of the form of the aethereal region. He sets out at the outset five notable properties by which it is separated and distinguished from the elementary region. The first is that it lies around the elementary region — in which respect it is compared with the elementary as container to contained — and it is called the place of the whole elementary region. Now every place, the higher it is, the more mobile it is believed by philosophers to be, and the body existing in it the more excellent, because it is removed further from these corruptible lower things and exists nearer and closer to those divine movers of the spheres, which ever enjoy the best and most blessed life. The second property is that it is luminous, in which it far surpasses the elementary region. For light is

far nobler than the properties of the elements. For these properties are active or passive, and mutually contrary, so much so that by their mutual struggle all these lower things are led to destruction and corruption; whereas light, free of all contrariety, pours into all these lower things life, being, and duration. There is added, too, that light is the object of the noblest sense, namely sight; and one whole discipline among the mathematical sciences — and the most beautiful of them, namely optics [perspectiva] — is occupied with it. The third property is that the aethereal region lacks all motion that would alter its substance. For the aethereal, or celestial, region can neither be altered, nor increased, nor diminished, nor generated, nor corrupted, according to the philosophers — the opposite of which we asserted above concerning the elements, since these are engaged in perpetual transmutation. The fourth property is that the aethereal region is moved by a perpetual and continuous circular motion without any interruption — a motion which among philosophers is the first of all others and the noblest, and is the cause of continual generation and corruption in these lower things. The motion of the elements, by contrast, is rectilinear by its very nature, and quickly comes to an end. The fifth and last property is that the aethereal region is called by philosophers the fifth essence. For the heaven, as Aristotle holds, is not an element, nor composed or made up of elements, but

[Margin: The properties of the aethereal region.]

[Margin: The fifth essence.]

is a body of a certain other, intermixed nature, far removed from the four elements. Hence, in order to distinguish it from the four elements, it has been called the fifth essence.

This fifth nature — that is, the celestial region — is called *Aether*, on the authority of Aristotle, from αἰ [Greek: αἰ (aei, "always")] and θέω [Greek: θέω (theō, "I turn" or "I run")], because the celestial bodies which constitute that region are turned and revolve always and perpetually. Some, however — among whom Anaxagoras and Cicero are counted — hold that it is called *aetherea* from αἶθω [Greek: αἶθω (aithō, "I blaze," "I shine")], for the aethereal region is indeed always luminous and shining.

[Margin: Why the aethereal region is so called.]

Of this region there are nine spheres, as was treated in the preceding chapter: namely those of the Moon, Mercury, Venus, the Sun, Mars, Jupiter, Saturn, the fixed stars, and the outermost heaven. Each higher of these spheres spherically surrounds the one below it. Of these there are two motions: one is that of the

outermost heaven upon the two extremities of the axis, namely the arctic and the antarctic pole, returning from the east through the west back to the east, which the equinoctial circle divides through the middle. There is also another motion of the lower spheres, oblique and opposite to this one, upon their own poles, which are distant 23 degrees and 33 minutes from the former poles.

[Margin: The order of the celestial spheres.]

[Margin: There are two motions of the celestial spheres.]

COMMENTARY.

He repeats the division of the aethereal region, which a little before he had divided, with respect to substance, into nine heavens; and here he lists their names and order.

Now all the celestial spheres, he says, are moved by two principal motions. The first is assigned to the outermost heaven, or primum mobile, and takes place upon the two poles of the world, namely the arctic and the antarctic, returning from the east through the west again to the east. That heaven is said to be moved from east to west which tends from the east toward the south — that is, toward that part of the meridian circle which stands above the horizon — into the west, and again from the west toward midnight — that is, toward that part of the meridian circle which lies hidden beneath the horizon — is turned back to the east. But that heaven is said to be moved from west to east which tends from the west toward the south into the east, and again from the east toward midnight slips back into the west. This must be carefully noted, so that the motion from east to west may easily be distinguished from the motion from west to east; for the former, beneath the earth, also proceeds from west to east, and the latter from east to west, and yet the former is said to go from rising to setting, and the latter from setting to rising — because the former, above the earth, goes from rising to setting, while the latter goes from setting to rising. This motion from east to west, the author says, the equinoctial circle divides through the middle. For since motion is divided in accordance with the division of the movable thing, as is held in *Physics* VI, and the primum mobile is divided by the equinoctial circle into two equal parts, as we said above, it is necessary that the same circle should distribute the motion of that same primum mobile — which, according to our author, is the ninth sphere, and which is carried along the equinoctial circle — into two equal parts.

[Margin: When some heaven is understood to be moved from rising to setting, and from setting to rising.]

The other motion belongs only to the eight lower spheres, and in no way to the primum mobile, and is opposite to that former motion. For the eight lower heavens are moved from west through the south to the east, and thence slip back through midnight into the west. Perhaps our author called this the second motion, describing it as "through the oblique," because it does not take place upon the poles of the former motion, but upon other poles distant from the poles of the former motion by 32 [?] degrees and 33 minutes — a distance which was observed by al-Ma'mūn [Almeone][?], and which is now smaller, namely about 23 degrees and 30 minutes, as we shall say in chapter 2. What a degree is has been stated above, where we spoke of the zodiacal circle. A minute is the sixtieth part of one degree; for astronomers divide any degree into sixty equal parts, which are called minutes — about which division you will have more in chapter 2, when we treat the zodiacal circle at greater length. Or rather, this posterior motion is called oblique because it takes place along the zodiacal circle, which, as was said above, obliquely cuts the equinoctial circle, in accordance with which the prior motion is accomplished. For hence it comes about that this posterior motion is in a certain way oblique, if it is compared with the prior.

But the first sphere carries all the others along with it by its own impetus once around the earth within a day and a night; yet with those others striving against it — as the eighth sphere moves one degree in a hundred years. This second motion the zodiac divides through its middle, beneath which each planet has its own sphere, in which it is carried by its own proper motion against the motion of the outermost heaven, and completes that motion in different spans of time: as Saturn in 30 years, Jupiter in 12, Mars in two; the Sun in 365 days and about six hours; Venus and Mercury nearly the same as the Sun; but the Moon in 27 days and eight hours.

[Margin: A comparison of the two motions of the celestial spheres with each other. The periods of the motions of the planets from setting to rising.]

COMMENTARY.

Here he compares the two aforesaid motions with each other, assigning also the times, or periods, in which such motions are completed. He says, then, that the first motion, or primum mobile — which according to him is the ninth heaven — carries all the other lower spheres along with it by its own impetus within a day and a night, that is, within the span of 24 hours, once around the earth. Hence such a motion is usually called "diurnal" not only by astronomers and philosophers, but also by common people, because it is completed in a natural day, which comprises 24 hours, as will be explained more fully in chapter 3.

[Margin: The diurnal motion.]

Next he asserts that all the lower spheres, although — as was just said — they are carried by that first motion from east to west, strive against it, that is, tend in the contrary direction, namely from west to east, being carried in different

COMMENTARIVS (continued) — on the nine spheres and their motions

at different times. For, as he says, the eighth sphere — that is, the starry heaven — completes one degree in 100 years by its own motion, which is stated according to Ptolemy's [Ptolemy] view. From this it follows that this entire motion is completed in a span of 36,000 years. The Zodiac circle divides this motion through its middle, just as the Equinoctial divides that first motion. For just as the first motion takes place about the poles of the world and along the Equinoctial circle, so too astronomers have found that the second motion takes place about the poles of the Zodiac and along the Zodiac circle.

Beneath this Zodiac, he says, each planet is carried in its own proper sphere by its own motion, contrary to the motion of the outermost heaven — that is, from West to East. You should not understand this as though the planets moved by themselves beneath the Zodiac; rather, the heavens themselves move about the poles of the Zodiac, and in this way carry the planets along with them, the planets always remaining beneath the Zodiac. And this happens at different times, as he himself clearly sets out, and as we shall explain more fully a little below.

[Margin: The harmony of the celestial motions.]

In this matter one may contemplate the following harmony of the celestial motions: the nearer a sphere is to the primum mobile — that is, to that first, most rapid motion — the less it resists in the opposite direction, and the more slowly it is carried by its own motion from West to East; whereas the farther off it is, the more it resists in the opposite direction, and the more swiftly it completes its own motion. Yet no fixed proportion is preserved in this slowness and swiftness, as is evident from the periods of all the motions that the author has reported. Hence, among all the eight lower spheres, the sphere of the fixed stars, because it is nearest the primum mobile, completes its course most slowly; and among the seven planets, because Saturn is the highest, it too moves by its own motion more slowly than the rest; and the Moon, finally, because it recedes farthest from the primum mobile, completes its motion most swiftly.

But since the author has here spoken of the number of the celestial spheres, their motion, and their order, I think it worthwhile to explain a little more fully how many heavens there are, and by what skill and diligence astronomers discovered their number; then, by how many motions they are moved, and by what reasoning these motions were detected; and finally, what order is established among the celestial spheres.

DE NVMERO ORBIVM COELESTIVM. [On the Number of the Celestial Spheres.]

[Margin: The opinion of those who posit a single heaven. Refutation of the opinion of those who posit a single heaven.]

Some of the ancient philosophers assert that there is only a single heaven, and a very few of the more recent thinkers follow them, persuaded by this one argument: All our knowledge, according to the doctrines of the philosophers, arises from the senses. Since, then, whenever we lift our eyes to the heaven we do not perceive by sight a multitude of heavens — for the Sun, the Moon, and all the other stars appear to exist in one and the same heaven — and since the heaven itself can fall under no other sense than sight, there is no reason for us to posit many heavens instead of one.

But this opinion can be defended by no reasoning. For no single body can move at the same moment with opposite and contrary motions; while it ascends it cannot at the same time descend, and while it proceeds from this place to that, it is impossible that at the same instant it should move from that place to this, since these are mutually contradictory. Yet in the stars diverse and opposite motions are found. Since, then, the stars do not move by themselves, like fish in water or birds in the air — as Aristotle [Aristotle] holds, along with the philosophers, and as we shall demonstrate a little later — but move with the motion of the sphere in which they are set, like a knot in a board with the motion of the board, or a nail fixed in a wheel with the motion of the wheel, we must grant that there are more heavens than one, in which are set those stars that are moved by diverse motions.

That diverse motions are found in the stars is established partly from what the author set out above concerning the twofold motion of the celestial bodies — namely from East to West, and conversely from West to East — and partly it will become clearer and more distinctly evident in what follows, when we discuss the motions of the heavens, where we shall also show by what diligence astronomers observed them. This opinion, therefore, must be rejected as empty and useless. As to the argument that the authors of this opinion put forward, we must reply that

it is indeed true that our knowledge, while we are in this mortal life, arises from the senses; but it must be denied that no more than one heaven is perceived by sense. For although we do not comprehend by sight the multitude of the heavens — indeed, not even a single one — nevertheless we perceive by sight very many stars, and we detect that they are continuously set in motion by diverse and opposite movements. Therefore, on account of this diversity of motions, more spheres must necessarily be posited.

[Margin: The opinion of those who posit eight heavens.]

Others, therefore — as were nearly all the Egyptians and Chaldeans, much devoted to astrology, and other astronomers down to the times of Plato and Aristotle — asserted that there are at least eight heavens, on account of the eight distinct motions they observed in the heavenly bodies. For when they saw the Sun and the Moon, and all the other stars as well, continuously moving from East to West, they learned by long observation and experience that not all the stars are always conjoined or separated by the same distance, since sometimes they were joined together and sometimes drawn apart — as we experience, more clearly than daylight, each month in the Sun and Moon; for at new moons these two planets are conjoined with one another, while at full moons they are opposite one another across the diameter. From this fact they clearly inferred that there are diverse motions in the stars.

For if the stars were carried by only a single motion, they would always be seen at the same distance and nearness. Hence they were compelled to affirm that there are more heavens — at least as many as the diverse motions they detected in the stars — since the stars are carried around not by themselves but together with the sphere in which they are, like a knot in a board. But since by long observation they came to know that a great number of stars — namely all those we call fixed — always advance uniformly at the same distance, in the same position and order: for example, the two hindmost stars of the Wain (which is in the Great Bear), together with the pole star (which is at the tip of the tail of the Little Bear) and that star which is in the left foot of Cepheus, always form a straight line; likewise that bright star which is in the more western pan of the Balance, together with Arctophylax (that is, Arcturus) and the last star in the tail of the Great Bear, are always positioned in an almost straight line; likewise the Great Dog, the Little Dog, and that star of the Wain which is nearer the Arctic pole are also arranged along a straight line; likewise the left foot of Orion, the Little Dog, and the tail of the Lion always form almost a straight line; the same has been observed in the eye of the Bull, the left shoulder of Orion, and the Great Dog;

likewise in the three stars that form the belt of Orion; again in the left foot of Orion, the eye of the Bull, and the bright star in the head of Medusa. Similarly the Ear of Corn of Virgo [Spica], Arctophylax [Boötes], and the tail of the Lion always form an isosceles triangle, whose base is formed by Arctophylax and the tail of the Lion; likewise the Heart of the Lion [Regulus], the Little Dog, and that bright star, the more eastern one of Gemini, form an isosceles triangle, whose base is formed by the Little Dog and that star of Gemini. The same, finally, has been observed in very many other stars. On this matter, read Ptolemy (*Almagest* [Dictio] VII), and the *Epitome* of Johannes Regiomontanus [Regiomontanus] on the same book, where many observations of this kind are adduced. For this reason they asserted that all those stars are set in a single celestial sphere, which they all called the Firmament, as was said above, and by whose motion they are carried around, always keeping the same remove, position, and distance from one another.

They observed, again, that among all the heavenly bodies there are seven stars, which they called wandering [the planets], which neither kept a distance from one another nor were found in the same position relative to the fixed stars. They concluded that these could not exist in the Firmament, where the fixed stars are — for then they would always keep the same distance from them, just as the fixed stars do among themselves; but neither were all seven placed together in some single other heaven, for on that supposition they would keep the same distance and position among themselves, even though they continually varied their arrangement relative to the fixed stars.

For this reason they concluded, by a most firm argument, that beneath the Firmament seven other spheres must be placed, which they named the seven spheres of the seven planets, or wandering stars. And since, besides these eight motions of the stars — entirely distinct and diverse from one another — they knew of no other, they were content with the number eight for the heavens, and supposed that the eighth sphere (that is, the Firmament containing the fixed stars) was the *primum mobile*.

[Margin: The opinion of those who posit nine heavens.]

But after these there arose other astronomers, among whom were Arsatilis [Aristyllus] and Timocharis, who flourished around the year 330 before the birth of Christ, and who, observing the courses of the heavenly bodies at Alexandria, detected that the stars of the Firmament — which antiquity had thought to be the *primum mobile* — are carried by another, very slow motion from West to East,

and not only by the daily motion from rising to setting, as the ancients had supposed. But because they had no observations of others with which they might compare their own, the result was that they left us almost nothing certain about this motion, but everything in doubt, on account of its excessive slowness.

Yet after them came Abrachis, also called Hipparchus [Hipparchus], nearly 200 years later, who, comparing his own observations with theirs, detected the aforesaid motion much more clearly and evidently. Then, after about 170 years, Agrias [Agrippa?] in Bithynia, Mileus the Geometer, also called Menelaus [Menelaus of Alexandria], at Rome, and after all these Ptolemy, the prince of astronomers, in the year of the Lord 131 or thereabouts, came to know this motion of the fixed stars from West to East still more clearly. By what diligence they detected it we shall soon disclose, when we have treated of the motions of the heavens.

Since, therefore, it is now beyond doubt that the fixed stars have a twofold motion, and no simple body can be carried by two motions, we must conclude that one of these is proper to the Firmament, by whose motion the fixed stars are carried around, while the other, which we find in the same Firmament, arises from another heaven — which must, of course, be placed above the Firmament, so as to be the ninth heaven and the *primum mobile*. For in this way the ninth heaven will be moved from rising to setting in the space of 24 hours, drawing the sphere of the fixed stars along with it at the same time; while the Firmament itself will be turned by its own motion from setting to rising, though very slowly.

Thus, then, the astronomers established nine celestial spheres by most certain observations, on account of the daily motion from rising to setting and that very slow one from setting to rising, both of which were detected in the fixed stars. And Johannes de Sacrobosco [Sacrobosco] follows this number of nine celestial spheres in this little work.

[Margin: The opinion of those who posit ten heavens.]

After Ptolemy, then, about 1,140 years having intervened, Thebit [Thābit ibn Qurra], and Alfonso, king of the Spaniards [Alfonso X of Castile], in the year of the Lord 1250, and then George Peurbach [Georg Peurbach] and Johannes de Regiomonte [Regiomontanus], distinguished astronomers, did indeed detect in the fixed stars the two aforesaid motions, but besides these they observed that the stars are agitated by a certain third motion, which they called access and recess [accessus et recessus — *trepidation*], as will be explained shortly. Therefore, since a simple body is fit to be carried by only one motion, as the philosophers hold, the

ninth heaven cannot be the *primum mobile*; rather, above it another heaven must be established to be the *primum mobile*. For thus it will come about that this tenth heaven, by the daily motion which it has as its own from East to West, draws with it all the lower heavens — indeed the Firmament too, with the fixed stars — in the space of 24 hours; then the ninth heaven carries around, by its own motion which it possesses, from West to East, both the Firmament and all the other heavens below it; and finally the eighth heaven, or Firmament, in which the fixed stars are, moves as if by its own motion, with that access and recess which the aforesaid astronomers discovered.

This tenfold number of celestial spheres, therefore, has remained the most celebrated in the schools of astronomers down to this day — though there are some who, so as not to seem to depart from the ancients, and especially from Aristotle, stubbornly try to maintain that there are only eight heavens. But since authors of this sort can in no way account for all the motions we see in the celestial bodies, their opinion is rightly rejected by astronomers, as we shall discuss when we treat of the motions of the heavens. Nor should the authority of the ancients and of Aristotle move us; for if they had detected the further motion beyond those eight, they would doubtless have admitted more spheres, since it was by no other reasoning than from the number of motions that the number eight for the heavens was reckoned by them.

Therefore in this matter we should rather trust the most experienced astronomers, who observed the said ten motions — namely seven distinct from one another belonging to the seven planets, and three others belonging to the fixed stars — than Aristotle, since he himself affirms in *Metaphysics* XII that astronomers are to be consulted in astronomical matters. Indeed, these very authors, who wish to be so devoted to Aristotle and the ancients that they will by no means depart from them in the number of the celestial spheres, do depart from them in the order of those same spheres, on account of the most manifest observations of the astronomers, as will later become clear.

[Margin: The opinion of those who posit eleven heavens.]

Finally, in our own time Nicolaus Copernicus [Copernicus], a most learned man and most worthy of all praise, observed in the fixed stars not merely three motions but four. Therefore, in order that we may account for them, three movable spheres must be placed above the Firmament, as we shall teach below — provided that we first set out the motions of the heavens according to the view of those who admit only ten movable heavens.

But if someone objects: every motion of the heaven, as Aristotle holds in *Metaphysics* XII, chapter 8, is for the sake of the motion of a star; since, then, in the ninth, tenth, and eleventh heaven there exists no star — for none appears there — it seems pointless to place, above the eight heavens in which all the stars (both fixed and wandering) are set, three other movable heavens marked by no star. The reply is: although in the ninth, tenth, and eleventh heaven there exists no star, nevertheless the motion of each of them redounds to some motion of the stars that exist in the other heavens. For by the motion of the eleventh heaven, or primum mobile, all the stars are moved from rising to setting; and by the motion of the tenth

heaven, from North to South and from South to North, through 24 minutes beneath the Colure of the Solstices; and by the motion of the ninth heaven they have a certain unequal libration from East to West and from West to East, beneath the Ecliptic of the tenth sphere, through 140 minutes; and finally, by the proper motion of the eighth sphere, the fixed stars are carried around from West to East. This suffices for the motion of the heaven to be appointed for the sake of the motion of a star. But these things will be perceived a little later more plainly and openly.

It can also be said that Aristotle, in the cited passage, was speaking of the motions of the heavens as they were then known, and that thus the motion of each heaven was ordered to the motion of a star existing in it — which, however, is not necessary, since no reasoning urges it, and experience has now taught the contrary.

[Margin: The Crystalline Heaven. The Empyrean Heaven.]

There is also added (if you please) the authority of Sacred Scripture and of the theologians, to confirm this elevenfold number of the heavens and to establish at least one more heaven above the Firmament. For we read in the sacred book of Genesis that God set a Firmament dividing the waters from the waters, and likewise in Psalm 148, "And all the waters that are above the heavens," and so forth. No one of sound judgment will understand that in that passage the waters above the eighth heaven are flowing and perishable, like these lower waters; rather, by the name of "waters" must be understood — as very many of the theologians explain — the ninth heaven, or rather the aggregate of the ninth, tenth, and eleventh heaven, which, on account of the brightness and transparency it has (since there are no denser parts there, as in the other spheres, such as the stars are), can with the fullest right be called by the name of waters.

For this reason it is usually called by some theologians the icy or watery heaven, and by others the Crystalline.

Above these eleven movable heavens the theologians — such as Strabus [Walafrid Strabo], the Venerable Bede [Bede], and now the whole company of theologians — affirm that there is another heaven, immovable indeed and endowed with no star, but the blessed seat and homeland of the angels and of the Blessed, which they call the Empyrean heaven, from fire, because it is wondrously bright and endowed with immense radiance. This heaven, however, can in no way be known by astronomers, since it does not move.

Nevertheless there are those who strive to prove, by certain observations, that it is very fitting that that twelfth heaven, entirely immovable, should exist above all the heavens. For, as Pliny [Pliny the Elder] testifies in book 8, chapter 16, in Europe between the rivers Achelous and Nestus there are begotten lions far superior in strength to those which Africa or Syria produces. Since this does not happen throughout that whole latitude, or tract of land from East to West, in which the said rivers are situated, the cause of this variety will be — as they assert — the influence of some unmoving heaven existing over that tract of land. For if the cause were the influence of the stars, or of the movable spheres, then throughout that whole tract of land from East to West, on account of the continuous motion of the stars, such lions ought to be born — the opposite of which we see.

Then, too, in Hungary at latitude 47 degrees the swiftest and strongest horses are produced, which are by no means produced in other regions of the same latitude. Finally, in Mauretania almost innumerable apes are generated. And many other experiments of this kind could be adduced — from vines, trees, fruits, and so on — all of which varied effects seem to be produced by a heaven that is simply at rest. I know that the philosophers reply that this diversity of effects in the same clime depends entirely on the varied disposition of the earth; but the aforesaid authors press their point: since the earth is variously disposed by the various aspects of the higher bodies, no sufficient cause can be given why in the same clime the disposition should not be the same, seeing that all parts of the same clime have successively the same aspects with respect to the movable heavens. But in truth, whatever is said on this matter, this much must be certain: that the Empyrean heaven, which is immovable, cannot be denied without great rashness — a heaven that the school of theologians now commonly admits.

[Margin: Twelve heavens according to the astronomers of this age.]

The astronomers of this age, therefore, establish that in all there are twelve heavens — eleven indeed movable, but one, according to the view of the theologians, entirely immovable. The reason why we admit eleven movable heavens will be clear when we treat by what diligence the eleven distinct motions were discovered by them. But first let us proceed to explaining the motions of the heavens, according to the view of those who allow only ten movable heavens.

DE MOTIBVS ORBIVM COELESTIVM. [On the Motions of the Celestial Spheres.]

[Margin: The opinion of those who removed all motion from the celestial sphere, and its refutation.]

The authors who believe that there is only a single heaven exclude all motion from the celestial sphere — though not all in the same way. For some assert that no celestial body moves, but that it always remains in the same place, and that the stars only appear to us to move from East to West (they cannot by any reasoning deny this daily motion, at least as an appearance, since every day we see the Sun and the other stars rise and set) on account of the motion of the earth, which, as they say, it has from West to East. For just as, to someone carried along the course of a ship on some swift river, the trees, houses, and everything set on the riverbank seem to come to meet him — as though he himself stood entirely still and everything else moved — so too it happens to us who exist on the earth. For since the earth moves with us from setting to rising with a most rapid motion, we seem to be at rest, and the stars seem to move in the same direction — namely from rising to setting — whereas in fact they are entirely immovable and it is we who move, as has been said. But this opinion is of no weight whatever, and is utterly ridiculous. For if it were true, the same position, order, and distance would perpetually be seen among the stars — which is contrary to all experience. For the planets continually vary among themselves their position, order, and distance, as is clearer than daylight in the case of the Sun and Moon, since these two planets are sometimes as it were conjoined and sometimes opposite across the diameter; and take it as commonly known that the same holds of the other planets.

[Margin: The opinion of those who say that the heaven is at rest and the stars move by themselves.]

But some assert that not only the heaven but also the earth is at rest, and that the stars move by themselves, like birds in the air or fish in the sea, from East to West. But since on this account the planets could not be carried by two motions

— which conflicts with experience, since we see the planets carried not only from rising to setting but also from setting to rising — for this reason others affirm that the heaven moves from East to West, carrying the stars around with it, while the individual stars also have their individual motions from West to East. For which reason, they say, it comes about that all the stars appear to complete the daily motion at the same time, while we detect that they move from setting to rising in unequal times. But neither is this opinion to be admitted, since — as we shall demonstrate in what follows — it is impossible for the stars to move by themselves, if the things that appear in their motions are true; rather, it is necessary that they be carried around only by the motion of the sphere in which they are.

[Margin: First opinion on the motions of the heavens, of those who posit eight heavens.]

Nor, in fact, do all who hold that there are several heavens agree about the motions of the celestial bodies. To begin with those who believe there are only eight heavens: some hold that each celestial orb is driven by its own motion from west to east. They cannot deny that the motions of the seven planets are distinct — both among themselves and when compared with the fixed stars — since the planets sometimes come into conjunction with one another and with the fixed stars, and sometimes part from them again. But the daily motion of the heavens from east to west they abolish entirely. It cannot happen, they say, that one and the same body should be moved at the same time by contrary and opposite motions, such as the motion from east to west and the motion from west to east. Yet since they saw that this conflicts with experience and the senses — for we see the Sun, the Moon, and the other stars slip daily from east to west, now rising above the horizon, now sinking below it — they devised the following: that the heavens with their stars appear to us to move from rising to setting because the earth is carried around with us from west to east by a motion swifter than the planets', namely in the span of twenty-four hours. Hence we suppose ourselves to be at rest while the stars advance to meet us, just as the authors of the first opinion maintained.

[Margin: Refutation of the first opinion.]

But we must not judge the celestial motions in this way either, because on this account not all the motions observed so far can be defended, as will become clear later. Moreover, the earth is by no means carried from west to east with such great speed, as will also be shown in what follows. Add to this that this opinion

assumes the motion of the heavens from east to west to be contrary to the motion from west to east — which will shortly be shown to be false.

[Margin: Second opinion on the motions of the heavens, according to those who allow eight heavens.]

Others, likewise believing the said two motions to be contrary to each other, assert that the heavens are moved only by the daily motion from east to west. Indeed, by this motion they say that not only the celestial orbs but all the elements as well are moved — a motion produced by a single intelligence, which they call the soul of the world [*anima mundi*]. Yet in such a way that the nearer any sphere lies to the soul of the world, the more swiftly it is moved by it, and the more remote it is, the more slowly — just as we observe in the motion of some wheel: the parts nearer the axle of the wheel, as to its center, are moved more slowly, while the parts closer to its circumference are carried more swiftly. Hence they say that the highest heaven is moved most swiftly of all, since it is nearest the soul of the world, but the earth most slowly — so slowly that its motion is not perceived, on account of its extreme slowness, because it has withdrawn farthest from the soul of the world. For this reason it appears to everyone to be at rest, though in fact it is gradually and, as it were, imperceptibly carried from east to west. This they try to establish by the following evidence. We see, they say, that on the western side the land continually and gradually tends to sink beneath the sea, while on the eastern side, on the contrary, it emerges more and more from the sea. This, they claim, is clearly demonstrated to us by the Pillars of Hercules set on the shore of the Western Ocean, and the pillars of the same set on the shore of the Eastern Ocean: for the former are now found many miles within the sea toward the western regions, while the latter, by contrast, are seen the same number of miles out of the sea in the eastern regions. It is therefore a clear sign, they say, that the earth is gradually being carried from east to west by that soul of the world.

Now since, besides this daily motion, the planets also seem to be moved from west to east — because they are not always at the same distance from one another, nor always situated beneath the same fixed stars, but recede eastward from them (which, however, these thinkers deny) — they assert that this is the reason why some heavens are believed to be carried from west to east, although in reality they are driven only from east to west. The cause is that the lower spheres, the farther they are from the highest heaven and from that soul of the world, are moved (as has been said) the less effectively, and for this reason are carried around more slowly and seem step by step to fall back from west to east.

Hence it also follows that the Moon, because among the celestial orbs it recedes farthest from the highest, is moved most slowly from east to west, and seems most swiftly — namely in the span of a single month — to complete a whole circuit from west to east. The remaining spheres, the higher they are, seem to us likewise the more slowly carried from setting to rising.

All of this they wish to set before our eyes by this single example. Let there be three parallel ranks of men arranged in straight lines. Let them set out together from the same place, from east to west, but under this rule: that those in the first rank advance at the swiftest pace, those in the second more slowly, and those in the third slowest of all. On this arrangement it is clear that the first rank, moving at that quickened pace, outstrips the other two — but the third rank more than the second. Hence, if someone were to watch these ranks from a distance, he would judge that the second and third ranks were gradually falling back, and the third at a quicker rate than the second, even though in reality they were all advancing, like the first rank, only from east toward west. For exactly the same reason, they say, the planets appear to us to be moved from west to east.

Alpetragius [al-Biṭrūjī] and Achillinus [Alessandro Achillini], along with other authorities, embrace this opinion the more readily because they can in no way imagine that one and the same celestial body is carried by two motions — namely from east toward west, and again from west toward east. For since these motions, as they say, are contrary, one of them must necessarily be violent, which cannot be; indeed it seems absurd to grant violence in the celestial bodies. First, because nothing violent is perpetual, whereas the motion of the heaven is perpetual, on Aristotle's view; and second, because everything violent is continually weakened more and more, whereas the motion of the heaven is always accomplished at the same speed without any failing. There is this further point, they say: a plurality of motions is not to be posited without necessity. Since, then, no necessity compels us to admit that the planets are moved from west to east — given that, for the reason already stated, they merely appear to us so moved — this plurality of motions would be introduced by the astronomers rashly and without warrant.

But this opinion cannot be true in any way, since it cannot account for everything that appears in the celestial motions. For if the lower orbs had no motions of their own from west to east, but were thought to be moved from setting to rising only because of that sort of falling-back or retardation, then the falling-back of the lower orbs would occur along the same line and about the same poles — namely along the equator [circulus Æquinoctialis] and about the poles of the world — since the daily motion runs straight along the equator and over the poles of the

world, from east to west. From this it would have to follow that all the stars and planets, by the daily motion, would always describe the same parallel circles on the near and far sides of the equator; that the stars and planets lying on the equator would never depart from it, but would remain forever beneath it; and that those on the near or far side of the equator would never approach it or recede from it more or less. Consequently neither the Sun, nor the Moon, nor any other star, fixed or wandering, would ever come nearer to the zenith of our heads, or withdraw farther from it, at one time than at another —

— all of which most plainly conflicts with sense and experience. For we see the Sun (to pass over the other planets and the stars in silence) describe various circles parallel to the equator itself, as the author will explain in chapter 3, and not always keep the same distance from the equator, since twice in the year it is found upon it, and deflects from it now toward the south, now toward the north. Hence it comes about that it is seen to rise and set at different points of the horizon over the course of the year. Hence too it comes about that in summer, standing at the beginning of Cancer, it approaches very close to our zenith, or vertical point, while in winter, placed at the beginning of Capricorn, it recedes farthest from the zenith. And it is truly astonishing: if all the heavens are moved only from east to west, while the lower ones — because they move more slowly — fall back in a way, or are retarded (as they claim), then no fixed proportion is to be seen in this retardation. For the eighth sphere completes its circuit in the span of 36,000 years; Saturn in 30 years; Jupiter in 12; Mars in 2; the Sun in one year; Venus and Mercury in about the same time; and the Moon, finally, in 27 days and 8 hours. Here you plainly see that no fixed proportion is found. It is therefore not credible that the planets lack motions of their own from west to east, and that they only seem to us to be moved from west to east because of that retardation.

Therefore, to Alpetragius and Achillinus's first argument the reply must be that those motions are not contrary, as will be shown below, and for that reason neither is violent. Add further that it does not follow [?] — even if we were to grant that one of them is in some way violent — that it would fail to be perpetual and could be weakened, since its moving cause is perpetual and untiring. For that violent motion alone is said to be unable to be perpetual which has an exhaustible and non-perpetual cause; and this is what is called violent simply and in itself. To the second argument the reply must be that a plurality of motions is most necessary for rendering the cause of all those appearances we have mentioned, and of many others of the same kind, which they themselves cannot account for. Finally, to what they allege about the motion of the earth, we reply that it is false that the earth moves; nor in this matter should we credit the tales

about the Pillars of Hercules. If at some time there was land where the sea now is, and the reverse, this in no way arises from a motion of the earth from east to west, even if it did move. For since earth and water form a single globe, as we shall show later, who does not see that the earth and the water would be moved and swept around by the prime mover at the same time together? And if they should say that the sea does not form a single globe with the earth, but that the water is higher — as many have supposed — then it would rather follow that the land would tend beneath the sea on the eastern side, since the water would continually cover it, and would emerge from the sea on the western side, since the water would abandon it: seeing that, on their view, the higher bodies, which are nearer the soul of the world, are moved more swiftly from rising to setting. We therefore give, with Aristotle in *Meteorologica* I, this as the cause of the matter: that, on account of the influences [aspectus] of the higher bodies, the sea consumes the land in certain parts through the increase of the waters, and so, where formerly there was land, there is now sea; and in the same way, because in other parts the sea decreases, there now appears land where before was sea. An indication of this can be that this exchange of sea for land, and of land for sea, is found to have occurred not only from east to west — which would follow on their view — but also in the north and the south and the other parts of the world.

[Margin: Third opinion on the motions of the heavens, of those who posit only eight heavens.]

Others — such as Augustinus Ricius [Agostino Ricci], whom Oronsus [Oronce Finé?] and some others follow — seeing that on this reasoning the appearances and the [Greek: φαίνόμενα (phainomena, "the appearances," observed phenomena)] can in no way be defended, and wishing to remain content with the number eight for the orbs, said that the whole aggregate of the eight orbs has one common motion from east to west, in such a way that this motion belongs to no particular orb as to a single thing, but to all of them taken together: just as the forward motion of an animal does not belong to this or that particular limb, but to the whole animal. And this is what is usually called the daily motion. But besides this motion common to the whole aggregate, each single orb, they say, has in addition its own peculiar motion from west to east, which the proper intelligence assisting each orb produces. Nor should this seem strange, as they assert, since even in animals we see that individual limbs can have a motion contrary to the forward motion of the whole animal. For it can happen that the whole animal advances from east toward west, and nevertheless the hand, or the head, or some other limb is meanwhile moved at the same time in the opposite direction — say, from west toward east.

And if you object that on this reasoning no prime mover [primum mobile] can be assigned, since the eighth sphere too is turned from setting to rising — which nevertheless the whole company of philosophers and astronomers admits by unanimous consent — Augustinus Ricius replies that the prime mover can be understood in two senses. In one way, so as to signify that body which is first turned by the first mover through itself; and in this sense no particular celestial sphere can be called the prime mover, since none is moved through itself first by the first mover, but only as a part along with the motion of the whole. In another way, the prime mover can be taken for that body which, among the other movable bodies, is called first in nobility and rank; and in this sense the eighth sphere, even though it is carried around from setting to rising, can be called the prime mover, because it is nearer and closer to the intelligences, or substances free of body.

[Margin: Refutation of the third opinion.]

But although this opinion seems at first sight ingenious enough and plausible, nevertheless, if we are willing to consider the matter more carefully, we shall find that it cannot be true. First, because it is impossible that the whole aggregate should be moved from rising to setting by a single intelligence, while the individual heavens in turn, none excepted, are carried in the contrary direction by their own intelligences. For in this way the whole aggregate would be moved both from rising to setting and from setting to rising at the same time — which can in no way happen, as is clear from the example adduced by the authors of this opinion. For although, if an animal advances from rising to setting by its own forward motion, the hand or some other limb can be moved in the contrary direction from setting to rising, nevertheless it seems repugnant to nature that all the parts of the animal together, none omitted, should [move] with this contrary motion about the poles. For thus the whole animal would proceed in contrary and opposite directions at the same time, which can by no means happen, nor even be grasped in thought. Second: if the whole aggregate of the heavens were carried from east to west, and then the individual orbs by their own peculiar motions from west to east, in such a way that no orb should drag another along by its motion (for it is chiefly on this account that they refuse to admit above the firmament another heaven that, as prime mover, would sweep the lower orbs along with its motion from rising to setting), then one and the same orb could not have more than two motions: one, namely, insofar as it is part of the whole aggregate; the other proper and peculiar to itself. But this is false, for in the celestial bodies more motions than two are detected.

For the total heaven of the Moon (setting aside the partial orbs) is moved from rising to setting, and from setting to rising, as experience teaches and as they themselves also admit. Again, besides these two motions, it is moved by yet another, different motion from east to west over the poles of the zodiac, as is established from the Theory of the Moon [Theorica Lunæ]; and this motion they can in no way uphold unless they concede a motion of rapture [motus raptus], as will soon be explained. For once this is granted, the heaven of the Moon will be moved: from east to west by the daily motion, over the poles of the world, according to the motion of the prime mover; from west to east, over the poles of the zodiac, according to the motion of the ninth sphere; and finally from east to west, over the poles of the zodiac as well, by its own third motion. Third: if the whole aggregate is moved from rising to setting, and not the individual heavens — because, they say, we see this motion to be common to all the heavens — I do not see why they should not, by the same reasoning, assert that all eight heavens, as one whole, are carried around from setting to rising by a single intelligence, seeing that all eight total heavens are carried at the same time and at the same speed from west to east. (For the diversity of the planets' motion that we observe does not come from the total heavens, but from the particular eccentric orbs in which the planets, or their epicycles, are fixed.) Indeed, they move with far greater uniformity and evenness from west to east than from rising to setting — which, however, they are by no means willing to admit. This opinion too, then, must be abandoned as impossible and unable to account for all the phenomena.

[Margin: The truer opinion on the motions of the heavens.]

Therefore we must speak of the motions of the heavens differently, in accord with the more learned astronomers. We say, then, that two principal motions, and those very well known, are observed in the heavens: one, namely, from east to west, the other from west to east. (Of that motion of advance and retreat [accessus et recessus — trepidation] which was observed in the eighth sphere we now say nothing, since it is not easily, and scarcely even by the most skilled, detected; but we shall set it out a little later, when we assign the periods of all the motions.) Of these, the former is proper and peculiar to the prime mover, or tenth sphere; hence it is usually called the first motion. For the tenth sphere, or prime mover, is moved by an utterly simple and most regular motion only, from east through the meridian to the west, and then again through midnight to the east. This motion is accomplished over the poles of the world and along the equator in a natural day — that is, in the span of 24 hours — once around the earth; for which reason it has commonly come to be called the daily motion. By this motion the prime mover, or tenth sphere, sweeps all the other nine lower spheres along

with it from east to west without any resistance, once around the earth each day. This motion is said to belong to these lower spheres by accident and not through themselves, since it is not their own but comes to them from outside; for they are moved by the rapture, or motion, of the prime mover — just like those who, sitting in a ship or a carriage, are swept and carried along by the motion of the ship or carriage. And if they were not carried around by the prime mover, they would in no way be moved from east to west — just as those sitting in a ship or carriage, if the ship or carriage were not moved, would not be carried along, but would remain motionless.

The latter motion is proper to the nine lower spheres, and in no way belongs to the tenth sphere, or prime mover. For all the lower spheres seem to resist that first motion in a way, by their own motions from west to east; so that, even though they are swept from rising to setting, they still continually slip from west, through the meridian, to the east, and then again through midnight to the west. This motion is accomplished over the poles of the zodiac, which are distant from the poles of the world — according to the observation of more recent astronomers — 23 degrees and 30 minutes, and along the zodiac circle. This motion is said to belong to the lower spheres through themselves, and not by accident. Just as, if someone carried in a ship from east to west were to walk by his own forward motion from west to east, then without doubt — though he would be moved much more swiftly westward by the ship than eastward by his own forward motion — he would still be said to tend westward by accident, through the motion of the ship, because he is carried by an external motion, but eastward through himself, because he moves by his own motion (by which he would be moved even if the ship stood still): so likewise this motion from west to east of the lower spheres is said to belong to them through themselves, because, even if they were in no way swept along by the prime mover, they would still tend eastward from west by this motion.

[Margin: The two motions of the heavens — from rising to setting, and from setting to rising — are not contrary. A twofold zodiac.]

Now since it seems impossible that one and the same heaven should be moved, at one and the same time, from east to west and from west to east — because east and west are opposite and contrary termini — some reply that this is no difficulty, because these two contrary motions occur over different poles and along different lines. For they are moved from east to west over the poles of the world, namely the Arctic and the Antarctic, and along the equator; but from west to east they are moved over other poles, namely the poles of the zodiac, and along

the zodiac circle. But this reply is unsatisfactory, because in it one and the same movable body is granted to be carried by contrary motions along different paths — which is utterly impossible. For if anything were moved from east to west, it cannot happen that at the same time it be moved from west to east. For on this reasoning it would approach the west and recede from it at the same time — which can happen neither along the same line nor along different lines, since these two are utterly at odds with each other. Therefore it must be said that the said two motions are in no way contrary to each other. For all the lower heavens, which are moved by the rapture of the prime mover — although they are carried by accident and against their own nature from rising to setting, namely by an external motion, yet through themselves are carried from setting to rising, that is, by their own motion and according to their own nature — are nonetheless, simply speaking, moved from east to west; and none simply from west to east, but only in a qualified sense, because they are moved toward the eastern signs, as will soon be explained. To understand this, note that there are two zodiacs, chiefly to be conceived in the celestial bodies. One, indeed, is in the prime mover, or tenth heaven, which alone is the true and proper zodiac that the astronomers mean when they speak of the zodiac without qualification: it consists of twelve equal parts, called the celestial signs, in this order — Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libra, Scorpio, Sagittarius, Capricorn, Aquarius, Pisces — which the astronomers usually express by these characters:

Aries	Taurus	Gemini	Cancer	Leo	Virgo
♈	♉	♊	♋	♌	♍

Libra	Scorpius	Sagittarius	Capricornus	Aquarius	Pisces
♎	♏	♐	♑	♒	♓

These characters signify, in the same order, the twelve signs already named. They must therefore be carefully noted and committed to memory, since astronomers use them very frequently and they will be introduced very often in what follows. Now any two of them — an upper one, that is, and a lower one — are set opposite each other across a diameter in the heavens, and this too is worth some notice, for mention of opposite signs will not seldom be made.

The other zodiac is to be conceived in the ninth sphere, set directly beneath the first zodiac, with the same twelve signs. That first zodiac is called by astronomers immobile and fixed — not because it is not moved by the motion of its own sphere, in which it lies, but because its signs always keep the same relation to the

equinoctial and to the colures of the *primum mobile*, so that the beginning of Aries always lies on the equinoctial circle, and likewise the beginning of Libra, precisely where the equinoctial colure cuts the equinoctial. Again, the beginning of Cancer is always found on the solstitial colure, and likewise the beginning of Capricorn. The same must be said, in due proportion, of the remaining signs and of the principal points of that zodiac.

The second zodiac is called mobile and not fixed — not merely on the ground that it is moved by the motion of its own sphere, in which it lies (for this it has in common with that first zodiac, which is nevertheless called immobile), but because its signs do not always keep the same relation to the equinoctial and to the colures of the *primum mobile*. For the beginnings of Aries and Libra of this zodiac are not always found on the equinoctial circle — that is, on the equinoctial colure of the *primum mobile* — nor the beginnings of Cancer and Capricorn on the solstitial colure. For this latter zodiac moves little by little beneath that former one, toward the eastern signs of the former zodiac — that is, toward those signs which rise and climb above the horizon later.

[Margin: In what sense the ninth zodiac, by the motion of its own sphere, is understood to move from west to east.]

Suppose, for example, that at this moment of time the beginning of Aries of the ninth heaven were exactly and directly set beneath the beginning of Aries of the *primum mobile*. Immediately afterward it would pass beneath the sign Taurus of the *primum mobile*; and once it had come precisely and exactly beneath Taurus, it would at once pass beneath Gemini, and so on it would gradually enter one sign after another — the signs that rise later — until once more it were set directly beneath Aries of the *primum mobile*. Yet in this respect the zodiac of the ninth heaven is moved simply, by the motion of the *primum mobile*, from east to west, because there is never an instant of time at which it is not receding farther from the east and approaching the west — as is plainly detected in any star whatever. It is not moved simply from west to east, since it never recedes farther from the west or approaches the east; rather the contrary appears, for we perpetually see the Sun, the Moon, and the other stars tending from their rising to their setting. It is, however, said in a certain respect to be moved somehow from west to east; for although it never leaves the west nor approaches the east, it does nonetheless approach the eastern signs, as has been said. Exactly the same must be said of the other spheres — of the eighth heaven and of the seven spheres of the planets.

[Margin: The lower heavens move simply from east to west, but in a certain respect from west to east.]

For although they are continually dragged along by the *primum mobile* from east to west, they nonetheless move gradually beneath the zodiac of the *primum mobile*, seeking the eastern signs — those, that is, which rise and set later. For instance, when the Sun has passed through the whole sign Aries of the *primum mobile*, it soon begins to move on from Aries beneath the sign Taurus, and so on, until once more it comes beneath Aries.

In this way, then, it is true both that all the heavens move simply from east to west — because there is no instant of time at which any point taken in them is not always receding farther from the east and approaching the west — and that, conversely, all the spheres below the *primum mobile* move from west to east in a certain respect: that is, not because they recede from the west toward the east, but only because they come to be found beneath other, more eastern signs, as we perceive plainly by the senses and by instruments. Now for something to be moved simply from one place to another, it must leave the one and approach the other. Since, then, we never see the Sun or the other stars leave the west and approach the east, we cannot say that the heavens move simply from west to east, but only in a certain respect — namely toward the eastern signs, as we have just explained. They are said to move simply from east to west because there is no instant of time at which they are not receding farther from the east and drawing nearer the west, on account of that most rapid motion of the *primum mobile* by which they are swept along. For if they were not swept along by the *primum mobile*, they would then be moved simply from west to east, since there would be no instant at which they were not withdrawing farther from the west and approaching the east. Likewise, if by their own motions they moved from west to east faster than they are moved from east to west by the motion of the *primum mobile*, they would again be carried simply from west to east, and only in a certain respect from east to west, for the reason just given: because on this reckoning they would always be removed farther and farther from the west and approach the east, and not the reverse.

[Margin: Examples clarifying the motion of the heavens from east to west simply, and from west to east in a certain respect.]

That all this can happen you will learn thoroughly from one or two examples. Let some ship move from east to west with the greatest speed; and let the shipmaster, at the same time, walk at a very slow pace along the ship from prow to stern. This granted, do you not see that the shipmaster is indeed moved simply from east to west, because by the ship's motion he is carried far faster than he moves the opposite way by his own motion, and for that reason is always receding farther

from the east and approaching the west — while at the same time he is moved in a certain respect toward the east, that is, toward the eastern parts of the ship, but not simply? And do you not also see that, if the ship stood still, the shipmaster would then be moved simply from west to east, since he would always be drawing nearer the east and receding from the west? And do you not, finally, observe the same thing if the shipmaster were to walk with a swifter motion than the ship? Just so, then, must it be understood that the lower heavens move beneath the zodiac of the *primum mobile* from west to east. Perhaps the matter will be grasped more clearly in the case of an ant, which walks at a slow pace against the very swift motion of some wheel that is moved from east to west. The same may be understood in some little transparent glass sphere. For if it is filled with clear water, and you so shake it toward yourself that the water gradually moves toward you, and then that glass sphere is quickly whirled around in the opposite direction, you will presently see the water contained in the glass moved along together with the motion of the little sphere, and at the same time moved toward you by its counter-thrust. By that little transparent glass sphere, then, we must picture in our minds the *primum mobile*, and by the water contained in it, the lower spheres straining against the *primum mobile*. This can also be seen in a basin, if it is filled with water.

From this explanation, and from the examples brought forward, it is left clear that the two aforesaid motions of the heavens — one of which is from east to west, the other from west to east — are not contrary, since they are not directed simply toward contrary termini, namely toward east and toward west, as we have explained. For contrary motions must be referred to one and the same fixed point, such that by the one motion that point is approached and by the other it is receded from — which we have said in no way happens in the motions of the heavens. Yet these two motions are, in the common way of speaking, called contrary and opposite, by reason of their contrary termini, namely east and west. For they are moved simply toward one of these, namely toward the west, but in a certain respect toward the other, namely toward the east — that is, toward the eastern parts, as has been said.

[Margin: Why the motion from east to west and that from west to east are not contrary, and yet are commonly called contrary. That the heavens could move about the same poles from west to east — the very poles about which they move from east to west — and why they do not now move so.]

From these same examples it is likewise plain that the heavens could be moved not only about different poles and along a different path, as in fact they are

moved, but that they could also have returned about the very same poles, and along the same path, from west to east, by which they revolve from east to west. Indeed, astronomers have learned from experience that one and the same celestial body is moved from east to west, and also, about the same poles, from west to east. For the sphere carrying the head and tail of the Dragon [the lunar nodes] in the lunar heaven is moved by its own motion (besides the diurnal motion, which occurs about the poles of the world) from east to west about the poles of the zodiac; and about those same poles it is carried, by the power of the heaven of Mercury, from west to east, as is set out in the *Theorics of the Planets*. But the reason why the lower spheres revolve by another path — namely along the zodiacal circle, and not along the same one, that is, the equinoctial circle; in other words, why they revolve about other poles, namely those of the zodiac, and not about the same ones, namely the poles of the world (which nonetheless could very well have been the case), from west to east, in the sense already explained — is, according to the philosophers, the governance of the world: namely so that, through the approach of the Sun and planets beneath the zodiac toward the north (Boreas) and toward the south (Auster, or the meridian), the various seasons of the year may come about, adapted to the various generations of things, as Aristotle says in book 2 of *On Generation and Corruption*.

ON THE PERIODS OF THE CELESTIAL MOTIONS

The tenth heaven, which is also called the *primum mobile*, completes its circuit from east to west with a uniform and regular motion — and that a most swift one — about the poles of the world and along the equinoctial circle, as has been said, in 24 equal hours, which are called equinoctial hours: that is, in the space of one natural day. Hence its motion has been called the diurnal motion. By the impetus of this motion all the lower spheres — indeed the whole sphere of fire, a great part of the air, and, by the opinion of some, a good part of the ocean — are swept from east to west. From this it comes about that, by this diurnal motion, the Sun and all the other heavenly bodies, and every single point of the heavens, daily describe about the poles of the world parallel circles at right angles to the axis of the world: larger circles the farther they lie from the poles, and smaller the nearer they approach the poles. Hence the equinoctial circle is the greatest of all the parallels, since it is described by the point most remote from either pole, namely by 90 degrees. Moreover, all the lower spheres would be carried around with exactly the same speed as the *primum mobile*, were it not that by their own peculiar motions they fall back somewhat. For the *primum mobile* meets with no resistance in the lower heavens.

[Margin: The periods [?] of the celestial motions.]

For the ninth sphere, beneath the *primum mobile*, advances in the space of 24 hours — that is, of one natural day — from west to east, according to the Alphonsine Tables, by four sixtieth-parts of those units which are called by astronomers "thirds," and by 20 "fourths"; so that in each single year it completes 26 seconds, 2 thirds, and 50 fourths, and in 200 years, 1 degree 28 minutes 9 seconds 47 thirds and 45 fourths. From this it follows that it completes its whole course through the zodiac in roughly the space of 49,000 years. For if we wish to speak precisely, in that span of years the ninth sphere completes, according to the said tables, a little more than a whole circle: it completes, namely, 360 degrees, 5 thirds, and 31 fourths. This span, or period, of 49,000 years is commonly called by many the Platonic Year. For in this interval, they suppose, all the stars will return to the same position — indeed, whatever they please: that then all things whatsoever that are in the world will return in the same order in which they are now seen. But they seem to assert this rashly; for since, according to most authorities, the motions of the heavens are mutually incommensurable, it cannot be that all the stars should ever be able to obtain the same position and order they now have, or once had. Perhaps what moved King Alphonso to assert that the period of this motion is completed in the space of 49,000 years was that he saw, in his own time, the equinoxes and solstices retreating each year in the calendar by 10 minutes 44 seconds of one hour, and in 400 years by nearly 3 days — so that in the said span of 49,000 years they would return, as it were, to their original seat. Ptolemy, however, affirms that this motion is accomplished in a circle of 36,000 years, so that the ninth sphere traverses 1 degree in 100 years. But al-Battānī [Albategnius] holds that this motion is completed in the space of 23,760 years, so that it would traverse one degree in 66 years. For what reason astronomers have judged so variously about the period of this motion will presently be explained. For now, let it be taken as settled and certain that the ninth sphere, by this very slow motion from west to east, draws along with it the 8 lower celestial spheres, but in no way the supreme sphere. For according to the opinion of astronomers, any higher sphere carries around by its motion the sphere contiguous and concentric beneath it, but not the one above it.

[Margin: The Platonic Year. Each sphere by its own motion moves the one contiguous and concentric beneath it, not the one above it.]

The eighth sphere, besides these two aforesaid motions impressed upon it by other spheres, has still a peculiar and proper motion of its own, which they call the motion of access and recess, or the motion of trepidation, as we said above.

This motion takes place about the beginnings of Aries and Libra of the ninth sphere as its poles. For the beginnings of Aries and Libra of the eighth sphere describe about the beginnings of Aries and Libra of the ninth sphere certain small circles whose radii contain 9 degrees. For by so much — 9 degrees — do the beginnings of Aries and Libra of the eighth sphere stand apart from the beginnings of Aries and Libra of the ninth sphere, according to the teaching of King Alphonso. From this motion of the beginnings of Aries and Libra of the eighth sphere about the beginnings of Aries and Libra of the ninth sphere, it follows that no other point of the eighth heaven completes a perfect circle, but rather in a manner totters — that is, now approaches the arctic pole and is removed from the antarctic, now again departs from the arctic pole and approaches the antarctic. The period of this motion embraces a span of 7,000 years, so that if those small circles be divided into 360 degrees, in about 20 years roughly one degree is completed. By this motion too the spheres of all the planets are moved, since they are concentric with the eighth sphere. But to confess the truth — although, on account of the phe-

[Margin: The motion of trepidation.]

nomena or appearances that we shall bring forward a little later, some motion of this kind, or something similar, seems necessarily to be granted in the eighth sphere — it is nonetheless very uncertain that it comes about just as the Alphonsines teach. For many absurdities seem to follow from it, as we shall presently show.

The globe of Saturn, besides the three motions mentioned, has a proper motion which it completes from west to east in about 30 years. For each single day it traverses in the zodiac about 2 minutes and 35 thirds [as printed].

Jupiter completes its circuit in about 12 years. For each day it passes through 4 minutes 59 seconds 15 thirds.

Mars accomplishes its motion from west to east in about 2 years. For it traverses in the zodiac on any given day 31 minutes 26 seconds 38 thirds.

The Sun completes its journey from west to east in 365 days, 5 hours, 49 minutes, 16 seconds. This span is commonly called the solar year. From this it is plain that the year does not precisely contain 365 days and 6 hours, as is supposed in the Roman calendar. For each single day the Sun completes 59 minutes 8 seconds 19 thirds 37 fourths. Understand this to be said according to the teaching of the Alphonsines. For Ptolemy found the quantity of the year greater, and al-Battānī smaller; while Copernicus in turn found the year in his own day nearly equal to

the Ptolemaic year — so that it is now accepted by all astronomers that the magnitude of the year is unequal. This matter will be discussed more fully in another place.

Venus completes its whole circuit in about the same time as the Sun. For it advances on any given day about 59 minutes 8 seconds and 19 thirds.

Mercury completes very nearly as much every day. For which reason it accomplishes its whole course in about the same time as Venus.

The Moon, lastly, traverses the whole zodiac in 27 days and about 8 hours. Thereafter it uses up roughly two days more before it catches up with the Sun. For since the Sun, in the meantime, in 27 days and 8 hours, traverses about 27 degrees — which the Moon completes in about two days — it necessarily follows that from one conjunction of the Moon with the Sun to the next, 29 days and about 12 hours intervene. Such a span is customarily called the lunar month. But all these things are explained more accurately and precisely in the *Theorics of the Planets*.

[Margin: In which spheres the periods of the planets' motions are to be understood.]

Furthermore, the periods of the planets' motions are to be understood not of the spheres, or total heavens, but of the proper spheres carrying the planets — which are eccentric, set in the midst of the heavens. For it is in these that the planets, or their epicycles, are fixed and carried along in the aforesaid times. For the total heavens of the planets are moved from west to east with exactly the same slowness with which the ninth heaven is moved. Again, they are moved by the motion of trepidation, following the motion of the eighth sphere. Yet no lower planet is moved by the proper motion of a higher planet, because they are not carried by their proper courses about the same center — as is usually explained more fully in the *Theorics of the Planets*.

Nor should this be passed over: that these nine spheres below the *primum mobile* would complete their courses in exactly the same times as they now complete them, and no faster, even if the *primum mobile* were at rest, or did not sweep them along with it from east to west — just as is clear in the case of the shipmaster, who by his proper motion moves against the motion of the ship, or of the ant, which is carried against the impetus of the wheel. Only then they would be carried simply from west to east, because no instant would then be given after another at which they were not receding farther from the west and approaching the east — just as that shipmaster, with the ship standing still, would in the same

time reach the stern, and would approach the east simply, and not merely the eastern parts of the ship.

HOW IT HAS BEEN DETERMINED THAT ALL THE HEAVENS MOVE SIMPLY FROM EAST TO WEST

Having set out the three motions of the heavens in general — of which we said one is from east to west simply, another from west to east in a certain respect (that is, from the western signs toward the eastern signs), and the third, finally, that of access and recess, which they call the motion of trepidation — it must now be shown by what path and method astronomers have detected this simple motion in the celestial bodies. That all the heavens move from east to west they learned by daily experience. For they saw that the Sun, the Moon, and all the other stars ascend little by little from the eastern quarter and rise above the horizon, until they reach the meridian, and then again decline toward the west, until once more they are found in the east. From this consideration they concluded easily and without hesitation that the motion of all the heavens is from east to west.

[Margin: By what means the motion from east to west was detected.]

That this motion, moreover, takes place simply from the east — that is, always recedes from the east and approaches the west — they gathered by many paths. First, from the shadow of bodies. For from the rising of the Sun up to noon, all shadows cast upon the horizon continually decrease, so that at noon the shadows become smallest, whereas from noon up to the setting of the Sun they increase again — which could by no means happen unless the Sun continually slid from east to west. The same you will say of the Moon, whose shadows always decrease while it moves from its rising to the meridian, and again increase while it inclines from the meridian toward its setting. Secondly, from the altitudes of the stars, which from their rising always become greater until they reach the meridian circle, where they obtain their greatest altitudes; but from the meridian circle to their setting they perpetually undergo a decrease of those same altitudes. This is indeed a plain indication that they simply depart from the east and approach the west.

By what reasoning it has been concluded that the motion of the heavens is from west to east

[Section heading]

Although all the heavens are carried, without qualification [*simpliciter*], from east to west — as we showed a little earlier — it has nevertheless been found that they are also driven the other way, from west to east: not without qualification (for without qualification they move only from east to west, as has already been shown), but in a qualified sense [*secundum quid*], namely by making their way toward the eastern signs, in the sense set out above. Astronomers first detected this in the seven planets, as may be gathered from Regiomontanus [Regiomontanus] in his *Epitome of Ptolemy's Almagest* (Book I, conclusion 6), by the following reasoning. They observed that the Sun, the Moon, and the other planets do not always keep the same position and distance among themselves: the Moon, for example, is on one day in conjunction with the Sun, but on another has withdrawn from it toward the eastern regions. And they found this variation not only in one planet with respect to another, but also in all the planets with respect to the fixed stars. For they saw a given planet on one day in conjunction with a particular fixed star, or standing at a particular degree of some sign, but on another day departed from that star or degree toward the eastern regions — just as we too, clearer than daylight, experience daily. There can therefore be no reason to doubt that the seven planetary orbs, besides the daily motion from east to west, also move gradually and, in a manner, retreat from west to east — that is, toward the eastern parts of the heaven — as we have explained.

Nor was it by a different method that astronomers found that the eighth heaven too moves from west to east. For although nearly all the ancients before Aristotle believed that the starry heaven was driven by that one motion alone, from east to west — since they saw all the fixed stars preserve the same distances among themselves, and the places of their risings and settings not varying on the same horizon, but the stars always rising and setting in the same places (this on account of the short interval of time in which they were making their observations) — yet after Aristotle it was found that the matter stands far otherwise. For, as Ptolemy [Ptolemy] says in Book VII, chapter 1 [*Almagest* VII.1], and Regiomontanus in his *Epitome* of the same book, proposition 2, the distances of the fixed stars from the solstitial and equinoctial points do not always remain the same, but grow and increase according to the succession of the signs — that is, advancing toward the eastern regions — so that very many stars which in ancient times stood before the solstitial and equinoctial points are now found

beyond those same points, while other stars have come nearer to them, as is plainly established from the observations of both the ancients and the moderns. And the greater the span of time between the observations of the ancients and those of the moderns, the more the stars are found to have moved away from their ancient seats and places according to the succession of the signs. Ptolemy and Regiomontanus, in the passages cited, bring forward many examples of this; we shall offer only one or two.

Timocharis [Timocharis], observing the course of the stars, found the star Azimech — which the Latins call Spica Virginis [the Ear of Virgo] — before the point of the autumnal equinox, that is, before the beginning of Libra, by about 8 degrees; this is a little past 22 degrees of Virgo, or at the beginning of the 23rd degree of Virgo. After him, about two hundred years having elapsed, Abrachis, also called Hipparchus [Hipparchus], found the same star only 6 degrees before that point, namely at the beginning of the 25th degree of Virgo. And after these, Ptolemy found that the same star had come still closer to the beginning of Libra, in proportion to the intervening time. The astronomers who followed him observed the same — such as al-Battānī [al-Battānī], Avenezra [Ibn Ezra?], Zacut [Abraham Zacuto], and others — so that in our own age this same star now stands beyond the beginning of Libra, namely at the 18th degree of Libra and beyond. Again, Hipparchus found the star called the Heart of the Lion [Cor Leonis, Regulus] at 50 minutes of the last degree of Cancer; but after him Ptolemy found the same standing at 30 minutes of the third degree of Leo; and now this same star stands at about the 24th degree of Leo. From these and very many other examples it is clearly gathered that all the celestial orbs below the *primum mobile*, besides the daily motion, also move according to the succession of the signs from west to east — though in a qualified sense, that is, as we have explained, toward the eastern regions. For if they were moved by the daily motion alone, all the stars and planets would necessarily remain equally distant from those four aforesaid points; but the observations of the most learned astronomers show the opposite. Nor should anyone doubt that the places of the stars were correctly determined by the astronomers named. For among the many instruments devised by craftsmen for determining the places of the stars, the most excellent is the one they call Ptolemy's Armilla [the armillary instrument], whose construction is taught in Book V of the *Almagest* [*Almagest* V].

By what means it has been observed that the lower heavens move from west to east about poles different from the poles of the world

[Section heading]

[Margin: The lower heavens move from west to east about the poles of the Zodiac; by what means this was observed.]

By long observation astronomers discovered that the lower heavens move from west to east not about the poles of the world and along the equinoctial circle, but about distinct poles — namely about the poles of the Zodiac and along the circle of the Zodiac. For all the planets always vary their points of rising and setting on the horizon, which is detected clearer than daylight in the Sun. For at one time it rises at the equinoctial point, at another beyond it, at another short of it; and this variation would not occur if the Sun moved from west to east about the poles of the world and along the equinoctial circle. In that case it would always rise at the same point of the horizon, just as the parallels of the equator — along one or another of which the Sun is necessarily carried by the daily motion — always intersect the horizon at the same points; and the same has been observed in the other planets. Again, the planets do not always keep the same distance from the poles of the world, but now approach the Arctic pole, now the Antarctic — which is easily gathered from the fact that they do not always have the same meridian altitude. The Sun is found to have its greatest meridian altitude at the Tropic of Cancer, and its least at the Tropic of Capricorn, as is plain from the meridian shadow of any gnomon, which is shortest when the Sun stays in Cancer, but longest when the same is in Capricorn. Hence too it comes about that the planets do not always describe the same parallels relative to the daily motion. By most certain reasoning, therefore, it is concluded that the planets make their way from west to east about different poles. And since astronomers noticed that this variation in the motion of the Sun and of the other planets is confined within nearly the same limits, and that they are carried around in a circle whose greatest declination from the equinoctial spans 23 and a half degrees, and whose poles are consequently distant from the poles of the world by the same number of degrees, they asserted that this motion takes place about the poles

of the Zodiac and along the circle of the Zodiac. This being posited, all the aforesaid variations very easily find their place, as may be plainly seen on some material sphere.

All this, moreover, was detected by infallible reasoning in the eighth sphere as well. For after those most diligent observers of the stars had understood that the fixed stars gradually make their way from west to east, they noticed that this motion takes place about poles distinct from the poles of the world. For the stars have not always risen in the same places in which they now rise, with respect to the same horizon; likewise the meridian altitudes of the fixed stars are different at this time from those which the ancient astronomers observed. The fixed stars, therefore, do not return from west to east about the poles of the world. Moreover, as Ptolemy (Book VII, chapter 3 [*Almagest* VII.3]) and Regiomontanus in his *Epitome* of the same book assert, and confirm by many observations, the fixed stars do not always keep an equal distance from the equinoctial circle. For their declinations from the equinoctial circle have been found to vary: so that, for those stars which are in the half of the sphere running from the beginning of Capricorn, through Aries, to the beginning of Cancer, the southern declinations have diminished while the northern have increased; and on the contrary, for those stars which are in the remaining half of the sphere, contained from the beginning of Cancer, through Libra, up to the beginning of Capricorn, the southern declinations have been found to increase while the northern diminish. (By "southern declination" we mean that a star which inclines from the equinoctial circle toward the Antarctic pole has one, while "northern declination" belongs to a star which slopes from that same circle toward the Arctic pole.) And the nearer the stars are to the beginning of Aries and of Libra of the *primum mobile*, the greater the variation of declination that has appeared; but the nearer they are to the beginning of Cancer and the beginning of Capricorn, the smaller the variation of declination they have undergone.

That this may be better understood, I shall add one or two examples from Ptolemy and Regiomontanus. The star which the Latins call the Eye of Taurus [Aldebaran] declined, in Timocharis's time, from the equinoctial toward the north by 8 degrees and a half and a little more; in the time of Abrachis, or Hipparchus, by 9 degrees 45 minutes; then in Ptolemy's time by nearly 11 degrees; and in our own time by about 16 degrees. It is therefore established that the northern declination of this star has always increased, since it lies precisely in that half of the sphere which stretches from the beginning of Capricorn, through Aries, to the beginning of Cancer. Similarly Alhabor, the star called the Great Dog [Sirius] (for this star is in the mouth of the Great Dog, and in ancient times stood in that same half of the sphere), had in Timocharis's time a southern or meridional declination of 16 degrees 20 minutes; then in the time of Abrachis, or Hipparchus, 16 degrees only; and finally in Ptolemy's time 15 degrees 35 minutes — from which it is likewise clear that the southern declination continually decreased. But in our

own age, since this same star is now found in the other half of the sphere, it again has a southern declination of about 16 degrees; and here it is manifestly seen that the southern declination is once more increasing.

Lastly (for you will find many more examples of this kind in Ptolemy and Regiomontanus): Azimech, the star called Spica of Virgo, had in Timocharis's time a northern declination of 1 degree 24 minutes; with Abraham, or Hipparchus, only 36 minutes; but with Ptolemy it had a southern declination of 0 degrees 40 minutes. Now it is found to have a southern declination of 8 degrees 57 minutes — as Erasmus Oswald Schreckenfuchs [printed: "Erasmus vater Schreckenfuchs"] relates in his *Theoricae Planetarum*, p. 407: that Johann Werner [Johann Werner], in the year 1514 at Nuremberg, on the 16th day of December, found the same declination of Spica to be 32 degrees 7 minutes, which, if it is subtracted from the altitude of the equator, 40 degrees 36 minutes 30 seconds, leaves its southern declination as 8 degrees 29 minutes 30 seconds — somewhat less than we ourselves stated. From this example it is clearly established that the northern declination of this star (since it lies in that half of the sphere which is comprehended between Cancer and Capricorn, proceeding through Aries) has always decreased, while its meridional declination has increased. In all these examples one may plainly observe that the greater variation of declinations has occurred near the equinoctial circle than near the tropics.

By a most firm demonstration, therefore, the astronomers concluded that the fixed stars, although their declinations from the equinoctial circle vary, as has been said, nevertheless always keep the same latitude — that is, the same distance from the ecliptic line which passes through the middle of the Zodiac — as is established from the observations of those same astronomers. For, to give an example, the star called Arctophylax, or Arcturus, has always been found to deviate from the ecliptic toward the north by 31 degrees 30 minutes; and the same, in a certain proportion, has been observed in all the other fixed stars. By necessary reasoning, then, it is concluded that they move precisely about the poles of the Zodiac and along the circle of the Zodiac; for on this supposition all the stars, in their motion from west to east, describe circles parallel to the Zodiac itself, and remain always equally distant from it.

[Margin: Two arguments against the motion of the fixed stars from west to east about the poles of the Zodiac, and their solution.]

I cannot at this point pass over in silence two arguments of a certain most learned and most noble man, who flourished not many years ago. By these he

strives to demonstrate, in certain writings composed for this purpose — which I read carefully enough in the congregation that was recently held at Rome by order of the Supreme Pontiff concerning the correction of the calendar — that this motion of the fixed stars from west to east about the poles of the Zodiac is entirely fictitious, and that all those phenomena by which Ptolemy and the other astronomers have tried to introduce the said motion into the schools are also fabricated. These arguments could indeed cause no little trouble to anyone versed in the knowledge of the stars. They are as follows.

Canopus, the very bright star that stands in the tiller of the Argo [Argo Navis], is not seen in Europe because it is too far south; but at Alexandria, as Pliny [Pliny] relates in the second book of his *Natural History*, chapter 70 [Natural History II.70], it projected in his time about a quarter of one sign above the horizon when it was set on the meridian circle; and on the island of Rhodes it seemed in a way to graze the earth, or the horizon. Since, then, now — as merchants report — that same star still in a manner grazes the horizon of that same island, who does not see that this star has always remained on the same parallel, and therefore has not been moved about the poles of the Zodiac? For otherwise it would have been carried along a circle parallel to the ecliptic, which obliquely cuts the parallel of the equator, and so could no longer touch that horizon.

Furthermore, the pole star, at the tip of the tail of Ursa Minor, which is 24 degrees distant from the pole of the Zodiac and stands near the Arctic pole: if it moves about the poles of the Zodiac, it must at some time come to be nearly 47 degrees and more distant from the pole of the world — in proportion, that is, to the semi-diameter of that parallel which it describes about the pole of the Zodiac, and to the distance of the pole of the world from the pole of the Zodiac; and it would therefore set on the Roman horizon, where the Arctic pole rises about 42 degrees above the horizon. Since, then, the pole star does not seem to have changed its seat with respect to the pole in so many centuries, it is not likely that it has been moved from west to east about the poles of the Zodiac. That motion, therefore, which the astronomers attribute to the fixed stars is entirely fictitious; otherwise the pole star would now be farther from the pole of the world than it once was, which seems false.

To both arguments we reply as follows. Since Canopus stands near the solstitial colure — so that in Pliny's time it was a little before it, and now is found a little after it — it comes about that the parallel of the ecliptic described by that star, in its motion from west to east, very nearly coincides in that place with the parallel of the equator drawn through the same star, as can be seen on an astronomical

globe. Hence it is no wonder that this star, in the 15 degrees which (according to Ptolemy's reckoning) it traverses from west to east from Pliny's time down to our own age, has not perceptibly changed its declination from the equator, and that it has therefore always seemed to graze the horizon of Rhodes — just as the Sun, around the solstices, in the 23 degrees which it traverses along the ecliptic (of which 11 are taken before and 11 after either solstice) barely changes its declination by half a degree. But it will come to pass that after a long time that star will alter its declination, and so will no longer touch the horizon of Rhodes — just as we see the declinations of other stars altered, because they are farther from the solstitial colure.

As for the pole star, we reply that it is situated in such a place of the heaven (as is established from the astronomical globe) that, from Hipparchus and Ptolemy down to the present, by that motion from west to east it approaches nearer and nearer to the pole. And this is what actually happens. For, as Ptolemy states in the first book of the *Geography*, chapter 7 [*Geography* I.7], the pole star in Hipparchus's time was 12 degrees 24 minutes distant from the pole, but now is only about 3 degrees and a half distant, or thereabouts. For its true distance, computed for the year 1600, is only 3 degrees 25 minutes. Thus from this change the motion of the stars from west to east is rather confirmed. In the course of time, however, this same pole star will move away from the pole. For it will be able to come at most within 30 minutes of the pole, which indeed happens, according to the Prutenic Tables [Prutenic Tables], around the year of our Lord 2282, because it will then be on the solstitial colure. Then it will again begin to recede from the pole, until it is 48 degrees distant from it, which, according to the same tables, will occur around the year of our Lord 15000. From these things I judge it clearly established that those two arguments do not prove this motion from west to east, detected in the fixed stars, to be fictitious. The experience of the astronomers, therefore, is to be trusted, until something to the contrary is brought forward by which it may be shown that what the astronomers hand down concerning the motion of the stars from west to east about the poles of the Zodiac is not true.

On account of what phenomena the astronomers attributed the motion of trepidation to the fixed stars

[Section heading]

[Margin: Why the astronomers place the motion of trepidation in the heaven.]

Since it was said above that the fixed stars move not only by those two motions — one of which is from east to west, the other from west to east — but have besides a proper motion of approach and recession, which they call trepidation, it must now be shown what phenomena or appearances compelled the astronomers to place this mode of motion in the heaven; for not a few think that this mode should be altogether hissed off from the schools of the astronomers as ridiculous. First, then, they say that the fixed stars advance unequally from west to east: for now more swiftly, now more slowly, now (as some of them say) not moving at all in the Zodiac, they seemed at one time to move back from east to west, besides that daily motion, and yet to keep the same distance from the center of the world. They therefore said that the stars move from north to south, and back again, as was declared above in that motion of approach and recession. For it is because of this motion that the whole of that inequality in the motion of the fixed stars arises, as can easily be understood from some material instrument constructed for this purpose. This too, the astronomers assert, is the reason why such varied opinions have arisen concerning the quantity, or period, of the motion of the fixed stars from west to east.

Again, they noticed that the greatest declination of the Sun stood differently at different times — now greater, now less, as we shall say in the second chapter. For this reason they were compelled to admit this motion of trepidation, so that they might render the cause of this variation in the greatest declination of the Sun. For, this motion being posited, it follows that the eighth sphere inclines now from north to south, now from south to north, and consequently that the two tropics in the solar orb become at one time nearer to the equinoctial circle, at another farther from it, as is explained in the *Theory of the Eighth Sphere*. Lastly, it was observed (as they say) that equinoxes have occurred before the Sun reached Aries of the *primum mobile*, or Libra — indeed, after it had already at some time passed the beginning of Aries or of Libra; and by the same reasoning that the solstices have taken place even though the Sun was not at the beginning of Cancer or of Capricorn. Since, then, the Sun must necessarily be found on the equinoctial circle for an equinox to occur, and likewise in the tropics for the solstices to happen, no other cause of this variation could be brought forward but the motion of trepidation; for that anticipation of the equinoxes and solstices easily follows from this motion. Moreover, by this same motion all the globes of the seven planets are also moved, so that the orbs of all the planets constantly accompany the Zodiac of the eighth sphere.

But although it seems certain that either the motion of trepidation, or something similar, must be granted in the eighth sphere on account of the phenomena

mentioned, yet the motion by which the astronomers explain it is most uncertain: namely, that the beginnings of Aries and of Libra of the eighth sphere describe circles about the beginnings of Aries and of Libra of the ninth sphere, whose semidiameters contain 9 degrees. For from this position many things follow which seem to conflict with experience, as we shall explain more fully in the following discussion, on the fourfold motion of the eighth sphere.

On the fourfold motion of the eighth sphere according to the opinion of the more recent astronomers

[Section heading]

So far we have set out the motion of the eighth sphere according to the opinion of the astronomers who follow Alfonso [the Alphonsine astronomers]. Now we shall discuss the same according to our own opinion and that of those who prefer to follow Nicolaus Copernicus [Copernicus].

To make this easier, I must briefly review the whole course that astronomers have followed in observing the motion of the fixed stars.

[Margin: The difficulty of knowing the motion of the eighth sphere.]

How obscure and hard to grasp the motion of that celestial sphere is — the sphere adorned with so great a multitude of stars, which we gaze on with deep delight as they glitter on a clear night, and which is commonly called the *Firmament*, the *starry heaven*, and the *eighth sphere* — is shown by the varied views and opinions of the greatest astronomers about it. This obscurity, or difficulty, seems to arise entirely from the slowness of its motion.

[Margin: Where the difficulty of knowing the motion of the eighth sphere arose.]

For since it is not completed except after the passage of many centuries — so much so that from the founding of the world down to our own age it has scarcely yet accomplished a fourth part — its magnitude and character cannot be reliably determined except through the observations of very many ages, compared with one another as carefully as possible. From this I would suppose it came about that all Antiquity thought the eighth heaven to be the *primum mobile*; for on account of the scarcity of observations they had noticed no motion in it beyond the daily one from east to west. It is therefore all the less surprising that the Babylonians (or Chaldeans) and the Egyptians — who inhabit flat regions and enjoy a very clear sky — handed down absolutely nothing about the advance of

the fixed stars from west to east (to say nothing here of their other phenomena), even though they devoted all their care to the knowledge of the stars.

[Margin: Ptolemy detected the motion of the eighth sphere about the poles of the zodiac.]

Hipparchus [Hipparchus] was the first (he is also called Abrachis). As we learn from Ptolemy and Pliny, about 130 years before the coming of Christ the Lord he observed the length of the year rather accurately and established the positions of the fixed stars with the greatest diligence. Comparing his own observations with those of Timocharis — who had preceded him by nearly 200 years — he discovered that the eighth sphere, with the stars fixed to it, advances from west to east by a very slow motion over and above the daily motion. This motion Ptolemy, easily the prince of astronomers, then confirmed far more clearly and evidently by many phenomena about 260 years later, and he observed that it takes place about the poles of the zodiac. For by very clear observations he found that the fixed stars [stellas inerrantes] gradually recede eastward from the equinoctial and solstitial points. To take an example: the star called Spica of Virgo was found by Timocharis to be 8 degrees before the autumnal equinox. After him, Hipparchus found the same star to be only 6 degrees from the same equinox. Later than both, Ptolemy observed that it had drawn still nearer to the same equinoctial point, in proportion to the intervening time, so that it was distant from it by only 3 and a third degrees. The same has always been observed in the following ages. For in our own time this same star is seen to have crossed that equinox and to be distant from it by eighteen degrees and more, toward the winter solstice [Brumam versus]. And although this star has been found to move continuously and gradually ever eastward, all astronomers have nonetheless noted that it has not changed its latitude — that is, its distance from the ecliptic — but has always remained 2 degrees south of it, whereas its declination — that is, its distance from the equator — has continuously varied. The same has been observed in a certain proportion for other stars as well, so that one may without any doubt conclude for certain that the eighth sphere is carried gradually from west to east about the poles of the zodiac, and not about the poles of the world (that is, of the equator).

[Margin: The period of the eighth sphere's motion according to Ptolemy.]

And because Ptolemy judged that the fixed stars — or rather the starry orb — are always carried uniformly by this motion from west to east (for in a few years the unevenness of that motion cannot be perceived), he not unreasonably concluded that the fixed stars complete only one degree beneath the primum mobile in the

span of 100 years, and that therefore the whole period of this motion is completed in an interval of 36000 years.

[Margin: The period of the eighth sphere's motion according to al-Battānī.]

Next al-Battānī [al-Battānī], most skilled in astronomical matters, around the year of our Lord 880 — that is, nearly 750 years after Ptolemy — observing the courses of the stars and comparing their positions with those Ptolemy had recorded, likewise rightly concluded that their motion, if uniform, is much swifter than Ptolemy had established: for by his reckoning one degree falls to a span of 66 years, and the whole period comprises 23760 years.

[Margin: The period of the eighth sphere's motion according to Alfonso.]

Alfonso, King of Castile [Alphonsus, King of Castile], together with the astronomers of his time, around the year of our Lord 1250 established this same motion as very slow, and held that it is completed in an interval of 49000 years, such that it traverses one degree and 28 minutes in 200 years. He also observed — as did Thebit the Arab [Thābit ibn Qurra] and other astronomers at various times — that the length of the year is uneven, now greater, now smaller, and that the maximum declination of the Sun is not always the same but has continuously decreased from Ptolemy's time down to his own.

[Margin: The motion of trepidation of the eighth sphere according to Thebit.]

For this reason Thebit, in order to account for these phenomena and for so great an unevenness in the motion of the fixed stars, devised the theory that the eighth sphere is not carried by a continuous motion from west to east, but is agitated by a certain motion of trepidation: namely, that the first points of Aries and Libra of the eighth heaven describe certain small circles around the first points of Aries and Libra of the ninth heaven (the diameters of these small circles being nearly equal to nine degrees), while all the other points of the starry orb waver and tremble in a way, moving now toward the south, now toward the north, now eastward, now westward. For on this account the fixed stars will indeed be seen to be carried gradually eastward, but by an uneven motion; and the length of the year, together with the maximum declination of the Sun, will vary, because on account of this motion the ecliptic of the eighth sphere intersects the equinoctial circle of the primum mobile at ever different points, and the angle it makes with the equator at that intersection — which measures the maximum declination of the Sun — is not always of the same magnitude, as can easily be perceived from some material instrument.

[Margin: The defect of Thebit's trepidation.]

But although this and its unevenness could in some fashion be defended by this motion, the stars could nevertheless not advance eastward by more degrees than nine — that is, by as many as we said are contained in the diameters of the small circles, and no more. This conflicts with experience, since we see that from Ptolemy's time down to our own age they have become more easterly by nearly 21 degrees.

[Margin: The motion of trepidation of the eighth sphere according to Alfonso.]

Therefore Alfonso the King, together with the astronomers of his age, held that the eighth heaven is indeed drawn eastward by the ninth sphere over a span of 49000 years, but he also laid down that it is set in motion by a trepidation-motion of its own, so that a cause could be given why the fixed stars advance from west to east with an uneven motion, why the length of the year is uneven, and why, finally, the maximum declination of the Sun turns out to be variable — just as Thebit had proposed. In Alfonso's account, however, the small circles that the first points of Aries and Libra of the eighth heaven describe around the first points of Aries and Libra of the ninth heaven have larger diameters than in Thebit's — namely, of 18 degrees.

[Margin: The three motions of the eighth sphere according to Alfonso.]

And so, on Alfonso's view, the eighth sphere has three motions: one from east to west about the poles of the world, in a span of 24 hours; another from west to east about the poles of the zodiac, over an interval of 49000 years; and finally a third, that of trepidation.

[Margin: Ten movable heavens according to Alfonso.]

From this it follows that not merely nine movable heavens are to be granted, as with Ptolemy, but altogether ten: seven, indeed, on account of the 7 planets, which are set in motion by different motions and therefore exist in 7 different orbs; and three on account of that threefold motion of the eighth sphere. For since a single simple body can have only a single simple motion, as the philosophers teach, the eighth sphere will have its daily motion from the tenth heaven — which is the primum mobile for Alfonso, and which carries all the lower orbs around with it from east to west. The ninth orb, in turn, will impart to the eighth sphere the motion from west to east, since by its very slow motion it draws all the lower spheres with it from west to east. The third motion, finally,

which we have called that of trepidation, will be reckoned as proper to the eighth sphere.

This view or opinion of Alfonso's has so prevailed down to our own age that it is taught in almost all public schools as the one theory able to give the cause and rationale of the threefold motion observed in the eighth sphere. But if we examine it a little more carefully, we shall easily see that it does not so much save the celestial phenomena as destroy them. For although it follows from it that the fixed stars advance continuously from the west by the motion of the ninth sphere, that on account of the trepidation of the eighth sphere these same stars are moved unevenly, and that the maximum declination of the Sun from the equator, and the length of the year, do not always remain the same — all of which the accurate observations of astronomers plainly teach — nevertheless many absurdities arise from it in the celestial motions, which conflict with the observations of all astronomers.

[Margin: First argument against the motion of trepidation.]

In the first place, from this motion of trepidation it follows that not all the fixed stars are carried by a similar motion, but some by a perfectly circular motion — namely those situated at the first points of Aries and Libra of the eighth heaven; some have a quasi-circular motion — namely those not far from those first points; and some, finally, are moved by an almost rectilinear motion, advancing now eastward, now back westward — namely those placed near the beginnings of Cancer and Capricorn of the eighth sphere. But this is entirely contrary to the phenomena, since all the fixed stars have been seen always to be carried by the same motion.

[Margin: Second argument against the motion of trepidation.]

Next — to say nothing of the other planets and the stars — the Sun would have at one and the same degree of the zodiac a perceptibly greater declination at one time and a smaller at another, especially near Aries and Libra of the eighth sphere, where it is driven more toward the north and the south by the motion of trepidation than elsewhere. Thus (assuming the centres of the small circles placed beneath the first points of Aries and Libra of the primum mobile) it could be 9 degrees distant from the equator on either side, and could be more southerly or more northerly by 18 degrees at one time than at another. From this it would follow that the noon altitude of the Sun, since it moves around Aries and Libra of the starry orb, would vary astonishingly within one and the same region, so that

it would not always be equal to the complement of the pole's altitude — which the daily experience of all climes contradicts.

[Margin: Third argument against the motion of trepidation.]

Again, it would sometimes happen that the intersections of the equator with the ecliptic of the eighth sphere, where the equinoxes occur, would be distant by 21 degrees and more — both eastward and westward — from the first points of Aries and Libra of the primum mobile; and consequently that the equinox could occur nearly 21 days before the Sun occupies the equinoctial points of the primum mobile, or after it has passed them. This great a distance would arise if the centres of the small circles of the trepidation-motion are conceived to be perpetually fixed to the first points of Aries and Libra of the primum mobile. But if those centres are supposed to recede continuously eastward from those first points — as the authors of this motion seem to hold, since they suppose them to be carried around by the ninth sphere's motion from west to east — then, if those centres of the small circles are supposed to lie near the solstitial points, the maximum declination of the Sun could differ by 9 degrees from that which the first points of Cancer and Capricorn of the primum mobile have. And consequently, given that maximum declination of the ecliptic of the primum mobile of 23 degrees, the maximum declination of the Sun that follows the trepidation-motion of the eighth sphere could sometimes amount to 32 degrees, and sometimes to only 14 degrees — all of which is ridiculous and unheard of. These and many other absurdities anyone may easily gather from the motion of trepidation, if he employs a material instrument. And they follow likewise from Thebit's motion of trepidation, except that the distance of the equinoctial and solstitial points of the eighth sphere from the equinoctial and solstitial points of the primum mobile is not as great as among the Alphonsines.

[Margin: Fourth argument against the motion of trepidation.]

To this may be added that the authors of this kind of trepidation-motion hand down no precepts by which the maximum declination of the Sun, the length of the year, the distance of the equinoctial points of the eighth sphere from the equinoctial points of the primum mobile, and other such things, could be computed for a given time — because they realized, of course, that a calculation derived from the trepidation-motion did not in the least agree with the phenomena and with experience. This is proof that this motion does not exist in the nature of things, but is wholly fictitious and fabricated without any foundation.

[Margin: Copernicus's view on the motion of the eighth sphere.]

Since, therefore, the motion of trepidation not only fails to answer exactly to the phenomena observed at various times, but even utterly overturns and destroys most of them, Nicolaus Copernicus of Prussia [Copernicus] — that outstanding restorer of astronomy in our own century, whom all posterity will ever celebrate and admire with grateful mind as a kind of second Ptolemy — comparing his own observations with those of all astronomers, both ancient and more recent, determined that the motion of the eighth sphere must be reasoned about differently. For on account of the phenomena discussed above, he assigned to the eighth heaven four different motions, prescribing their periods (that is, their slowness and speed), together with precepts by which both the maximum declination of the Sun and the uneven motion of the fixed stars, along with the length of the year, could be computed for a given time. Two of these motions he makes absolute and complete — namely those that describe entire circuits from east to west and from west to east — but two he makes imperfect and incomplete, since they do not accomplish full revolutions. By the one of them the sphere is agitated through a certain small span — embracing only 24 minutes of one degree — from north to south and back again from south to north, unevenly however, over a span of nearly 3432 of our years; this motion brings it about that the maximum declination of the Sun is now increased, now diminished. By the other, over a span likewise small yet a little greater than the former — that is, through only 2 and a third degrees — it is set in motion from east to west and back from west to east, again with an uneven motion, over an interval of nearly 1716 of our years. By this motion it comes about that the motion of the fixed stars from west to east — which he established as being completed in nearly 25800 years — and the length of the year appear uneven. Thus you would more properly call these latter two motions certain librations of the eighth sphere rather than motions or revolutions.

[Margin: Copernicus's absurd hypothesis.]

But just as we gladly receive and embrace this fourfold motion of the eighth sphere, together with the periods prescribed for them by Copernicus, so we entirely reject the manner in which he explains them. For in order to set before our eyes the latter two motions — or rather librations — of the eighth sphere, he assumes hypotheses that are quite discordant and absurd, remote from the common sense of mankind (not to say reckless): since he places the Sun at the centre of the world, devoid of all motion, and gives the earth a manifold motion, placing it — together with the rest of the elements and the lunar globe — in the

third heaven, between Venus and Mars. Then he speaks confusedly, and explains and expounds himself with great difficulty, so that he can scarcely be understood — for he seems to me to write things wholly contradictory about the latter two motions. For he holds that the former, by which the maximum declination of the Sun is changed, comes about through the approach and recession of the pole of the world to and from the pole of the zodiac through 24 minutes along the Colure of the Solstices; but the latter, which renders uneven the motion of the fixed stars — which he himself calls the precession of the equinoxes — is effected through the departure of that same pole of the world to either side of the Colure by so great an interval that the equator, when it is most distant from the Colure, is traced out by it so as to intersect the ecliptic at two points which are distant from the equinoctial points of the primum mobile, both eastward and westward, by 1 degree and 10 minutes. Thus, by this motion, the pole of the equator describes a kind of figure resembling a twisted garland [*intortæ corollæ*], as he himself puts it, which the Colure divides in two — such as two ellipses touching each other along their breadth would roughly present, so that their minor axes form a straight line and cut off 24 minutes from the Colure. But who does not see that these things are entirely contradictory? For if the pole creeps up and down, as it were, along the Colure, how can it be understood that at the same time it can wander outside the Colure? Or if it strays this way and that, how can the same pole at the same time be moved up and down along the Colure? For my part, I frankly confess that I have never been able to understand this contradiction perfectly.

[Margin: Eleven movable heavens, from Magini and our own view.]

For this reason Giovanni Antonio Magini [Giovanni Antonio Magini], a most learned man, prudently rejecting these hypotheses but retaining the periods of the motions that Copernicus established, endeavours to uphold and defend that fourfold motion of the eighth sphere by means of the usual hypotheses, received by all astronomers and philosophers — since he places this terrestrial globe, devoid of all motion, at the centre of the whole universe, as reason demands. But just as, according to the view of the Alphonsines and of the astronomers received down to the present day, we are compelled — on account of the three motions detected in the eighth heaven — to set up two movable heavens above the eighth orb, as was explained above, so now, in order to uphold the four motions observed in that same eighth heaven, we must place above it not merely two movable orbs but three; so that now not merely 10 movable heavens are to be granted, as with the Alphonsines, but altogether eleven — if we wish to preserve and uphold the celestial phenomena by a sure and probable method, such that

nothing absurd follows from the assumed hypotheses. For the eleventh will be the primum mobile; the tenth and the ninth, enclosed between the primum mobile and the starry sphere, will impart to the fixed stars those two imperfect motions of Copernicus — or rather librations; while the eighth heaven itself will carry the fixed stars around from west to east by its own very slow motion. In what manner this comes about I have resolved to explain a little more carefully, following Magini, yet I shall set the whole matter out somewhat more simply than Magini himself does, and — unless I am mistaken — more suitably for understanding, since I employ fewer circles and lines to explain the motions.

[Margin: The motion of the primum mobile.]

The eleventh heaven, then, which we have called the primum mobile, is carried with a most rapid and uniform course from east to west, about the poles of the world (or of the equator), in a span of 24 hours, carrying all the lower celestial orbs around with it.

[Margin: How great is the maximum declination of the ecliptic of the primum mobile, and why it is called the mean.]

In this primum mobile are to be conceived nearly all the movable circles that are usually set out in the sphere — chiefly the equator, the zodiac, the Colure of the Equinoxes, the Colure of the Solstices, the Tropic of Cancer, and the Tropic of Capricorn. The zodiac — or rather the ecliptic — has such an inclination to the equator that its poles are distant from the poles of the equator by 23 degrees and 40 minutes; and by just this interval too the two tropics are removed from the equator, and so great is the maximum declination of the ecliptic, or of the Sun. This maximum declination is usually called the *mean* [media] in the astronomical tables, just as the ecliptic, with its poles and tropics, is called the *mean*.

[Margin: The ecliptic of the primum mobile, with its poles and tropics, is called the mean.]

For the true ecliptic, which is conceived in the tenth heaven — to which, of course, the ecliptics of the other lower spheres accommodate themselves — now has a greater declination, now a smaller, and deflects from the ecliptic of the primum mobile by equal spaces both toward the north and toward the south, while this ecliptic of the primum mobile meanwhile remains fixed and immovable, midway between the two limits to which the other strays, as we shall say in treating the motion of the tenth sphere.

[Margin: The true equinoxes and solstices occur at the intersections of the ecliptic of the primum mobile with the equator, and on the Colure of the Solstices.]

But although the ecliptic of the primum mobile is called the *mean*, its intersections with the equator are nonetheless called the points of the *true* equinoxes, since it is truly at them that the Sun brings about both equinoxes, the vernal and the autumnal, throughout the whole world; and consequently both solstices, the summer and the winter, occur when the Sun reaches the Colure of the Solstices of the primum mobile, as will become clear in treating the motion of the eighth sphere. But never before or after those intersections and the Colure of the Solstices can the equinoxes and solstices occur — as the authors of the trepidation-motion wrongly held, and as would necessarily also have to be granted according to Copernicus's hypotheses.

[Margin: The equator and Colures of the primum mobile are not called mean, but true.]

And so the Colures and the equator of the primum mobile are not to be called *mean*, but *true*, since upon them depend both the true equinoxes and solstices, and from the equator are reckoned the declinations of the stars.

[Margin: The proper motion of the tenth sphere.]

The tenth sphere, next, which is to be conceived beneath the primum mobile with the same poles, equator, and ecliptic, besides the daily motion by which it is swept along by the primum mobile, has another motion of its own — a libration from north to south and from south to north, through 24 minutes, beneath the Colure of the Solstices of the primum mobile — such that the poles of the zodiac of this tenth sphere move back and forth from the poles of the zodiac of the primum mobile by only 12 minutes, and do not complete the whole circuit. And since the poles of the ecliptic of the primum mobile are distant from the poles of the world by 23 degrees 40 minutes, as we said a little before, it comes about that the maximum distance of the poles of the ecliptic of the tenth heaven from the poles of the world amounts to 23 degrees 52 minutes, and the minimum to 23 degrees 28 minutes. And you should understand the same of the maximum declination of the ecliptic of this same tenth heaven from the equator — that is, of the maximum declination of the Sun. For this too can be increased up to 23 degrees 52 minutes, and can decrease down to 23 degrees 28 minutes. The maximum, indeed,

[The maximum solar declination] will occur when the north pole of the ecliptic of the tenth heaven is 12 minutes distant, toward the south, from the pole of the

ecliptic of the *primum mobile*; and the minimum, when that same pole is 12 minutes distant toward the north from the pole of the ecliptic of the *primum mobile*.

[Margin: By how much the maximum declination of the Sun can increase and decrease, and where it becomes greatest and where least.]

This motion — or rather libration — of the tenth sphere takes its start from the extreme southern terminus, and the pole of the ecliptic moves non-uniformly beneath the colure of the *primum mobile* up to the extreme northern limit, from which it returns again with the same irregularity to the southern terminus. When it has reached this, one whole period of this libration will be complete. This libration is slowest near each extreme limit, but fastest in the middle — that is, near the pole of the ecliptic of the *primum mobile*. The whole period of this libration — from the southern terminus, through the northern, back to the same southern — comprises, according to Copernicus, 3434 Egyptian years; that is, 3431 Julian years (the years we use) and about 239 days. In the tables this interval is called the *period of the anomaly of the obliquity of the zodiac* [periodus anomalix obliquitatis Zodiaci], which is reduced to regularity in the following way.

[Margin: Where the libration of the tenth sphere begins.]

[Margin: How great the period of the tenth sphere's libration is.]

Let the solstitial colure in the *primum mobile* — or rather a segment of it, AC, containing 24 minutes of one degree — be taken, and let the pole E of the ecliptic of that same *primum mobile* lie at its midpoint. About E, through A and C, imagine a circle ABCD drawn, divided into four quadrants by the two diameters AC and BD, and let its circumference be divided into 360 degrees. Let point A face north and C face south; that is, let A be the northern limit of this libration and C the southern. So when the pole of the zodiac of the tenth sphere is placed at C, the libration begins, and there the distance of that pole from the pole of the world will be greatest, namely $23^{\circ} 52'$. At E the pole of the ecliptic of the tenth sphere will lie directly beneath the pole of the ecliptic of the *primum mobile*, and will have its mean distance from the world-pole, $23^{\circ} 40'$; and the ecliptic of the tenth sphere will not differ from the ecliptic of the *primum mobile*. At A the same pole of the tenth sphere will attain its least distance from the pole of the world, $23^{\circ} 28'$, and half of the libration will be complete. And as soon as the same pole of the tenth sphere has returned to C, the whole period of the libration will be complete.

[Margin: What the anomaly of the obliquity of the zodiac is.]

[Margin: How the irregularity of the tenth sphere's libration is reduced to regularity.]

Now if, about the radius EF, a circle EHFL is described from its midpoint G, and this same radius is imagined to be carried around uniformly — beginning from the radius EC, toward the right or the left — so that the point F traverses the whole circumference in about 3431 years and 239 days, then on each single day it will cover 1" 2''' 2'''.

Diagram. A large circular figure (woodcut) laid over a rectangular coordinate grid, illustrating the combined libration of obliquity and of precession. The four cardinal directions are engraved around the rim: **SEPTENTRIO** (north, top), **MERIDIES** (south, bottom — printed mirror-reversed), **OCCIDENS** (west, left), **ORIENS** (east, right). Two perpendicular axes cross at the center point **E**:

- Horizontal axis (west–east): labeled **CIRCVLVS ECLIPTICÆ** ("circle of the ecliptic," the words broken across the figure as CIR = ... CVLVS / ECLI... PTICA) and, along it, **Libratio præcessionis æquinoctiorum continens Minuta 140** ("libration of the precession of the equinoxes, containing 140 minutes"). Degree scale from E: rightward (toward Oriens) 10, 20, 30, 40, 50, 60, 70; leftward (toward Occidens) 10, 20, 30, 40, 50, 60 (the left-hand digits printed mirror-reversed).
- Vertical axis (north–south): labeled **COLVRVS SOLSTITIORVM** ("solstitial colure") and **Libratio obliquitatis continens Minuta 24** ("libration of obliquity, containing 24 minutes"). Scale upward 3, 6, 9, 12; downward 3, 6, 9.

Additional curved-arc and line labels: **Præcessionis æquinoctiorum** (along the upper-left arc), **Eclipticæ obliquitatis / obliquitatis** (along the diagonal line running to the lower-right), and **Initium anomalïæ** with the numeral **12** at the top (repeated, mirror-reversed, at the bottom) marking the start of the anomaly. A smaller circle (the equant circle) is drawn about the midpoint **G** of the radius.

Readable point-letters, by position:

- E (center): common center / mean pole.
- O, I, B, P (on the west/upper-left arc): B stands at the west (OCCIDENS) position.
- N, M (upper-right).
- L, K (right / lower-right).
- G (center of the smaller circle).

- H (lower portion of the figure).

The circumference of the circle EHFL will perpetually cut the colure AC, except when the radius EF coincides with the radius ED or EB; for then the circumference will touch the colure at E. This intersection occurs successively at all points of the circumference EHFL and of the segment CA of the colure, twice in one complete revolution of the libration. And since the line FH drawn is perpendicular to AC — [Margin: from III.31] because the angle EHF, being in a semicircle, is right — and since perpendiculars that intercept equal arcs on the quadrant CD cut off larger segments from the radius CE near the center E than near the extremity C (by Proposition 1 of the *Treatise on Sines* [Tractatus sinuum]), it follows that, while the radius EF traverses equal arcs of the circle CDAB in equal times, the intersections H — which the perpendicular drawn from F always marks — traverse unequal arcs on the colure CA in those same times: smaller ones near C and A, but larger near E and B. But since the irregularity of the pole of the zodiac of the tenth sphere, from C to A and from A to C, is such that it advances with the same slowness or swiftness as the intersection H — so that the pole is never displaced from the intersection H — it follows that the libration of the tenth sphere is slowest at C, at the beginning of the first [quadrant]...

[Margin: What sort the irregularity of the tenth sphere's libration is, and where it is slowest and fastest.]

[that the libration is] slowest at C — the beginning of the first quadrant of anomaly CD — and at A — the end of the second quadrant DA, or the beginning of the third quadrant AB; but fastest near the middle pole at E, that is, at the end of the first quadrant of anomaly CD (or the beginning of the second quadrant DA), and at the end of the third quadrant AB (or the beginning of the fourth quadrant BC).

[Margin: What the circle of the anomaly of obliquity is.]

The circle of the whole period of the anomaly of obliquity, then, is ABCD, whose circumference the point F traverses in the space of about 3431 years and 239 days, covering each day $1'' 2''' 2''''$.

[Margin: What the equant circle is.]

The circle EHFL is not inaptly called the *equant*, since its intersection with the colure equalizes the irregularity of the tenth heaven's libration, inasmuch as the irregular motion of the ecliptic's pole depends on it.

[Margin: What the mean motion of the anomaly (the argument) is.]

The mean or uniform motion of the anomaly of obliquity — which may rightly be called the *argument of obliquity* [argumentum obliquitatis] — is the arc of the circle of anomaly ABCD, counted from the beginning of the anomaly at C, proceeding toward D up to the diameter of the equant circle EHFL: such as the arc CF. So if the point F has reached D, or M, or A, or O, or B, or P, the mean motion of the anomaly (the argument) will be the arc CD, or CM, or CDA, or CAO, or CAB, or CAP.

[Margin: What the mean motion of obliquity is.]

The mean or uniform motion of obliquity is the mean obliquity itself: namely the arc of the solstitial colure counted from the north pole of the world to the mean pole of the zodiac (which is the pole of the ecliptic of the *primum mobile*) — the arc from the north pole of the equator up to E, which we said contains 23° 40'.

[Margin: What the true motion of obliquity is.]

The true or apparent motion of obliquity is the arc of the solstitial colure counted from the north pole of the equator to the true pole of the zodiac — which we said always lies at the intersection of the equant circle EHFL with the colure. This intersection, that is, the true pole of the zodiac, is marked by the perpendicular line dropped to the colure from the terminus of the uniform motion of anomaly. For example, when the true pole of the zodiac is set at C, the true motion of obliquity will be the arc of the colure reckoned from the north pole of the world up to C, comprising 23° 52'; but when the true pole of the zodiac is at H, the true motion of obliquity will be the arc enclosed between that same world-pole and the point H — and so for the rest.

Diagram. The identical libration woodcut printed on the preceding page is repeated here at the foot of the page (so that the figure is at hand whether the reader is on p. 37 or p. 38 of the original). Same cardinal-direction labels (SEPTENTRIO / MERIDIES / OCCIDENS / ORIENS), same two axes through center E (horizontal ECLIPTICA scale with "Libratio præcessionis æquinociorum continens Minuta 140"; vertical solstitial-colure scale with "Libratio obliquitatis continens Minuta 24"), and the same point-letters (E, O, I, B, P, N, M, L, K, G, H). See fig-p49-1 for the full label list.

[Margin: What the equation of the anomaly of obliquity is.]

The equation of the anomaly of obliquity — that is, the difference between the mean and true motion of obliquity — is the arc of the solstitial colure lying between E, the mean pole of the ecliptic, and the true pole of that same ecliptic.

Thus when the true pole of the zodiac is at H or N, the equation of the anomaly will be EH or EN; but when that same true pole is at C or A, the equation will be the greatest of all, EC or EA; and at E, finally, the equation will be nothing.

[Margin: When the equation of the anomaly is to be added to the mean obliquity, and when subtracted.]

When the mean motion of the anomaly of obliquity lies in the semicircle BCD — which happens when it is less than 90° in the first quadrant CD, or greater than 270° in the fourth quadrant BC — the true obliquity is greater than the mean; and so the equation EH or EC must then be added to the mean obliquity of $23^\circ 40'$, in order to obtain the true obliquity, that is, the distance of the pole of the zodiac of the tenth sphere from the pole of the world. But when the mean motion of the anomaly lies in the semicircle DAB — which occurs when it is greater than 90° yet less than 270° — the true obliquity of the zodiac is less than the mean. Therefore the equation EN or EA must then be subtracted from the mean obliquity, so that the true may remain. And finally, when the mean motion of the anomaly is exactly 90° or 270° — as when it is at D or B — the true obliquity does not differ from the mean. So then nothing is to be added to, or subtracted from, the mean obliquity.

[Margin: How the magnitude of the equation is to be found from a given mean motion of anomaly.]

For the rest, the magnitude of the equation will be easily known, whatever point of the circle ABCD the mean motion of the anomaly occupies. For since the equation of obliquity is always equal to the sine of the complement of the mean motion of the anomaly — a semicircle being first subtracted from the mean motion, if necessary — once the mean motion of the anomaly is known, the sine of its complement will also be known. Since, then, the whole sine EC (or EA) comprises 12 minutes, it will be impossible not to know how many minutes belong to the sine of the complement of any given mean motion of anomaly — that is, how many minutes the equation of a given mean motion of anomaly contains — provided one sets up the proportion: as the whole sine is to 12 minutes, so is the sine of the complement of the given mean motion of anomaly to the sought value. Do not be troubled that we explain and investigate these things by means of straight lines, even though in the heavens everything is curved and spherical: for on account of the tiny magnitude of 12 minutes, the circle ABCD will differ little or not at all from a plane surface, and its lines from straight lines.

[Margin: The proper motion of the ninth sphere.]

The ninth sphere, which is placed beneath the tenth with entirely the same poles and circles — equator and zodiac — has, besides the diurnal motion by which it is carried along by the *primum mobile*, and the libratory motion beneath the solstitial colure from north to south and from south to north which the tenth sphere imparts to it, also a certain proper libratory motion of its own beneath the ecliptic of the tenth sphere and about its poles (for the poles and ecliptic of the ninth sphere do not depart in any direction whatever from the poles and ecliptic of the tenth sphere): from east to west and from west to east through 140 minutes, that is, through $2^{\circ} 20'$. Thus the first points of Aries and Libra of the ninth heaven move back and forth, beneath the ecliptic of that same tenth heaven, from the first points of Aries and Libra of the tenth — that is, from the intersections of the equator with the ecliptic, which do not differ from the intersections made in the *primum mobile* — by 70 minutes, or $1^{\circ} 10'$, according to Copernicus. For the Prutenic Tables [Prutenicæ tabulæ] make this libration, on either side of the Aries and Libra of the tenth heaven (or the *primum mobile*), a little greater — namely $1^{\circ} 11' 22'' 30'''$ — so that the whole libration comprises $2^{\circ} 22' 45''$.

This libration begins its motion from the very intersection of the equator and the ecliptic in the tenth sphere (or *primum mobile*), and proceeds with a non-uniform course toward the west up to $1^{\circ} 10'$; then with the same non-uniformity it returns to the same intersection, and proceeds further toward the east up to $1^{\circ} 10'$, and from there returns once more to that intersection of the equator and the ecliptic. It is fastest at the beginning and middle of the whole period, that is, near the intersection of the ecliptic and equator; but slowest around each limit, the western and the eastern.

[Margin: How great the period of the ninth sphere's libration is.]

The whole period of this second libration of the ninth sphere comprises, according to Copernicus, 1717 Egyptian years — that is, 1715 Julian years (those in use among us) and about 302 days — so that this period of the second libration is half as long as the period of that first libration of the tenth heaven, and is completed twice in the time in which the former is completed once. The time of the period of this second libration is called the *period of the anomaly of the precession of the equinoxes*, or of the motion of the eighth sphere; and it is reduced to regularity in the following way.

[Margin: Where the libration of the ninth sphere begins.]

[Margin: What the anomaly of the precession of the equinoxes, or the motion of the eighth sphere, is.]

Let there be the ecliptic — or rather a segment of the ecliptic — in the tenth sphere, BD, comprising 140 minutes, or $2^{\circ} 20'$, at whose midpoint lies E, the beginning of Aries of the tenth sphere, which lies directly beneath the first point of Aries of the *primum mobile*, that is, beneath the intersection of the ecliptic BD with the equator IK. About E, through B and D, let a circle ABCD be imagined drawn, divided into four quadrants by the diameters BD and AC, and let its circumference be divided into 360 degrees. Let point B face west, D east, A north, and C south, so that B is the western limit or terminus of this second libration, and D the eastern.

[Margin: The true and the mean equinox, what.]

So when the beginning of Aries of the ninth sphere is placed at E, the libration begins, and it will be no distance from the true equinox — which, as we said above, always occurs at E, the intersection of the ecliptic and equator of the *primum mobile*. The beginning of Aries of the ninth sphere, wherever it lies on the libration line BD, is called the *mean equinox*, since the Sun, when it is there, does not produce an [actual] equinox, but — always at an equal distance with respect to the motion of the eighth sphere, as we shall say below — recedes from it daily; and accordingly the mean equinox is said to occur as soon as the Sun reaches it. At B and D the mean equinox — that is, the Aries of the ninth sphere — will be at its greatest distance from the true equinox, i.e. from the Aries E of the *primum mobile*, namely $1^{\circ} 10'$.

The beginning of Aries of the ninth sphere moves toward the west to B, then from there passes through E and D, and from D returns again to E; and only then will the whole period of the libration be complete. Now if the radius EF, together with its circle of the figure above, is imagined to be carried around uniformly — beginning from the northern radius EA (this beginning could also be made from the southern radius EC), toward the west — so that it traverses the whole circumference in about 1715 years and 302 days, then on each single day it will cover $2'' 4''' 4''''$.

The circumference of the circle EHFL will perpetually cut the ecliptic BD, except when the radius EF coincides with the radius EA or EC at the beginning and middle of the libration; for then the circumference will touch the ecliptic at E. This intersection occurs successively at all points of the circumference EHFL [printed here "EHPL"] and of the segment BD of the ecliptic, twice in one

complete revolution of the libration. And since the line FL drawn is perpendicular to BD — [Margin: from III.31] because the angle ELF, being in a semicircle, is right — we shall show, as in the earlier libration, that while the radius EF traverses equal arcs of the circle ABCD in equal times, the intersections L (upon which the perpendiculars drawn from F fall) traverse in those same times unequal arcs on the ecliptic BD: larger ones near E, but smaller near the extreme limits B and D.

[Margin: What sort the irregularity of the ninth sphere's libration is, and where it is fastest and slowest.]

Therefore, since the irregularity of the beginning of Aries of the ninth sphere — from E to B, and from B to D, and from D to E — is such that it never departs from the intersection L, but advances with exactly the same swiftness and slowness as the point L, it comes about that the libration of the ninth sphere is fastest at E — that is, at the beginning of the first quadrant of anomaly AB, and at the end of the second quadrant BC (or the beginning of the third quadrant CD); but slowest at B — the end of the first quadrant AB (or the beginning of the second quadrant BC) — and at D — the end of the third quadrant CD (or the beginning of the fourth quadrant DA).

[Margin: What the circle of the anomaly of the precession of the equinoxes, or of the motion of the eighth sphere, is.]

The circle of the whole period of the anomaly of the precession of the equinoxes — or of the motion of the eighth sphere — is therefore ABCD, whose circumference the point F traverses in the space of about 1715 years and 302 days, and covers each day $2''\ 4'''\ 4''''$.

[Margin: What the equant circle is.]

The circle EHFL will not ineptly be called the *equant*, since its intersection with the ecliptic equalizes not only the libration of the ninth heaven — for the irregular motion of the first point of Aries of the ninth sphere depends on it — but also the irregular motion of the eighth sphere, as we shall say below.

The mean or uniform motion of the anomaly of the precession of the equinoxes, which may most aptly be called the *ar-gument...*

[Margin: What the mean motion of the anomaly of the precession of the equinoxes, or the argument, is.]

the argument of the anomaly is the arc of circle ABCD, which we called the anomaly, numbered from the beginning of the anomaly A toward B, proceeding up to the diameter of the equant circle EHFL — such as the arc ABF. But if point F reaches O, or B, or P, or C, or D, or M, the mean motion of the anomaly (or argument) will be the arc AO, or AB, or AP, or ABC, or ABD, or ACM. What the mean and true motion of the precession of the equinoxes (or of the eighth sphere) is will be stated below.

[Margin: What the equation of the anomaly of the precession of the equinoxes, or of the motion of the eighth sphere, is.]

The equation of the anomaly of the precession of the equinoxes — that is, of the motion of the eighth sphere — that is, the difference between the mean and true motion of the precession of the equinoxes (or of the eighth sphere), is the arc of the Ecliptic between E (the true equinox) and the beginning of Aries of the ninth sphere, that is, the mean equinox, which we have always said occurs at L, the intersection of circle EHFL and the Ecliptic. Thus, if the beginning of Aries of the ninth sphere is placed at L or Q, the equation of the anomaly will be EL or EQ. But when that same beginning of Aries lies at B or D, the equation will be greatest, EB or ED. Finally, at E there will be no equation at all. We will explain the use of this equation in [our discussion of] the eighth sphere.

[Margin: How the magnitude of the equation of the precession of the equinoxes is known from the given mean motion of the anomaly.]

Moreover, the magnitude of the equation will be easily found, once it is known how great the mean motion of the anomaly is. For since the equation of the precession is always equal to the right sine of the mean motion of the anomaly — after first subtracting a semicircle from the mean motion, if it can be subtracted — then, the mean motion of the anomaly being known, its right sine will also be known. Since, therefore, the whole sine EB (or ED) comprises 70 minutes, it will not be impossible to determine how many minutes correspond to the right sine of the given mean motion of the anomaly — that is, how many minutes the equation of the given mean motion of the anomaly contains — namely if the following proportion is made: as the whole sine is to 70, so is the right sine of the given mean motion of the anomaly to another [number]. For here too the whole figure can be taken as plane, although it is spherical, because of the smallness of the diameter BD, which is 2 degrees and 20 minutes.

Diagram. A large circular figure occupying the lower half of the page, combining the two librations. The four cardinal directions are engraved around the

periphery: SEPTENTRIO (north, top), MERIDIES (south, bottom), OCCIDENS (west, left), ORIENS (east, right). A horizontal diameter runs west–east through the centre E; it is the Ecliptic, labelled **ECLIPTICA** (split across the figure as "ECLI... PTICA") and graduated 10, 20, 30, 40, 50, 60, 70 to each side of the centre. A vertical diameter runs north–south through E; it is the solstitial colure, labelled **CIRCVLVS SOLSTITIORVM**, graduated 3, 6, 9 (and higher) each way. The large outer circle carries the label **Libratio præcessionis æqui[noctiorum]** ("Libration of the precession of the equinoxes") and along its horizontal axis the note **continens Minuta 140** ("containing 140 minutes" — i.e. the $\pm 70' = 2^\circ 20'$ precession libration). A smaller circle in the lower/right region is labelled **ÆQVANS** and **Libratio obliquitatis** ("the equant" / "libration of obliquity"), with the note **continens Minuta 24** ("containing 24 minutes" — the obliquity libration). Along an upper radius runs **Præcessionis æquinocetiorum**; on the right side **Ecliptica obliquitatis**; near the centre **COLVRVS. Initium Anomaliae** ("beginning of the anomaly") appears at the top of the circle, and again as **Initium anomaliae** at the bottom.

Labelled points read on the figure:

- E (centre): intersection of Ecliptic and colure
- B (west end of Ecliptic / horizontal diameter)
- C (on the Ecliptic, left of centre, at the foot of a dotted vertical from O)
- O (upper-left arc)
- P (lower-left, foot of the large circle)
- H (bottom, on the colure)
- N (upper, on the colure near centre)
- M (upper-right arc)
- K (right, on the smaller circle) [?]
- L (right of centre, near the smaller circle) [?]
- G (mid-figure, on an interior diagonal line) [?]
- A (lower, near "Initium anomaliae") [?]
- I / L (left, on a radius near "Præcessionis æquinocetiorum") [?]

[Margin: The Ecliptics of both the ninth and the eighth sphere always cut the Equator at the beginning of Aries of the primum mobile, although they recede from the Ecliptic of that same primum mobile.]

[Margin: The simple anomaly is called that of obliquity; the doubled one is called that of precession.]

Now although the poles of the Ecliptic of the ninth heaven approach and recede from the poles of the Ecliptic of the primum mobile in keeping with the libration-motion of the tenth [heaven] beneath the colure of solstices — and thus the Ecliptic of both the ninth and the eighth sphere is moved away from the Ecliptic of the primum mobile — nevertheless it will always intersect the Equator at the same points, one of which is point E. For since the colure of solstices passes through the poles of the Equator and of the Ecliptic, these circles will in turn pass through its poles (by the scholium to Proposition 15 of Book 1 of Theodosius); and therefore the intersection of the Equator and the Ecliptic will be the pole of the colure of solstices. Hence (by the corollary to Proposition 16 of the same) it will be distant a quadrant of a great circle from any point of the colure. Therefore, wherever the pole of the Ecliptic is set upon the colure, the Ecliptic described from it will pass through the intersection of the Equator and the Ecliptic of the primum mobile. And so, although the Ecliptic of the eighth sphere recedes from the Ecliptic of the primum mobile, the equinox will nevertheless always fall at the beginning of Aries of the primum mobile.

Finally, since this libration of the ninth sphere is twice as fast as that libration of the tenth, as we said, it has come about that in the Prutenic Tables the libration of the tenth Sphere is called the "simple anomaly," while the libration of the ninth Sphere is called the "doubled anomaly." Thus in the tables the Anomaly is to be taken simply for the obliquity of the Zodiac, but the same doubled for the precession of the equinoxes; and there is no need to compose two tables for those two librations, but one will serve both, as has been explained.

[Margin: The proper motion of the eighth sphere.]

The eighth sphere, finally, besides the threefold motion by which it is carried along by the three higher spheres, has yet a fourth motion of its own, and that the slowest of all: from west to east beneath the Ecliptic of the ninth, or tenth, heaven. For the poles are altogether the same, and the Ecliptics of the eighth, ninth, and tenth heaven are the same.

[Margin: In what respect the motion of the eighth sphere is regular.]

This motion, however, is irregular and non-uniform if it is referred to the Aries of the primum mobile, but uniform if it is referred to the Aries of the ninth sphere. For from the first point of Aries of the ninth heaven (which is wandering and mobile, since it moves back and forth into west and east from the first point of Aries of the primum mobile, as has been said) — namely from point L of the figure above — the first star of Aries, which is in its right horn, continually

recedes with a uniform motion, namely in the space of one natural day, by 8 thirds and 15 fourths toward the east; so that if that star were at this moment of time conjoined with that first point of Aries of the ninth sphere, after 24 hours had passed it would be distant from it by 8 thirds and 15 fourths, and after another 24 hours had elapsed, by 16 thirds and 30 fourths, and so on in succession — however irregularly that point of Aries wanders back and forth from the beginning of Aries of the primum mobile.

[Margin: The magnitude of the motion of the eighth sphere, and its period.]

From this it follows that the first star of Aries, together with the whole eighth sphere, completes an entire period — that is, returns to the same point of the Ecliptic of the ninth heaven from which it departed — in the space of 25816 Egyptian years, which make about 25798 Julian years and 120 days. And because we said that the first point of Aries of the ninth heaven moves non-uniformly, it comes about that the eighth sphere too is carried irregularly from west to east, since its irregularity depends on that wandering and mobile starting-point.

[Margin: Where the motion of the eighth sphere is fastest, where slowest, and where intermediate.]

The eighth sphere will be seen to move more quickly when the first point of Aries of the ninth sphere is carried from B to D — that is, from west to east — because then that point follows the first star of Aries eastward, and so the two motions from west to east run together at once; but more slowly when it goes back from D to B — that is, from east to west — because then that point, from which the first star of Aries is uniformly elongated, flees from that first star by retreating in the opposite direction. And so near the beginning and the end of the Anomaly — that is, around the northern point A — the motion of the eighth sphere is slowest; near the middle of the anomaly, around the southern point C, it is fastest; and finally at both limits B and D, the western and the eastern, it is intermediate, because then the first point of Aries of the ninth sphere seems to advance neither into the west nor into the east.

[Margin: Why the motion of the eighth sphere is called the precession of the equinoxes by Copernicus.]

This motion of the eighth sphere is called by Copernicus, and in the Prutenic Tables, the precession of the equinoxes. For Copernicus, according to his own hypotheses, makes the first star of Aries, together with the whole eighth heaven, motionless, but sets the point of the true equinox E to move away from that star from east to west — that is, against the order of the Signs, which astronomers call

moving "in antecedence," just as they call motion from west to east, that is, according to the order of the Signs, motion "in consequence." And so, just as for us the first star truly recedes from the true equinox toward the east, so for Copernicus the true equinox moved away from that fixed and unmoving star toward the west, in antecedence; and therefore that motion was called the precession of the equinoxes.

[Margin: What the mean motion of the eighth sphere, or the mean precession of the equinoxes, is.]

The mean motion of the eighth sphere, then, or the mean precession of the equinoxes, is the arc of the Ecliptic intercepted between two great circles: one drawn through the poles of the Zodiac and the first point of Aries of the ninth sphere (that is, the mean equinox); the other through the poles of the Zodiac and the first star of Aries.

[Margin: What the true motion of the eighth sphere, or the true precession of the equinoxes, is.]

The true motion, however, or the true precession of the equinoxes, is the arc of the Ecliptic enclosed between two great circles: one of which is drawn through the poles of the Zodiac and the first point of Aries of the primum mobile (that is, the true equinox); the other through the poles of the Zodiac and the first star of Aries.

[Margin: What the equation of the motion of the eighth sphere, or of the precession of the equinoxes, is, and when it is to be added or subtracted.]

The equation of the motion of the eighth sphere, or of the precession of the equinoxes, is the same as the equation of the anomaly of the precession which was discussed for the ninth sphere. It is subtracted from the mean motion in the first semicircle ABC — that is, when the mean motion of the Anomaly is less than 180 degrees — because then the mean motion is greater than the true, and the mean equinox occurs before the true; but in the latter semicircle CDA — that is, when the mean motion of the anomaly is greater than 180 degrees — it is added, because then the mean motion is less [than the true], and the mean equinox occurs after the true.

[Margin: Why astronomers at different times found the fixed stars to move variously, and the length of the year, and the maximum declination of the Sun, not to be the same.]

From all this it appears why the fixed stars were found by some astronomers to move more slowly, and by others more quickly, at different times: namely because they are advanced non-uniformly from west to east, on account of the anomaly of the precession of the equinoxes. Likewise why the length of the year is not always the same: because the Sun, which is driven also by the motion of the eighth sphere, returns to the true equinox now more slowly, now more quickly, on account of the same anomaly of the precession of the equinoxes. And finally why different astronomers at different times found different values for the maximum declination of the Sun: because the Ecliptic of the eighth sphere, beneath which the Sun perpetually moves, wanders — in keeping with the libration of the tenth heaven — now northward, now southward, away from the Ecliptic of the primum mobile.

[Margin: What the four motions of the eighth sphere are.]

These, then, are the four motions which astronomers observed in the fixed stars, or in the eighth heaven: (1) from east to west in the space of 24 hours, by the motion of the primum mobile about the poles of the world; (2) from north to south and back through 24 minutes, by the libration of the tenth sphere, in the space of 3434 Egyptian years; (3) from east to west and back, about the poles of the Zodiac, through 70 minutes, going to and fro from the true equinox and returning in the space of 1717 Egyptian years; and (4) from west to east, likewise about the poles of the Zodiac, completing the whole circuit in the space of 25816 Egyptian years.

[Margin: The latitudes of the stars with respect to the true Ecliptic — which is in the tenth, ninth, and eighth heaven — do not change; although with respect to the Ecliptic of the primum mobile, which is the mean [Ecliptic], they do change.]

But if someone should object that from the libration of the tenth sphere it follows that the fixed stars change their latitudes with respect to the Ecliptic of the primum mobile — which seems to conflict with the observations of astronomers, who teach that the latitudes of the stars do not change — we reply that this is true: for the points of the eighth heaven near the colure of solstices, where that change is greatest, can be 24 minutes more southerly or more northerly at one time than at another; but that this distance of the stars from the Ecliptic of the primum mobile is not to be called latitude — which astronomers have found not to vary in one and the same star. For the latitudes of the stars are to be referred to the true Ecliptic, which the Sun describes by its annual motion beneath the Ecliptic of the tenth, ninth, and eighth heaven. For they perpetually keep their distances from this Ecliptic — that is, from the Sun's path — the same, as has been

found by astronomers. And indeed, if it were absurd for the fixed stars to recede 12 minutes to either side from the Ecliptic of the primum mobile near the solstitial points, it would be far more absurd in the motion of trepidation, on account of which the stars near the beginning of Aries and Libra of the eighth heaven can be moved to either side of the Ecliptic of the primum mobile (or of the ninth sphere) not only by 12 minutes but by 9 degrees, that is, by 540 minutes.

[Margin: That the fixed stars cannot become stationary or retrograde, even if the motion of trepidation is granted.]

If again someone should object that from the libration of the ninth sphere it follows that the fixed stars are perpetually carried from west to east by the motion of the eighth sphere, and are never stationary or retrograde from east to west — whereas we asserted above, following the opinion of the authors of the trepidation-motion, that this could happen — we frankly admit that this is true, and that the observations of all astronomers teach the very same thing; for the fixed stars have been continually found to move eastward, even in the time of Alfonso, when their motion is thought to be slowest. Indeed, even if we were to grant that the stars are moved by the motion of trepidation, it still could not happen that they should be stationary or retrograde, because their motion from west to east by the motion of the ninth sphere is always faster than the motion by which they can be moved from east to west by the trepidation of the eighth sphere — just as their motion from west to east, by which the eighth heaven carries them around, is faster than that motion by which they are drawn westward by the libration of the ninth sphere. For the first point of Aries of the eighth sphere, according to the Alphonsines, in the space of 35000 years — in which half the period of trepidation is completed — travels 18 degrees from east to west, namely the whole diameter of the little circle; but in the same time, by the motion of the ninth sphere, the stars complete 25 degrees and more toward the east, even reckoning by the period of 49000 years, as the Alphonsines will have it. Likewise the stars, by the libration of the ninth sphere, in the space of about 858 years — in which half the period of the libration is completed — travel 2 degrees 20 minutes from east to west; but in the same time the stars complete 11 degrees and more from west to east by the motion of the eighth sphere. From which it is plainly established that the motion of the stars from west to east is always faster than the motion of trepidation, or the libration of the ninth sphere, from east to west.

[Margin: That the equinoxes and solstices never occurred before or after the equinoctial and solstitial points of the primum mobile.]

Finally, that which the Alphonsines adduced in confirmation of the motion of trepidation — namely that the equinoxes and solstices had sometimes occurred before or after the equinoctial and solstitial points of the primum mobile — is an utterly old-womanish fiction; nor could they ever confirm it by the observation of any competent astronomer, but it is merely asserted by them because it necessarily follows from that motion of trepidation. A clear proof of this is that not even among the Alphonsines themselves is there agreement as to which point the motions are to be referred to — whether, that is, to the Aries of the primum mobile, or to the intersection of the Ecliptic of the eighth sphere with the Equator of the primum mobile. This controversy would have no place if the equinox really did fall outside the first point of Aries of the primum mobile. For reason seems to require that the motions be reckoned from the true equinox — which is exactly observed in our libration of the ninth sphere. For this reason it is more probable that the eighth sphere is moved by a fourfold motion, as we have explained, than by a motion of trepidation; since by that account all the phenomena are accounted for, and nothing absurd follows from it.

DE ORDINE SPHÆRARVM CŒLESTIVM.

[On the order of the celestial spheres]

[Margin: That the heavens are immediately contiguous to one another.]

From what has been said about the motions of the heavens, it clearly remains that all the heavens do not form a single continuous body, since the heavens are carried by various and diverse motions that are in a sense opposed, as has been said; and no single body is fit to be carried by contrary motions at the same time. Therefore all the heavens so far discovered are concentric with the whole universe and contiguous to one another, in such a way that between any two neighbouring orbs there is nothing intermediate; for if there were either a vacuum or some body [between them], the motion of the higher orb could not be communicated to the lower. Nor indeed is the argument valid that is commonly brought forward to prove that the heavens cannot be contiguous, which runs thus: Let a straight line be drawn from the centre of the world to the convex surface of, say, the tenth heaven, and let the point be taken where that line touches or cuts the convex surface of the ninth orb, which we call A; and let another point besides be taken where the same line touches or intersects the concave surface of the tenth sphere, which we call B. If, then, the convex surface of the ninth sphere is immediately adjacent and contiguous to the concave surface of the tenth, the two points A and B, lying on the same line, will be

immediately next to each other — so that the tenth heaven cannot be immediately adjacent to the ninth; and the same reasoning holds for the remaining celestial spheres. This argument, I say, has no force, because one and the same point of that line touches both the convex surface of the ninth heaven and the concave surface of the tenth; hence the two points conceived there are one and the same point, since they touch each other as wholes (having no parts), and therefore exist in the same place — if indeed a point can be said to occupy a place. Those two points are therefore two in reason but one in reality, since they coincide, no otherwise than if two lines were joined at their end-points: for then those two end-points would coincide entirely into one. And if this argument proved anything, no two bodies could ever be contiguous and immediate — which is plainly false, as is evident in the case of some ball placed in the air. For nothing can be intermediate between the ball and the air; otherwise there would be a process to infinity. And yet, if a straight line were drawn through the centre of the ball, it would certainly cut both the concave surface of the air and the convex surface of the ball. It remains, therefore, that the heavens are distinct from one another yet contiguous — and their order is now to be discussed.

[Margin: The first opinion on the order of the heavens.]

Among the ancients, then, there were some — whose leader was Aristarchus of Samos, 400 years before Ptolemy [recte: Ptolemæum; printed *Prolemæum*], and whom, among more recent writers, Nicolaus Copernicus followed in his work *On the Revolutions of the Heavens* — who devised this order among the bodies of the whole Universe: that the Sun is set motionless at the centre or middle of the world; around it the orb of Mercury; then the orb of Venus; around this the great orb, containing the Earth together with the elements and the Moon; around which the orb of Mars; then the heaven of Jupiter; afterward the globe of Saturn; and last of all follows the sphere of the fixed stars. But this opinion is contradicted by many experiments and by the common judgement of all philosophers and astrologers. For the Earth must rest at the middle of the whole world, as we shall afterward demonstrate by very many observations and phenomena.

[Margin: The second opinion on the order of the heavens.]

The most ancient Egyptians, however — together with Plato in the *Timæus*, Aristotle in *On the Heavens* II, chapter 12, and *Meteorology* I, chapter 4 — held the order in the celestial spheres to be this: that the Moon occupied the lowest place; immediately after it followed the Sun; then Mercury; then Venus; fifth Mars; sixth Jupiter; seventh Saturn; and eighth and last the starry heaven, or firmament.

Aristotle alone, in the little book *On the World, to Alexander* (if indeed it is his), placed Venus immediately above the Sun and below Mercury. But such an order of the planets or heavens too has long since been refuted by the astronomers.

COMMENTARY (continued)

We therefore establish, together with Ptolemy and Regiomontanus [Ioan. de Regiomon.], that order of the heavens which our author set out above: so that the Moon holds the first, or lowest, place; Mercury is set above it; in the third place Venus follows; the Sun fourth; Mars fifth; Jupiter sixth; Saturn seventh; and in the eighth and last place the Firmament. You see, then, that all the opinions agree in this: that the sphere of the fixed stars is placed in the highest station, and beneath it Saturn, beneath Saturn Jupiter, and then Mars. It is only over the remaining four planets that the whole disagreement lies. We shall therefore confirm briefly the order just recounted. First, from parallax [diuersitas aspectus]. Next, from the speed and slowness of motion. Third, from eclipses or occultations of the planets. For it is chiefly by this threefold means that the order of the heavens is usually confirmed by astronomers.

[Margin: The truer opinion concerning the order of the heavens.]

As for parallax, the argument runs thus. That heavenly body is nearer the Earth which, other things being equal, has the greater parallax. But the Moon has been found to suffer the greatest parallax, then Mercury, after that Venus, and next the Sun. It is therefore established that the Moon must be placed in the first station, Mercury in the second, Venus in the third, and the Sun in the fourth. Concerning the remaining planets, nothing certain can be determined by this route, since on account of their immense distance from the Earth they have no parallax. To make this fuller understood, a few words must be said about this parallax.

[Margin: The order of the planets is confirmed from parallax. What is parallax? What is the true place? What is the apparent place?]

Parallax, then — what others call the difference of aspect — is the difference between the true and the apparent place of some heavenly body. The true place of a body is that point of the great circle passing through the zenith and through the body which is marked off by a straight line drawn from the center of the Earth through the center of the body and produced to that great circle. The apparent place of the body is that point of the same great circle which is marked off by a straight line drawn from our eye through the center of the body and produced to that great circle.

An example. Let the center of the Earth be A; let the great circle passing through the zenith of the head D, and through the star, be CDE. Let the place on the Earth's surface lying beneath the zenith D be B. Let there be any star, K, through whose center a straight line AKS is drawn from the center of the Earth; and likewise, through the center of the same star, let a straight line BKT be drawn from B, the observer's place on the Earth. The true place of the star K, then, is the point S; the apparent place is the point T. The difference between the true and apparent places — namely the arc ST — is called the parallax of the star K. The angle formed at the center of the star by those two straight lines (in the present example the angle AKB) is usually called by astronomers the quantity of the parallax. So that if for two stars such angles are made equal, the stars are said to have equal parallax; but of two stars, the one at whose center the greater angle is contained has the greater parallax.

Diagram. A semicircular figure representing the celestial hemisphere standing above the horizon. The horizontal diameter (the horizon) runs along the base from C (left corner) through the center to E (right corner). At the bottom center is A (the center of the Earth), with B just above it (the observer's place on the Earth's surface). At the top center is D (the zenith), with M just below it. A single star is shown in successive positions descending from the zenith toward the horizon on each side: on the left K, H, and near the horizon F, with G and I low toward the left; on the right O, P, and R; and L and N near the center. Radial lines drawn from A and from B through each star position are extended to the outer arc, where their endpoints (the "true" locus reached via A and the "apparent" locus via B) are marked by small clusters of letters reading S, T, V repeated around the rim.

- D (top center): zenith
- M (just below D): star at the vertex
- A (bottom center): center of the Earth
- B (above A): observer's place on the Earth's surface
- C (left corner of base): horizon endpoint
- E (right corner of base): horizon endpoint
- K, H, F (left side): successive star positions toward the horizon
- G, I (lower left): star positions
- L, N (center): star positions
- O, P, R (right side): successive star positions
- Peripheral "S / T / V" clusters around the outer arc: true and apparent loci
[?] (several small labels not individually resolvable)

From this it is clear that if two stars in the same heaven are equally distant from the zenith M — such as the stars H and O — they have equal parallax. For the two sides HA, AB of the triangle ABH are equal to the two sides OA, AB of the triangle ABO, [Margin: a — Elements III.27] and the angles at M are equal, on account of the equality of the arcs MH, MO which measure the said distances of the stars from the zenith M. [Margin: b — Elements I.4] Therefore the bases BH, BO, and the angles H, O, which show the quantity of parallax, will also be equal.

By like reasoning it follows that the same star, the nearer it is to the horizon, the greater parallax it has — so that when it is on the horizon it has the greatest — whereas the farther it is from the horizon, the smaller its parallax, so that when it is at the zenith of the head, where it is most removed from the horizon, it has no parallax at all. All of which we shall demonstrate in order. Let one and the same star be now at the point M (that is, at the zenith), now at the point K (approaching the horizon), now at the point H (which is nearer the horizon), and finally at the point F (that is, on the horizon). From the center of the Earth A, and from the eye B, let straight lines be drawn through the center of this star wherever it stands. Let the arc MO be taken equal to the arc MH, so that the two stars, in the points noted, may have equal altitudes above the horizon; [Margin: a — Elements III.27; b — Elements I.4] and therefore, as was just demonstrated, the same parallax.

[Margin: The star, the nearer it is to the horizon, the greater parallax it has.]

Connect the points K and O by the straight line KO. Since, then, BO is equal to BH, as was just demonstrated — but BH is greater than BK — BO too will be greater than BK; [Margin: c — Elements III.7] and on that account the angle BKO is greater than the angle BOK. But the whole angles AKO and AOK are equal. [Margin: d — Elements I.5] Therefore the remaining angle AOB will be greater than the remaining angle AKB; and accordingly the star at O, and consequently at the point H, will have a greater parallax than at the point K. Hence it is established that any star, the nearer it is to the horizon, the greater parallax it has. [Margin: e — Elements I.4] [Margin: The star at the horizon has the greatest parallax.]

[Margin: The star at the zenith has no parallax.]

Again, let some star be on the horizon, namely at G, and another in the same heaven at the point L, above the horizon; and let the horizon GB be produced as far as R, and let the straight lines AG, AR, AL, BL, LR be joined. [Margin: c — Elements I.4] The bases BG, BR, and the two angles AGB, ARB, will be equal. But the angle ARB is greater than the angle ALB — which indeed can be

demonstrated in the same manner as it was shown that the angle AOB is greater than the angle AKB. Therefore the angle AGB too will be greater than the same angle ALB; and on that account the star existing on the horizon will have the greatest parallax. By the same reasoning it will be demonstrated that the angle AGB is greater than any other. And you easily perceive that the star existing at the point M has no parallax at all, since for it the apparent and the true place are one and the same.

[Margin: Of two stars having the same true or apparent place, that which is nearer the center of the Earth has the greater parallax.]

Again, from the same figure it is gathered that of two stars which have the same true or apparent place, the one that is nearer the center of the Earth has the greater parallax. For the stars F and G, or R and Q, have the same apparent place S; but the true place of the star F, or Q, is T, while that of the star G, or R, is V. Here it is plainly seen that the parallax of the star G, or R — namely the arc SV — because it is nearer the center of the Earth, is greater than the arc ST, that is, than the parallax of the star F, or Q, which recedes farther from the center of the Earth. The same is likewise seen in the stars P and O; likewise L and K; likewise I and H, the true place of all of which is shown by the point S. From these things, thus set forth, this first route drawn from parallax is clearly understood.

NEXT, from the speed and slowness of motion astronomers gather this same order of the heavens, by the following reasoning. The more a heaven recedes from the nature and condition of the *primum mobile*, the lower the station in which it too is to be placed. But since the Moon, of all the planets, is carried most swiftly from west to east — as we said above — it seems to recede most of all from the motion and condition of the *primum mobile*, and on that account to conform least to the first heaven, or *primum mobile*. It will therefore possess the lowest station. By the same reasoning the starry heaven will be placed in the highest station, since it is carried most slowly against the motion of the *primum mobile*. Then will follow the sphere of Saturn, after that of Jupiter, and so on for the rest, always setting the order stated above.

[Margin: The order of the heavens is proved from the speed and slowness of motion.]

But by this route nothing certain can be determined about the order of the Sun, Venus, and Mercury among themselves. For although it is gathered from it that these three planets are placed above the Moon, since they are carried more slowly than it from west to east, as we said above; and that below the Firmament,

Saturn, Jupiter, and Mars are situated, since they are carried more swiftly against the *primum mobile* — nevertheless which of them is to be set above the other cannot be known for certain, since they complete their proper motions from west to east in nearly the same time. Indeed Alpetragius [al-Bīṭrūjī], as Regiomontanus attests (*Epitome*, Book 9, proposition 1), gathers from this reasoning that the heaven of Venus is placed below Mars, and below Venus the heaven of the Sun, then Mercury, and last of all the Moon — because Venus, by reason of its epicycle, completes its course more slowly than the Sun, and the Sun more slowly than Mercury, while the Moon, finally, completes its own period most swiftly of all.

[Margin: The order of the heavens is confirmed from eclipses.]

FINALLY, from eclipses or occultations of the planets and stars, the same order of the heavens is gathered by astronomers. For there can be no doubt that the body which conceals another from us is the lower. Since, therefore, the Moon, when it is in conjunction with the other planets, sometimes snatches them from our sight, it is necessary to grant it the lowest station. By the same reasoning Mercury will be below Venus, and Venus below Mars, and so on in succession. These, then, are the chief arguments by which astronomers conclude the order of the heavens which our author set forth. And although none of them by itself sufficiently establishes this order, yet all taken together confirm that the heavens are arranged in that order. For from parallax the order of the Moon, Mercury, Venus, and the Sun is infallibly gathered; from speed and slowness of motion, Mars is fittingly placed above these four planets, then Jupiter, last Saturn, and above all the planets the Firmament, or eighth heaven, which the ninth and tenth spheres, established beneath the *primum mobile*, follow. From eclipses, finally, although the order of not all the planets can be firmly gathered, yet we are compelled to place the Moon in the lowest station, and all the planets beneath the Firmament.

That a fuller knowledge of this order may be had, I judge it not out of place to bring forward some other arguments of the astronomers, from which the great fitness of this order will shine forth.

[Margin: That the Moon is placed in the lowest station is proved from the shadow.]

That the Moon, then, is placed in the lowest station can be demonstrated by the following reasoning. A luminous body, the higher and farther it is from the Earth, other things being equal, the smaller the shadows of bodies appear on the plane of the horizon; and the nearer the luminous body is to the Earth, the longer the

shadows the bodies cast, as may be seen in this figure. In it each star has the same altitude above the horizon AB with respect to the center of the world — that is, it holds the same true place with respect to the horizon — although they differ in apparent place; and yet the lower star casts a longer shadow of the gnomon CD, say to the point E, than the higher, which casts the shadow of the same gnomon only to the point F.

Diagram. A woodcut showing the celestial hemisphere as a semicircular arc standing on a horizontal base line. At the upper left is the Sun, drawn as a radiant face casting rays. Along the base, from left to right, are the points **A** (left endpoint), then **C**, **F**, **E** near the center-right, and **B** (right endpoint). A small upright gnomon (a little triangle) stands at **C**, with its apex at **D** above. Rays from the luminous body pass over the gnomon's tip **D** and cast the shadow along the base: the shorter shadow tip falls at **F**, the longer at **E**.

- Sun (upper left): the luminous body, drawn with rays
- A (left end of base): horizon endpoint
- B (right end of base): horizon endpoint
- C (base, center): foot of the gnomon
- D (above C): apex of the gnomon
- F (base, near gnomon): tip of the shorter shadow
- E (base, beyond F): tip of the longer shadow

Now the shadow of an erect gnomon, when the Sun shines, is shorter than the shadow of the same gnomon when the Moon shines, all else being equal — that is, at equal degrees with the Sun, but distant from the horizon at a different time. This anyone can easily test. At the time of the equinox let the meridian altitude of the Sun be noted, the Sun holding the beginning of Aries [♈] or of Libra [♎] — which altitude at Rome is about 48 degrees — and let the gnomon's shadow be marked on some plane. Afterward let the same be done with the Moon situated in the same place of the zodiac in which the Sun was before — that is, in the beginning of Aries [♈] or of Libra [♎] — holding the meridian circle and lacking all latitude. For the shadow of the gnomon, when the Moon shines, will be found much longer than before with the Sun, even though the altitude, or distance, of each planet from the horizon is the same — namely 48 degrees — with respect to the center of the Earth. It follows, therefore, that the sphere of the Sun is far higher than that of the Moon.

What we have said of the Moon with respect to the Sun can be applied with respect to the other planets. For although the other planets do not shine so as to

cast shadows, it can nevertheless be known how far their rays are cast past the tip of a gnomon. Wherefore, beyond all controversy, it is established that the Moon is lower than all the planets.

[Margin: That the Sun is fittingly placed in the middle of the planets.]

How fittingly, too, the Sun is placed above Mercury and Venus — that is, set in the middle of the planets — Regiomontanus brings forward (*Epitome*, Book 9, proposition 1). Ptolemy (*Almagest* [Dict.] V.15), from whom Albategnius [al-Battānī] does not dissent, shows in chapter 50 of his own work, by sure reasons, that the distance of the Sun from the center of the Earth, when it is least — that is, when the Sun is at the point opposite its apogee — contains 1070 semidiameters of the Earth; while the distance of the Moon from the center of the Earth, when it is greatest — that is, when the Moon is at its apogee — contains only 64 semidiameters of the Earth. Hence the difference between the least distance of the Sun and the greatest distance of the Moon will contain 1006 semidiameters of the Earth; for so much is left when the greatest distance of the Moon is subtracted from the least distance of the Sun.

Since, therefore, no void can be granted between the heaven of the Moon and the heaven of the Sun — for nature abhors a vacuum — and since it is not consonant with reason that the deferents of the apogees of the Sun and Moon should be endowed with so great a bulk (for such a great mass would be utterly useless and superfluous), then with the fullest right and fittingness that whole intermediate space will be assigned to the orbs of Mercury and Venus. And so the Sun will be placed in the middle of the planets — namely above the Moon, Mercury, and Venus, and below Saturn, Jupiter, and Mars.

There is also this, that the motion of the Sun is the rule and measure of the motions of the other planets, though in one way and another. For Mars, Jupiter, and Saturn agree with the Sun in motion by reason of their epicycle; the Moon, Mercury, and Venus, however, are conformed to the motion of the Sun in their deferent orbs, as is explained in the Theories of the planets. Wherefore not unjustly the Sun will be placed in the middle of these, so as to separate the three upper planets from the three lower, since they do not observe uniformity of motion with it in the same way.

To these reasons may be added that the Sun is the king, and as it were the heart, of all the planets; wherefore not without merit it will be established in the middle of them, just as a king is placed in the middle of his kingdom, and the heart in the middle of the living creature, so that it may

be able to succor and provide for all the members equally. So that in a certain way (as most jest) a commonwealth is constituted from the seven planets. For the Sun is king of all; Saturn, on account of his old age, is his counselor; Jupiter, for his magnanimity, is judge of all; Mars is commander of the army; Venus, dispenser of all good things, in the likeness of a matron of the household; Mercury is his scribe and chancellor; and the Moon, finally, performs the office of messenger. Whence too it has the swiftest motion from west to east, so that each month it may carry the king's commands to any one whatever.

Moreover, since according to the astronomers and philosophers all the stars and planets receive their light from the Sun — at any rate more perfectly, as we clearly see in a lunar eclipse, in which the Moon, by entering the shadow of the Earth, loses its light; and besides is illuminated in different ways by the Sun at different times: for now it appears horned, now half-illuminated, now it seems full, and so on — which would not happen if it had light of its own. Form the same judgment about the others; for they are of the same nature as the Moon. This can also be proved from the fact that we see the planets that are nearer the Sun more intensely illuminated, as appears in Mars and Venus. Wherefore, in order that the Sun might impart its light equally to all the planets and stars, it is most conveniently placed in the middle of them.

Albumasar [Abū Ma'shar] adds, in his *Great Introduction* (treatise 3, difference 3), that on this account glorious God placed the Sun, the noblest of the planets and the most active, in the middle of the other planets: because, if it had been set immediately below the eighth heaven and above Saturn, it could not, on account of its too great distance from the Earth, conveniently act upon these lower things — indeed all these lower things would in a manner grow cold; whereas, if it had been placed immediately above the Moon, it too would not act conveniently enough upon these lower things by its motion, because it would then be carried too slowly from east to west, on account of its too great distance from the *primum mobile*. Just as, in any wheel, those parts which recede more from the circumference and approach more toward the center or axis are moved more slackly. Add that then the Sun, on account of its too great nearness to the Earth, would burn up all these lower things. For which reason it is fittingly placed in the middle of the planets, so that it may have its action tempered and better fitted to these lower things. So that not without reason, in Ovid (*Metamorphoses* II), Phoebus warned Phaethon, about to mount the chariot of the Sun rashly, saying:

*Altius egressus cœlestia signa cremabis: Inferius terras: medio tutissimis
ibis.*

("Going too high, you will scorch the heavenly signs; too low, the lands; in the middle you will travel most safely.")

For Ovid meant, in that place, to signify that the Sun has its action tempered in the middle station of the planets, and not in any other, and that therefore its proper place is there.

That Mercury too is fittingly placed immediately above the Moon and below Venus, its irregular motion seems to persuade us. For Mercury is much more irregular in its motion than Venus — on account of which the astrologers assigned to Mercury five orbs and an epicycle, but to Venus only three orbs and an epicycle. It seems, therefore, consonant with reason that Mercury should be established above the Moon rather than Venus.

[Margin: That Mercury is fittingly placed above the Moon and below Venus.]

The order of the planets, moreover, which we have hitherto approved, all the ancient founders and namers of the week seem to confirm. For they imposed names on the days from the planets — each day, that is, from the planet which obtains dominion over the first hour of that day. For the individual planets are said by astronomers to preside, in their own order, over the individual hours of the day; and how true this is, this is not the place to discuss. Hence, since a day contains 24 hours, it is necessary that if on the Sabbath Saturn dominates the first hour — from which the day of Saturn [Saturday] is named — then on the following day the first hour will be dominated by the planet next in retrograde order, two being passed over, namely the Sun, from which the day of the Sun [Sunday] is named.

[Margin: The order of the planets is confirmed from the dominion of the planets and the naming of the days.]

For if Saturn dominates the first hour, the second will be dominated by Jupiter; the 3rd Mars; 4th Sun; 5th Venus; 6th Mercury; 7th Moon; 8th Saturn; 9th Jupiter; 10th Mars; 11th Sun; 12th Venus; 13th Mercury; 14th Moon; 15th Saturn; 16th Jupiter; 17th Mars; 18th Sun; 19th Venus; 20th Mercury; 21st Moon; 22nd Saturn; 23rd Jupiter; 24th Mars. Then the first hour of the following day is the Sun, and so on in succession. From this it is plain why the days are not named according to the order of the planets immediately, but always according to the retrograde order, two being passed over, because in this order the planets preside over the hours of the day — an order of days which would by no means be such, unless the planets were located in that order. On this matter two verses exist, that it may

be known over which hours of the day each planet holds dominion; in which it also appears what order they have among [themselves] [?]:

*Cynthia, Mercurius, Venus, & Sol, Mars, Ioue, Satur[nus], Ordine
retrogrado sibi quiuis vendicat horam.*

("Cynthia [the Moon], Mercury, Venus, and the Sun, Mars, Jupiter, Saturn — in retrograde order each claims its own hour.")

Ioannes Xiphilinus, from Book 36 of Dio's [Cassius] *Pompey*, writes that this order of the days was instituted by the Egyptians, whom he says established the aforesaid order in the planets. He then adds another reason for this naming of the days, from the consonance of Music which is called διὰ τεσσάρων [Greek: *diatessarōn*, "through four" — the interval of the fourth, the *diatessaron*], which according to the ancients was believed to be the foundation of all Music. For on account of this consonance and harmony, that the days might in a musical manner in some way agree with the ornament of the heaven, after one day had been named from one planet, they named the following day from the fourth planet after it, but in retrograde order — as after Saturn there follows in the fourth place the Sun, then the Moon, then Mars, and so on.

It is established, therefore, from all those things which we have said, that the order prescribed by our Author among the planets is truer and more conformable to the skilled astronomers. To be exploded, therefore, is the opinion of Metrodorus and Crates, who placed the Sun and Moon as the highest of the planets. To be rejected also is the opinion of Democritus, who made Mercury higher than the Sun. The view likewise of Alpetragius [al-Bīṭrūjī], who thought Venus higher than the Sun, is of no moment. And, finally, let the opinion of Plato and Aristotle fall — those who placed the Sun and Moon in the lowest station.

But some object that the Sun never suffers eclipse from Mercury and Venus, and that therefore the Sun is by no means to be established above them: for otherwise it would sometimes be concealed by them, just as we see it concealed by the Moon, since the Moon is placed above it. Nevertheless this objection has no force. For, as Ptolemy says (*Almagest* [Dict.] IX.1) and Regiomontanus (*Epitome*, Book 9, proposition 1), two planets can be in conjunction — that is, be in the same degree of the zodiac — in such a way that a straight line issuing from the eye and passing through the center of one does not pass through the center of the other; which is nevertheless required for an eclipse. Hence it comes about that we very often see the Moon in conjunction with the Sun at the new moons, yet not concealing it.

Moreover, according to Albategnius [al-Battānī] and Thebit [Thābit ibn Qurra] and other astronomers, the visual diameter of the Sun, to the

[Margin: Why the Sun is not eclipsed by Mercury and Venus, although they are below it.]

[Margin: What the visual diameters of the heavenly bodies are.]

the visual diameter of Venus (the visual diameters being those of the circles that appear to us in the case of the stars) has a tenfold proportion [decuplam]. Hence, according to the geometrical demonstrations, the visual circle of the Sun will have to the visual circle of Venus a hundredfold proportion [centuplam].

[Margin (a): Euclid, *Elements* XII.2] [Margin (b): Euclid, *Elements* VI.20]

(a) For circles have between themselves the same proportion as the squares of their diameters; and (b) the proportion of the squares described on the diameters of the circles is the duplicate of the proportion the diameters have. It follows that when the visual diameters of the circles of the Sun and of Venus have a tenfold proportion, the squares of the diameters — and therefore the visual circles as well — have a hundredfold proportion. For the hundredfold is the duplicate of the tenfold, as is plain in these numbers 1, 10, 100, which stand in a continued tenfold proportion.

For, as is established from Definition 10 of Euclid Book 5, when there are three magnitudes in continued proportion, the third is said to have to the first a proportion that is the duplicate of the proportion which the second has to the first, or the third to the second. Therefore, since the said three numbers 1, 10, 100 are in continued proportion in a tenfold ratio, the hundredfold proportion that the third number, 100, has to the first, 1, is the duplicate of the tenfold proportion that the second number, 10, has to the first, 1 — or the third, 100, to the second, 10. From this it follows that the visual circle of the Sun has to the visual circle of Venus a hundredfold proportion, since the diameters of those circles have a tenfold proportion, and the circles have the duplicate of the proportion that the diameters have, as has been said.

By the same reasoning, if the diameters of two circles have a twofold proportion, the circles themselves will have a fourfold proportion; for the fourfold is the duplicate of the twofold, as appears in these numbers 1, 2, 4, in continued proportion in a twofold ratio. So too, if the diameters of two circles have a hundredfold proportion, the circles will have the proportion of 10000 to 1, as is clear in these three numbers 1, 100, 10000, which have a continued hundredfold

proportion. By this method we shall know the proportion of any circles whatever, once the proportion that their diameters have is known.

To find out easily which proportion is called the duplicate of another, one must multiply the denominator of the proportion by itself, for the product will be the denominator of the duplicate proportion. For example, since the denominator of the tenfold proportion is 10, if 10 is multiplied by 10, 100 is produced — namely the denominator of the duplicate of the tenfold proportion. By the same reasoning, the duplicate of a threefold proportion will be ninefold [noncupla], and so on. On which matter, read what we have written on Definition 10 of Euclid Book 5.

From this it is clear that Venus can in no way cover the Sun, even if it comes between our sight and the Sun, since it would hide only a hundredth part of it, which is of no significance and can scarcely be noticed. Still less, then, will Mercury be able to do this, since its visual diameter is far smaller than the visual diameter of Venus.

[Margin: Why the Moon sometimes eclipses the Sun, even though it is much smaller than the Sun.]

But if someone asks why the Moon then sometimes snatches the Sun from our sight, even though the Moon is astonishingly smaller than the Sun itself, the answer is that this happens because of the Moon's very great nearness to the earth and its very great distance from the Sun. This makes the visual diameter of the Moon sometimes appear to us larger than the visual diameter of the Sun, and therefore the whole Moon is seen as larger than the Sun. So it is no wonder that the Moon can sometimes cover the Sun so that it cannot be seen.

Diagram. A geocentric diagram of the universe, printed as a set of concentric circles with the Earth at the center. The globe of the Earth is rendered as a small hatched woodcut roundel at the middle. Reading the labelled spheres from the outermost inward, each named on the arc at the left side of the figure (the planetary symbol is also repeated on the corresponding arc at the right side):

- Cælum Empyreum. — the Empyrean Heaven (outermost)
- Primum mobile. — the Prime Mover (First Movable)
- Decimum cælum. — the Tenth Heaven
- Nonum cælum. — the Ninth Heaven
- Firmamentum. — the Firmament (the sphere of the fixed stars, drawn as scattered star-asterisks filling this and the neighbouring rings)

- ♄ Saturnus. — Saturn
- ♃ Iuppiter — Jupiter
- ♂ Mars — Mars
- ☉ Sol — Sun
- ♀ Venus — Venus
- ☿ Mercurius — Mercury
- ☾ Luna. — Moon (innermost sphere)
- (center): the Earth, shown as a small hatched globe

From all this, both the number and the order of all the bodies of the whole universe can be gathered.

[Margin: The number and order of all the bodies composing the universe.]

For in the whole universe there will be sixteen spherical bodies making up the entire world, arranged in the order shown partly in the treatise on the elements and partly here in the treatment of the celestial bodies — namely the four elements and the twelve celestial spheres. This the figure set alongside seems to indicate clearly: in it you see the order and position of the whole universe, together with the symbols of the planets by which astronomers are accustomed to represent and depict them.

[Margin: That there is nothing outside the world.]

Beyond this world, however — that is, beyond the empyrean heaven — there exists no body at all, but a certain infinite space (if it is permissible to speak so), throughout the whole of which God too exists by his essence, and in which he could fashion infinitely many other worlds, even more perfect than this one, if he willed, as the theologians assert.

THAT THE HEAVEN MOVES FROM EAST TO WEST

Lemma (Sacrobosco). That the heaven turns from east to west, there is a sign. The stars that rise in the east are always lifted up, gradually and one after another, until they come to the middle of the sky; and they always keep the same nearness and distance from one another, and so remaining ever the same, they move on to their setting continuously and uniformly.

[Margin: That the heaven moves from east to west is proved from the stars that rise and set.]

COMMENTARY.

This is the fourth and last part of this first chapter, in which the author sets out six propositions concerning the ethereal and the elemental region — propositions that in the preceding part he seemed to assume as certain and beyond doubt. The first is that the heaven moves from east to west. The second, that the heaven is round. The third, that both the earth and the water are round. The fourth, that the earth is the center of the world. The fifth, that the earth is motionless. The sixth and last, that the earth has an absolute and finite magnitude, and indeed a known one, although to ordinary people it seems immense.

[Margin: What is treated in the remaining part of this chapter.]

For the astronomer must have the magnitude of the earth ascertained, since it is by means of it that the magnitudes of the heavens and the stars are known.

Now, as regards the first proposition: someone might deny that the heaven moves from east to west and claim instead that the stars move by themselves — like fish in the sea or birds in the air — while the heaven remains entirely at rest, as many have dared to assert. Against this, the author proves by a twofold argument that it is not true. One of these arguments is drawn from the stars that rise and set for us; the other from the stars that never rise or set for us, but are perpetually visible. These arguments are taken from Ptolemy, *Almagest* I.3 [Dict. 1, cap. 3], and from Johannes Regiomontanus [Regiomontanus], Book 1, Conclusion 1.

The first argument runs as follows. All the stars that rise and set for us move gradually, always at the same distance and in the same position relative to one another, from the east through the meridian to the west. Therefore the stars fixed in the heaven move with the motion of the heaven, like a nail with the motion of a wheel, or a knot with the motion of a board. The antecedent is manifest from daily experience; the consequence is clear, because if the stars moved by themselves they would not always keep the same distance and arrangement among themselves, nor would they always proceed uniformly, but sometimes one would outstrip another — especially since they are unequal among themselves and describe unequal circles. For it would seem rash to assert that the smaller stars have the same motive power as the larger ones.

Lemma (Sacrobosco). There is yet another sign. The stars that are near the Arctic pole, which never set for us, move continuously and uniformly about the pole, describing their circles, and are always at an equal distance and nearness to one another. Hence, from these two continuous motions of the stars — both of those that tend toward setting and of those that do not — it is clear that the firmament moves from east to west.

[Margin: That the heaven moves from east to west is proved from the stars that neither rise nor set.]

COMMENTARY.

He puts forward the second argument roughly to this effect. The stars near the Arctic pole, which never set for us, by their always-uniform motion describe in the same time different circles — some larger, namely those farther from the pole, others smaller, namely those nearer the pole — and are always seen at the same nearness to one another. Therefore they move not by themselves, but with the motion of the sphere of which they are parts. For if they advanced in the heaven by their own power and by themselves, then those describing larger circles would move in a longer time, and those describing smaller circles in a shorter time; indeed, unequal stars placed on the same circle would move unequally — all of which is contrary to the senses and to experience.

[Margin: Two further observations, by which it is concluded that the heaven moves, and not the stars themselves.]

No less force in persuading us that the heaven moves from east to west, and by its motion carries all the stars around with it, is possessed by two observations, which I shall now bring forward. The first is taken from the Milky Way [via Lactea]. Since this is either an infinite multitude of the tiniest stars, or — what I rather approve — a denser and continuous part of the eighth heaven (though not uniformly dense), how could that whole band of brightness, encircling the entire heaven, advance so regularly from east to west, unless it were carried around by the motion of the eighth sphere in which it lies?

The second observation concerns the rarer parts of the heaven, of which not a few are seen near the Antarctic pole (as a certain learned and devout man, living in the province of Peru — which has the Antarctic pole elevated above the horizon — attests in a booklet that he entitled *On the Situation and Nature of the West Indies*), so that in many places of the heaven a certain blackness appears, as if the heaven were somehow pierced through. Since these rarer parts are carried uniformly, along with the stars, from east to west in the space of 24 hours — as has more than once been observed by those living in that region of the earth — who would say that they move by themselves, and are not rather carried around by the motion of the heaven, seeing that they are not stars but wholly rare and dark parts? For what would drive those parts, if they were not carried around together with the heaven? Since this is so, it is likely that the whole heaven is driven from east to west, dragging along with it both the stars and the other,

denser parts (such as those that make up the Milky Way) and the rarer or darker parts, and...

of which we have just spoken, and such as are also those spots which are seen on the Moon and are carried around uniformly with the Moon.

[Margin: Aristotle's argument proving that the stars do not move by themselves.]

Aristotle, in Book 2 of *On the Heavens* [*De caelo* II], likewise proves that the stars do not move by themselves, by this argument. If the stars move by themselves while the heaven is at rest, then either they are fixed in the heaven, or else they are on the outermost surface of the heaven — whether its concave or its convex surface — so that there is some space interposed between any two heavens in which the stars can move. If they are fixed in the heaven, there will result either a splitting of the heaven or an interpenetration of bodies, both of which are impossible. But if they move on the outermost surface of the heaven — as, for example, a man on a pavement, or a fly or an ant on some ceiling — then the space in which they move will be either a void, which Aristotle long ago banished from nature in Book 4 of the *Physics*, or a body. And this body will be either celestial — in which case the first difficulty follows again — or elemental, which cannot remain perpetually outside its natural place; yet it would be outside its place, if it were there. Therefore the stars do not move by themselves.

Aristotle brings other arguments in the passage cited, but leaving these aside, we can confirm this conclusion of our author by a single observation, which in my judgment has the greatest force.

[Margin: A convincing argument that the stars in fact do not move by themselves, but with the motion of the heaven.]

Take any star you like, whether fixed or wandering, which someone claims moves by itself. This star moves with motions that are in a way opposite, as we said above. For it moves absolutely and continuously from east to west, and at the same time, in a certain respect, also continuously from west to east, as was set out and demonstrated above. But no one and the same body can be set in motion by different — indeed opposite — motions at the same time. For it involves a contradiction that one and the same body should advance simultaneously from east to west and at the same instant from west to east, with neither motion interrupting the other, but each proceeding uniformly without any break — unless it be moved by the one motion as by the vehicle of the other.

Therefore the stars do not move as free and detached from the celestial bodies, because a single body can move with only one motion at the same time — as we plainly see in animals and in other things that we push from one place to another. For it cannot happen that at the same time they are driven by another force in the opposite direction, unless the first motion is halted or interrupted. Rather, they are carried along with the motion of the spheres in which they lie; for in this way one and the same heavenly body can be set in motion by different displacements, as was explained above, with various examples adduced.

This very point is confirmed all the more in the case of the planets. For they move with still more motions than those two — from east to west and from west to east; and now they seem to move more swiftly from west to east, now more slowly. Sometimes they seem to stand still, sometimes to move backward toward the west, and so on, as is explained in the *Theorics of the Planets* [*Theoricae planetarum*]. If, then, the stars moved by themselves, no sufficient explanation of this variety could be given; but if they are said to move with the motion of the heaven, all the appearances are readily accounted for, as will be explained in the *Theorics of the Planets*.

[Margin: The opinion of those who say the stars move in channels, and its refutation.]

Seeing, then, that on this view the multiplicity of motions in the stars cannot be accounted for, some have devised another theory, by which they try to persuade us that the stars move by themselves and are not fixed in the celestial bodies. For they say that there is only a single heaven, and that this heaven moves with a single motion from east to west, together with all the stars; but that the stars are carried by their own motions from west to east, detached (as they say) from the celestial spheres — not, however, like fish in the sea or birds in the air (lest there be an interpenetration of bodies or a splitting of the heaven), but through certain channels [canales].

For they have imagined that each individual star has its own channel matching its proper motions, of such breadth as the star's own size, so that each star fills its whole channel. In these channels, moreover, they have placed a certain fluid body, like air, which can give way to the stars as they move from west to east. And so, according to these authors, the whole heaven will be crammed with these channels, in proportion to the multitude of the stars — like an animal, which is filled with various and manifold veins. They embrace this opinion all the more readily because they are unwilling to admit a motion of being swept along

[motum raptus]; for they say that it is impossible for one heaven to sweep another along, however contiguous it may be to it.

Nevertheless, this opinion is both absurd and inadequate. Absurd, because without any necessity or plausible reason it supposes the celestial body to be pierced through by so many channels and filled everywhere with that fluid body — something that no philosopher has hitherto been seen to concede. Inadequate, because on this view it is impossible to account for all the phenomena in the celestial motions which astronomers have most carefully observed.

For, first, whether they wish it or not, they cannot avoid a motion of being swept along. For since the stars are (as they themselves say) detached and free, and in no way inhere in the heaven, and yet move with the motion of the heaven from east to west, they must be swept along by the heaven without any resistance or violence — for this reason alone, that they are contiguous to the channels in which they lie.

Second, although on this view a twofold motion — namely from east to west and, conversely, from west to east — can somehow be defended, yet no star can in any way have more motions than these two, for the reason we adduced above against those who claimed that the stars move of themselves. Since, therefore, more motions have been detected in the Moon — six, at the least — and the same must be said of the other planets, and indeed the fixed stars have a fourfold motion, as we showed above, this opinion can in no way be true.

Third, the planets, as is clear from the *Theorics of the Planets*, are not always equally distant from the center of the earth, but appear now nearer, now farther away — which could in no way happen if the stars moved by themselves in the said channels, unless one were to say that those channels are eccentric to the world, so that one part recedes farther from the center of the world and another comes nearer to it: which cannot be said. For since those channels are fixed in the celestial body, it would necessarily follow that any given planet would always be at its greatest distance from the earth in the same part of the heaven, and so on — which is utterly false; for the Moon has at one time or another been seen at every point of the zodiac both at its farthest from the earth and at its nearest.

I pass over the appearances concerning the variation of the latitudes of all the planets (the Sun alone excepted), and also concerning retrogradation, and so on — which the aforesaid opinion can in no way uphold, as is usually explained more fully in the *Theorics of the Planets*. It is established, therefore, that the stars do not move by themselves, but with the motion of the heavens in which they are

fixed; for in this way the heavens can be understood to have several motions — one indeed proper to them, but the others extrinsic, namely serving as the vehicle for the rest, as was explained above. Hence it is no wonder that so great a multitude of motions is observed in the stars.

[Margin: The opinion of the ancients, who said that the stars move with a rectilinear, not a circular, motion, and its refutation.]

Ptolemy, in *Almagest* Book 1 [Dict. 1], reports the opinion of certain people who said that the stars do indeed move with the motion of the heaven from east to west, but by a rectilinear motion extending to infinity, not by a circular motion. This opinion is utterly ridiculous, and therefore to be rejected by astronomers. First, because on this reckoning one and the same star would not appear to us at the same nearness, but would come closer to us at the meridian than at its rising or setting...

set (which is false). Again, we see every day the same stars, by number, return to the East after they have lain hidden for a while beneath the earth. This could never happen if they were carried along in a straight line. From all this, then, it can be plain to anyone that the heavens themselves move together with the stars fixed in them, from East to West, in a circular motion; and the same must be said of the motion from West to East that the lower spheres possess.

THAT THE HEAVEN IS OF SPHERICAL SHAPE

[*Lemma*] That the heaven is round there is a threefold reason: Likeness, Convenience, and Necessity. Likeness, because the sensible world was made in the likeness of the archetypal world, in which there is neither beginning nor end. Hence, made after the likeness of that world, the sensible world has a round form, in which one cannot assign a beginning or an end.

[Margin: That the heaven is round, by reason of its likeness to the archetypal world.]

COMMENTARY

Here the author proves the second Conclusion — namely, that the heaven is round — by three means, of which the first is drawn from likeness, the second from convenience, and the third from necessity. From likeness he argues as follows. This sensible world was fashioned in the likeness of the archetypal world, that is, of God, the Best and Greatest, in whom one can assign neither beginning nor end, since He is infinite. The world must therefore be round, so

that no beginning or end can be assigned in it; for in this way it will be in some fashion like that archetypal world, since the round figure alone, among all the others, possesses in a certain manner infinity.

But this argument seems to prove nothing at all. For by the same reasoning it would be proved that man ought to have been created round, in the likeness of the archetypal world; and you would say the same of all other creatures. Nevertheless, one must answer with St. Augustine [B. Aug.] that God founded His creatures for the manifestation of His goodness and perfection. Since, then, a single creature displays the perfection of God to us only most imperfectly, God made round rather the whole universe — in which all creatures are contained, and which more effectively and more exactly manifests and declares the perfection and goodness of God — than He made the individual creatures round; although the individual creatures too, so far as can be, everywhere imitate the round figure, as appears in the trunks of trees, in their branches, in the extremities of the limbs of animals, and in fruits. For all these are in some fashion round — yet not entirely so, in order that there might be greater beauty and splendor in so great a variety of creatures. From this answer, then, it is clear that our author is chiefly proving that the world, or heaven, is round as regards its convex surface — which indeed is enough, for we are accustomed to judge the figures of bodies from their convexity. A little later, however, we shall confirm that all the heavens are round, both as regards the concave and as regards the convex.

[Lemma] Convenience, because among all isoperimetric bodies the sphere is the greatest, and among all forms the round is likewise the most capacious. Since, therefore, it is at once greatest and round, it is for that reason the most capacious; and so, since the world contains all things, such a form was useful and convenient for it.

[Margin: That the heaven is round, by reason of convenience.]

COMMENTARY

The argument drawn from convenience is roughly this. This world contains all things within itself; it therefore had to be granted the figure most useful and convenient to this end — namely, the one most capacious of all — for Nature, avoiding fault, aims as much as possible at convenience. But the sphere is the greatest and most capacious among all corporeal isoperimetric figures. Therefore such a figure was rightly granted it by nature.

Yet this argument too, taken simply, seems to prove nothing. For someone might say that, although among isoperimetric bodies the sphere is the most capacious, as the argument holds, God could nonetheless have made the world of another figure, larger than it now is, so that it would contain all things within itself just as well as it now does. But since God and Nature do nothing in vain, and always produce what is better, it seems consonant with reason that the world was founded round by God — inasmuch as the round figure is the most capacious and the noblest — especially since that excess of any other, larger figure would seem superfluous, and established with no reason at all, that is, without necessity.

We can also add another argument from convenience. Since Nature always strives to bring about what is better, she seems with the best right to have granted to the celestial body — which is the noblest of all — the noblest figure, namely the round or spherical, for many reasons. For just as the Circle holds the primacy among plane figures, so the Sphere holds it among solids. Just as the Circle, by its simplicity, by the likeness, equality, sameness of place, strength, and capacity of its parts, excels all other plane figures, so too must one speak of the sphere, if it be compared with the other solid figures. First, a single line encloses the circle, and a single surface encloses the sphere. Second, just as in the circle there are arcs uniformly curved, so in the Sphere there are portions uniformly convex. Third, just as in the circle the center is equally distant from the extremes, whence its length and breadth are measured by equal diameters in every direction, so it holds also in a spherical body, whose length, breadth, and depth three equal diameters measure toward every part. Fourth, just as in the circle, so in the sphere we can find neither beginning nor end. Fifth, just as the circle, so also the sphere, revolved about its center, always occupies the same place; whence to both circle and sphere is granted, in the highest degree, ease of motion and firmness of parts, nothing external opposing. Sixth and last, each figure — the circular as well as the spherical — is, among isoperimetric figures, the most capacious: plane figures, if we speak of the circle; solid, if the discussion concerns the sphere — as we have shown in our *Geometria practica*. There is this too, that the circle touches a straight line, and the sphere touches a plane surface, in a single point only; of which the former is clearly gathered from Propositions 2 and 16 of the third book of Euclid, and the latter was demonstrated by Theodosius in Proposition 3...

[Margin: Another argument, from convenience, proving that the heaven is round.] [Margin: The various excellences of the circle and the sphere.]

(Proposition 3 of the first book of his *Elements of Spherics*) most clearly. Since, then, a spherical body stands out among all others as so noble, on account of so many and so remarkable excellences and superiorities, who can now doubt or hesitate that the heaven is endowed with such a figure? — especially since the heaven, as was said in the preceding Conclusion, is continually turned in circular motion; to which motion a spherical body is, among all the rest, the most suited, on account of the continuous and uniform succession of its parts, so that nothing external can be an impediment; and this because it is carried around the center within the same bounds of place at all times. Hence too it moves most easily.

[Margin: What an isoperimetric figure is.]

Now, so that this second argument of the author, drawn from convenience, may be more perfectly understood, a few things must be said about isoperimetric figures. Figures are called Isoperimetric when they have circumferences, or bounding lines, equal to one another. Thus a square having six palms in its circuit is said to be isoperimetric with a triangle, or with any other figure whatever (whether it be rectilinear, or curvilinear, or mixed of these), having six palms likewise in its circuit; so that the four straight sides of the square's perimeter, joined together into one and the same straight line, are exactly equated to the three straight lines of the triangle, or to all the sides of whatever other figure, these too being set out straight and continuous. The same must be understood of any isoperimetric bodies whatever, taking surfaces in place of lines.

[Margin: Among rectilinear isoperimetric figures, the more capacious is the one that has more angles; and therefore the circle is the most capacious. (a) Euclid I.8. (b) Euclid I.4 or I.38. (c) Euclid I.34. (d) Euclid I.34. (e) Euclid I.19.]

Among all regular rectilinear isoperimetric figures, the one that contains more angles is the greater and more capacious. This we shall confirm briefly, and with a certain rough treatment, in the equilateral, or isosceles, triangle, and in a figure longer on one side. More accurately and more fully we have dealt with this matter in our *Geometria practica*. Let there be, then, an equilateral or isosceles triangle ABC, whose side BC is divided into equal parts at the point D, and let the straight line DA be drawn, which will be perpendicular to BC. For the two sides AD, DC of the triangle ADC — and the base AB is posited equal to the base AC — and on this account (by definition) each [angle at D] is a right angle. Let the rectangular parallelogram ADCE be completed. **(a)** The two angles ADB, ADC will therefore be equal. **(b)** Since, then, the triangle ADB is equal to the triangle ADC, **(c)** and to this same triangle ADC the triangle ACE is equal, the triangles ADB and ACE will be equal to one another. Therefore, adding the common triangle ADC,

the parallelogram ADCE will be equal to the triangle ABC. And since the two sides AE, DC of the parallelogram **(d)** are equal to one another, taken together they are equal to the side BC of the triangle ABC; while the remaining two sides AD, CE of the parallelogram ADCE (because they are opposed to the smaller angles, namely the acute ones, in the triangles ABD [and ACE]) **(e)** are smaller than the remaining two sides AB, AC of the triangle ABC (because these in the same triangles are opposed to the larger angles, namely the right ones). The perimeter of the parallelogram ADCE will therefore be smaller than the perimeter [of the triangle]. Hence, that the perimeter of the parallelogram may be made equal to the perimeter of the triangle, the sides DA, CE must be produced to the equality of the sides AB, AC.

Diagram. A geometric construction. An isosceles triangle stands on base BC (B at lower left, C at lower right), with D the midpoint of the base and A the apex, drawn toward the upper left. Perpendicular AD rises from D to A. Above, a rectangle is constructed and extended, its corners labeled G (upper left) and F (upper right), with A and E along its lower edge. The lines AB, AD, AC are drawn from the apex region to the base.

- G (top left): corner of the extended rectangle
- F (top right): corner of the extended rectangle
- A (left, apex region): apex of the triangle / rectangle corner
- E (right of A): rectangle corner
- B (bottom left): base vertex
- D (bottom middle): midpoint of base BC
- C (bottom right): base vertex

Let there be, then, the straight line DAG, equal to the side AB, and the straight line CEF, equal to the side AC, and let the straight line FG be drawn. From these we shall bring it about that the parallelogram CFGD and the triangle ABC are isoperimetric. But since the parallelogram CFGD exceeds the parallelogram ADCE by the quantity AEFG, and it has been shown that the parallelogram ADCE is equal to the triangle ABC, the parallelogram CFGH [recte: CFGD] will also be greater than the triangle ABC by that same quantity AEFG. Therefore the quadrilateral figure is more capacious than the triangular figure isoperimetric with it — which was to be shown. Since the same reasoning appears to hold in the other rectilinear figures of more sides, isoperimetric with the given figure, the more sides such a figure has, in the more places its sides recede from the center and the middle; and this leads us to the circle, which in a certain manner includes infinite angles and sides, and is, of all isoperimetric figures, the most capacious.

The same must be said of the sphere, if it be compared with other bodies isoperimetric with it.

[Margin: Among isoperimetric rectilinear figures having an equal number of sides, the more capacious is the one that is both equilateral and equiangular, an equal number of sides being posited in each; and therefore the circle is the most capacious.]

Again, of rectilinear isoperimetric figures having an equal number of sides, the greater is the one that has both its sides equal and its angles equal. For let there be some square having 6 on each side, so that its whole perimeter contains 24. The area of this square, according to the precepts of the Arithmeticians, will be 36. For thus you see that the whole square is divided into 36 little squares. Let there be also some rectangular parallelogram having each of two opposite sides 10, and each of the remaining two 2, so that its perimeter is equal to the perimeter of that [square]... this parallelogram will comprehend only 20 little squares out of those 36 which we said were contained in the square. By like reasoning, if each of two opposite sides of some parallelogram were 9, and each of the other two 3, it would indeed be isoperimetric with the square, but its area would contain only 27 little squares. Again, if two opposite sides of some parallelogram each had 8, and the other two [each] 4, it would be isoperimetric with the square, but its area would contain only 32 little squares. Again, if two opposite sides of some parallelogram each had 7, and the other two...

Diagram. A group of grid figures, each ruled into unit squares, illustrating isoperimetric rectangles of perimeter 24. All bear the same perimeter as the reference square but enclose progressively smaller areas as they depart from equilateral:

- A square, 6 by 6 (area 36 little squares), labeled 6 on top, left, and bottom edges.
- A rectangle, 10 by 2 (area 20), labeled 10 (top) and 2 (side).
- A rectangle, 9 by 3 (area 27), labeled 9 and 3 [?].
- A longer rectangle, 12 by 3 (area 36, but perimeter 30 — of equal area to the square yet larger perimeter), labeled 12 (top and bottom) and 3 (each side).

each 5 [i.e., two opposite sides each 5, the other two each 7], it would still be isoperimetric with the square, but its area would include only 35 little squares, and so on. Here you see clearly that the more isoperimetric figures approach the equilateral figure with which they are isoperimetric, the greater the area they

comprehend, and the less they differ in capacity from the equilateral figure. But if some rectangular parallelogram, longer on one side, be of the same capacity as the square, it must necessarily contain a larger perimeter. Thus, if each of two opposite sides of some parallelogram contained 12, and each of the other two 3, its area would indeed be equal to the area of the square, since it would contain 36 little squares; yet its perimeter would exceed the perimeter of the square: for the former will be 30, this latter 24. All of which is plain in the figures set alongside.

[Margin: Euclid I.35.]

Now let there be a parallelogram of unequal angles, ABCD, and from the points C, D let the perpendicular lines CF and DE be drawn to the straight line CD. Then, AB being produced as far as F, **(f)** the parallelogram ABCD will be equal...

to the parallelogram CDEF, since these parallelograms are constructed between the same parallels CD, AF, and upon the same base CD. **(b)** And since the sides BC, AD are larger than the sides CF, DE, and the side AB is equal to the side EF **((c))** because each is equal to the opposite side CD, in the parallelograms ABCD, CDEF), and the side CD is common, the perimeter of the parallelogram CDEF will be smaller than the perimeter of the parallelogram ABCD. Hence, if CF, DE are produced to G and H, in such a way that CG is equal to BC itself, and DH to AD itself, and the parallelogram CDHG is completed (that is, the straight line GH being drawn), the parallelogram CDHG will be isoperimetric with the parallelogram ABCD. But the parallelogram CDHG is greater than the parallelogram CDEF — that is, than the parallelogram ABCD — by the quantity EFGH. It is therefore established that, among isoperimetric rectilinear figures, the one which is both equilateral and equiangular is the greatest of all. For the same reasoning must be applied to the isoperimetric figures that contain more sides and more angles. Wherefore, since the circle comprehends very nearly infinite equal sides, and likewise, in a certain manner, infinite equal angles — because its circumference is always curved uniformly — it comes about that it is the most capacious among all isoperimetric figures. And it is chiefly by these arguments that some authors endeavor to confirm that the circle is the most capacious. From all this I judge it made manifest what our author means in this second argument drawn from convenience, in which he made mention of Isoperimetric figures.

[Margin: b. Euclid I.19. c. Euclid I.34.]

Diagram. A geometric construction of two parallelograms on a common base. Along the top edge, from left to right, are labeled A, H, B, G; slightly below H and

G are E and F; at the bottom, D (left) and C (right). The oblique parallelogram ABCD and the constructions CDEF and CDHG share the base DC.

- C (bottom right): base vertex

[Lemma] Necessity, because if the world were of another form than round — that is, three-sided, or four-sided, or many-sided — two impossibilities would follow: namely, that some place would be empty, and that a body would be without place; each of which is false, as is plain in the case of elevated and turned-about angles.

[Margin: That the heaven is round is proved from necessity.]

COMMENTARY

From necessity he confirms that the heaven is round as follows. The heaven, as has been shown, moves; if, then, it were not of round figure, but many-sided — three-sided, that is, or four-sided, and so on (by the name "three-sided figure" understand the pyramidal, and by "four-sided" the cubic) — two impossibilities would follow: one, that there would be some place without a body; the other, that a body would be given without a place — each of which is at war with the nature of things. It is necessary, therefore, that the heaven be round. The consequence is manifest from the elevation and depression of the angles of any many-sided figure whatever, if it were to move about the center.

[Margin: That the heaven is round is proved from necessity.]

This argument concludes only that the heaven is round in some fashion — that is, not angular — on account of those unsuitable consequences to which the Author is led if it were of angular figure; it does not, however, simply gather from this that the heaven is spherical. For someone might say that it is of oval figure, or lenticular, conical, or cylindrical. For if the heaven be supposed to be of any of these forms, all those absurdities will be avoided with ease; since, this being granted, the heaven can be so moved about its axis that its parts continually

succeed one another in the same places, just as we see happen in a spherical or globular body. Nevertheless it must be said that the aforesaid argument from necessity does conclude that the heaven is most perfectly spherical, and can in no way have another figure.

[Margin: The argument from necessity is confirmed.]

For the lower heavens, as was shown above, are moved with a motion opposite to the motion of the *primum mobile*, upon different poles from the poles of the *primum mobile*: but they could not be moved with this motion, if they were not spherical, unless there came about a penetration of bodies, or a splitting of the heavens — as is manifest to one who considers the matter more carefully; and each of these is impossible. Likewise the same absurdities brought forward by the Author against the angular figure would follow. For let there be an oval, upper orb — if it can be so — ABC, whose axis is ADC, its poles A and C; and let the inner orb, likewise oval, be EHFG, which, since the heavens according to all Philosophers are uniform as to their thickness and density, will be situated according to the situation and length of the upper orb, so that their lengths have the same diameter, as you see here. Let now the axis of the inner orb be GDH, about which it is moved from West to East. It is now manifest that, at the motion of the inner orb upon the axis GDH, the surrounding celestial body is cut apart and penetrated. For the part E will be carried, about the pole G, into the point I, and the part F, about the pole H, into the point K. Wherefore the parts E and F will be left empty, as you discern in the figure set before you.

Diagram. A schematic of two overlapping, lens-shaped (oval) orbs sharing the axis A–C, illustrating why a non-spherical heaven would require the surrounding body to be split. The outer oval spans from A (left) through B (top) to C (right), with D at the center; the inner oval is drawn within it. Hatched (shaded) crescents at upper left and lower right mark the regions that would be left empty. Point-letters cluster at the two ends of the minor axis.

- A (left): pole / axis end of the upper orb
- B (top): vertex of the outer oval
- C (right): pole / axis end
- D (center): common center
- E (upper left, interior): part carried toward I
- G (lower left): pole of the inner orb
- I (bottom left): point into which part E is carried
- H (upper right): pole of the inner orb

- F (lower right, interior): part carried toward K
- K (upper right): point into which part F is carried

We can also, with Ptolemy in the *Almagest* [in Dict.], confirm that the heaven is spherical from this: that we see all the fixed stars move always at the same distance and nearness to us; and that those which are nearer the poles describe smaller circles, while those which are more remote describe proportionally larger ones — which could in no way happen if the heaven were not round and spherical. For only in a spherical body are all the parts equally distant from the center. Hence, if the heaven were of another figure, some parts would be farther from us, some nearer, and on that account not all the stars would be seen at the same distance from us — which is at war with sense and experience. Again, all the instruments of the Astronomers agree with the motions of the celestial bodies exactly as if the heavens were most perfectly spherical; which indeed is manifest in the altitudes of the stars above the Horizon, which, before they reach the Meridian, increase in that proportion, and after they have passed the Meridian decrease, which we can assign only to a spherical body. The same is shown by all the other appearances, and most of all by the Solar clocks [horologia Solaria, sundials], which are constructed on the supposition of a spherical heaven. Finally, we see...

[Margin: Another argument, proving that the heaven is round and spherical.]

let us suppose two stars situated on the same circle of longitude drawn through the poles of the world, one of which is more southerly, and grant that it also has a smaller meridian altitude — so that the two differ in their meridian altitudes by exactly as many degrees as one star is found by instruments made for this purpose to be distant from the other. This reasoning carries great weight with me, since all instruments are built round, so as in some way to imitate the roundness of the heavens. If, then, the heaven were not spherical, these instruments could not, however they were turned, be made to agree with the celestial appearances as regards the altitudes and the mutual distances of the stars. Since we do see that they agree — as is observed above all in the material sphere, the celestial globe, the astrolabe, and the quadrant — we shall rightly conclude that the heaven is perfectly spherical; otherwise neither the instruments of astronomers nor the appearances themselves would make any sense.

[Lemma — Sacrobosco:]

[Margin: *Cælum non esse planum* — "That the heaven is not flat."]

Again, as al-Farghānī [Alphraganus] says: if the heaven were flat, one part of it would be nearer to us than another — namely the part directly above our head. A star located there would therefore be nearer to us than one at its rising or setting; but things that are nearer to us look larger. Hence the Sun, or any other star, when at mid-heaven ought to appear larger than when it is at its rising or setting. Yet we see the opposite happen: the Sun, or another star, appears larger when it is in the east or west than at mid-heaven.

COMMENTARY

Our author confirms this same conclusion by an argument of al-Farghānī, which the latter sets down in his second Difference [Distinction], in the following way. If the heaven were not round but flat or extended, then the part of the sky overhanging our head would be nearer to us; and so the Sun, or some star located there, would appear larger to us than elsewhere, since nearer things are seen as larger than more distant ones. But we experience the contrary: the Sun and the Moon appear larger near the horizon than overhead.

Yet this argument of al-Farghānī, if taken exactly as it is proposed, has no force whatever. For since — as was shown above — the stars are not moved by themselves but by the motion of the heaven in which they are set, who does not see that, whatever figure be assigned to the heaven, every star draws equally near to the earth, seeing that by the heaven's motion it describes a circle around the earth that is everywhere equally distant from it? This is plainly seen in the following figure, in which the heaven is supposed to have an angular shape. For if the heaven moves around the earth, each star will describe its own circle about the earth — star A the outer circle, star B the inner circle. If, on the other hand, the heaven were at rest and the stars moved of themselves, the argument would have the greatest force and validity, as can be seen in the same figure.

Diagram. A circular figure representing the heaven conceived as an angular (polygonal) shape around the earth. At the center is a small circle marked **C** (the earth), containing a sprig/plant device. Two concentric circles are drawn; the vertices of the inscribed angular figure carry the labels. The four "corner" points (top, left on the horizontal diameter, right on the horizontal diameter, and bottom) are each marked **A**, and lie on the outer circle. The intermediate points (roughly the mid-sides, in the upper-left, upper-right, lower-left, lower-right positions) are each marked **B**, and lie on the inner circle. Small star-bursts mark each labelled point. The figure illustrates the text: star A (at an angle/corner of the heaven) describes the outer circle, star B (not at an angle) the inner circle.

- A (top, on outer circle): star at a corner
- A (left, on horizontal diameter): star at a corner
- A (right, on horizontal diameter): star at a corner
- A (bottom, on outer circle): star at a corner
- B (upper-left, upper-right, lower-left, lower-right, on inner circle): stars not at corners
- C (center): the earth

Nevertheless this same argument can be put better in the following way. If the heaven were flat, or of any other shape whatever, then although each star would describe its own circle around the earth, and so would always remain equally distant from it, still not all the fixed stars would recede from the earth at an equal distance; rather, some would appear nearer and some farther off. Thus, in the figure set out above, star A, placed at a corner of the heaven, has a greater distance than star B, which is not set at a corner — a result that is, however, contrary to experience. Furthermore, if all the heavens were of a many-sided figure, and not spherical, the lower heavens could not carry the planets and the fixed stars from west to east, from one sign into another, without there being a splitting and interpenetration of the celestial bodies. Since this is absurd, we must grant that the heaven is spherical. And this same argument proves too that the heaven is neither oval nor lens-shaped, and so on, as we also showed a little above.

[Margin: *Cælum à centro terræ, non autem à quouis puncto in superficie terræ assignato æqualiter distat, si Geometrice loquamur, sed solum, quoad sensum.* — "The heaven is equidistant from the center of the earth, but not from any point assigned on the earth's surface, if we speak geometrically — only as regards sense-perception."]

Now although our sense judges — and it is commonly said by philosophers and astronomers — that the heaven is everywhere equally distant from us who exist on the earth's surface, yet if we examine the matter more carefully we shall find that it recedes equally only from the center of the earth, and not from any point assigned on its surface. For the eastern, western, northern, and southern regions, and finally all the parts near the horizon, are farther from us than the part placed above our head; and that part of the sky which is opposite our zenith will be far more remote still. The reason for this is that between us and the zenith only two elements are interposed, namely air and fire; but between us and the other parts of the sky near the horizon, besides these two elements, a semidiameter of the earth also lies between; and between us and the part of the sky opposite our

zenith, besides the same two elements, the whole diameter of the earth is intercepted. If, then, we wish to speak geometrically and precisely, we cannot be equally distant from all parts of the sky.

[Margin: *Cur cœlum appareat longius distare à nobis iuxta Horizontem quam prope verticem capitis.* — "Why the heaven appears to be farther from us at the horizon than near the zenith."]

Nevertheless, since the earth's semidiameter is of insensible magnitude in comparison with the sky's distance from the earth's center, the heaven cannot appear sensibly farther from us at the horizon than at the zenith. It is just as if someone were to see some object 20 or 30 miles away: if he came 6 or 8 paces nearer, the same object would still appear to him of the same size, neither larger nor smaller so far as sense goes, because so few paces have an almost insensible ratio to 30,000 paces — even though this ratio is in fact larger than the ratio of the earth's semidiameter to the distance of the firmament, which, according to al-Farghānī (as we shall say at the end of this chapter), contains about 45,225 earth-semidiameters. And so astronomers and philosophers, following the judgment of vision, rightly assert that the heaven is equally distant from us in all its parts, even though by reason and truth the matter is not so. From all this it is clear that one and the same star, near the horizon in serene weather (all vapors and exhalations set aside), appears to us of the same size in which it is seen near the meridian, even though there it is farther from us and here nearer; because, namely, between that greater distance and this lesser one there is not so great a difference as can fall under the senses. And if anyone should object that at first glance it does seem to sense that the heaven is farther off at the horizon than overhead — so that it would be false [to say] that this diversity is...

insensible: the answer is that this is indeed true, but not therefore [sensible or] notable. For the sense is deceived, as the theorists of optics [Perspectivi] show, who by the interposed bodies are wont to judge and measure any interval; and so, because between us and the sky overhead it sees no body interposed, whereas from any part of the horizon it beholds the whole mass of the earth stretched out, it judges that distance to be much greater — when in fact it is greater only insensibly, so that by instruments the heaven is judged to be equidistant from us. Indeed, for this very cause the sense also judges that the heaven near the horizon in a way touches the earth itself, precisely because it perceives no other body between sky and earth. We see the same thing happen with mountain-tops: two summits sometimes seem to be entirely joined, because we do not see the bodies lying between them, though in fact they are separated by a very great interval.

[Margin: *Cur cœlum appareat longius distare à nobis iuxta Horizontem quam prope verticem capitis.* — "Why the heaven appears to be farther from us at the horizon than near the zenith." (This gloss is repeated from the facing page.)]

[Lemma — *Sacrobosco*:]

[Margin: *Cur Sol & stella maiores appareant iuxta Horizontem, quam in medio cœli.* — "Why the Sun and stars appear larger near the horizon than at mid-heaven."]

But since the truth of the matter is not so, the cause of this appearance is that in wintry or rainy weather certain vapors rise up between our sight and the Sun, or another star; and since those vapors are a transparent body, they scatter our visual rays, so that they do not apprehend the object in its natural and true size — as is evident in a coin cast into the depth of clear water, which, on account of a like scattering of the rays, appears larger than its true size.

COMMENTARY

He had said, in al-Farghānī's argument, that the Sun and Moon, or any other star, appear larger near the horizon than overhead; from this someone might infer that the heaven is not round, since it is not equidistant from the earth on every side. For where the star appears larger, there the heaven will be nearer; where smaller, there farther off. Accordingly he meets this tacit objection, giving as the reason why the Sun or Moon, or another star, appears larger at rising and setting than at mid-heaven or the zenith, not that it is farther off there than here, at least sensibly, but that there are vapors raised from the earth which are interposed between the Sun (or any other heavenly body) and our vision. Hence it comes about that those vapors, being denser and thicker near the horizon, alter our visual rays, and so we do not see the object in its own proper size. This is quite evident, as he says, in a coin lying at the bottom of translucent and clear water.

[Margin: *Stellæ omnes sphæricam figuram habent.* — "All the stars have a spherical shape."]

Al-Farghānī brings forward this same cause in his first Difference, and all the theorists of optics demonstrate it. For from that variation of the visual rays any nearer object appears — and hence appears larger. From the same cause it happens that an object can be seen by rays sometimes refracted, when by direct rays it could not by any means reach our eye. We have a very clear example in a coin cast into the bottom of some empty vessel of moderate height. If we draw back far enough that we can no longer see the coin, because the sides of the

vessel come between it and our sight, and then the vessel is filled with clear water, the coin will suddenly appear and offer itself to our view. Hence it comes about, finally, that we sometimes see the Sun, the Moon, and the other stars before they have risen above the horizon — from which arose among the wise the common saying: When the Sun appears on the horizon earlier than usual, it is a sign of coming rain; for then many thick vapors are interposed between our sight and the Sun, out of which rain is generated.

There remains, finally, a brief little question: whether, namely, all the stars are also of spherical figure — since from what has been said it is left clear that the heaven is spherical. On this point there have not been wanting some who supposed there to be as many various shapes among the heavenly bodies as there are among these lower ones. But since they seem to have asserted this rashly, without any probable reason, we must say, with all astronomers and philosophers, that all the stars are of round and spherical figure. This is plainly evident in the Moon, which receives light from the Sun in a circular fashion — which could in no way happen unless it were itself spherical. Since, then, the same reasoning seems to hold for all the heavenly bodies, we must conclude that they are all spherical. The same can be confirmed from this: that wherever they are placed in the heaven, they appear round to us, which could not happen unless they were round and spherical. This appears far more evidently in the planets. For since, according to the common opinion of astronomers, they are carried around in epicycles, they cannot always turn one and the same side toward us. Therefore, since they always appear round, they must necessarily be spherical on every side; for the spherical figure has this privilege among all bodies, that it appears circular and round when inspected from any part. Add to this that nature in these lower things has above all striven after roundness, so far as it could — as may be seen in the limbs of animals, the trunks of trees, in fruits and other such things, all of which seem to tend, as far as may be, toward a round figure; because, namely, as was said above, the round figure is the noblest. For this reason it is not without cause that nature seems to have granted to all the heavenly bodies — which surpass all others in nobility — the noblest figure, which is the round and spherical; and this too especially to the end that they might equally on every side pour forth their rays, and be more fully illuminated on every side by the Sun.

That the Earth and Water Are Round

[Lemma — Sacrobosco:]

[Margin: *Terram rotundam esse ab ortu in occasum.* — "That the earth is round from east to west."]

That the earth too is round is shown thus. The signs and stars do not rise and set at the same time for people existing everywhere; rather, they rise and set earlier for those toward the east. And that they rise and set earlier for some and later for others is caused by the bulge of the earth — which is well shown by what takes place on high. For one and the same eclipse of the Moon, numerically single, which appears to us in the first hour of the night, appears to peoples farther east about the third hour of the night. From this it is established that night came earlier for them, and the Sun set for them earlier than for us; and the sole cause of this is the bulge of the earth.

COMMENTARY

This is the third conclusion: namely, that the earth and water are of round figure. Since this contains two parts, he confirms in the first place the prior part of it — namely, that the earth is round — by this single argument: the earth is round from east to west, and likewise from north to south; therefore the whole earth is round. The consequence is evident from a sufficient enumeration of the parts: for if the earth is round from east to west, wherever you begin and whithersoever you proceed, and likewise from north to south, in whatever direction you turn, then absolutely no particle of the earth will be left that is devoid of roundness. The antecedent he proves in two ways. First, since it has two parts, he shows the prior — namely, that the earth is round from east to west — by this reasoning: The signs and stars rise for the Easterners first, reach mid-heaven first, and set first, before they do for the Westerners, as is evidently shown in a lunar eclipse — in which (since it is universal to the whole world, for the Moon is eclipsed on account of its own entry into the earth's shadow, as we shall explain in the fourth chapter) at the same instant of time the Moon is hidden from all people by whom it can then be seen; and yet, if, say, the beginning of the eclipse appears to us in the first hour of the night, this same eclipse is known, from the books of history or from the report of others, to have begun for more easterly peoples about the third hour of the night, for example. From this it is clear that they had night first, and consequently that the Sun rose and set for them two hours earlier than for us. And the sole cause of this is the roundness of the earth from east to west, since thus are produced different horizons from east to west — which would not happen if the earth were not round; just as it happens on some mountain, on which, because it is round and gibbous, many things occur, and are seen, on one side, which cannot be seen on the other side of the mountain, on account of the

interposed bulge of the mountain. This you may see most clearly in the adjoining figure, in which let the East be on the side of A, the West on the side of B.

Diagram. A circular figure representing the terrestrial globe within the sphere of the heavens. An outer circle is divided by tick-marks into equal parts (the 24 hours). Within it is a second, inner circle; at the center is a small circle marked **C** (the earth's center). Two labels **MERID.** (for *Meridianus* / meridian) are written along a curved arc at the top. A radiating shaft or columnar figure (with a bundle of lines/rays) rises from near the center **C** toward the upper right. The horizontal diameter runs from **B** at the left to **A** at the right. A second (tilted) diameter runs from **E** at the lower left to a point at the upper right marked **D** (printed in a form resembling "II"/"Д"). At **E**, in the lower left, is a Sun with a radiant face.

- A (right end of the horizontal diameter): East [Oriens]
- B (left end of the horizontal diameter): West [Occidens]
- C (center): the earth
- D (upper right, end of the tilted diameter): endpoint of the second horizon D–E [label uncertain — printed form resembles "II" [?]]
- E (lower left, at the Sun): endpoint of the second horizon D–E; the Sun is figured here
- MERID. (top, twice): the meridian [Meridianus]

You see, therefore, two different horizons, A B and D E, on account of the roundness of the earth C. For the zenith of each dweller on the earth ought to stand perpendicular, that is, at right angles, to the surface of the horizon and of the sky. You see, again, that the Sun rose earlier, reached mid-heaven or the meridian earlier, and finally set earlier, for those people whose horizon is A B than for those who have the horizon D E. Hence, then, it comes about that if an eclipse of the Moon begins while the Moon is above both horizons — and consequently while the Sun is depressed below each horizon as well — more hours will have elapsed since the Sun's setting with respect to horizon A B than with respect to horizon D E. And that this may be understood still more plainly, it must be known: Since the equinoctial circle [Æquinoctialis], divided into 360 equal parts called degrees, is wholly raised above any given horizon in the space of 24 hours by a uniform motion, it must be that in each single hour fifteen of its degrees are raised. Hence, since regions are called more or less easterly with respect to the equinoctial, which extends from east to west or the reverse, it is left clear that in all regions which are fifteen degrees more easterly than we are, the stars rise and set earlier by the space of one hour; while in those that are thirty degrees more easterly, the stars rise and set earlier by the space of two hours;

and so on in turn, adding or subtracting according to the number of degrees by which one region is more easterly than another — yet under this law and condition, that four minutes of an hour be assigned to each degree. For since an entire hour comprises 60 minutes, four such minutes will correspond to each single degree. All this may be observed in the figure set out above, in which you see the larger circle divided into 24 equal hours, the beginning taken from the setting of the Sun, as is done in Italy. The degrees lying between any two cities, of which one is eastern and the other western, are known by the arc of the equinoctial circle intercepted between the meridians of the two cities. This can easily be understood from those descriptions of the world which they call maps [Mappas mundi]: for in them the lines proceeding from one pole to the other mark the meridians, while the line equally removed from both poles represents the equinoctial circle. Hence, if two meridians be taken passing through two cities, the arc of the equinoctial circle placed between the two meridians will at once show by how much one city is more easterly than the other. But these matters are to be sought from the cosmographers.

Furthermore, as to what our author says — that the Sun rose and set two hours earlier for more easterly peoples than for less easterly ones, if indeed those peoples exist thirty degrees more to the east — this must be understood of two cities that are equally distant from the equator, that is, that have the same elevation of the pole. For when they have different elevations of the pole, and consequently are not equally distant from the equator, it is not necessary that for the city which is thirty degrees more easterly than the other the Sun rise and set two hours earlier. For it may happen that for the city which has the greater elevation of the pole — that is, which lies more toward the north — the Sun rises at the same instant of time as for the city which has the lesser elevation of the pole, even though the latter is more easterly. This indeed comes about on account of the obliquity of the horizon. Hence it happens that, when the Sun is in the northern signs — at the beginning, for example, of ♋ [Cancer? — zodiac symbol, reading uncertain] — the more northerly city has a longer day than the less northerly one. So, although the Sun reaches the meridian of that city later than of this one — because this one is placed more to the east — nevertheless, since the time from sunrise to the meridian of that city is greater than of this one, it can happen that the Sun rises at the same time for both cities.

For example: Let two cities be placed not having the same elevation of the pole, of which one is more easterly than the other by fifteen degrees, so that noon comes to the more easterly one hour before the other. Let the more easterly city have a longest day of 14 hours, and the more westerly one of 16 hours, so that in the

former seven hours run from sunrise to noon, but in the latter eight. This being posited, who does not see that the Sun rises for both cities at the same instant of time? For when it is noon for the former, seven hours will have elapsed since its sunrise, and the latter city will still lack one hour until its noon. Since, then, this latter city has eight hours from sunrise to noon, it must be that when it is noon for the former city, seven hours have likewise elapsed since sunrise for the latter. Therefore the Sun did not rise earlier for the one than for the other, even though the one is more easterly than the other. But if a more westerly and more northerly city has a longest...

[continuation of the commentary on the day-length and eclipse-timing argument]

whose longest day is 17 hours, the Sun will rise earlier for it than for a more easterly city whose longest day contains 14 hours, as is clear. Conversely, if a more northerly city is also more easterly, it can happen that the Sun does not set for it any earlier than for a more westerly and more southerly city, but at the same time, or even later. Indeed, there can be two cities of which neither is more easterly than the other, yet which have unequal elevations of the pole — namely because one inclines more toward the North than the other — and for which, nonetheless, the Sun does *not* rise and set at the same time, even though midday occurs at the same moment in both. Rather, it rises much earlier and sets much later for the more northerly city than for the less northerly one, because the former has a longer day than the latter.

But if we are speaking of the hours reckoned from midday, then the statement of the author and of the astronomers will hold true for any cities whatever of which one is more easterly than the other — even if they are not situated under the same parallel, but under different ones, and have different elevations of the pole. For a city that is more easterly than another by, say, 30 degrees will always reach midday two hours earlier, whatever be the case regarding the anticipation of the Sun's rising or setting. By the same reasoning, when there are two cities of which neither is more easterly than the other — even though the one lying farther north has a longer day, so that the Sun rises earlier and sets later for it — they will nevertheless reach midday at the same instant of time. Hence for both cities the beginning of some eclipse of the Moon will appear at the same hour before or after midday; which can by no means happen for two cities of which one is more easterly than the other, since midday plainly comes sooner for the more easterly one, because its meridian lies closer to the eastern regions.

[*Sacrobosco's text:*] That the earth likewise has a bulge [tumor] from north to south, and the reverse, is clear as follows. For people situated toward the north,

certain stars are of everlasting appearance — namely those that draw close to the Arctic pole — while others are of everlasting concealment, namely those that lie close to the Antarctic pole. If, then, someone were to travel from north toward south, he could go so far that stars which had previously been of everlasting appearance to him would now sink toward setting; and the farther he advanced toward the south, the more they would move toward setting. That same man could, in turn, come to see stars which had previously been of everlasting concealment to him. And the reverse would happen to someone traveling from south toward north. The cause of all this is simply the bulge of the earth.

COMMENTARY

Here [Sacrobosco] confirms the latter part of the preceding [proposition] — namely that the earth is round from north to south as well — by the following argument. There is no doubt that certain fixed stars always appear to us who live in the oblique sphere and in the northern regions — namely those near the Arctic pole — while certain others are always hidden, namely those that lie near the Antarctic pole. Again, it is established that if someone were to travel straight from north to south — that is, always under the same meridian — the stars that had always appeared to him before would begin to be hidden; and conversely, those he could not see before, near the Antarctic pole, would gradually lift themselves above the horizon and come into view. For we see that in Germany, which is more northerly, more stars are permanently visible than in Italy, which is less northerly; while, on the contrary, in Italy more stars are seen in the southern quarter than in Germany. It is therefore a clear sign that the earth is round from north to south — just as the reason why, when we climb some rounded mountain, we begin to see things we did not see before, and can no longer look upon things we saw before, is simply the bulge of the mountain.

But from these considerations it seems we can conclude only that the earth is round from north to south *in some fashion* — that is, that it is not flat — and not that it is of spherical figure. [Margin: That the roundness of the earth is spherical.] Hence this very point must be confirmed in the following way. When someone, remaining always under the same meridian, travels from north to south, he finds that the elevation of the pole above the horizon continuously decreases, and in this fixed proportion: if in one place the pole's altitude is, say, 40 degrees, then after he has covered 62 miles toward the south he finds the pole lowered [*reperiat polum eleuari* (?) — verb as printed reads "raised," but the context (40°→39°, "decreases," "has decreased by one degree") requires depression] just enough to stand at 39 degrees; and so on in succession — as often

as he covers 62 miles, he finds the pole's altitude to have decreased by one degree. For this proportion in the decrease of the pole's altitude can belong only to a spherical figure, as is evident among the geometers and astronomers.

In the same way it will be shown that the earth is spherical from east to west — not round in merely some fashion, but [truly] spherical. For that anticipation of the rising and setting of the Sun, and also of midday, cannot at all preserve the aforesaid proportion (namely, that for a city more easterly than another by 15 degrees the Sun rises and sets one hour earlier; for one more easterly by 30 degrees, two hours earlier; and so on for the rest) unless we assign a spherical figure to the earth. This is why our author rightly demonstrated that the earth is round.

[*Sacrobosco's text:*] Again, if the earth were flat from east to west, the stars would rise as quickly for the western regions as for the eastern — which is plainly false. Likewise, if the earth were flat from north to south, and the reverse, the stars that were of everlasting appearance to someone would always appear to him, wherever he traveled — which is false. But that it *appears* flat is owing to its enormous size relative to human sight.

COMMENTARY

[Sacrobosco] now proves the same antecedent with respect to both its parts by excluding an absurdity — in particular by excluding from the earth the flat figure that the earth is commonly believed to possess; and this by the following argument, which is in a way an explanation and confirmation of the preceding. If the earth were not round from east to west (or the reverse) but, say, flat, the stars would rise as quickly for the western regions as for the eastern, and would set for both at the same time, since all would have as their horizon the flat plane of the earth. And if it were likewise flat from north to south, rather than round, then for the same reason — whether one traveled from north to south or the reverse — the stars that were permanently above the horizon would never be hidden, nor would those permanently hidden from him ever begin to appear, since he would never change his horizon but would always remain on that flat plane of the earth. Both of these are contrary to common experience, as is clear from the preceding

reasoning; and this argument, together with the present one, is drawn from Ptolemy [Ptolemy] (*Almagest* I.4 [Dict. 1. cap. 4]), from Johannes Regiomontanus [Regiomontanus] (*Epitome of the Almagest* I, conclusion 2), and from al-Farghānī [al-Battānī? — recte al-Farghānī, "Alphraganus"] (*Elements of Astronomy*, Differentia 3).

[Margin: That the earth is not hollow.] Ptolemy, in the place cited, adds another argument by which he proves that the earth cannot be hollow. For if it were hollow, he says, the stars would rise sooner for the western regions than for the eastern — as we see happen in valleys, where the western parts are lit by the Sun sooner than the eastern parts. Moreover, the farther one advanced from north to south, the more stars would appear to him near the Arctic pole, and the more, on the opposite southern side, would be hidden. All of which is absurd and conflicts with experience, as has been said.

[Margin: Why the earth appears flat.] As for why the earth appears flat to our sight, our author says the cause is its enormous size. For what appears to us of the earth is so very small in relation to the whole circumference of the earth that it is no wonder it looks flat to us — just as, if someone were to cut off the smallest part from the circumference of some very great circle, that little piece, considered on its own, would undoubtedly be judged by anyone to be a straight line.

[*Sacrobosco's text:*] [Margin: That the water is round.] That the water, too, has a bulge and approaches roundness is clear as follows. Let a marker be set up on the seashore, and let a ship leave the harbor and move so far off that the eye of a person near the foot of the mast cannot see the marker; yet, with the ship standing still, the eye of that same person, stationed at the top of the mast, will see that marker well. But the eye of one near the foot of the mast ought to see the marker *better* than one at the top of the mast, as is clear from the lines drawn from each point to the marker; and there is no other cause of this than the bulge of the water. For let all other impediments — such as mists and rising vapors — be excluded.

COMMENTARY

Here [Sacrobosco] confirms the latter part of the proposed third conclusion — namely that the water is round — by a twofold argument. The first is this. If some notable marker is set up on the seashore — say, some tower, or a house is noted — and a ship leaves the harbor, then, after some distance of the ship from the shore, those in the ship near the foot of the mast will no longer see that noted marker; but if someone then climbs to the top of the mast, he will still see the marker. And this happens even when all other impediments, such as mists and vapors, have been set aside. It therefore plainly follows that the cause of this was solely the bulge of the water interposed between the ship and that marker on the shore. For unless the bulge of the water were the impediment — that is, if the water were flat — those at the foot of the mast ought to see the marker better than one at the top of the mast, since they are closer to it, as is clear from the

straight lines drawn from the marker to the foot of the mast and to its top. [Margin: note *a* — Euclid, *Elements* I.19.] For the line drawn to the top of the mast would be longer than the one extending to the foot of the mast, since it is subtended by a greater angle, as appears in the adjoining figure.

Diagram. A woodcut showing the terraqueous globe: a rounded mass of land bearing a walled tower and buildings on its upper left and mountains across its face, encircled by the sea drawn as waves. To the right, a ship under sail rides on the water, its hull below and its mast rising above the curve of the water's bulge — illustrating that the marker (tower) on the shore is hidden by the swell of the sea from an eye at the foot of the mast, but visible from the masthead. No lettered labels.

Although this argument — which is that of all the astronomers — demonstrates very well that the water has a round figure once the mists and vapors that impede our sight have been set aside, nevertheless, because the weather is scarcely ever so clear that there are no vapors raised from the sea, and because from it one can conclude only that the water is round in some fashion (that is, not flat), and not that it is spherical, we shall therefore be able to prove more satisfactorily and more effectively that the water is round and spherical by the same means through which the author gathered the roundness of the earth: namely, by comparing more easterly islands with less easterly ones — as when one sails from Syria to Spain, and thence toward that part of New Spain, or America, which is called Florida, or the reverse — and, likewise, by comparing more northerly islands with less northerly ones, as when a voyage is made from Portugal [Lusitania] toward Flanders, or the reverse, and from Portugal by way of the Fortunate Isles [Canary Islands] toward Cape Verde. For all the observations adduced above to prove the roundness of the earth — namely, the anticipation of the rising and setting of the stars, and also the variation of the pole's altitude — have been found by sailors on the ocean and sea to hold in the same proportion. It is therefore necessary that the water, too, is round and spherical.

[*Sacrobosco's text:*] Again, since water is a homogeneous body, the whole will be of the same nature as its parts; but the parts of water (as happens in droplets and in the dew on plants) naturally seek a round form; therefore so does the whole, of which they are the parts.

COMMENTARY

This is the second argument. The parts of water naturally seek a round figure, as we see in droplets and in dew upon the leaves of plants. Since, then, water is a

homogeneous body, and consequently the whole is of the same nature as its parts, the whole body of water, too, will be of round figure. But this argument is not very cogent. For those droplets, fleeing the dryness that is hostile to them, love the round figure out of a natural and universal propensity, so as to preserve themselves longer; for the spherical figure is the most suitable for that, since its parts are more united than those of other figures. Hence we see that droplets of water, if they lose their spherical figure, are quickly and easily destroyed and dried up.

To these two arguments we can add another, which Aristotle [Aristotle] too brings forward in *On the Heavens* [*De caelo*] II, in this way. Water, of its own nature, flows together toward lower places, as we have learned from daily experience; therefore it is round. For otherwise it would not flow together toward lower places. Suppose the surface of the water to be — if it were possible — flat, or of some other non-circular figure, spread over the earth along the line ADB; and from C, the center of the world, let the circle EGF be described; and from C let CD be drawn perpendicular to AB; and let the straight lines AC, BC be joined. [Margin: Corollary to Euclid, *Elements* I.19.] Now since the straight line CD is smaller than CA or CB, the point D will be in a lower place — that is, closer to the center — than point A or B. The water, then, being unimpeded, will *not* flow toward lower places. And since this conflicts with experience

Diagram. [Margin label: "Corollary to I.19."] A circle with center C. Across its upper part runs the straight line AB, a chord, with its midpoint D; from the center C the perpendicular CD rises to D, and the straight lines CA and CB are drawn to the ends of the chord, forming a triangle. The arc of the circle above the chord carries the point G at the top, with E and F marking the circle to either side (the bulge EGF).

- A (left end of the upper chord): endpoint of line ADB
- D (midpoint of the chord AB): foot of the perpendicular CD
- B (right end of the upper chord): endpoint of line ADB
- G (top of the circle, above D): summit of the water's bulge
- E (circle, left): point to which the near part of the water subsides
- F (circle, right): point to which the near part of the water subsides
- C (center): center of the world

it is necessary that the middle part of the water, namely D, be raised to point G, and that the parts of the water near A and B subside and arrive at points E and F, so that the whole body of water may have the bulge EGF and be equally distant

from the center of the world. For in this way it will naturally come to rest, balanced. And from this argument it will be proved that the water can have no figure other than the spherical; for otherwise it would always have some parts farther from the center of the earth (since only the spherical figure everywhere approaches the center equally), and consequently it would not flow down toward lower places — which conflicts with the nature of water. Indeed, from this argument it follows that any liquid contained in some vessel has a bulge, or circumference, whose center is the same as the center of the world.

[Margin: Archimedes' demonstration, proving that every liquid has a spherical figure.] But the most elegant of all is the demonstration of Archimedes [Archimedes] in Book I of *On Floating Bodies* [*On the things carried in water*], by which he proves that not only the Ocean and the other seas, but indeed any standing and settled liquid, has a spherical figure whose center is the same as the center of the world, toward which all heavy things are borne by their own nature. He first assumes that the nature of a fluid is such that, when its parts lie evenly and are continuous with one another, the less compressed part is driven out by the more compressed; and that each of its parts is pressed by the fluid lying vertically above it, if the fluid is descending in some direction, or is pressed by some other. This we have learned by experience to be true; for whenever we press some liquid in one part, either with the hand or with some other fluid poured over it, the other surrounding parts give way and are driven out. He then demonstrates that if some surface is cut by a plane always through the same point, and the section is the circumference of a circle having, as its center, that point through which it is cut by the plane, then that surface is spherical, with that same point as its center. The demonstration of this is as follows. Let some surface be cut by a plane drawn through the point A, and let the section always be the circumference of a circle having the point A as its center. I say that this surface is spherical, with A as its center — that is, that all the lines drawn from the point A to that surface are equal to one another. For let two straight lines AB, AC be drawn in any manner from A to the surface, as in the first figure. [Margin: note *b* — Euclid, *Elements* XI.2 (*secundum undecimi*).] Through these, since they lie in the same plane, let a plane be drawn producing on the proposed surface the line BC, which, by hypothesis, will be the circumference of a circle. The straight line AC will therefore be equal to the straight line AB, by the definition of a circle. By the same reasoning we shall show that all the other straight lines drawn from A to the proposed surface are equal to AB, since through AB and any other straight line drawn from A to the given surface a plane can be drawn producing a circle on the proposed surface. Therefore all the straight lines will be equal to one another, and accordingly the surface will be spherical, with A as its center.

Diagram. "The first figure." A circle (the section of the surface) with its center A at the bottom. Two straight lines AB and AC rise from A to the points B and C on the circumference, and the chord BC joins them across the top, so that AB, AC, and BC form a triangle inscribed with its apex at the center.

- A (bottom, center of the circle): the point through which the cutting plane passes
- B (upper left, on the circumference): endpoint of line AB
- C (upper right, on the circumference): endpoint of line AC

Now let some fluid, or standing and settled liquid, be understood, whose surface is cut by a plane drawn through D, the center of the earth, producing a line on the surface EFGH. I say that the line EFGH is the circumference of a circle whose center is D. For if it is not, not all the straight lines drawn from D to the line EFGH will be equal to one another. Let DE, DG, then, be unequal, with DG greater than DE; and between these let the straight line DF be drawn, greater indeed than DE but smaller than DG. Now if, in the cutting plane, a circle IFKH is described from D with radius DF, it will necessarily cut the straight line DE beyond point E, at point I, and the straight line DG below point G, at point K; and there will be formed at D two arbitrary angles FDI, FDG. Let there also be described, in the liquid and in the plane of the circle IFKH, the circle LMN. The parts of the fluid near the circumference LMN therefore lie evenly and are continuous with one another, since they are equally distant from the center D; and of these, the ones near the circumference MN are pressed more by the liquid near FG than the ones near the circumference LM are pressed by the liquid near EF, since the former is heavier than the latter, as is clear. Therefore the parts near LM will be driven out by the parts near MN, and consequently the fluid will not stay at rest — but it was assumed to be standing and settled, which is absurd. The line EFGH, therefore, is the circumference of a circle whose center is D. It will be demonstrated in the same way that, however else the surface of the liquid is cut by a plane through D, the center of the earth, the section is the circumference of a circle whose center is D. Therefore, as we showed a little earlier, the surface itself will be spherical, with center D, the same as that of the earth — seeing that it is of such a kind that, when cut always through the center of the earth, it produces the circumference of a circle having the center of the earth as its center. Which was to be demonstrated.

Diagram. [Margin label: "note *b* — XI.2."] A large semicircle representing the surface of the liquid, EFGH, standing on a horizontal base; D is the center of the earth on the base, and the vertical line rises from D through the interior up to G

at the top of the arc. F is on the arc at the left, H on the arc at the right. Two concentric inner arcs (the circles IFKH and LMN) are drawn about D; on the vertical line, K and N lie below G, and M lies in the interior toward the left; along the base at the lower left are the points I, E, and L.

- G (top of the outer arc): summit, on the vertical through D
- F (outer arc, left): where DF meets the surface
- H (outer arc, right): the surface EFGH
- D (center of the base): center of the earth
- K (on the vertical, below G): where the circle IFKH cuts DG
- N (on the vertical, below K): inner circle LMN
- M (interior, toward the left): inner circle LMN
- I (lower left, on the base): where the circle IFKH cuts DE produced
- E (base, left): endpoint of DE on the surface
- L (base, left of center): inner circle LMN

WHETHER FROM EARTH AND WATER A SINGLE GLOBE IS MADE — that is, whether the convex surfaces of these elements have the same center

[Margin: The opinion of those who posit two centers, one of the earth and the other of the water.] Although it has been rightly proved by the author that both the earth and the water are round, some nevertheless call into question whether these two elements are so round and spherical as to constitute a single globe — or (what is the same) to have one and the same center. For some assert that the earth and water in no way have the same center, but two distinct ones, and that therefore they do not form from themselves a single sphere only, but two. For they say that at the beginning of the world the earth and the water were created round indeed, and concentric, about the center of the world; that the water then withdrew from one side and was gathered onto the opposite side in a great bulge, while the earth meanwhile remained motionless at the center of the universe. And so they say that from that separation of the water from the earth two globes were produced, distinct and diverse from each other — one of the earth, the other of the water — although neither of these globes appears whole and entire, but the two intersect one another. From this opinion it follows that two centers must be posited: one of the whole universe, which they say is the same as the center of the earth, and the other of the water itself. For, convinced by arguments and

observations, they cannot deny that both the earth and the water are round and spherical. And if you object to them that it would follow from this that the water must either be held in place by force or else be able to flow down and cover the earth, they reply that the water, by a supernatural favor and miracle of God, is held there and cannot cover the earth — though it would indeed most certainly cover it if it were left to the condition of its own nature, by which it strives to flow together toward lower places.

Clavius, *Opera Mathematica* Tomus III — Commentary on Sacrobosco's *Sphere*

(Continuation of the commentary on CHAPTER ONE, within the question whether earth and water make a single globe. This batch presents the "three-centre" opinion, refutes both rival opinions, and then argues positively that earth and water form one globe with one common centre — the centre of the Universe.)

[Margin: *The opinion of those who posit three centres — one for the earth, another for the water, and a third for the whole Universe.*]

Others, however, while likewise constituting these same two globes out of earth and water, are unwilling to admit anything supernatural. They hold instead that by God's command not only the water but the earth as well withdrew from the centre of the world, and that the water is no longer held back supernaturally to keep it from flowing to a lower place and covering the earth. Hence these Authors imagine three centres: one of the whole Universe, another of the earth, and finally a third of the water itself. The reason why all the aforesaid Authors make two globes out of earth and water seems to be this: they suppose that water is much larger than the earth itself, so that if the water were concentric with the earth it would certainly cover it. For two unequal circles or globes cannot be concentric without the larger enclosing the whole of the smaller, as is evident from geometry.

[Margin: *Refutation of both of the foregoing opinions.*]

But either opinion can easily be attacked. The first, because without any necessity it takes refuge in miracles. The second, because while it tries to defend the view that everything is constituted naturally, it cannot escape conceding something supernatural — namely that the centre of the world is not the centre of the earth, to which it is naturally owed on account of its supreme heaviness, as all philosophers admit. Add that it conflicts with all experience to hold that the earth

is not placed at the centre of the whole Universe together with the water. For, as we shall demonstrate a little later, the convex surface of the earth, as much as that of the water, is equidistant from the centre of the world — which both opinions deny.

Next, since the Authors of both opinions admit that water is much larger than the earth itself, they will also necessarily be forced to concede that more stadia or miles correspond to each degree of the surface of the sea (or of the water) than to each degree of the earth. For the terrestrial globe is divided into as many degrees as the watery globe is divided into, just as every celestial circle is customarily divided. So if water is larger than earth, the degrees of the water must be larger than the degrees of the earth, and accordingly each of them will contain more stadia or miles than each of those [of the earth]. But all sailors assert the opposite: they testify that they have often found by experience that each degree on the surface of the earth comprises exactly as many stadia or miles as [each degree] on the surface of the sea.

Again, if the aforesaid opinions were true, no antipodes could be assigned to any part of the earth; for the part opposite to this inhabited part of the earth is, on their account, mostly covered by the depth of the waters — as the Authors of them tell tales. But daily experience of the Portuguese and Spaniards teaches us well enough that antipodes are assigned to many parts of the earth, whether on the mainland or on islands: so that the inhabitants at the Cape of Good Hope are nearly antipodal to the far part of the province of China. The province of Peru, too, is roughly opposite that part of the East Indies where the trading-port of Calicut is found. Likewise Malacca in the East Indies is opposite, almost diametrically, to Brazil in the West Indies, and so on.

Diagram. An uncaptioned woodcut roundel showing the shape that earth and water would take according to the rejected opinions. Within a roughly circular (slightly egg-shaped) frame: at the top, a walled town with towers and houses set right-side-up upon hilly land; the middle and lower body of the circle filled with wavy lines representing the sea; and at the bottom, a second town shown inverted (the antipodes), with buildings and small downward-pointing arrows/steps. The figure carries no letter-labels. It illustrates the antipodes and the islands scattered through the Ocean, and the "oblong or otherwise-shaped" earth that the rival opinions would entail (the *supraposita figura* referred to below).

Furthermore, since on their view the water is not equally distant from the centre of the Universe but is raised up in a remarkable way, it would follow that a ship

leaving harbour would be climbing uphill in whatever direction it sailed, and coming in to the same harbour would be going downhill; and so, with the wind being equal, it would descend to the harbour faster than it climbed away from it — which is contrary to experience. Indeed, a ship stationed outside a harbour could in no way stay at rest without running down to the harbour of its own accord, since every heavy thing tends downward. Yet this is not in fact true.

Lastly, the very thing which the first opinion most wants to avoid — that water, held by a supernatural power, would cover the whole earth — it in no way avoids. For since there are antipodes (as those who sail daily nowadays find by experience), and since the whole sea of the Ocean is sprinkled with almost infinite islands, then if the water, left to its natural condition, flowed down so as to cover this habitable earth (according to the Authors of that opinion), that part which our antipodes inhabit would surely be more and more uncovered; and you may say the same of the islands. Therefore, while the Authors of this opinion try to show that water left to its first condition could cover the earth, they wholly uncover another part — which I think they would by no means concede. The same follows on the second opinion, provided that God again placed these two elements about the same centre. For then, according to this view, the earth would be covered by the water; and so that part which our antipodes now inhabit would remain all the more uncovered. But perhaps they will say (as some replied to me when I was disputing with them) that our antipodes and the islands are contained within the same circumference as the whole earth, and that the sea heaves up between any two islands into a certain swelling and mound. Hence, if it flowed down, it would cover the whole earth, including that part which is among the antipodes, together with all the islands. But this reply is absurd. First, because if it were so, the whole body of water would not have a single centre, but each mound of water between two islands would have its own — which is against the common view of everyone, and seems rashly asserted. Next, it would follow that, if someone were stationed on some island from which he could scarcely make out another island lying farther off, then if he sailed toward the mainland — that is, receding farther from that island — he ought to make it out better and more easily than while he was scarcely doing so in the harbour; since, according to the aforesaid reply, on leaving that island he would be climbing a certain mountain of water. And this is contrary to all experience. For if from one place at sea something can scarcely be seen, it is seen much less from another place farther off. I pass over very many other absurdities of this kind that follow upon that reply.

There is added, finally, that on either opinion the earth could not be spherical, but rather oblong or of some other shape — since antipodes really do exist, and almost innumerable islands are found throughout the whole Ocean. All of which you see in the figure placed above.

[Margin: *That earth and water form a single globe.*]

These opinions, then, being rejected as absurd and at war with experience, we must say that earth and water form a single globe — or, what is the same thing, that they have one common centre, which is the centre of the whole Universe. For the centre of the whole Universe, since it is equally distant on every side from the heaven and consequently occupies the lowest place in the world, is endowed with such a nature that all heavy bodies descend toward it of their own nature, unless hindered by something else. Hence it is not without reason called by the philosophers the *centre of gravity* [centrum gravitatis]; for all heavy bodies by their nature seek to be in the lower place, as we have learned both by experience and by natural reasoning.

For there is no greater reason why some heavy body should naturally want to be here, outside the centre of the world, rather than there, since every part removed from the centre is nearer to the heaven and therefore in a higher place. From this it follows that water, since it too is heavy, of its own nature, if unhindered, flows together toward the lower places, so that it may equally surround the centre of the whole Universe, lest one part be in a higher place than another — which would be contrary to its nature. This too Aristotle assumed above [Aristotle, *De Caelo*] in his demonstration, as something confirmed by the most certain experiences. And so, together with all astronomers and philosophers who judge more rightly, we say that the convex surface of the earth, as much as that of the water, is everywhere equally distant from the centre of the whole world; and that for this reason the centre of these two elements is one and the same, namely the centre of the whole Universe — so that the convex surface of the one in no way intersects the convex surface of the other (as the earlier opinions maintained), but the convex surface of the water is continuous with the convex surface of the earth, so that a single [globe] is made out of both. And although this could be very easily impressed upon anyone who rightly weighs the heaviness of each element, we shall nevertheless now demonstrate this very point by several arguments. Let the first be as follows.

[Margin: *First argument* (1. Ratio).]

In whatever part of the globe, earth and water, when unhindered and let fall freely, descend along one and the same line of air. Therefore they seek exactly the same centre — which we said just above is the centre of the whole Universe — and consequently they constitute a single globe. The antecedent is established by experiment; the consequence, however, is demonstrated by the mathematicians. For from the opposite of the consequent is inferred the opposite of the antecedent. For if two heavy bodies dropped from some point, in any place of the world, sought different centres, they would necessarily descend along different lines as well. For although from that place which corresponds to both centres along one and the same straight line they would, when dropped, descend along that same line, yet from all other places they would, when dropped, tend along different lines toward those two centres — as appears clearer than light in this figure, in which let the centre of the earth be **B** and the centre of the water **A**.

Diagram. A circle (the globe of earth-and-water) with a horizontal line drawn through it. On this horizontal line, from left to right: **E** (a point outside the circle, at the left end of the line), then inside the circle **B**, **F**, and **A**. Above the circle is the apex point **C**; below it is the point **D**. Dotted (bead-like) lines run from **C** down to **B** and to **A**, and from **D** up to **B** and to **A**, meeting the two interior centres. Per the text: **B** = centre of the earth, **A** = centre of the water, **F** = centre of the world/Universe; **E** is the external point collinear with both centres.

- **A** (on horizontal line, right of centre): centre of the water
- **B** (on horizontal line, left of centre): centre of the earth
- **F** (on horizontal line, between **B** and **A**): centre of the world (Universe)
- **E** (left, outside the circle, on line **EA**): the point from which earth and water descend along the single line **EA**
- **C** (top, apex): external point; lines **CB** (earth) and **CA** (water)
- **D** (bottom): external point; lines **DB** (earth) and **DA** (water)

For only from the point **E**, which corresponds to both centres along the same straight line **EA**, will the earth tend to its own centre **B**, and the water to its own centre **A**, along that same line **EA**. But from any other point — for instance from **C** — they will descend along different lines: the earth, namely, along line **CB**, and the water along line **CA**. And you will say the same of the point **D**. This would not happen if both elements were carried to the centre of the world, **F**. Therefore the centre of the earth, of the water, and of the whole Universe is the same, and consequently one and the same sphere, or globe, will be constituted out of earth and water. For if they constituted two different globes, one globe would intersect

the other — [a] just as, likewise, two mutually intersecting circles cannot have the same centre.

[Margin: a — (Euclid, *Elements* III.5): two circles that cut one another do not have the same centre.]

[Margin: *The reply of the Authors of the contrary opinion.*]

But the Authors of the contrary opinion reply that from this argument only this is gathered: that the centre of the whole Universe is indeed the *centre of gravity* of earth and water — toward which, of course, they naturally tend — but not the centre of their *magnitude*. For one and the same body can have a centre of gravity different from the centre of its magnitude.

[Margin: *What the centre of gravity of each body is.*]

To understand this, one must know that the centre of gravity of some body is that point which always, along the perpendicular, tends toward the centre of the whole Universe, in whatever way and however often the body is suspended, provided it hangs freely. Or, as Pappus [Pappus of Alexandria] defines it, that point situated within the body from which, if a weight is conceived in the mind to be hung, then while the body is carried it stays at rest and keeps the position it had at the beginning, and is not turned about during the motion itself. By this account every body, whether round or not, has a centre of gravity.

[Margin: *What the centre of magnitude of each body is.*]

The centre of magnitude, on the other hand, is the point equally distant from all the outermost parts; and this indeed is found properly only in a spherical body, but in regular [rectilinear] bodies improperly. For that point is said to be the centre of magnitude in any body which is the centre of the sphere that can be circumscribed about it or inscribed in it. These two centres are one and the same in a spherical body that is uniform in heaviness — for example, in a leaden or iron sphere, and the like. But in a spherical body non-uniform in heaviness — as in a sphere partly of wood, partly of stone, of lead, or of iron, etc. — the centre of gravity is one thing and the centre of magnitude another. For in the middle of that globe will be the centre of magnitude, but the centre of gravity will be a point lying in the heavier part; and this indeed would be joined with the centre of the whole Universe, and become one with it, if that body were carried to it unhindered.

[Margin: *How the centre of gravity is found in any body whatever.*]

The centre of gravity of any body whatever — even an irregular and non-uniform one — is found by this method. Let the body whose centre is being investigated be suspended freely, and from the point of suspension let down a thread with a plumb-bob, and mark the line which the thread traces on the body. Then suspend the same body from another point, from which again let down a thread with a plumb-bob, likewise marking the line of that thread on the body. Now since, in whatever way the body hangs, the centre of gravity is found on that line which inclines toward the centre of the world, both perpendiculars must necessarily pass through the centre of gravity. Therefore that point of the body at which those two perpendicular lines intersect will indicate the centre of gravity — as you see in this diagram; in which let the first point of suspension be A, the line of the plumb marked on the body AB; and let the second point of suspension be C, and the line of the plumb marked on the same body CD, cutting the former line AB at the point E, which we assert indicates the centre of gravity.

Diagram. An irregular, roughly star-shaped (blob-like) body used to illustrate finding a centre of gravity by two suspensions. Two straight chords are drawn across it and cross at an interior point.

- A (upper left, on the outline): first point of suspension
- B (right, on the outline): lower end of the first plumb-line; line AB
- C (top, on the outline): second point of suspension
- D (bottom, on the outline): lower end of the second plumb-line; line CD
- E (interior, where AB and CD cross): the centre of gravity

Thus, then, those Authors say that the centre of the whole Universe is the centre of gravity of earth and water — since, as experience teaches, they tend toward it and are of non-uniform heaviness — but that the centre of magnitude of the earth is different from the centre of magnitude of the water; indeed, that each centre of magnitude, both of earth and of water, can be distinct from the centre of the whole world (which is the centre of gravity) — thereby positing three centres.

[Margin: *Refutation of the reply of the Authors of the contrary opinion.*]

[Margin: *That the centre of gravity and of magnitude is the same, both in earth and in water.*]

But this reply amounts to nothing. For both in earth and in water the same centre of gravity and of magnitude must necessarily be posited. Since, then, in each element the centre of the whole Universe — toward which, when dropped from

any place, they are carried (as is left proven by argument) — is the centre of gravity, it becomes clear that the centre of magnitude is the same, namely the centre of the Universe, in earth and water; and hence that these two elements constitute a single globe. That the centre of gravity and of magnitude is the same in the earth, we shall demonstrate as follows. Weights, and all heavy bodies, which are carried from a high place to the surface of the earth, make similar and equal angles upon it, and are not carried in parallel (equidistant) lines, as the senses judge — since they meet at the centre of the Universe, which is the centre of gravity. Therefore the centre of magnitude of the earth and the centre of its gravity — that is, of the Universe — are one and the same.

The antecedent is confirmed by common experience, as may be seen in the plumb-lines that craftsmen use in constructing buildings: these bend neither to one side nor to the other, but rest evenly upon the surface of the earth. For from whatever place they are let down onto the earth they always make similar and equal angles with it, and the threads of those plumb-lines are always along the diameter of the heaven and the earth — otherwise buildings could not stand for long. The same antecedent is Aristotle's, in the second book of *On the Heavens* [*De Caelo* II]. The consequence, moreover, is very clear among the geometers; for from the opposite of the consequent is inferred the opposite of the antecedent. For let the centre of gravity, or of the Universe, be E (if it can be so), but let the centre of the earth's magnitude be another, namely F; and let some weight be carried from on high toward the centre E of the whole Universe along the line BGE, but not toward the centre of the earth F. I say that this weight, striking the earth, does not make equal or similar angles with the surface of the earth, but wholly unequal and dissimilar ones.

Diagram. A large outer circle containing a smaller concentric-ish inner circle (the inner circle representing the surface of the earth/water; the outer, the region of the falling weight). A vertical diameter runs from A (top) through D, F, E down to C (bottom). Additional straight lines are drawn to the interior points G and I.

- A (top, on outer circle): upper end of the vertical diameter
- C (bottom, on outer circle): lower end of the vertical diameter
- D (upper, on inner circle, just below A): point on the earth's surface
- F (interior, centre of the inner circle): centre of the earth's magnitude
- E (interior, below F): centre of gravity / of the Universe
- G (left, on inner circle): point where line BGE meets the earth's surface
- H (left, on outer circle): where the semidiameter FG is extended to

- B (upper left, on outer circle): the high point from which the weight falls along line BGE
- B (right, on outer circle) [second label read as "B" as printed — see anomaly note]
- I (lower centre, on inner circle): point where line BIE meets the earth's surface
- K (lower right, on outer circle): where the semidiameter FIK is extended to
- L (bottom centre, on inner circle): point on the earth's surface

For if the semidiameter of the earth FG is drawn and extended as far as H, the two angles EGD and FGL will be equal, since they belong to equal semicircles; and consequently, by the same reasoning, the two exterior angles DGH and LGH will be equal, as is evident if one angle be superimposed on the other. For the arc GD would coincide with the arc GL, and the straight line HF would be common. Since, then, the angle DGB is less than the angle DGH, and the angle BGL greater than the angle LGH, the angle DGB will be many times less than the angle BGL. Therefore a weight let down along the straight line BGE will not be carried at equal or similar angles onto the surface of the earth. Which was to be demonstrated. You will say the same if along the straight line BIE some heavy body descends to the centre E of the Universe: for if the earth's semidiameter FIK is drawn, again the angle BID on the surface of the earth will be less than the angle BIL. Only those weights which are carried along a straight line (which would happen in very few places) — namely along the line extending through the centre of gravity, that is, of the Universe, and through the centre of the earth's magnitude, that is, along line ADFE or CLEF — strike the surface of the earth at equal angles, and no others besides these, as we have demonstrated. And since this conflicts with experience and with Aristotle, it must be said that the centre of magnitude in the earth is the same as the centre of gravity, or of the Universe; so that from whatever place heavy bodies are dropped, they are carried to the centre of the earth. For only in this way will there be formed on the surface the equal angles which experience teaches must be equal.

Exactly the same judgment must be held about the centre of magnitude in the water, and the same demonstration can be applied, provided that the circle DGL represents the globe of water, whose centre is F. For just as the plumb-lines rest upon the surface of the earth at equal angles, so too the same make equal angles with the surface of the water. Yet by a proper and special argument it can be confirmed that in the water the centre of gravity and of magnitude are the same. For since water, when unhindered, always flows of its own nature to lower places, as experience shows, its convex surface must necessarily recede equally

from the centre of gravity. But that point from which all the convex parts are equally distant is, by definition, the centre of magnitude. Therefore the centre of gravity cannot be different from the centre of magnitude of the water. And the major premise is proven: for if the convex surface of the water receded more from the centre of gravity (or of the Universe) on one side than on another, then that part, being farther removed from the centre of gravity, would not flow down to a lower place — which without doubt is the one nearer to the centre of gravity, or of the Universe — as appears from the first figure of this question, in which the centre of the earth's magnitude is the same as the centre of the world, but the centre of the water's magnitude is distinct from it. And since this is absurd and conflicts with the nature of water, it follows that the centre of magnitude and of gravity in water are the same — which was to be shown. For which reason it must be concluded that, since earth and water have the same centre of gravity — namely that of the whole Universe, toward which they naturally incline, and which has been shown not to differ from the centre of magnitude of each element — a single sphere, or globe, is composed of both elements, and by no means two globes mutually intersecting each other.

[Margin: *Second argument* (2. ratio).]

Secondly, we shall demonstrate, by many experiments of the astronomers, that earth and water have one and the same convex surface, and consequently the same centre. For just as the Sun and the other stars rise, reach mid-heaven, and set an hour earlier for a city that is fifteen degrees more to the east [than another], and two hours earlier for one that is thirty degrees more to the east, and so on — in whatever tract of the earth from east to west those cities are found, provided they lie under the same parallel — so too the most experienced sailors have found that the same thing happens on the sea and Ocean. For sailors voyaging to more western regions — for example from Portugal to America, or New Spain, especially to that province called Florida — after they had advanced fifteen degrees, found, by the clearest signs, above all from a lunar eclipse, that the Sun and the other stars rise and set a full hour earlier in Portugal; and they observed that the same happens, in the same proportion, throughout the whole Ocean from east toward west. But this could in no way come about unless the convex surface of the sea were uniformly continuous with the convex surface of the earth, as is very well known to all geometers. For if the sea gradually rose into some swelling or mountain, as those of the contrary opinion fable, then the Sun would rise earlier for those who sail, after they had completed some degrees, than when they were on land. By the same reasoning, if someone were to say that the sea gradually sinks down, that proportional variation in the rising and setting

of the Sun and the other stars could not be preserved. Since this is false, it is clear that earth and water hold one and the same convex surface, from any part of the east toward the west.

Furthermore: just as, if someone proceeded on land from north to south, in whatever direction, and after walking a whole degree would find the Arctic pole depressed by one more degree — and if he had traversed two degrees on land, [would find it] depressed by two degrees as well, and so on proportionally — so exactly the same has been observed at sea. For when a voyage is undertaken from north to south — as, for example, from Portugal (where the elevation of the pole is 40 degrees) toward the Canary or Fortunate Islands — after a journey of a whole degree has been made, the pole is found to have an altitude of only 39 degrees, and so on proportionally. The contrary was observed when one sails from south to north, as from the aforesaid islands toward Portugal, or from Portugal to Britain. It is therefore a most manifest sign that the water has the same convex surface as the earth, [reckoning] from the north...

from the north to the south, in such a way that neither the land nor the sea is raised any higher, but both elements are set an equal distance from the centre of the world. Otherwise the stated proportion could not hold constant amid the variation in the pole's altitude. Since, then, the convex surface of the water nowhere differs from the convex surface of the land — neither from east to west nor from north to south — no room is any longer left for doubting that a single globe is constituted from both elements.

This argument carried such weight with a certain man who was maintaining the contrary opinion (as I have learned from trustworthy men who were on familiar terms with him) that at his own expense he sailed off in various directions, taking various mathematical instruments with him, to test whether this proportion — which we have said is preserved in the rising and setting of the stars and in the elevation of the pole — was true, or was a fabrication of the astronomers. And when he found it to be entirely true, he abandoned his earlier mistaken opinion and embraced the true view.

[Margin: 3. Argument.] Thirdly, our conclusion can be established from lunar eclipses, by the following reasoning. In every eclipse of the Moon the shadow of the aggregate of land and water is round, in whatever part of the sky the eclipse occurs. Therefore the land and water must compose a single globe.

The antecedent is clear from the still-uneclipsed parts of the Moon: these are horned, that is, bounded by a circular arc, as experience has made known to all

astronomers, and even to those who have observed but a single lunar eclipse. The shadow must therefore be of the same shape, namely circular. For if it were square, or triangular, or of any shape other than spherical, the Moon would not be seen to enter the shadow in a circular manner, but after the manner of a shadow that is not round — which conflicts with experience. And the inference is a necessary one. For as the writers on optics [Perspectiui] show, the shape of every shadow imitates the shape of the opaque body that casts it: if the opaque or shadow-casting body is round, a round shadow too is projected; if the shadow-casting body has straight sides, a shadow of the same figure is seen; and so with the rest, as anyone can very easily verify.

Since, therefore, the shadow appears perfectly round in every lunar eclipse — as the still-uneclipsed parts indicate — we must necessarily conclude that the body producing that shadow, namely the compound of land and water, is round and spherical. For if the aggregate of land and water were of some other shape — somewhat oblong, say, and irregular, as the opposing view maintains — the shadow in the eclipse would likewise take on such a shape, which is false.

Now if those who hold the contrary view should reply that, even if the whole Ocean and sea were heaped up into a very high swelling above the land, it would still not follow that the shadow would fail to appear in a lunar eclipse — since, they say, the water casts no shadow of its own, but only the land, which is round — the answer is that this reply is quite absurd. For the whole Ocean and sea is strewn with almost countless islands, so that, whichever way one sails, if the sailors of our time are to be believed, there are always found either continents or islands; and since these are continuous with the mainland (for no one would say that they float upon the waters), who does not see that, if the arrangement of these two elements were such as they imagine, the shadow of the earth together with the shadows of all the islands would necessarily be produced marvelously broken and misshapen? Since this runs contrary to experience, these two elements are not arranged as our opponents would have it; rather, they make up a single globe, so that the islands found in mid-ocean are no farther from the centre of the world than the continents, but equally distant, so that the shadow in an eclipse is produced round, as experience teaches. There is this too: water undoubtedly casts some shadow of its own, as experience attests, especially seawater, which is denser and thicker than other waters. Let us conclude, then, that since the shadow of the aggregate is always round, the aggregate itself is likewise round and spherical.

This same truth can be confirmed by a common experience, which Ptolemy also adduces (*Almagest* I.4) and Johannes Regiomontanus [Regiomontanus] (Book I, conclusion 2), and which is roughly this. When we are in the middle of the sea we see nothing at all but sky and water; but when we make for the shore, then first the mountains, cliffs, citadels, towers, and other such things are seen gradually to rise up, as if they were emerging from the water — and this in such a proportion that first the peaks of the mountains and the tops of the towers appear, then their middle parts, and last of all their lowest parts near the shore. This would by no means happen in so orderly a way if the sea were raised above the land, or if the surface of the sea were not continuous with the surface of the land so as to make one surface out of both. For if the sea were raised up in the middle, so that its circumference were not continuous with the circumference of the land, then, once someone had climbed the summit of the swelling that (according to those authors) the sea forms, he would at once see everything set along the shore — just as, when someone reaches the top of a mountain, he immediately takes in at a single glance everything lying on the plain below. But that is absurd: for it is first the things that are higher on the shore, and then those set in a lower place, that come into view.

There is a further point. If the land and water did not have one and the same continuous convex surface, but the water rose gradually, it would follow that a man who sails out of a harbour in a ship could not fail to see a marker set up by the shore, since it would be rising up — which is against experience. Add to this that, since water by its own nature flows together to the lower places, as experience shows, it will always be received into the hollows of the land until it fills them and is brought to a level with the land. For in this way it stands equally distant from the centre of the world, is set in equilibrium, and so makes one spherical surface together with the land.

This view will also be confirmed very clearly a little later, when, together with our author, we shall demonstrate that both the surface of the land and that of the water surround the centre of the whole Universe equally — from which it plainly follows that the centre of both elements is one and the same, and that therefore a single globe is constituted from them.

[Margin: Why the earth alone occupies the centre of the world, and not also the water.] But someone will perhaps ask: since water and land possess the same centre, as has been proved — the centre to which, when unhindered, they descend along the same straight line — for what reason does the land alone occupy the centre, and not the water as well? For we see the water spread out

above the surface of the land. The answer is that there is a natural distinction between the element of earth and the element of water: the earth, by its greater weight, occupies the centre, whereas the water, being not so heavy, naturally remains above the earth, as the philosophers assert. So much so that, if the earth were perfectly round and formed a smooth globe, the element of water would cover the whole earth on every side; and this would also happen if there were so great a quantity of water that it filled all the hollows of the land and rose above the mountains. But since the earth is not perfectly spherical — because of its mountains, crags, rocks, and valleys — and since there does not exist so great a quantity of water as to be able to cover the whole surface of the land, the result is that all the water has been received into the various hollows of the land, yet always standing, along its convex surface, equally distant from the centre of the world, as the foregoing arguments have shown.

[Margin: How it is to be understood that a single globe is constituted from land and water.]

But when we said that a single globe is made from land and water, this must not be understood as though the perfect globe that the geometers define resulted from the two elements. For that is false, if we wish to speak geometrically and strictly. First, because the straight lines going out from the centre of this globe to the tops of the highest mountains will undoubtedly be longer than the straight lines drawn to the lowest parts of the deepest valleys, so that the definition of a geometrical globe cannot fit it in every respect. And second, because the convex surface of the water is contained beneath the surface of the land at an equal distance, like a smaller circle beneath a larger one having the same centre — so much so that, if the whole surface of the water were completed about the centre of the world, and likewise the whole surface of the land, the former would be contained beneath the latter at this same constant distance. But since this unevenness or inequality, compared with the whole mass composed of land and water, is of practically no account — so that it is scarcely perceived by the senses — the result is that the aggregate of land and water is simply called by the astronomers a round, or spherical, globe.

That the surface of the water is contained beneath the surface of the land at an always equal distance can easily be made convincing, once we assume that from east to west, along the equinoctial circle [*Æquinoctialis*], continents, islands, peninsulas, and so on are traversed — a thing that the navigation of our own time, especially that of the Portuguese, plainly teaches, though it was quite unknown to the ancients. For if a great circle is described upon the land, lying

directly beneath the celestial equator, passing through the island of São Tomé [insula D. Thomæ], through Africa, through Taprobane [Taprobana; Sri Lanka] in the East Indies, through the Molucca Islands, through the province of America or New Spain that is called Peru, until it comes round again to the island of São Tomé — this circle, at least near the shores, will contain beneath itself the surface of the sea, seeing that one descends from land to sea on every side, as is clear from the running-down of the rivers. From this we shall now draw our intended conclusion, as follows. The arc described on the surface of that sea which lies between Africa, for example, and Taprobane is at an equal distance from the arc of the described circle on the land, which passes through Africa and Taprobane, and so on. And the same must be said of any arc of the sea's surface lying between any two lands whatever. Therefore the whole surface of the water is contained beneath the whole surface of the land at an equal distance. The inference is excellent, resting on a sufficient enumeration of parts. And the antecedent is proved: for if that arc described on the sea were not equidistant from the arc of the land, but rose higher in the middle, or sank lower, or even crossed over the arc of the land by cutting it, it would follow that the two arcs do not have the same centre, as is established among the geometers — which we have already refuted, since it has been proved that the centre of both elements is one and the same.

It remains for us to bring forward, and to resolve, some objections that might be raised against our view. For although the experiences adduced so far show clearly that the centre of land and water is one and the same, and hence that a single globe is constituted from them, there are nonetheless some considerations that seem to create a difficulty and to prove that these two elements can in no way make up a single globe.

[Margin: 1. Objection.] First, then, one might try to prove that the centre of land and water is not the same, and hence that a single globe is not composed of them, as follows. Land and water differ in weight, for it is agreed that land is heavier than water. Therefore they cannot have the same centre of gravity and of magnitude; rather, the land by its weight will drive the water out of the continuous [region] of the whole universe, which is owed to the land because of its supreme weight — just as a globe that is partly of wood and partly of lead cannot possess the same centre of gravity and of magnitude, since the latter is at its middle, while the former is in the leaden part, as the heavier.

[Margin: Solution of the objection.] To this objection the reply is that it proceeds from a false assumption: for it supposes that the land is entirely on one side and

the whole sea on the opposite side, which is false. For by the voyages of our own age — under the poles as well as under the equinoctial circle, in the east as well as in the west, and in short over the whole globe — there have been found either continents, or islands, or peninsulas, so that over almost the whole globe land and water are intermingled. For the sea is strewn with almost countless islands, so much so that more land, or at least not much less, appears outside the sea than is covered by the waters — as Alessandro Piccolomini [Alexander Piccolomineus] admirably proves in his little book *On the Quantity of Land and Water*. Hence we say that this globe, which we assert is made up of land and water, is so constituted that the land stands out on every side while the water settles down in the lower parts. The land, then, presents the appearance of a kind of wooden globe in which there are very many hollows in which water can be received. For in this way this globe is so balanced by an equality of weights that it has the same centre of gravity and of magnitude. And Aristotle too seems to be of this opinion (*Meteorology* I), where he says: [Margin: "The mass of the earth, which has embraced even the whole quantity of water, does not amount to the ratio of a single particle in comparison with the surrounding magnitude."] By these words he plainly seems to assert that the water is contained within the hollows of the land, since he says that the land holds within itself the whole quantity of water. Indeed, natural reasoning drawn from experiment seems to persuade us of this very thing. For we find that waters flow together and fall away toward the lower and more hollow parts of the land, so that they are contained within the higher places of the land no otherwise than valleys are contained within mountains, until all the parts are brought to a level and made exactly even — as Aristotle rightly demonstrated (*On the Heavens* II), whose argument we adduced above.

[Margin: 2. Objection.] Next, someone will object in this way. The uncovered parts of the land are less heavy than the parts covered by seawater, on account of the air enclosed in caverns and the heat of the Sun, which continually dries them out. Since, then, the centre of gravity in a body of uneven weight lies in its heavier part, the centre of gravity of the land will be nearer to those parts that are covered by the waters than to those that are uncovered; and so the centre of gravity of the land will be different from its centre of magnitude.

[Margin: Solution of the objection.] But this objection too seems to assume the same thing as the previous one, namely that the uncovered parts of the land belong to one hemisphere and the covered parts to the other — which is not true, as we have said. We reply, then, that the uncovered parts are indeed less heavy, absolutely speaking, on account of the causes mentioned, which without doubt diminish their weight; but since the enclosed air and the Sun's heat penetrate an

almost imperceptible part of them, if that is compared with the whole depth of the land (for the air scarcely reaches, by penetrating, one or two miles, whereas the whole depth of the land embraces 3,579 [?] miles and more, as we shall say at the end of this chapter), and since there stand in those very uncovered parts immense and numerous mountains and crags, while in the covered parts almost countless islands are found which rise above the sea, furnished even with the highest cliffs, and finally the whole earth is full of water, as experience shows (since everywhere, when the ground is dug, water is found) — the result is that the uncovered parts, together with the covered ones, with the addition also of the seawater that is spread above the covered parts, are so balanced, and the weight of all the parts is as it were compensated, that the centre of gravity of both ele-

—ments, namely of the land and of the water, is equally distant from their surface, just as it in fact is, as we demonstrated above by many experiments. Nor is it any objection that the surface of the land is somewhat higher than the surface of the sea, as we said above, so as to prevent the centre of gravity from being at an equal distance from each surface. For that excess is exceedingly small in comparison with so great a magnitude, so that both surfaces may rightly be said to be equally distant from the centre — if we consult the senses, which report the water to be of the same height as the land, although, precisely and geometrically speaking, this is not true.

By this too is dissolved the argument that we urged above against the authors who defend the position opposed to our view — namely, that according to them more miles must correspond to one degree at sea than on land, seeing that they make the sea higher than the land, and by more. For now this same argument could be turned back against us, since we make the land higher than the water, from which it seems to follow that more miles correspond to one degree of land than of sea. This argument, turned back against us, is dissolved, I say, because that excess of the land's height above the sea's height, which we posit, is of no account but altogether imperceptible. Hence nothing is concluded against us; but against our adversaries it has the greatest force, since they posit the water to be many times larger than the land — namely in a tenfold proportion — from which it necessarily follows that there are more miles in one degree of the sea's surface than in a degree of land.

[Margin: 3. Objection.] Thirdly, someone relying on the judgment of the senses might rise up against us with this reasoning. How can a single globe be made from land and water, when neither the land nor the water appears to be round? For when someone climbs the top of some mountain, from which he may look out

over a great plain of land and the surface of the sea, both the sea and the land are judged by the senses to be flat and by no means round; and the difficulty seems especially great with respect to the land, on account of so many mountains of enormous height and valleys of marvelous depth. It happens too that the Sun, when it rises or sets, seems to be cut off by the surface of the land along a straight line; therefore the land is flat. And the same must be said of the sea. For if the land and the sea were round, they would surely cut off curved parts, and not straight ones, from the rising and setting Sun — just as we see that the Moon, because it is round and spherical, cuts off curved parts from the Sun in a solar eclipse.

[Margin: Solution of the objection.] Yet this objection must be met by pointing out that our senses are here deceived in a remarkable way. For that portion of the surface of the land and sea which someone stationed on a mountain, however high, can survey is so small in comparison with the whole magnitude of the land and water that no curvature can be perceived in it — no otherwise than if, from some very large circle whose circumference embraces, say, 2,000 paces, a portion of three or four hand-breadths were taken away. For in that portion taken away we should perceive no curvature at all, but it would appear entirely straight; and the same holds of a sphere of the same magnitude. It ought not, then, to seem surprising that our sight cannot perceive the roundness, or the convex surface, of either the land or the water.

As for the mountains and valleys existing on the land, we must say that the earth, on account of the excessive hardness of its rocks and the dryness of its other parts, could not coalesce into a globe so perfectly and completely as the water did, and that for this reason it has remained so rough and full of all those hills, mountains, and valleys — in which respect nature seems in a way to have taken thought for the plants and animals dwelling on the land, for such mountains and valleys are of great benefit to them, as experience teaches. Nevertheless, although these eminences and hollows of the land, considered in themselves, appear enormous, yet when compared with the whole terrestrial globe they are so small that they scarcely hinder its roundness at all, as is plainly evident in a lunar eclipse. Just as some huge stone globe, though roughly wrought and rough with many bumps and hollows, is nonetheless said to be, and is, round, so too must it be said of the earth, even though these eminences and hollows exist in it. Moreover, just as, if in that stone globe some tiny animal were found, it would perceive nothing but a plain, mountains, and valleys (for so great would those little roughnesses of the stone globe appear to it), so too it happens to us, who are of a tiny and imperceptible size in comparison with the terrestrial sphere, as we

walk about on the land. Finally, just as in that same globe those roughnesses do not prevent its shadow from being produced round and appearing so, in the same way these terrestrial eminences cannot be an obstacle to the earth's shadow being round, as we see in a lunar eclipse.

As for what was brought forward, finally, concerning the rising and setting Sun, the answer is that this happens because, since the land appears to the senses much larger than the Sun, from which we are very far distant, only a very small portion of the land seems to be taken in by the Sun at rising or setting — which, on account of the excessive size of the land, appears straight, as we said above concerning a small portion of a circle that has an enormous circumference. But since the Moon appears to our sight spherical on every side and of nearly the same magnitude as the Sun, the result is that in a solar eclipse it takes away circular, and not straight, portions from the Sun.

[Margin: The senses are deceived, because the sky appears to overhang the earth like an oven-vault, and the earth to touch the sky itself at the horizon, etc.] From what we have said about the globe composed of land and water, it is easy to gather how much the senses are deceived, which suppose that the sky overhangs the land like an oven-vault; and likewise that both sky and land touch at the edge of the horizon, as if these bodies were contiguous; and, on the same principle, that the Sun, when it rises, emerges from the Ocean, and when it sets, is plunged beneath the same — as the poets too tell in their fables. For since it has been proved that the land and water are concentric with the sky, a single globe must necessarily be constituted from them, so that they are equally distant from the sky on every side. Therefore the senses are deluded, because from the direction of the horizon they do not take in that space which is contained between the sky and the land.

[Margin: The error of certain Peripatetics, who set up a tenfold proportion among the elements.] From what has been said it can also be clearly gathered how absurd is the opinion of certain Peripatetics who hold — following, as they claim, Aristotle and the truth — that a tenfold proportion is preserved among the elements: so that water is ten times larger than land, air surpasses water in a tenfold proportion, and fire, finally, is ten times larger than air. For since land and water have the same convex surface, and since either the greater part of the land, or at least not much less, is uncovered than is covered by the waters, as we have said, the falsity of that opinion is clearly perceived. For so far is it from being the case that on this reasoning water is ten times larger than the land, that on the contrary the land rather surpasses the water in magnitude — seeing that

the depth of the land extends all the way to the centre and embraces 3,500 miles and more, as we shall say at the end of this chapter, whereas the depth of the sea scarcely reaches two or three miles, indeed for the most part does not exceed half a mile, as the sailors of our age have found by experience, who, even in the middle of the Ocean, investigating the depth of the sea with a sounding-lead, everywhere find the bottom, and not far from the surface of the sea. From all this it is established that the water is much smaller than the land.

COMMENTARIVS (continued) — AN EX TERRA ET AQVA VNVS FIAT GLOBVS

The same opinion can also be attacked geometrically. For if the elements preserved a continuous proportion, then the whole composite would contain the earth only one thousand, one hundred, and eleven times, as is evident in this continuous tenfold proportion 1.10.100.1000. — for all these numbers collected into a single sum make 1111. But this is utterly false and rashly asserted. For according to the astronomers, the semidiameter of the whole elemental region — that is, the distance from the center of the world to the concave [surface] of the Moon — contains the earth's semidiameter thirty-three times; indeed, according to some, this distance is greater. Hence the whole diameter of the sphere of the elements will likewise contain the whole diameter of the earth as many times, [Margin: a — (Euclid) V.15] since the proportion of the diameters is the same as that of the semidiameters. [Margin: b — (Euclid) XII.18] And since spheres are in the triplicate proportion of their diameters, it comes about that the whole sphere of the elements contains the terrestrial sphere thirty-five thousand, nine hundred and thirty-seven times (35937), as you discern in these numbers: 1.33.10809.35937. [recte: the geometric mean should be 1089 = 33^2 , so the printed "10809" appears to be a compositor error]

Add that, according to their own opinion, the distance from the center of the world to the concave of the Moon would contain the earth's semidiameter only ten times, and a little more — so that, by the law of triplicate proportion, the sphere of the elements would contain the terrestrial sphere one thousand, one hundred, and eleven times (i.e. millies, centies, & vndecies), as they wish. From which it would follow that our eye is distant from the lunar orb by only nine earth-semidiameters — which is against the experience of all astronomers.

But if anyone should say, as some of them wish, that this tenfold proportion should be understood of the diameters or semidiameters of the elements, and not of the quantity or mass of the bodies, this will be far more absurd. First, because

it is utterly false that the Moon's distance from the earth contains 1111 earth-semidiameters, since this conflicts with all astronomers, and scarcely even the Sun is removed from the center of the world by so great an interval. [Margin: c — (Euclid) XII.18] Next, since spheres have the triplicate proportion of their diameters, it would follow that water is a thousand times greater than earth, and that the whole sphere of the elements would have to the earth the proportion which this number 1000000000 has to 1 — as is evident in these numbers: 1. 1000. 1000000. 1000000000. This is indeed ridiculous, and no astronomer ever asserted it. For who would say that water is a thousand times greater than earth, when on the contrary earth is much greater than water on account of water's slight depth, as we said a little earlier is established by the experience of the navigators of our own time? It remains, therefore, that the opinion of those Peripatetics is absurd.

Indeed, not only do the elements by no means preserve this tenfold proportion, but not any other continuous one either, as Alessandro Piccolomini [Alex. Piccolom.] rightly proves in his little work *On the Quantity of Earth and Water* [*de Quantitate terræ et aquæ*], and as Jean Fernel of Amiens [Fernelius Ambianus] confirms in his *Cosmotheoria*. Nor does the authority of Aristotle [Aristoteles] stand in the way — the authority which the said Peripatetics adduce in confirmation of their opinion, when he says that from one handful [pugillus] of earth ten handfuls of water are generated, from one of water ten of air, and finally from one of air ten of fire. For Aristotle asserted this either by way of example, or, if he really thought so, it must be understood thus: if water had to be generated out of the whole quantity of earth, the water so produced would be tenfold greater than the earth, and so of the rest — not, however, that the elements now actually existing have such a proportion. For in that case there would have to be equal matter in all the elements, which Aristotle nowhere affirmed; indeed it seems to be contrary to experience.

For not only is water smaller than earth, as we said, but air too seems to be smaller by many parts. For it is likely that the aerial region is only that in which the vapors drawn from earth and water — even the most subtle — have their dwelling, since there is no better reason why they should be able to exist in one part of the air rather than in another, if in any. And since the highest elevation of vapors is to 52 miles or thereabouts — as is proved geometrically by Alhazen [Ibn al-Haytham] in book 7 of his *Perspectiva*, by Witelo [Vitellio] in book 10, proposition 60, and by us toward the end, in the *Digression on Twilights*, proposition 6 — it must be said that the height or depth of the air contains 52 miles or thereabouts, and no more, so that at so great an interval from the earth lies the boundary of air and fire. Otherwise vapors could ascend still higher,

unless the dryness and heat of fire resisted; and this has been seen by no one to happen up to now.

Since these things are so, we shall easily find how much smaller air is than earth and fire. [Margin: By how much air is smaller than earth and fire; and likewise by how much fire is larger than earth.]

For since the semidiameter of the earth, according to Ptolemy [Ptolemæus], comprises about 3579 miles, and its whole diameter 7158 miles; and since the distance from the center of the earth to the convex [surface] of the air comprises 3631 miles [as semidiameter], and the whole diameter of the globe composed of earth, water, and air 7262 miles — hence, by the precepts handed down at the end of this chapter, we shall find the greatest circle of each globe (both of the one made of earth and water, and of the one made of earth, water, and air), and from this the solidity [volume] of each globe.

For if we multiply 7158, the diameter of earth and water together, by $3\frac{1}{7}$, we produce the circumference of the greatest circle of the terrestrial globe, $22496\frac{1}{2}$ miles, whose half is $11248\frac{2}{7}$. If this be multiplied by 3579, the earth's semidiameter, there is produced the greatest circle [area] of $40257614\frac{4}{7}$ square miles; and if this in turn be drawn into 4772 — that is, $\frac{2}{3}$ of the whole diameter of the earth — there is produced the solidity of the terrestrial globe, $192109336734\frac{2}{5}$ cubic miles.

Again, if we multiply 7262, the diameter of the globe made of earth, water, and air, by $3\frac{1}{7}$, we shall find the circumference of its greatest circle, $22823\frac{1}{2}$ miles, whose half is $11411\frac{1}{2}$. If this be drawn into 3631, the semidiameter of the same globe, there is generated the greatest circle of that globe, $41435934\frac{4}{7}$ square miles; and if this in turn be drawn into $4841\frac{1}{3}$ — that is, $\frac{2}{3}$ of the whole diameter of the same globe — there is produced the solidity of the same globe, 200605171238[?] cubic miles. From this solidity, if the solidity of earth and water already found be subtracted, there remains [the solidity of the air], 8495834503[?] cubic miles; from which it comes about that earth and water together have to the air alone a proportion greater than 22 to 1, but less than 23 to 1.

Furthermore, since the semidiameter of the concave [of the Moon] [comprises $120630\frac{2}{5}$ miles], a little less, and the whole diameter $241261\frac{1}{2}$ miles: if we multiply this diameter [by $3\frac{1}{7}$], we find the circumference of the greatest circle of the sphere of the elements to contain 758250[?] miles, whose half is 379125[?]. If this be drawn into $120630\frac{2}{5}$, the semidiameter of the concave [of the Moon], there will be completed the greatest circle of the elementary sphere, 4573413186[?]

square miles; which if we again multiply into 160840 $\frac{20}{21}$ — that is, $\frac{2}{3}$ of the whole diameter of the same sphere — we shall procreate the solidity of the same elementary sphere, 73559213251333313[?] cubic miles, that is, roughly 7355921325133313 $\frac{1}{4}$. And if from this solidity we subtract the solidity of the globe made of earth, water, and air which we found a little before, the remainder becomes the solidity of the fire alone, 73557207199620754 $\frac{1}{2}$ cubic miles. From which it comes about that fire has to earth a proportion greater than 38289 to 1 but less than 38290 to 1; and that the same fire has to air a proportion greater than 865803 to 1 but less than 865804 to 1.

And so, if the globe made of earth

and water be put as 23, the quantity of air will be about 1, and of fire about 865803 — for here we neglect the small fractions that do not make up a unit. I have said these things so that it may appear how rashly some men dare to affirm that there is a tenfold proportion among the elements.

But if anyone should contend that air extends beyond 52 miles, even though vapors do not ascend farther, on account of the excessive dryness and heat of that air, the dispute will be about a word. For that very thing which is exceedingly dry and hot above the air, we call fire — just as Aristotle too affirms in book 1 of the *Meteorologica*, treatise 1, chapter 4, where he says:

But we must understand that, of the air we have spoken of, the part which is around the earth is as it were moist and hot, because it holds the vapor and exhalation of the earth; but the part above this is now hot and dry. For the nature of vapor is moist and hot, while that of exhalation is hot and dry.

Likewise in the same book, treatise 2, chapter 1, writing thus:

For first, beneath the circular motion, is the hot and dry, which we call fire. It is unnamed, and common in every smoky dispersion; nevertheless, since such a body is most apt to be burned up, it is necessary to use these names thus. And beneath this nature is air.

Indeed the same Aristotle, in other places, calls the exhalation "fire" [when it is] beneath the concave of the Moon, as in the same book, treatise 2, chapter 4, writing to this effect:

For it is assumed by us that, of that [part] of the world which is around the earth, insofar as it is beneath the circular motion, the first part is the dry and hot exhalation. And this itself, together with much of the air

continuous beneath it, is carried around the earth by the [heavenly] course and circular motion.

From all these passages it seems evident that Aristotle calls "air" only that part beneath the concave of the Moon in which vapors exist, and the rest "fire." Wholly empty, therefore, and to be rejected is the opinion of those who posit a tenfold proportion among the elements, since there is no continuous proportion among them at all; indeed both water and air are smaller than earth, as is clearly evident from what we have said.

It is gathered again from what we have said — namely, that all heavy things tend toward the center of the whole universe, which is also the center of water and of earth — that all plumb-lines and heavy bodies, freely let down from different places, draw near to one another, so much so that at the center of the earth, or of the Universe, if they should reach it, they would meet at a single point, as you observe in the figure set beside. [Margin: That buildings constructed to the perpendicular are not parallel, but would come together at the center of the world if they were extended.] But since the whole distance to the center, considered in itself, is exceedingly great, it comes about that in a small space this convergence of the plumb-lines cannot be perceived. For if two plumb-lines are distant from one another by ten spans, or a hundred, or even more, then — because this distance is exceedingly small in comparison with the earth's semidiameter, and consequently the angle of their meeting at the center of the world turns out to be very small — they will seem to be altogether equidistant. And this is the reason why buildings constructed to the perpendicular appear equally distant, or parallel, even though in reality, in the lower place, they are nearer one another, while in the upper they are more separated one from another. And you will say the same of any two walls whatever. And so, if a well were dug to the perpendicular right down to the center of the world, its sides would continually taper inward, though imperceptibly, until, meeting at the center, they completed the figure of a pyramid whose base would be the mouth of the well, and whose vertex the center of the whole Universe. Similarly, if a tower of as great a height as the earth is deep were built to the perpendicular, its sides at the summit would be wonderfully distant from one another. From which it follows that all walls built to the perpendicular tend straight toward the center, just as any straight lines of a circle issuing from the center meet at the center. And unless this were observed by the builders, buildings could stand by no reasoning.

Diagram. A circular woodcut (representing the globe, or the mouth of a well) with two nearly-vertical plumb-lines descending from above and converging toward a single point at the center of the circle. It illustrates that plumb-lines and walls built to the perpendicular from different places are not truly parallel but would meet at the center of the world. No lettered labels appear on the figure.

From this it is further inferred that no pavement built to the level or to the perpendicular is flat, but lies "librated" [level] — that is, equally removed on all sides from the center — and is a portion of some sphere whose center is the center of the world, or of the earth; [Margin: That a pavement built to the level or the perpendicular is not flat, but is a portion of a sphere whose center is the same as the earth's.] since the plumb-lines, always inclining toward the center, are gradually drawn together, as we said, and compel the pavement to be round. But this roundness cannot be perceived in a modest space, just as neither can the roundness of earth or water. Yet some huge pavement — of, say, 3000 or 4000 paces — built to the level would altogether display some swelling. Hence it comes about that some immense rectilinear pavement, that is, laid out along a straight line, cannot in the least be called "librated." For those things are properly called "librated" which are equally removed from the center of the world — such as the outermost surface of water, wherever it is placed — the kind of thing which a rectilinear or flat surface cannot be. For if from the center of the world very many straight lines be extended to that [surface], the shortest of all will be the one which stands perpendicular to the surface; while the rest, the farther they are from the perpendicular, will also be so much the longer, as you discern in this figure, and as can easily be proved from proposition 19 of book 1 of Euclid. Wherefore that point in the plane upon which the perpendicular falls will be nearest the center, and consequently lowest; whereas the remaining points of the plane will be farther from the center, and therefore higher, so that the extremities of the plane are highest and nearest the heaven. Wherefore, if someone were to walk in that plane around the point nearest the center, he would think he was walking altogether on a level, since he would feel no rise in so small a space — whereas in truth he would now be ascending, now descending, so that the farther he had withdrawn from it, the more steeply he would ascend, until at last the steepness denied him further ascent — as can be perceived more clearly than daylight in the figure set forth. Hence it also comes about that, if anyone walks about on some librated pavement (such as the surface of earth or water), his head is carried more swiftly than the middle parts of his body — because, of course, in the same time both the head and the middle parts of the body describe a portion of a circle whose center is the same as that of the earth; and it is clear that the head describes a greater circle, since it is farther

from the center than are the middle parts of the body, which are nearer the center.

Diagram. A woodcut showing a globe (a shaded semicircle at the bottom) from whose upper region many straight lines fan out to a horizontal line above, each line tipped with an arrow. The central line is perpendicular (and shortest); the lines toward the edges are progressively longer and more oblique. It illustrates that a level pavement is really a portion of a sphere, the perpendicular being the shortest line from the center to the surface. No lettered labels appear on the figure.

It is likewise left clear from what has been said that any vessel whatever receives more water when placed in a lower position than in a higher — as, for example, at the foot of a very high mountain than at its summit. [Margin: That more water is contained in a vessel at the foot of a mountain than at its summit.] For since, as we showed above, every portion of resting water, in whatever place it is contained, lies "librated" — because by its own nature it flows together toward lower places and produces a spherical surface whose center is the center of the world — it is clearer than

daylight that the surface of water, the nearer it is to the center, forms the smaller sphere, since it possesses the smaller diameter. And since one and the same straight line cuts off a greater swelling from a smaller circle or sphere than from a larger, it comes about that the same vessel cuts off a greater part from the smaller sphere than from the larger, and therefore receives a greater quantity of water in the lower place than in the higher, as you discern in the figure set forth. But since so small an interval — such as is that from the foot of a mountain, even the highest, to its summit — is of no moment if it be compared with the whole semidiameter of the earth, it comes about that this difference is scarcely felt. If, however, access lay open all the way to the center, we should there plainly behold with our eyes, and observe, the heap or spherical swelling of water standing upon the full vessel. For the more the water draws near to the center, the more perceptibly does it also acquire roundness; so much so that, if the earth were to withdraw from the center of the world and access were opened to the water itself, the whole multitude of the water would at once flow together to the middle of the world, and at the first rush would surge this way and that, until little by little, the impetus of its motion being slackened, it came together into a most perfect globe and equally surrounded the center of the whole world. Many other things like these can be gathered from what has been said, but which for brevity's sake I judge should be passed over.

Diagram. A woodcut of two concentric circles (the outer representing the sphere of fire, the inner the sphere of air, or the convex surfaces of the elements). Within the inner circle are drawn two truncated (trapezoidal) vessel-shapes seen in cross-section: a smaller one near the top, and a larger one at the center. It accompanies the discussion of how a vessel holds more water lower down, and of the spherical figures of the elements. [Margin: *Figura aeris & ignis*[?] — "Figure of air and fire"; the marginal caption ends with an unclear word ("*qua*"[?]).] No lettered labels appear on the figure.

Finally, that we may say something also about the figures of the remaining two elements — namely air and fire — it seems it can be concluded clearly enough that they are of spherical figure. For in the first place air, as regards its concave surface, is round, since it surrounds and encircles the round globe which we said is constituted of water and earth; and as regards its convex surface it is necessarily round, since it lies beneath the concave of the Moon. By the same reasoning Fire, as regards its convex surface [is round]. And because both fire and air seem equally to recede from the center on account of their lightness — not otherwise than heavy things tend toward the center on account of their gravity — it comes about that air (according to its convex surface) and fire (according to its concave surface) are also of spherical figure. Otherwise, that part of air or fire which drew nearer to the center of the world would not seek to ascend upward [but rather to descend], which is contrary to the natural inclination of each element[?]. It is likely, nevertheless, that neither the concave of fire nor [the convex of air is perfectly uniform][?]: for more fire seems to be generated under the torrid zone — that is, under the Equator, or near it — where the Sun continually dwells and the heaven is turned with the greatest velocity; but more air under the cold zones — that is, under the poles, or near them — on account of the great distance of the Sun, the cold, and the slowness of motion.

Nor indeed should this be passed over: that Plato [Plato], in the *Timaeus*, assigned to the heaven and to the four elements the figures of the five regular bodies (concerning which he treats in books 13, 14, 15, and 16 of Euclid), on account of certain likenesses. [Margin: In what manner Plato assigned to the four elements and to the heaven the figures of the five regular bodies.] For to Fire, on account of the sharpness of its flame, he assigned the pyramid, or Tetrahedron; for every little particle of fire ascends after the manner of a pyramid. To Air, however, the Octahedron: for just as air comes closest to fire, so too the Octahedron obtains the greatest likeness with the Tetrahedron, since it consists of two pyramids. To Water he next grants the Icosahedron, on account of its excessive mobility and fluidity. But the Cube, or Hexahedron, he assigns to Earth, on account of its

immobility and stability: for among all the regular bodies the cube is least apt for motion. Finally, to the Heaven he ascribes the Dodecahedron: for just as the heaven in its whole circuit embraces the twelve equal signs, so too the Dodecahedron is contained by twelve equal faces. I pass over the other causes or properties on account of which Plato likened the five simple bodies composing the world to the regular bodies; for you will find these treated more fully among the Platonists.

It is not, however, to be supposed in any way — as many falsely think — that the eminent philosopher Plato believed the Heaven and the four elements to be truly endowed with such figures. For he says, in the same *Timaeus*, that the World, together with all its principal parts (such as are the heavenly bodies and the elements), was made round, so that nothing rounder can be conceived; yet by a certain likeness — on account of the many properties common to the heaven and the elements with the regular bodies — he attributed such figures to them, in order the more easily to explain both their nature and their mutual transmutation of one into another. But chiefly because, just as it is altogether impossible that more regular bodies be given than those five enumerated (as has been most clearly demonstrated by us at the end of Euclid book 13), so likewise only five such simple bodies are found in the whole Universe, as is established from book 1 *On the Heaven*. Wherefore Plato means, in the *Timaeus*, only that the five simple bodies composing the whole universe correspond, by a certain proportion, to those five regular bodies.

TERRAM ESSE CENTRVM MVNDI

[Margin: That the earth is situated at the center of the world.]

That the earth is situated in the middle of the Firmament is clear as follows. To those existing on the surface of the earth, the stars appear of the same size, whether they are in the middle of the heaven, or near their rising, or near their setting; and this is so because the earth is equally distant from them.

COMMENTARIVS

In this place the Author demonstrates the fourth conclusion, namely, that the Earth is the center of the world. Understand "earth" together with water. For although the Author here speaks expressly of earth alone, the same reasons nevertheless have force for the whole aggregate of earth and water. Now since the center of any sphere ought to have two conditions — one, that it be in the

middle of it, equally removed from all its extremities; the other, that it be a point, and altogether insensible in comparison with that of which it is called the center — the Author therefore shows in this place that both conditions belong to the earth in relation to the heaven. That the earth is in the middle of the heaven, or of the whole world, he urges by two arguments, of which the first is this: When we exist on the surface of the earth, and in whatever region, the

of the same magnitude both at their rising and setting as at mid-heaven, once all vapours, mists, and exhalations that could impede our sight are set aside. Therefore we are equally distant from all parts of the heaven; and consequently the earth on which we are will be at the middle of the world, or — what is the same thing — at the centre of the world. The antecedent is confirmed by experience, while the consequence is easily proved. For if we were not equally distant from the heaven, but from one side came nearer to it than from another, then — since things that are nearer appear larger — the stars would appear larger to us when we are in the nearer part of the earth than when in the more remote part. And this is contrary to experience.

This argument is taken from Alfraganus [al-Farghānī], Difference 4. It does not conclude — if we speak strictly and geometrically — that a person in one and the same place is equally distant from all parts of the heaven; for we said above that this is false, since the heaven is farther from us on the side of the horizon, on account of the earth's semidiameter that lies between. It concludes only that we are equidistant from every part of the heaven so far as the judgment of the senses goes. For the excess is so small — as was also said above — that it cannot make the stars appear smaller, in clear weather, on the side of the horizon than at mid-heaven. Hence the stars can rightly be said, so far as the senses are concerned, to be equally distant from every place on the earth. Nevertheless the argument proves excellently that the centre of the earth is equally distant from the heaven — that is, that it is the same as the centre of the world. Otherwise some parts of the earth's surface would sensibly recede from the centre of the world, and so too the same stars would appear sensibly larger or smaller in those same regions, which is false.

Furthermore, since at rising and setting there are almost always vapours or exhalations that impede the true judgment of the senses, it does not seem firm enough to infer from the aforesaid argument that any given person is equally distant from the heaven. Hence the same argument, drawn instead from the size of the stars, will be better presented in this way. To the same person — placed now under that meridian in which the Sun is when it rises to us; now under that

beneath which we ourselves are; now under that in which the Sun is when it sets to us; and finally under any meridian whatever — the same stars appear to be of the same size when they reach the meridian, where there are no vapours in clear weather. Therefore the surface of the earth is equally distant from the stars along all those parts lying beneath the said meridians. And this argument, whether it be put in this latter way or in that former one, has the same force in the case of water; for the same appearance holds also on the sea.

From this it is clearly gathered — as we proved above — that the earth and the water have the same centre as the centre of the whole universe, since the convex surface of each is equidistant from the centre of the world, as is inferred from the argument that was drawn from experience.

[Lemma — Sacrobosco] For if the earth came nearer to the firmament in one part than in another, it would follow that someone standing in that part of the earth's surface which came nearer to the firmament would not see half of the heaven. But this is contrary to Ptolemy and to all the philosophers, who say that wherever a person may be, six signs rise for him and six set, and half of the heaven is always visible to him while the other half is hidden.

[Margin: Another argument proving that the earth is at the centre of the world.]

COMMENTARIUS

The second argument is roughly this. Wherever a person is, six signs always rise for him and six set, and one half of the heaven is always visible to him while the other half is hidden from him. Therefore the earth is at the middle of the firmament. The antecedent belongs to Ptolemy (Book 1, chapters 5 and 6 [*Almagest* I.5–6]), to Alfraganus (Difference 4), and to all the other astronomers and philosophers, who, taught by experience, all confess with one voice that we behold half of the heaven in whatever place we are, and so on. The consequence, in turn, is necessary. For if the earth were not at the middle of the heaven, but came nearer to one part than to another, then the person who was in the part nearer to the heaven would not see half of the heaven but a smaller part, while the one who was in the other, more remote part would behold more than half — because not every horizon separating the visible part of the heaven from the invisible would pass through the centre of the world, and consequently it would not be a great circle, and so would not divide the heaven into two equal parts. And since this is false and contrary to experience, it will also be false that the earth is not at the middle of the heaven.

This argument is found in Alfraganus and Ptolemy at the passages cited. Here only this needs to be noted in passing: that it is impossible for anyone placed on the earth's surface to see exactly half of the heaven. For the horizon [horizon] that bounds our sight is conceived as a certain flat circular surface lying upon the earth, because when we are set in some large level plain we suppose that the visible part of the earth is flat and there touches the heaven. As a result, that horizon cannot divide the heaven into two equal halves; for there will be missing that part of the heaven which is intercepted between the surface touching (or lying upon) the earth and the surface that passes through the centre of the earth parallel to the first. For this latter alone will divide the heaven into two equal parts (Theodosius, Book 1, proposition 11 [*Spherics* I.11]), as can also be seen in the accompanying figure. But that portion which lies between the two surfaces is of no significance, of practically no magnitude in comparison with the whole fabric of the heaven. For since the heaven is wondrously distant from us — as we shall say later — it comes about that, if from our eye and from the centre of the earth two parallel lines were drawn up to the firmament, sight would simply judge them to meet there, on account of their too-great distance from us, and consequently would see practically no interval at all intercepted between them. Just as also in some long building whose interior walls are parallel, the walls appear to us nearer to one another at the far end than at the near one from which we look at them, on account of that distance. Much more, then, will this happen in the case of the heaven, since it is beyond comparison far more distant.

[Margin: How it is true that a person sees half the heaven.]

Diagram. A circle representing the celestial sphere, filled with vertical hatching. Two horizontal parallel lines cross it near the middle: the upper one is labelled **HORIZON**, and a small orb/eye symbol sits at the centre where the lower line passes. The figure illustrates the horizon plane touching the earth's surface and the parallel plane through the earth's centre, which are sensibly indistinguishable at the firmament.

- HORIZON (upper horizontal line): the sensible horizon
- (centre): observer's eye / earth
- (lower horizontal line): the plane through the centre of the earth, parallel to the horizon

Hence, as regards the judgment of the senses, it can very well be said that from our place on the earth — once the obstructions of mountains and valleys are set aside — we behold half of the heaven. This is clearly shown by the phenomena, that is, the celestial appearances. For we see the two luminaries — the Sun and

the Moon — when they are diametrically opposite, at nearly the same time above the horizon, the one in the east and the other in the west; or at any rate, when one sets, we see the other rise at once. This could not happen if the portion of the heaven intercepted between the two aforesaid surfaces were of any appreciable size. The same appears most clearly also from the fact that everywhere, once obstructions are set aside, six signs appear above the horizon and six below, and these occupy half of the heaven. Indeed, on the authority of Pliny (Book 2, chapter 13 [*Natural History* II.13]), the Moon has sometimes been seen to be eclipsed at the point of the east while the Sun was still in some manner above the horizon at the point of the west; and yet at that time those two luminaries were diametrically opposite.

To the two arguments already stated we can add others that establish the same thesis — namely, that the earth is at the middle of the firmament, or of the whole universe. Let the first of these, drawn from Ptolemy (Book 1, chapter 5 [*Almagest* I.5]), be as follows.

[Margin: Ptolemy's argument proving that the earth is at the centre of the world.]

If the earth is not situated at the middle of the firmament, or of the whole universe, it will necessarily occupy one of these positions. Either it will be in the plane of the equinoctial circle, outside the axis of the world (for if it were on the axis of the world and in the plane of the equator, it would be at the centre of the world); or it will be on the axis of the world, outside the plane of the equinoctial circle; or, finally, it will be placed neither in the plane of the equinoctial circle nor on the axis of the world. From all these positions very many absurdities follow.

For if it were in the plane of the equator outside the axis of the world, the first result would be that in a right sphere [sphæra recta] an equinox [æquinoctium] would never occur except at that horizon which passes through the centre of the world. For let there be a sphere BDCE whose centre is A, its equator DE, the axis of the world [axis mundi] BC, and the earth at F, whether above the axis of the world or below it; and let the right horizon HG not pass through the centre of the world A — it will be parallel to the axis BC, since the equator stands at right angles to the right horizon. It is therefore clear that both the equator and the remaining parallels of the Sun are divided unequally by the right horizon, since it does not pass through the centre or the poles of the world. Hence the days will perpetually be unequal to the nights — which is contrary to all experience, since in a right sphere there is a perpetual equinox.

[Margin: That the earth is not in the plane of the equator outside the axis of the world.]

Diagram. A circle (the celestial sphere) filled with vertical hatching (the Sun's parallels). The vertical diameter D (top)–E (bottom) is the equator seen edge-on; the horizontal diameter B (left)–A (centre)–C (right) is the axis of the world. Two horizontal chords represent the right horizon and its parallel, on which the earth's position F is marked twice (above and below the axis).

- D (top): pole of vertical diameter (equator DE)
- G (upper left): end of upper horizontal chord (right horizon HG)
- F (upper middle, on upper chord): earth, above the axis
- H (upper right): end of upper chord
- B (left, horizontal diameter): axis endpoint
- A (centre): centre of the sphere / centre of the world
- C (right, horizontal diameter): axis endpoint
- G (lower left): end of lower horizontal chord
- F (lower middle, on lower chord): earth, below the axis
- E (bottom): pole of vertical diameter

Next: no one in the same right sphere would see half of the heaven, but a part either smaller or larger than half, as the same figure indicates — which is contrary to the senses; for there are always six signs above the horizon and six below. Only at that horizon which is drawn through the centre of the world would half of the heaven be seen.

Third: the same stars would not always appear of the same size in clear weather. For if the earth is in the plane of the equinoctial circle and outside the axis of the world toward the south — that is, toward the zenith — the same stars will appear larger when set on the meridian circle than in the east or west, since there they are nearer. But if it inclines toward midnight — that is, toward the nadir — they will be seen larger when placed in the east or west than on the meridian circle. And if it is situated toward the east or the west, they will appear larger when placed in the east or the west as well. All of which conflicts with experience. There is the further point that, on this latter supposition, the time before noon will be by no means equal to the time after noon, because the meridian circle passes through the vertex of the head, which on this reckoning cannot be at the middle of the hemisphere, but comes nearer either to the east or to the west, as is plainly established from a material sphere. Therefore the phenomena will hold

good only in a right sphere, when the earth is placed at the middle of the world, as at point A, with the right horizon being BC.

Fourth: in an oblique sphere [sphaera obliqua] either no equinox would occur at all, or at any rate, if it occurred anywhere, it would not fall at the midpoint between the summer and the winter solstice — which we see to be contrary to common experience. For let there again be a sphere ABCD whose centre is E, its equator BD, the two tropics IL and XH, the axis of the world AC. If, then, the earth lies in the plane of the equinoctial circle outside the axis, as at F, let there first be an oblique horizon ZFY, cutting all the parallels into unequal parts and cutting the axis at ϕ , outside the parallels. It is therefore manifest that no equinox occurs at the said horizon, since the horizon bisects only that parallel which is described through ϕ — which, however, the Sun can never reach, since it does not depart from the equator beyond the tropic XH. Next let there be another oblique horizon OFM, cutting the axis AC within the parallels at N. It is now clear that an equinox occurs at the aforesaid horizon while the Sun describes the parallel through N, since this parallel is bisected by the horizon; but this can in no way happen at the time midway between the two solstices, since the equator BD alone is equally removed from each solstice. And it is manifest that, when the Sun is on the equator BD, there cannot be an equinox, but only before or after — which is indeed absurd and unfitting.

Diagram. A large circle (the oblique celestial sphere ABCD) filled with vertical hatching (the Sun's parallels). The horizontal diameter runs C (left)–K–E (centre)–N–G–A (right); the vertical diameter runs B (top)–E–D (bottom, the equator BD edge-on). Two chords represent the tropics (IL and XH); two oblique lines represent the oblique horizons ZFY and OFM, crossing near the earth-positions and the axis-points ϕ and N.

- B (top): equator pole / top of vertical diameter
- I (upper left, inside near top): tropic endpoint
- X (upper right): tropic endpoint
- O (upper left, on circle): endpoint of oblique horizon OFM
- Z (left, below O): endpoint of oblique horizon ZFY
- Q (interior, below O): construction point
- V (interior, mid-left): construction point
- F (interior, centre-upper): earth, on the horizon lines
- C (left end of horizontal diameter): axis endpoint
- K (interior, left of centre): construction point

- E (centre): centre of the sphere / centre of the world
- N (interior, right of centre): where horizon OFM cuts the axis
- G (right of N): outermost-parallel point on the axis
- φ (right of G): where horizon ZFY cuts the axis, outside the parallels
- P [?] (small mark below N/G; text references triangle PNG — label not clearly resolved on the scan)
- A (right end of horizontal diameter): axis endpoint
- Y (lower right, below A): endpoint of oblique horizon ZFY
- T (lower right): construction point
- M (right, below Y): endpoint of oblique horizon OFM
- R (lower right): construction point
- L (lower left): tropic endpoint
- H (bottom right): tropic endpoint
- D (bottom): equator pole / bottom of vertical diameter

Fifth: no horizon would divide the heaven into two equal parts except the one that coincides with the equinoctial circle — such as BD — and the others that are drawn through the straight line BC. Hence not everyone would behold half of the heaven.

Sixth: the excess of the longest day over the equinoctial day would not be equal to the deficiency of the shortest day by which it falls short of the equinoctial day — which is contrary to daily experience. For instance, if A is the north pole, PG will be the excess of the longest day XP over XG, the equinoctial day; but KQ will be the deficiency by which the shortest day IQ falls short of the same equinoctial day IK. All these absurdities, however, are avoided if the earth is placed at the centre E. For then, at any oblique horizon whatever — namely SR — an equinox will occur when the Sun is on the equator; the heaven will be divided into equal halves, and TG, the excess of the longest day, will be equal to KV, the deficiency of the shortest day, and so on.

But if the earth were placed on the axis of the world outside the plane of the equator — namely at the point φ — all these unfitting consequences would follow. First: no horizon except the right one would cut the heaven into two equal parts, and therefore neither would it cut the zodiac — which conflicts with the appearances. For half of the zodiac is always above any given horizon and half below, since six signs are always above the horizon.

[Margin: That the earth is not on the axis of the world outside the plane of the equator.]

Next: an equinox would occur only in a right sphere, since only the right horizon would bisect the equator — as is clear from the figure above, in which the equator is BD, the right horizon AC, and the oblique horizon YZ, cutting the equator at F into unequal parts. And if an equinox happened to occur at some oblique horizon, it would by no means fall at the time midway between the two solstices, but the equinox would be much nearer to one of the solstices than to the other. For example, if the earth were placed at N, between the tropic XH and the equator BD, an equinox would occur when the Sun runs along the parallel described through N; and this equinox is far nearer to the summer solstice than to the winter one. And if the earth were situated at G, an equinox would fall on the very day of the summer solstice. All of which is utterly absurd.

Third: the whole series and proportion of the increase and decrease of the days and nights would be thrown into confusion — the series which everywhere outside a right sphere appears before and after the equinox. It is such that twice a year the days are made equal to the nights, namely at the time midway between the longest and the shortest day; that the longest day is equal to the longest night, and the shortest day to the shortest night; and that the excess of the longest day over the equinoctial day is as great as the deficiency of the shortest day from the same equinoctial day. The same must be said of any two days equally removed from the equinoctial day, of which one is before and the other after the equinox, and other things of this kind. This perpetual series and proportion can hold and be preserved only if the earth is placed at the centre E. For on this arrangement any oblique horizon whatever — namely SR — will divide the equator BD into equal parts, so that as great a portion of it stands above the horizon as lies hidden below the horizon, and accordingly the day will be as long as the night. In like manner the tropics XH and IL will be cut into unequal parts, yet so that the alternate segments are equal — namely TX and VL, and likewise TH and VI — as Theodosius demonstrates (Book 2, proposition 19 [*Spherics* II.19]). From this it comes about that the longest day XT is equal to the longest night LV, and the shortest day IV to the shortest night HT. Finally, TG, the excess of the longest day XT over the equinoctial day XG, will be equal to KV, the deficiency of the shortest day IV from the equinoctial day IK, on account of the similarity and equality of the triangles TEG and VEK. But if the earth is set on the axis outside the centre E, as at ϕ , outside all the parallels, no equinox can occur in an oblique sphere, as has been said; and the days will always be longer than the nights, or the nights than the days. And if the earth is placed at the point G, through which the outermost parallel passes, only a single equinox would occur in an oblique sphere, namely at one of the solstices; and for the rest of the year all the days would be either greater or smaller than the nights. But if the earth is set within

the parallels at the point N, an equinox would indeed occur twice a year, and on both sides the spans of the days and nights would increase and decrease; yet these increases and decreases of the days would be equal neither in number nor in magnitude to the decreases and increases of the nights — which even the eyes can very easily judge, by comparing the two triangles PNG and QNK with each other, since both more and larger segments of the parallels are comprised in triangle QNK than in triangle PNG.

Diagram. The oblique celestial sphere, repeating the construction of the previous figure. A large circle filled with vertical hatching (the Sun's parallels); the horizontal diameter runs C (left)–K–E (centre)–N–G–A (right); the vertical diameter runs B (top)–E–D (bottom). Chords represent the tropics IL and XH; oblique lines represent the horizons ZFY and OFM.

- B (top): equator pole
- I (upper left): tropic endpoint
- X (upper right): tropic endpoint
- O (upper left, on circle): horizon OFM endpoint
- Z (left, below O): horizon ZFY endpoint
- Q (interior, upper): construction point
- V (interior, mid-left): construction point
- F (interior, centre-upper): earth, on the horizon lines
- C (left, horizontal diameter): axis endpoint
- K (interior, left of centre): construction point
- E (centre): centre of the world
- N (interior, right of centre): horizon OFM $\cap$ axis
- G (right of N): outermost-parallel axis point
- φ (right of G): horizon ZFY $\cap$ axis
- P [?] (small mark near N/G; text references triangle PNG — not clearly resolved on the scan)
- A (right, horizontal diameter): axis endpoint
- Y (lower right, below A): horizon ZFY endpoint
- T (lower right): construction point
- M (right, below Y): horizon OFM endpoint
- R (lower right): construction point
- L (lower left): tropic endpoint
- H (bottom right): tropic endpoint
- D (bottom): equator pole

Fourth: the shadows of gnomons [gnomon] that make right angles with the horizon would not, at the time of the equinoxes, be cast along one and the same straight line from east to west when the Sun is precisely at its rising and its setting, if the earth were unequally removed from each pole and its centre were not the same as the centre of the world. For let the earth first be at A, situated in the plane of the equinoctial circle — which the line BC represents for us — and let a gnomon be erected upon the plane of the horizon, which the circle BC stands for. You now see clearly that when the Sun rises at B, the shadow of the style AD is cast along the straight line AC; and likewise, when the Sun sets at C, the same shadow is cast along the straight line AB, which with the former AC makes one straight and continuous line. This the appearances observed by astronomers show us most clearly, and the cause of it is simply this: that the earth is situated in the plane of the equator. For if it were placed outside that plane — yet on the axis of the world, or even toward any part whatever, namely at E — and if an erect style were raised upon the horizon, such as EF, who does not see that when the Sun rises at B at the time of the equinox the shadow of the style is thrown along the straight line EG, but when the Sun sets at C the same shadow is extended along the straight line EH, which by no means makes a straight line with the former EG, but the two intersect each other at the point E, since when produced they would arrive at the points B and C? And experience teaches us the contrary of this.

Diagram. A circle with a vertical diameter D (top)–A–E (centre)–F (bottom) and a horizontal diameter B (left)–E–C (right). From the centre E two rays descend to H (lower left) and G (lower right), representing the equinoctial shadows cast when the earth (or style) is displaced from the centre of the world. AD/EF is the erect style; BC is the equinoctial line (east B, west C).

- D (top): top of the style AD
- A (below D): earth / foot of style in the equatorial plane
- E (centre): displaced position / foot of style EF
- F (bottom): foot of the erect style EF
- B (left, horizontal): east — sunrise point
- C (right, horizontal): west — sunset point
- H (lower left): end of shadow EH (sunset shadow from displaced position)
- G (lower right): end of shadow EG (sunrise shadow from displaced position)

Fifth: two signs of the zodiac diametrically opposite would never be seen through a dioptra [dioptra] — which is contrary to experience, which testifies that the

rising and setting of the Sun at the equinoxes are seen through a dioptra along one straight line; and in like manner the rising at the summer solstice and the setting at the winter solstice; likewise the rising at the winter solstice and the setting at the summer solstice, through a dioptra along a line ...

(continuing the commentary on Chapter One, still within Ptolemy's demonstration that the earth lies at the center of the world)

to correspond to one another along a straight line in any horizon whatever. This could not possibly happen unless the earth were set in the plane of the equatorial circle and at the center. For let the horizon be BDCE; the equator [æquator] BC; the axis of the world [axis mundi] DE; the Tropic of Cancer FG; the Tropic of Capricorn HI; and let the earth first be placed at the center, A. You then see plainly that the equinoctial rising B and the equinoctial setting C correspond to one another along the straight line BC; the summer rising F and the winter setting I along the straight line FI; and finally the winter rising H and the summer setting G along the straight line GH — just as the case requires. This the phenomena of the astronomers attest, and Euclid assumes it as most certain at the beginning of his *Phaenomena* [Greek: φαινομένων (phainomenōn, "appearances")]; Pliny too affirms it (book 2, chapter 71), on the view of all the astronomers. Next, let the earth be placed on the axis of the world, outside the equator — namely at K. On this supposition it is clearer than daylight that the whole opposite result follows. For the winter setting I, along the straight line that is drawn through the earth, will no longer correspond to the summer rising F, but to the point L. Likewise the summer setting G will correspond to the point M, and not to the winter rising H.

[Margin: That the earth is not outside the equator or off the axis of the world.]

Diagram. A circle (the horizon) with a horizontal diameter and a vertical diameter meeting at the center, two chords parallel to the horizontal diameter (the two tropics), and several oblique lines running to a second point near the center. Readable labels:

- D [?] (top): pole on the axis of the world (glyph resembles "B"; assigned D per "axis mundi DE" — see QA)
- E (bottom): opposite pole on the axis
- B (left, on the equator): equinoctial rising
- C (right, on the equator): equinoctial setting
- F (upper left): summer rising, on the Tropic of Cancer
- G (upper right): summer setting, on the Tropic of Cancer
- H (lower left): winter rising, on the Tropic of Capricorn

- I (lower right): winter setting, on the Tropic of Capricorn
- A (center): earth first placed at the center
- K (center, just above A): earth displaced onto the axis outside the equator
- M (left, between F and B): point of the displaced correspondence
- L [?] (lower right, near I): point of the displaced correspondence (label not clearly resolved)
- T [?] (upper left, near F): unresolved label

Finally, if the earth were placed neither in the plane of the equatorial circle nor on the axis of the world, but somewhere else, we would fall into all the absurdities already named — as anyone can easily deduce from what has been said. For in the right sphere no equinox would occur, while in the oblique sphere only that horizon would cut the sphere into equal parts which passed through the center of the world; and the whole series of the increases of days and nights, and so on, would be thrown into confusion.

[Margin: Another argument of Ptolemy proving that the earth is at the middle of the world.]

A **second** argument, likewise drawn from the passage of Ptolemy cited, and which Averroes too employs (*On the Heavens*, book 2), runs thus. If the earth were not situated at the middle of the world, eclipses of the Moon would not always occur when the two luminaries are opposed along a diameter, but would generally happen when they are not in opposite places of the Zodiac — which is false. For the observations of astronomers attest that a lunar eclipse occurs only, and always, when the Moon is opposed to the Sun, and never otherwise. Let A be the center of the world: if the earth is set there, it is manifest that an eclipse occurs when the luminaries are opposed along a diameter, since then the earth itself is interposed between the two; whereas when they are not opposed along a diameter, no eclipse can occur, for the earth cannot then be an obstacle to prevent the Moon from being lit by the Sun. But if the earth had its seat outside the center — say at B — the two luminaries could stand at opposite points of the Zodiac and yet no eclipse occur, because the earth would not be found on that diameter of the world along which they are opposed. Indeed the Moon would for the most part suffer eclipse when it is less than a semicircle distant from the Sun. In short, a lunar eclipse can occur only when the diameter of opposition has passed through the center of the earth and of the universe — all of which conflicts with the phenomena.

Diagram. Within two concentric circles (representing the heavens), two dark shaded globes and a radiant Sun at the right, with shadow-lines drawn from the Sun past the globes toward the left. Readable labels:

- A (lower globe, at the center of the world): the earth placed at the center
- B (upper globe, above and left of A): the earth placed off-center
- (radiant disc at right): the Sun

From this argument, again, we may likewise establish our thesis in this way. Let two lunar eclipses be taken which have occurred at different places of the Zodiac. Since each eclipse took place when the Moon was set opposite the Sun along a diameter — as both experience and astronomical computation have shown — it follows that the earth was necessarily on each of those diameters, and therefore at their common intersection. Since, then, all the diameters of the world intersect one another at the center of the world, the earth must be placed at the middle of the world, as appears in the figure set out.

[Margin: The argument of Johannes Regiomontanus.]

Diagram. Within concentric circles (the Zodiac) two radiant Suns stand at the top, and two diameters cross one another at the center, each ending in a small circle (the eclipsed Moon) at the lower left and lower right. No letter labels are legible.

The **third** argument is that of Johannes Regiomontanus [Regiomontanus] (*Epitome*, book 1, conclusion 3), which he seems to have taken from Aristotle (*On the Heavens*, book 2). All heavy bodies, descending freely along a diameter of the world, meet the surface of the earth at equal angles at whatever part of the sphere; otherwise they would not meet the earth's surface at equal angles. And because the diameters of the world, along which heavy bodies are carried, pass through the earth's center, intersecting there, it follows that the center of the earth and the center of the world are one and the same. Since the earth is heaviest, it certainly tends toward the lowest place, namely toward the center of the world. Naturally, then, it comes to rest there, as in its proper seat — elsewhere only by force.

[Margin: The argument of Aristotle.]

The **fourth** argument is Aristotle's. Since the earth is heaviest, it tends in every case to the lowest place — that is, to the point most remote from the heaven, which is the center of the world. Naturally, therefore, it rests there, as in its proper seat, but elsewhere by force.

[Margin: Another argument proving that the earth is at the middle of the world.]

There is this too: if this heavy mass of the earth, of the same figure, magnitude, and weight, were cut into any number of equal parts, and these were set in different places beneath the concave [sphere] of the Moon and let fall freely, then without doubt all the parts — being of the same nature, weight, magnitude, and figure — would descend with equal motion and at the same moment to the same place, converging at the center of the world. This could in no way happen unless [the earth is at the middle]. And indeed Nature, with the best right, seems to have placed the earth at the middle of the world, so that it might be equally removed from all parts of the heaven — which is the most excellent body — lest any part might be able to complain why this rude mass came nearer to it than to another part.

[Margin: That the earth is like a point with respect to the firmament.]

This too is a sign that the earth is, as it were, a center and a point with respect to the Firmament [Firmamentum]: for if the earth were of any magnitude with respect to the Firmament, it would not come about that half of the heaven is seen...

COMMENTARIVS.

By three intermediate [proofs] Johannes de Sacro Bosco now confirms the other property of a center as well — namely, that it is something imperceptible and like an indivisible point — as belonging to the earth with respect to the celestial machine. The first of these is this. If the earth had a perceptible and notable magnitude with respect to the Firmament, and did not rather exist as a wholly indivisible point, we would not be able to see half of the heaven — which is against experience and against all the astronomers, as was said above. The consequence is confirmed. For if the earth, compared with the celestial body, were of some magnitude that fell under the senses, then without doubt the surface of the earth too would recede notably from the center of the world — which we have already proved to be the same as the center of the earth. Hence the horizon, resting upon the earth's surface, would notably cut the heaven into two unequal parts, as you see more clearly than daylight in the figure set out.

Diagram. A circle crossed by two horizontal chords, with a small hatched globe (the earth) near the center between them. No letter labels.

[Margin: Confirmation of the preceding argument.]

You will find this same argument in Ptolemy (*Almagest*, book 1, chapter 6) and in al-Farghānī [al-Farghānī] (Difference 4), and it is [the view] of all the other

astronomers. You see that it has the same force in the case of the sea. For if the sea were much greater and higher than the earth — as some fancifully claim — we would not, when set in the middle of the sea, be able to see half of the heaven, or at least not equally well as on land; whereas daily experience teaches us the opposite.

Likewise, if a flat surface is understood [as passing] over the center of the earth, and consequently over the Firmament, an eye existing at the center of the earth [would see half of the heaven; and the same eye] existing on the surface of the earth sees the same half. Therefore it is evident that the magnitude of the earth which lies from the surface to the center is imperceptible, and consequently that the magnitude of the whole earth is imperceptible with respect to the Firmament.

COMMENTARIUS.

Explaining and in a way confirming the first intermediate [proof], the argument is this. If we were to imagine a flat circular surface of enormous magnitude passing through the center of the world, or of the earth, it would divide both the earth and the Firmament into equal segments; and consequently some eye existing at the center of the world, upon that surface, would look upon exactly half of the heaven — were it not impeded by the density of the earth. But the same eye, set on the surface of the earth, discerns the same half, so far as the judgment of sense goes, as Ptolemy and all the astronomers hold; and this has been ascertained by daily experience, as we said above. Therefore all that earth which lies between the center of the earth and its surface is of no account with respect to the Firmament; since the two visual rays (that is, straight lines) parallel to one another — one of which runs out from the center of the world, or of the earth, the other from the convex surface of the earth up to the heaven — intercept no magnitude whatever of any moment in the Firmament, but seem to meet exactly in the same point. This could in no way happen if this portion of the earth had any notable bulk compared with the magnitude of the Firmament. From this it is clear that the whole earth is, as it were, a point, if it be compared with the Firmament.

To make it plainer in what way those two visual rays subtract something imperceptible from the Firmament, it must be briefly explained how great is that [portion] which is intercepted between those two rays in the Firmament — which will be done in this way. Since, according to al-Farghānī, the distance from the center of the earth to the concave of the Firmament contains 22612 and a half earth-semidiameters, so that the proportion of the semidiameter of the Firmament to the semidiameter of the earth is the same [as 22612½ to 1]: let the

whole sine [sinus totus] of the Firmament be set as 100000 parts, and the semidiameter of the earth [be found accordingly].

Diagram. A large circle with the word **HORIZON** engraved across its horizontal diameter, and a small hatched globe (the earth) at the center on that diameter; a second horizontal chord runs above it. The only lettered content is the word HORIZON.

[Margin: How great is the arc of the firmament intercepted between the two parallel visual rays, one of which goes out from the center of the earth, the other of which touches the earth.]

Since, then, the semidiameter of the earth is the right sine [sinus rectus] of that arc of the Firmament — as is clear from the adjoining figure and from the definition of the right sine — and corresponds to the right sine of 4 and a half parts and a little more, there will be intercepted in the Firmament, between those two rays, an arc containing 0 degrees, 0 minutes, 9 seconds, and a little more. So tiny is that which the semidiameter of the earth cuts off from the concave of the Firmament — which is imperceptible with respect to the whole circuit of the Firmament, since the whole circuit of the Firmament comprises 1296000 seconds — so that that arc of 9 seconds is $1/144000$ of the whole circuit, or $1/400$ of one degree. And since the diameter of the Sun occupies half of one degree, it comes about that that arc is $1/200$ of the Sun's diameter; and this quantity is imperceptible when compared with the whole circuit of the heaven, as is evident.

And this arc of the Firmament is subtracted from the semidiameter [of the earth], if the ray issuing from the eye is set parallel to that ray which goes out from the center of the earth. But since the ray sent out from the eye is not parallel to that other one, but rather approaches it the more and more, the farther it is produced — for it touches the earth's surface at a different point than the one placed at the top of the head — it comes about that a much smaller arc of the Firmament is intercepted between those two rays than $1/200$ of the Sun's diameter. Indeed it may perhaps happen that an eye set on a high mountain sees somewhat more than half of the heaven, on account of that inclination of the straight line issuing from the eye to the line drawn from the center of the earth.

[Margin: Other arguments proving that the earth is like a center with respect to the Firmament.]

It is fitting to add to these two arguments certain others drawn from the Phenomena, or appearances, by which it is most evidently concluded that this

whole globe — which is composed of earth and water — obtains, with respect to the whole compass of the universe's heaven,

the position, as it were, of a point. The **first** [of these arguments] is Ptolemy's (*Almagest*, book 1, chapter 6), roughly in this manner. We see every day that the extreme shadows of gnomons on sundials, and of other bodies whether set on planes parallel to the horizon or on any surfaces whatever, advance so uniformly and regularly, and are so conformed to the motion of the Sun, as if the tips of those gnomons or bodies were placed at the center of the earth. It is therefore most certain that any gnomon or style set on the surface of the earth does not perceptibly differ from the center of the world, since the Sun moves with uniform motion both about the center of the world and about a style of this kind. For this could in no way happen if the style were notably distant from the center of the world; for it is impossible that the Sun should move regularly about two centers distinct from one another, as is demonstrated in the *Theory of Mercury* by Erasmus Reinhold [Erasmus Reinhold]. It is therefore clear that this mass of the earth, which is intercepted between its center and its convex surface, must be judged of almost no magnitude with respect to the heaven of the Sun, and therefore much more with respect to the Firmament — [to be judged] as a point.

The **second** argument, which in a way declares the preceding one more fully, is this. With the instruments of the mathematicians — such as the astrolabe, the quadrant, the ring [armilla], and so on — we, standing on the surface of the earth, observe the true altitudes of the fixed stars and of the planets (excluding, however, the three lower planets, namely the Moon, Mercury, and Venus), and the motions and places of those same stars, no differently than if we were observing all these things while existing at the center of the earth — so that we commit no error in this matter that could fall under the senses. For through the Mediclinium, or Dioptra, we see two heavenly bodies opposed along a diameter, as though the Dioptra indicated to us the exact diameter of the world; and hold the same judgment concerning the rest of the observations. It is therefore manifestly concluded that the mass of the earth is of no moment with respect to the celestial machine, since the centers of the said instruments, standing on the surface of the earth, coincide entirely with the center of the earth — if we consult the judgment of the senses. For if instruments of this kind were perceptibly distant from the middle of the earth, astronomers would be deceived in their observations in a remarkable way, and no solar clock could indicate the hours correctly — all of which is repugnant to daily experience.

The **third** argument is likewise Ptolemy's, in the passage cited, namely this. In all parts of the earth and all climates of the world, the magnitude and distance of one and the same star — of Mars, namely — has been found the same, at the same time, by various astronomers; and we have ascertained the same in all the other observations that have been made in different climates, so that they do not perceptibly differ among themselves. For which reason the earth is rightly to be judged an indivisible point, since no place of the earth differs perceptibly from another with respect to one and the same celestial point.

The **fourth** argument may be this. If the earth were of some notable magnitude compared with the Firmament — or even with the heaven of the Sun — all those absurdities would follow which we inferred a little before [as following] if the earth were not situated at the middle of the world; and this for the reason that, if the earth were not like a point, we who dwell on its surface would by no means be set at the middle, or center, of the world.

Diagram. A circle crossed by two horizontal chords, with a small hatched globe (the earth of sensible magnitude) near the center between them — dividing the heaven into unequal parts. No letter labels.

Hence it would follow, **first**, that no horizon would divide the heaven into two equal parts. Therefore half of the heaven would nowhere be seen, nor could an equinox ever occur; but perpetually the day at the time of the [would-be] equinox would be shorter than the night, since the nocturnal arc would be notably greater than the diurnal arc. **Next**, the same stars would appear smaller, in clear weather, when set near the horizon than at mid-heaven, because near the horizon they would be notably more remote from us — which, however, is false. **Thirdly**, the shadows of gnomons on any surfaces whatever would in no way be projected along a straight line at the time of the equinoxes (as would pertain to the science of the drawing of sundials), if the vertex of the gnomon were not, so far as the judgment of sense goes, [the same as] the center of the earth. But this is most clearly [in agreement with] experience: in whatever plane a style is fixed, and the tips of its shadows are noted at various hours at certain points, all these points will be found to lie in one straight line — which happens because the vertex of the style is taken as the center of the world, as we most clearly demonstrated in our *Gnomonics*. **Fourthly**, neither would the rising of the summer solstice correspond, along a straight line, to the setting of the winter solstice; nor the rising of the winter solstice to the setting of the summer solstice. **Fifthly**, the whole proportion that we now discern in the increase and decrease of days before and after each equinox would be thrown into confusion. Since all

these are absurd and are opposed to daily experience and to all the observations of skilled astronomers, we must conclude that the earth is as an imperceptible point, if it be compared with the celestial body.

The **fifth** and last argument may be this. According to the common opinion of the astronomers, the semidiameter of the Firmament, as far as its concave surface, contains the earth's semidiameter twenty-two thousand six hundred and twelve times and a half — that is, twenty thousand, and two thousand, and six hundred, and twelve times, and a little more — so that the proportion of the whole semidiameter of the Firmament to the semidiameter of the globe (which is composed of earth and water) is such as [the proportion] of this number $22612\frac{1}{2}$ to 1. For so great is the distance of the Firmament from the center of the earth found to be — as we shall say at the end of this chapter — namely that from the earth up to the Firmament there are contained $22612\frac{1}{2}$ earth-semidiameters. [Margin a: 15. quin. (Euclid, *Elements* V.15)] And therefore, since the proportion of the diameters is the same as that of the semidiameters, the whole diameter of the Firmament will likewise contain the whole diameter of the earth just as many times. [Margin b: 18. duod. (Euclid, *Elements* XII.18)] Since, then, the proportion of spheres is the triplicate of [the proportion of] their diameters, the whole world contained within the concave of the Firmament will have to the earth-globe the same proportion that $11562340095703\frac{1}{8}$ has to 1 — as appears in these continuously proportional numbers: 1; $22612\frac{1}{2}$; $511325156\frac{1}{4}$; $11562340095703\frac{1}{8}$. Since this is so, the earth will not undeservedly be called of imperceptible magnitude if it be compared with the firmament, since unity is almost nothing with respect to so great a number. And that it may be still more plainly perceived that the whole earth is like a point with respect to the Firmament, we shall take a little sphere [sphaerula] whose diameter has to the ancient Geometric foot nearly the proportion of 1 to 44 — such as the little sphere set beside [these words] in this figure.

Diagram. A small circle with a vertical diameter and a dot at the center — the "little sphere" (*sphaerula*) used for the comparison. No letter labels.

For if we take another sphere whose diameter contains 400 feet, so that the proportion of this [small] diameter to that [larger] diameter is as 1 to 17600 — who will doubt that that little sphere is nearly as a point, indivisible with respect to this [larger] sphere? Since, therefore, the earth with respect to the Firmament is much smaller [than...]

Clavius, *Opera Mathematica*, Tomus III — Commentary on Sacrobosco's *Sphere*

(Commentary on Chapter 1 continued — the earth as a point relative to the Firmament.)

than that little sphere is in relation to this sphere. For if the earth is taken as 1, the whole sphere of the world out to the concave surface of the Firmament amounts to 11,562,340,095,703 — and a little more, as we said; whereas if the aforesaid little sphere is taken as 1, that other sphere will amount to only 5,451,776,000,000. This latter number stands to unity in the triplicate ratio of that which the diameter of that sphere bears to the diameter of the aforesaid little sphere, as appears in these numbers: 1 — 17600 — 309760000 — 5451776000000. Far more, then, shall we say that the earth is a point in relation to the Firmament than that the little sphere is a point in relation to the other sphere.

[Margin: Confirmatio h[uius] [in?] quintæ rationis [?] — Confirmation of this, in(?) the fifth argument.]

[Sacrobosco's lemma (*italic*):]

Al-Farghānī also says that the smallest of the fixed stars perceptible to sight is larger than the whole earth; yet that star, in relation to the entire Firmament, is as a point and a centre. Much more forcibly, then, is the earth a point in relation to the Firmament, since it is smaller than that star.

[Margin: Alia ratio probans terram esse veluti punctum respectu Firmamenti — Another argument proving that the earth is as it were a point in relation to the Firmament.]

COMMENTARIVS.

He confirms it by a third middle term, one that rests on the authority of al-Farghānī [Alfraganus] — namely, that the earth is as it were a point — as is plain in the text itself. And it is not al-Farghānī alone who says that the earth is larger than the smallest of the stars perceptible to sight; nearly all astronomers assert the very same thing.

Now, so that it may be understood which "smallest stars" our author, following the opinion of al-Farghānī and of other astronomers, is speaking of, it seems to me that a few things ought to be said about the stars in general: how many, that

is, have been observed in number by the astronomers, and what proportion their magnitudes bear to the magnitude of the earth. The astronomers, then, carefully observing all the stars in the Firmament that are perceptible to sight — that is, those that can always be conveniently seen when the sky is clear — found them to be 1022 in number. There are indeed very many other, extremely small stars (this I shall never deny) which, because they do not present themselves distinctly and clearly to the gaze, or because they are not seen at every season of the year on account of their smallness, the astronomers deliberately pass over; and they speak only of those that the eyes, lifted to the sky, can conveniently take in. But since it seems incredible to ordinary people that there should be only 1022 stars conveniently visible in the Firmament — because sight, gazing at them confusedly on a clear night without any order, supposes them to be almost innumerable — it has seemed good to list here all 1022 stars observed by the astronomers in the order in which they are customarily depicted on the celestial globe. For in this way it will come about that, if anyone on a clear night carefully observes the stars and compares the globe with the stars he sees, he will find no star other than those marked on the globe; indeed, he will scarcely be able to make out with his sight even the very small ones marked there. Hence it cannot seem strange to him that there are no more bright stars in the Firmament than 1022.

[Margin: Quomodo Astronomi numerum stellarum inuestigarint — How the astronomers investigated the number of the stars.]

They investigated this number by the following method. Out of all the stars that are conveniently perceived by sight, the astronomers noted 48 constellations, asterisms, or images. (A constellation, asterism, or image is a certain group of stars which by its arrangement and order represents the shape of some animal or the figure of some other thing.) From this they could easily grasp the number of stars in each constellation considered by itself. For those most ancient and most diligent observers of the stars seem to have formed the stars into images of this kind for no other reason — as Theon the Younger testifies in his exposition of Aratus [in expositione Aratea] — than that so great a multitude of them might be distinguished into separate parts, and that all the stars might be designated in a certain order. And it is agreed that this was done many ages ago, since even in the book of Job the Holy Scriptures name Orion, Arcturus, the Hyades, and the Pleiades, and the names of many other constellations are read in Homer and in Hesiod, those most ancient poets.

Besides this, they observed that certain stars were much more brilliant than others, so that they distinguished altogether six grades in the stars with respect to their magnitude and their greater or lesser splendour; these grades the astronomers called "differences of magnitude." From this they were able, with long practice, quite easily to make out the number of stars of each difference. Thus they found that in the first difference are contained 15 of the largest and brightest stars, which are called stars of the first magnitude. In the 2nd difference they found smaller and less bright stars, 45 of them, which they called stars of the second magnitude. In the 3rd difference they found 208 stars, still smaller, and named them of the third magnitude. In the 4th difference, or magnitude, they observed 474 still smaller stars. In the 5th difference or magnitude they counted 217 still smaller stars. In the 6th and last difference or magnitude they recorded 49 stars, which are the smallest of all. Besides all these stars there are found another five called nebulous, and nine dimmer ones, which scarcely present themselves to our senses; and for that reason they are not referred to any of the said magnitudes, since their sizes could not be recorded because of their dimness. If, then, you gather all these stars into one sum, you will find precisely the number 1022, as you see in the adjoining table.

[Margin: Sex differentiæ magnitudinum stellarum, & quot in qualibet differentia contineantur — The six differences of magnitude of the stars, and how many are contained in each difference.]

(Table headers: "Magnitude — Number of Stars"; rows for magnitudes 1–6, then "Nebulous" 5, "Dimmer ones" 9, "All together" 1022. The eight itemized values sum exactly to 1022. This identical summary table is reprinted at the head of the following page, printed p. 74.)

As for the fact that in winter, on a clear night, an almost infinite multitude of stars appears (to answer the common opinion of the crowd), especially toward the Arctic pole, I judge that this comes about from one of two causes. Either it is because, since the air is then more purified than in summer, it comes about that even the smallest stars can be seen — stars which for that reason are not recorded among the six aforesaid differences, because they do not always appear. Or else it is because, since the stars then twinkle very strongly, it comes about that the sight is deceived and supposes that it perceives more stars than it does — when in fact it does not see stars, but certain appearances of stars generated by that violent twinkling or scintillation. A sign of this is that, if anyone wishes to fix the keenness of his eyes upon one of those stars...

[Margin: Cur in hyeme plures stellæ videantur, quam in æstate — Why more stars appear in winter than in summer.]

he either loses it altogether, or at least detects it wavering, so that it does not stay in the same place — which does not happen with the other stars. And beyond doubt, if the multitude of stars were as great as it then appears to the sight, it would be astonishing that they had not been recorded by the astronomers, seeing that they have in fact recorded far smaller ones — indeed, even those that are found outside the images or constellations, and of which there is no use whatever among the astronomers, as will appear from the following table.

(The magnitude-summary table is here reprinted, identical to the one above:)

There is also that which the Sacred Scriptures report: that God said to Abraham (Genesis, ch. 12 [?] — the passage is Genesis 15:5), *"Look up at the heaven and number the stars, if you can,"* and said to him, *"So shall your seed be."* Likewise in

ch. 22: *"I will bless you, and I will multiply your seed like the stars of heaven, and like the sand that is on the seashore."* Likewise in ch. 26: *"And I will multiply your seed like the stars of heaven."* This must be understood according to the common opinion of ordinary people, who suppose the multitude of stars to be infinite when they gaze at them confusedly and without order on a clear night — not, however, as though the multitude of stars were in truth as great as the future multitude of the children of Israel who were said to spring from Abraham. For since there are 48 images, in which all the 1022 stars are placed (granted that some few are set outside them), surely no one will assert that in each single constellation there are 10,000 stars, since not even 100 are seen, even in the largest constellation. And it would certainly be astonishing that the astronomers had erred, in numbering the stars in each constellation, by so great a figure — nearly 10,000. For if it were so, how could it happen that those stars which they recorded in the constellations could be distinguished amid so great a multitude?

Indeed, even if we should grant that in each single constellation there are 10,000 stars, the words of Scripture will still not have to be understood as they sound — namely, that there are as many stars as there would be children of Israel. For on this reckoning there would be in the whole heaven only 480,000 stars; yet who would say that the children of Israel were not far more numerous? Those words of Scripture, therefore, are not to be taken in this sense, so that we should say the stars are infinite. It can also be said that Scripture is speaking of all the stars that are in the heaven, including those that are smaller than the ones contained in the six differences — stars that are perhaps innumerable — and that God then so directed the keenness of Abraham's eyes that he might behold them all in the heaven. But if anyone wishes absolutely to maintain that the stars are more numerous, he shall have my leave to think what he pleases: for my part I readily persuade myself that there are not more than 1022 contained in the six said differences, since, on considering the constellations in themselves, I find no more than those recorded by the astronomers — except in winter, when at times more seem to appear, especially near the Arctic pole, for the causes stated a little earlier, and above all on account of the deception of sight.

And so, out of all the 1022 stars, the mathematicians, with wonderful care and skill, constructed, as has been said, 48 images or constellations, whose names and order we have set out in the table placed below, following for the most part the observations of Nicolaus Copernicus [Copernicus]. For the positions, or longitudes, of all the stars are now found to have changed from the times of Ptolemy [Ptolemy] down to our own age, on account of that very slow motion by which we said they are moved from west to east; so much so that at the present

time the longitudes of the stars are other than those set down in the tables of the *Almagest* by Ptolemy — although the latitudes of the same stars have always been found the same, as the observations of the most learned astronomers testify. Accordingly, in the following table the longitudes do indeed differ from the longitudes of Ptolemy; but the latitudes in no way disagree with the latitudes that Ptolemy explained in the *Almagest*. Indeed, from this perpetual constancy of the latitudes we asserted above that it may most firmly be concluded that the stars are moved from west to east about the poles of the Zodiac — just as it was found by continuous change of longitude that they are gradually moved from setting to rising.

We call the "longitude" of any star its distance from the beginning of ♈ [Aries], toward the eastern signs, that is, proceeding through ♉ [Taurus], ♊ [Gemini], ♋ [Cancer], ♌ [Leo], and so on. The "latitude," on the other hand, we call its distance from the Ecliptic, whether toward the north or toward the south. But in the following table the longitudes of the stars are reckoned from the first star of Aries, as we shall say a little later in the use of the table. Yet more concerning longitudes and latitudes you will find in the 2nd chapter, when we shall treat of the Zodiac.

We have corrected the longitudes of many stars partly from a manuscript *Almagest*, partly also from the observations of Ptolemy and of other astronomers. For when it has been observed that three particular stars, for example, form in the heaven a nearly straight line, if this is not preserved on the celestial globe when the stars are described in the tables according to the longitudes and latitudes there recorded, it is an argument that those longitudes or latitudes of the stars are not the true ones, and that they must therefore be corrected — yet in such a way that the stars retain that position in the constellations which has been observed by the astronomers. This is what we have observed in our correction. Moreover, in order to distinguish those stars whose longitudes or latitudes we have corrected from the others, we have set beside them an asterisk, in this way: *. Again, certain stars were sometimes said in the tables to be, for instance, in the left hand, or in some other part, whereas in fact they are in the right hand, or elsewhere, as the pictures require. These too, therefore, we have emended, and to them we have affixed the same asterisk.

But let us now set the aforesaid table before the eyes, the use of which we shall explain after its end. The whole table is distributed into three parts: in the first are contained all the stars that incline from the Zodiac toward the north; the

second embraces all the stars that are found in the Zodiac; and in the third, finally, are placed all the stars that bend from the Zodiac toward the south.

[Tycho Brahe] the Dane, an excellent astronomer of our age, observed in Denmark more stars than 1022 — yet fewer than 1100 — and in some of those 1022 he found longitudes, and also latitudes, differing somewhat from those recorded in our following table. Whoever, then, judges that his observations are to be trusted more than those of other astronomers may consult either the works of Tycho himself, which are now printed, or else the *Sphere* of Friar Francesco Piffieri [F. Francisci Pifferii], written in Italian, in which he described the stars according to the opinion of Tycho. For my own part I think it superfluous to weave that table into these commentaries of ours — both lest the book grow larger than...

is fitting, and also because there is not so great a difference between Tycho's stars and ours as to introduce any notable error in the instruments or in the observations — especially since, as I have said, the stars observed by him can be found elsewhere and compared with ours.

I do not, however, wish the reader to remain unaware, in this place, that not long ago there was brought from Belgium a certain instrument, in the shape of a long tube, in whose ends are fitted two pieces of glass, or lenses, by which objects far removed from us appear very near, and indeed far larger than they really are. With this instrument very many stars in the Firmament are discerned which without it can in no way be seen — especially in the Pleiades; around the Nebula of Cancer; in Orion; in the Milky Way; and elsewhere. But this does not conflict with what we reported above concerning the number of the 1022 stars, because we were speaking of the stars that can be conveniently seen without the aid of that instrument. The Moon too, when it is crescent or half-full, appears wonderfully broken and rough, so that I cannot sufficiently marvel that there are such great inequalities in the lunar body. But on this matter consult the little book of Galileo Galilei [Galileo Galilei], which he entitled the *Sidereal Messenger* [*Sidereus Nuncius*], printed at Venice in the year 1610, in which he describes the various observations of the stars first made by himself.

Among the other things that are seen with this instrument, this holds no last place: namely, that Venus receives light from the Sun after the manner of the Moon, so that it appears now more, now less, crescent, according to its distance from the Sun. This I have myself observed more than once, together with others, here at Rome. Saturn, too, has joined to it two stars smaller than itself, one toward the east and the other toward the west. Jupiter, finally, has four

wandering stars, which vary wonderfully in position both among themselves and with respect to Jupiter, as Galileo Galilei describes diligently and accurately.

Since these things are so, let the astronomers see in what way the celestial orbs are to be arranged, so that these phenomena may be preserved [saved].

SEQVITVR TABVLA STELLARVM.

(Display heading: "There follows the Table of the Stars." — announcing the star catalogue to come in subsequent pages.)

TABLE OF THE STARS (Star Catalogue)

FIRST PART OF THE TABLE [TABVLÆ PRIMA PARS]

Verbatim caption: TABVLÆ PRIMA PARS COMPLECTENS NOMINA omnium constellationum, quæ à Zodiaco ad eius polum Boreum vergunt, una cum numero, ordine, longitudinibus, latitudinibus, atque magnitudinibus stellarum.

Translation: The first part of the table, containing the names of all the constellations that incline from the Zodiac toward its northern pole, together with the number, order, longitudes, latitudes, and magnitudes of the stars.

Column headers (verbatim): FORMÆ STELLARVM (Forms of the Stars) | Longit. G. | M. (Longitude: degrees | minutes) | Latit. G. | M. (Latitude: degrees | minutes) | Magnitudo (Magnitude)

Throughout, the longitude is an absolute ecliptic longitude measured from 0° Aries (0–360°), not a sign-plus-degree value. In every table below the columns are, in order: star number; position within the figure (English translation of the Latin FORMÆ STELLARVM description); longitude degrees; longitude minutes; latitude degrees; latitude minutes; magnitude.

[Margin: Vrsa minor.]

10	In the right elbow	357	40	50	0	6
11	In the foot of the seat	8	20	52	40	4

No .	Star (position)	Long. °	'	Lat. °	'	Mag .
12	In the middle of the ascent (of the back)	1	10	51	40	3
13	At the extremity	357	0	51	40	6

Summary (verbatim): *Omnes stellæ 13. Tertiæ magnit. 4. Quartæ 6. Quintæ 1. Sextæ 2.* — All the stars: 13. Of the third magnitude 4, of the fourth 6, of the fifth 1, of the sixth 2. [4+6+1+2 = 13; verified against transcribed magnitudes.]

Constellation XI — PERSEVS [Perseus]

[Margin: Perseus.]

No .	Star (position)	Long. °	'	Lat. °	'	Mag .
1	At the tip of the right hand	21	0	40	30	Neb .
2	In the right elbow	24	30	37	30	4
3	In the right shoulder	26	0	34	30	4
4	In the left shoulder	20	50	32	20	4
5	In the head, or the nebula	24	0	34	30	4
6	In the shoulder blades	24	50	31	10	4
7	Shining in the right side	28	10	30	0	2
8	The preceding of three on the same side	28	40	27	30	4
9	The middle one	30	20	27	40	4
10	The remaining of three	31	0	27	30	3
11	In the left elbow	24	0	27	0	4
12	Shining, in the left hand and the head of Medusa	23	0	23	0	2
13	The following of the same head	22	30	21	0	4
14	The one that precedes in the same head	21	0	21	0	4
15	The one preceding even this	20	10	22	15	4
16	In the right knee	38	10	28	15	4

No .	Star (position)	Long. °	'	Lat. °	'	Mag .
17	Preceding this one, in the knee	37	10	28	10	4
18	The preceding of two at the back of the knee	35	40	25	10	4
19	The following	37	20	26	15	4
20	In the right leg	37	30	24	30	5
21	In the right foot	39	40	18	45	5
22	In the left hip	30	10	21	40	4
23	In the left knee	32	0	19	50	3
24	In the left leg	31	40	13	45	3
25	In the left heel	27	30	12	0	3
26	At the top of the foot, on the left part	29	40	11	0	3

Summary (verbatim): *Omnes stellæ num. 26. Secundæ magnit. 2. Tertiæ 5.*

Quartæ 16. Quintæ 2. Nebulosa 1. — All the stars in number: 26. Of the second magnitude 2, of the third 5, of the fourth 16, of the fifth 2, nebulous 1.

[2+5+16+2+1 = 26; verified against transcribed magnitudes.]

Unformed stars around Perseus (INFORMES CIRCA PERSEA)

N o.	Star (position)	Long. °	'	Lat. °	'	Mag.
1	The one to the east, off the left knee	34	10	18	0	5
2	To the north, off the right knee	38	20	31	0	5
3	Preceding, off the head of Medusa	18	0	20	40	obsc.

["obsc." = *obscura*, faint/obscure. No separate summary line printed for these three unformed stars.]

Constellation XII — AVRIGA, QVI ET HENIOCHVS, SEV ERICHTONIVS [The Charioteer, also Heniochus, or Erichthonius]

[Margin: Erichtonius, siue Auriga.]

N						
o.	Star (position)	Long. °	'	Lat. °	'	Mag.
1	The more southern of two in the head	55	50	30	0	4
2	The one further north	55	40	30	50	4
3	Shining in the left shoulder, Capella, or the She-goat (Hircus)	48	20	22	30	1
4	In the right shoulder	56	10	20	0	5 [?]
5	In the right elbow	54	30	15	15	4
6	In the right palm	56	10	13	30	4
7	In the left elbow	45	20	20	40	4
8	The preceding of the Kids (hoedi)	45	30	18	0	4
9	The following of the Kids, in the left palm	46	0	18	0	4
10	In the left ankle	43	10	10	10	3
11	In the right foot, and at the tip of the northern horn of ♂ Taurus	49	0	5	0	3
12	In the right calf	49	20	8	30	5
13	In the haunch	49	40	12	20	5
14	A tiny one in the left foot	44	0	10	20	6

Summary (verbatim): *Omnes stellæ 14. Primæ magnit. 1. Secundæ 1. Tertiæ 2. Quartæ 7. Quintæ 2. Sextæ 1.* — All the stars: 14. Of the first magnitude 1, of the second 1, of the third 2, of the fourth 7, of the fifth 2, of the sixth 1. [1+1+2+7+2+1 = 14. Transcribed magnitudes tally as 1(one), 5(three), 4(seven), 6(one) and 2(zero) unless star 4 is read as 2 — see anomaly (b).]

Constellation XIII — OPHIVCHVS, SEV SERPENTARIVS [Ophiuchus, or the Serpent-holder]

[Margin: Ophiuchus.]

[The latitude-direction column below records the printed **Bor.** (*Borealis*, north of the ecliptic) / **Aust.** (*Australis*, south) notes; stars 1–13 carry no note (north).]

N o.	Star (position)	Long. °	'	Lat. °	'	Ma g.	Lat. dir.

N o.	Star (position)	Long. °	'	Lat. °	'	Ma g.	Lat. dir.
1 8	The one touching the heel	229	3 0	1	0	5	Aust.
1 9	In the left knee	215	3 0	11	5 0	3	Bor.
2 0	The more northern of three in a straight line, in the left leg	215	0	5	2 0	5	Bor.
2 1	The middle of them	214	0	3	1 0	5	Bor.
2 2	The more southern of three	213	1 0	1	4 0	5	Bor.
2 3	In the left heel	215	4 0	0	4 0	5	Aust.
2 4	Touching the sole of the left foot	214	0	0	4 5	4	Aust.

Summary (verbatim): *Omnes stellæ 24. Tertiæ magnit. 5. Quartæ 13. Quintæ 6. —*
All the stars: 24. Of the third magnitude 5, of the fourth 13, of the fifth 6. [5+13+6 =
24; verified against transcribed magnitudes.]

Unformed stars around Ophiuchus (INFORMES CIRCA OPHIVCHVM)

No .	Star (position)	Long. °	'	Lat. °	'	Mag .
1	The most northern of three, from the east toward the right shoulder	235	20	28	10	4
2	The middle of three	236	0	26	20	4
3	The southern of three	233	40	25	0	4
4	A further one following the three	237	0	27	0	4
5	Separated from the four, toward the north	238	0	33	0	4

Summary (verbatim): *Omnes stellæ 5. magnitudinis Quartæ. —* All the stars: 5, of
the fourth magnitude. [Verified.]

Constellation XIV — SERPENS OPHIVCHI [The Serpent of Ophiuchus]

[Margin: Serpens Ophiuchi.]

N o.	Star (position)	Long. °	'	Lat. °	'	Ma g.
1	The one in the quadrilateral, on the cheek	192	10	38	0	4
2	The one touching the nostrils	195	0	40	0	4
3	In the temple	197	40	35	0	3
4	At the outgrowth of the neck	195	20	34	1 [?]	3
5	The middle one of the quadrilateral, and in the mouth	194	40	37	1 [?]	4
6	From the head, toward the north	196	30	42	30	4
7	In the first coil of the neck	195	0	29	15	3
8	The northern of three following	198	10	26	30	4
9	The middle of them	197	40	25	20	3
10	The more southern of three	199	40	24	0	3
11	The preceding of two, before the left hand of the Serpent-holder	202	0	16	30	4
12	The one that follows the same hand	211	30	16	15	5
13	The one behind the right hip	227	0	10	30	4
14	The southern of two following	230	20	8	30	4
15	The northern one	231	10	10	30	4
16	Behind the right hand, at the bend of the tail	237	0	20	0	4
17	The following, in the tail	242	0	21	10	4
18	At the tip of the tail	251	40	27	0	4

Summary (verbatim): *Omnes stellæ 18. Tertiæ magnit. 5. Quartæ 12. Quintæ 1.* — All the stars: 18. Of the third magnitude 5, of the fourth 12, of the fifth 1. [5+12+1 = 18; verified against transcribed magnitudes.]

Constellation XV — SAGITTA, SIVE TELVM [The Arrow, or the Dart]

[Margin: Sagitta.]

No .	Star (position)	Long. °	'	Lat. °	'	Mag .
1	In the point	273	30	39	20	4
2	The following of three, in the shaft	270	0	39	10	6
3	The middle of them	269	10	39	50	5
4	The preceding of three	268	0	39	0	5
5	In the notch (Glyphis)	266	40	38	45	5

Summary (verbatim): *Omnes stellæ 5. Quartæ magnit. 1. Quintæ 3. Sextæ 1.* — All the stars: 5. Of the fourth magnitude 1, of the fifth 3, of the sixth 1. [1+3+1 = 5; verified against transcribed magnitudes.]

Tabula Stellarum — Star Catalogue (continued)

Column rubric (repeated at the head of each page): **FORMÆ STELLARVM** ("Configurations of the stars") | **Longit.** G. | M. | **Latit.** G. | M. | **Magnitudo.** Longitude and latitude are given in degrees (G. = *gradus*) and minutes (M. = *minuta*). In the northern constellations below, all latitudes are north of the ecliptic (implicit). In the zodiacal section (from Aries onward), each latitude carries an explicit hemisphere marker printed at the right margin — **Bor.** (*Borealis*, north of the ecliptic) or **Aust.** (*Australis*, south of the ecliptic) — reproduced here as a final column.

[Margin: Aquila]

AQVILA, SEV VVLTVR VOLANS — The Eagle, or the Flying Vulture (Constellatio XVI)

No .	Configuration	Long. G	M	Lat. G	M	Mag.
1	On the middle of the head	270	3 0	26	5 0	4
2	On the neck	268	1	27	1	3

No .	Configuration	Long. G	M	Lat. G	M	Mag.
			0		0	
3	The bright one on the shoulder-blades, which they call the Eagle [Altair]	267	1	29	1	2
			0		0	
4	Next to it, more toward the north	268	0	30	0	3

1							

Summary (unformed stars around Taurus). All the stars 11. Of the fourth magnitude 1; of the fifth 10.

GEMINI — Constellation XXIII

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	On the head of the leading Twin, Castor	76	40	9	30	2	Bor.
2	On the head of the following Twin, yellowish, Pollux	79	50	6	15	2	Bor.
3	On the left elbow of the leading Twin	70	0	10	0	4	Bor.
4	On the same arm	72	0	7	20	4	Bor.
5	On the shoulder-blades of the same Twin	75	20	5	30	4	Bor.
6	On the right shoulder of the same	77	20	4	50	4	Bor.
7	On the left shoulder of the following Twin	80	0	2	40	4	Bor.
8	On the right side of the preceding Twin	75	0	2	40	5	Bor.
9	On the left side of the following Twin	76	30	3	0	5	Bor.
1	On the left knee of the leading Twin	66	30	1	30	3	Bor.
1	On the left knee of the following one	71	40	2	30	3	Aust.
1	On the left groin of the same	75	0	0	30	3	Aust.
2							

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1 3	In the right hollow of the same	74	40	6	40	3	Aust.
1 4	On the foot of the leading Twin, the leading one	60	0	1	30	4	Aust.
1 5	On the same foot, the following one	61	30	1	15	4	Aust.
1 6	At the tip [of the foot] of the leading Twin, Propus	63	30	3	30	4	Aust.
1 7	On the top of the left foot of the following Twin	65	20	7	30	3	Aust.
1 8	On the bottom of the right foot of the same Twin	68	0	10	30	4	Aust.

Summary (Gemini). All the stars 18. Of the second magnitude 2; of the third 5; of the fourth 9; of the fifth 2.

UNFORMED STARS AROUND GEMINI [Informes circa Geminos]

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	The leading one, near the top of the foot of the leading Twin	57	30	0	40	4	Aust.
2	The one that shines before the knee of the same	59	50	5	50	4	Bor.
3	Preceding the left knee of the following Twin	68	30	2	15	5	Aust.
4	Of the three following the right hand of the following Twin, the northern	81	40	1	20	5	Aust.
5	The middle one	79	40	3	20	5	Aust.
6	The southern of the three	79	20	4	30	5	Aust.
7	The bright one following the three	84	0	2	40	4	Aust.

Summary (unformed stars around Gemini). All the stars 7. Of the fourth magnitude 3; of the fifth 4.

CANCER — Constellation XXV

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	In the breast, the nebulous middle one, called Praesepe (the Manger)	93	40	0	40	ne b.	Bor.
2	Of the two leading stars of the quadrilateral, the northern	91	0	1	15	4	Bor.
3	The southern one	91	20	1	10	4	Aust.
4	Of the two following stars, called the Asses [Aselli], the northern	93	40	2	40	4	Bor.
5	The southern Ass	94	40	0	10	4	Aust.
6	In the claw, or southern arm	99	50	5	30	4	Aust.
7	In the northern arm	91	40	11	50	4	Bor.
8	At the tip of the northern foot	86	0	1	0	5	Bor.
9	At the tip of the southern foot	90	30	7	30	4	Aust.

Summary (Cancer). All the stars 9. Of the fourth magnitude 7; of the fifth 1; nebulous 1.

UNFORMED STARS AROUND CANCER [Informes circa Cancrum]

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	Above the elbow of the southern claw	103	0	2	40	4	Aust.
2	Following, from the tip of the same claw	105	0	5	40	4	Aust.
3	Above the little cloud, the	97	20	4	50	5	Bor.

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
	leading of two						
4	Following this one	100	20	7	15	5	Bor.

Summary (unformed stars around Cancer). All the stars 4. Of the fourth magnitude 2; of the fifth 2.

LEO — Constellation XXVI

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	In the nostrils	101	40	10	0	4	Bor.
2	In the open mouth	104	30	7	30	4	Bor.
3	Of the two on the head, the northern	107	40	12	0	3	Bor.
4	The southern one	107	30	9	30	3	Bor.
5	Of the three on the neck, the northern	113	30	11	0	3	Bor.
6	The middle one	115	30	8	30	2	Bor.
7	The southern of the three	114	0	4	30	3	Bor.
8	In the heart, Basiliscus, or Regulus; the Heart of the Lion [Cor Leonis, ♌]	115	50	0	10	1	Bor.
9	Of the two on the breast, the southern	116	50	1	50	4	Aust.
10	Preceding the one in the heart	113	20	0	15	5	Aust.
11	On the right foreknee	110	40	0	0	5	Aust.
12	On the "drace" [?] right, forward	107	30	3	40	6	Aust.
13	On the "drace" [?] left, forward	110	50	4	10	4	Aust.
14	On the left foreknee	115	30	4	15	4	Aust.
15	In the left armpit	122	30	0	10	4	Aust.

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
5							
1	Of the three on the belly,	120	20	4	0	6	Bor.
6	the preceding						
1	Of the two following, the	126	20	5	20	6	Bor.
7	northern						
1	The southern one	125	40	2	20	6	Bor.
8							
1	Of the two on the loins, the	124	40	12	15	5	Bor.
9	one that goes before						
2	The one that follows	127	30	13	40	2	Bor.
0							
2	Of the two on the haunch,	127	40	11	30	5	Bor.
1	the northern						
2	The southern one	129	40	9	40	3	Bor.
2							
2	On the hind hip	133	40	5	50	3	Bor.
3							
2	In the hollow	135	0	1	15	4	Bor.
4							
2	On the hind elbow	135	0	0	50	4	Aust.
5							
2	On the hind foot	140	0	3	0	5	Aust.
6							
2	At the tip of the tail	137	50	11	50	1	Bor.
7	[Denebola]						

Summary (Leo). All the stars 27. Of the first magnitude 2; of the second 2; of the third 6; of the fourth 8; of the fifth 5; of the sixth 4.

UNFORMED STARS AROUND LEO [Informes circa Leonem]

#	Star position	Long. °	Long. '	Lat. °	Lat. '	Mag.	Hem is.
1	Of the two above the back, the leading	119	20	13	20	5	Bor.

#	Star position	Long. °	Long. '	Lat. °	Lat. '	Mag.	Hem is.
2	The one that follows	121	30	15	30	5	Bor.
3	Of the three below the belly, the northern	129	50	1	10	4	Bor.
4	The middle one	130	30	0	30	5	Aust.
5	The southern of the three	131	20	2	40	5	Aust.
6	Between the extremities of Leo and the Bear, [a star] of the nebulous cluster which they call Berenice's Hair [Coma Berenices], the most northern one	138	30	30	0	luminous	—
7	Of the two southern ones, the leading	137	50	25	0	obscure	—
8	The one that follows, in the shape of an ivy leaf	141	50	25	30	obscure	—

Summary (unformed stars around Leo). All the stars 8. Of the fourth magnitude 1; of the fifth 4; luminous 1; obscure 2.

(Magnitude entries for stars 6–8, the Coma Berenices stars: "Lumi." = *luminosa*, "obscu." = *obscura*.)

VIRGO — Constellation XXVII

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	Of the two on the top of the head, the leading southern one	139	40	4	15	5	Bor.
2	The following, more northern one	140	20	5	40	5	Bor.
3	Of the two on the face, the northern	144	0	8	0	5	Bor.

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
4	The southern one	143	30	5	30	5	Bor.
5	At the tip of the left wing, and southern	142	20	0	9 [?]	3	Bor.
6	Of those on the left wing, the leading of four	151	30	1	10	3	Bor.
7	The second following one	156	30	2	50	3	Bor.
8	The third one	160	30	2	50	5	Bor.
9	The last, following the four	164	20	1	40	4	Bor.
1 0	On the right side, below the girdle	157	40	8	30	3	Bor.
1 1	On the right and northern wing, the leading of three	151	30	13	50	5	Bor.
1 2	Of the remaining two, the southern	153	30	11	40	6	Bor.
1 3	The northern of them, called Vindemiator (the Grape-gatherer)	155	30	15	10	5	Bor.
1 4	In the left hand, the star called Spica [♊]	170	0	2	0	1	Aust.
1 5	Below the girdle, and on the right haunch	168	10	8	40	3	Bor.
1 6	On the left thigh, of the leading stars of the quadrilateral, the northern	169	40	2	20	5	Bor.
1 7	The southern one	170	20	0	10	6	Bor.
1 8	Of the two following, the northern	173	20	1	30	4	Bor.
1 9	The southern one	171	20	0	20	5	Bor.
2 0	On the left knee	175	0	1	30	5	Bor.

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
2	At the end of the right thigh	171	20	8	30	5	Bor.
2	On the train [of the robe], the middle one	180	0	7	30	4	Bor.
2	The southern one	180	40	2	40	4	Bor.
2	The northern one	181	40	11	40	4	Bor.
2	On the left and southern foot	183	20	0	30	4	Bor.
2	On the right and northern foot	186	0	9	50	3	Bor.

Summary (Virgo). All the stars 26. Of the first magnitude 1; of the third 6; of the fourth 6; of the fifth 11; of the sixth 2.

UNFORMED STARS AROUND VIRGO [Informes circa Virginem]

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	Below the left arm, in a straight line, the leading of three	158	0	3	30	5	Aust.
2	The middle one	162	20	3	30	5	Aust.
3	The following one	165	40	3	30	5	Aust.
4	Below Spica, as if in a straight line, the leading of three	170	30	7	20	6	Aust.
5	The middle of them, which is also double	171	30	8	20	5	Aust.
6	The following of the three	173	20	7	50	6	Aust.

Summary (unformed stars around Virgo). All the stars 6. Of the fifth magnitude 4; of the sixth 2.

LIBRA — Constellation XXVIII

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	Of the two at the tip of the southern claw, the bright one	191	20	0	40	2	Bor.
2	The dimmer one, toward the north	190	20	2	20	5	Bor.
3	Of the two at the tip of the northern claw, the bright one	195	30	8	30	2	Bor.
4	The dimmer one, preceding this	191	0	8	30	5	Bor.
5	In the middle of the southern claw	197	20	1	40	4	Bor.
6	In the same, the one that goes before	194	40	1	15	4	Bor.
7	In the middle of the northern claw	200	50	3	45	4	Bor.
8	In the same, the one that follows	206	0	4	30	4	Bor.

Summary (Libra). All the stars 8. Of the second magnitude 2; of the fourth 4; of the fifth 2.

UNFORMED STARS AROUND LIBRA [Informes circa Libram]

(This list is not yet complete on the page; the printed catchword "8 Reli-" shows that star 8, "Reliquarum...", begins on the next page.)

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
1	Toward the north from the northern claw, the leading of three	199	30	9	0	5	Bor.
2	Of the two following, the southern	207	0	6	40	4	Bor.
3	The northern of them	207	40	9	15	4	Bor.

#	Star position	Long. °	Long. '	Lat. °	Lat. '	M ag.	Hem is.
4	Between the claws, of three, the one that follows	205	50	5	30	6	Bor.
5	Of the remaining two leading ones, the northern	203	40	2	0	4	Bor.
6	The southern one	204	30	1	30	5	Bor.
7	Below the southern claw, the leading of three	196	20	7	30	3	Bor.

Tabula Stellarum (Star Catalogue) — Scorpius through Pisces

Column headers as printed: FORMÆ STELLARVM (form/description of the stars) | Longit. G. | M. (longitude, degrees | minutes) | Latit. G. | M. (latitude, degrees | minutes) | Magnitudo (magnitude) followed by the hemisphere of latitude, Bor. = Boreal/northern, Aust. = Austral/southern.

[Informes circa Libram, continued]

(Continuation of the unformed stars around Libra begun on the preceding folio; only stars 8–9 fall on this page, followed by the constellation's summary line.)

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
8	Of the two remaining following stars, the northern	204	30	8	10	4	Aust.
9	The southern	205	20	9	40	4	Aust.

All stars 9. Of the third magnitude 1. Of the fourth 5. Of the fifth 2. Of the sixth 1.

SCORPIVS. — Constellatio XXIX.

[Margin: Scorpius]

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1	In the forehead, the northern of three bright stars	209	40	1	20	3	Bor.
2	The middle one	209	0	1	40	3	Aust.
3	The southern of the three	209	0	5	0	3	Aust.
4	The one further south, and in the foot	209	20	7	50	3	Aust.
5	Of two joined stars, the bright northern	210	20	1	40	4	Bor.
6	The southern	210	40	0	30	4	Bor.
7	In the body, the leading of three bright stars	213	0	3	40	3	Aust.
8	The middle, glowing, Antares, called the Heart of the Scorpion [Cor Scorpii; scorpion glyph in the source]	216	0	4	0	2	Aust.
9	The following of the three	217	50	5	30	3	Aust.
10	In the last vertebra, the leading of two	212	40	6	10	5	Aust.
11	The following	213	50	6	40	5	Aust.
12	In the first vertebra of the body	221	50	11	0	3	Aust.
13	In the second vertebra	222	10	15	0	4	Aust.
14	In the third, the southern of the double	223	20	18	40	4	Aust.
15	The northern of the double	223	30	18	0	3	Aust.
16	In the fourth vertebra	226	30	19	30	3	Aust.
17	In the fifth	231	30	18	50	3	Aust.
18	In the sixth vertebra	233	50	16	40	3	Aust.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .

All stars 21. Of the second magnitude 1. Of the third 13. Of the fourth 5. Of the fifth 2.

INFORMES CIRCA SCORPIVM. (Unformed stars around the Scorpion)

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1	The nebulous star following the	234	30	13	15	neb	Aust.
	sting					.	
2	From the sting toward the	228	50	6	10	5	Aust.
	north, the following of two						
3	The one that follows	232	50	4	10	5	Aust.

SAGITTARIVS. — Constellatio XXX.

[Margin: Sagittarius]

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1	On the point of the arrow	237	50	6	30	3	Aust.
2	On the grip of the left hand	241	0	6	30	3	Aust.
3	In the southern part of the bow	241	20	10	50	3	Aust.
4	In the northern part, the more	242	20	1	30	3	Aust.
	southern of two						
5	Further north, at the tip of the	240	0	2	50	4	Bor.
	bow						
6	In the left shoulder	248	40	3	10	3	Aust.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
7	The one preceding it, on the dart	246	20	3	50	4	Aust.
8	In the eye, a double nebulous star	248	30	0	45	neb .	Bor.
9	In the head, the foremost of three	249	0	2	10	4	Bor.
1 0	The middle one	251	0	1	30	4	Bor.
1 1	The following	152 [?]	30	2	0	4	Bor.
1 2	At the northern junction, the more southern of three	254	40	2	50	4	Bor.
1 3	The middle one	255	40	4	30	4	Bor.
1 4	The northern of the three	256	10	6	30	4	Bor.
1 5	Three faint stars following	259	0	5	30	6	Bor.
1 6	At the southern junction, the northern of two	262	50	5	0	5	Bor.
1 7	The southern	261	0	2	0	6	Bor.
1 8	In the right shoulder	255	40	1	50	5	Aust.
1 9	In the right elbow	258	10	2	50	5	Aust.
2 0	In the shoulder blades	253	20	2	30	5	Aust.
2 1	In the shoulder (foreleg)	251	0	4	30	4	Aust.
2 2	Under the armpit	249	40	6	45	3	Aust.
2	In the left front hock	251	0	23	0	2	Aust.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
3							
2	In the knee of the same leg	250	20	18	0	2	Aust.
4							
2	In the right front hock	240	0	13	0	3	Aust.
5							
2	In the left shoulder blade	260	40	13	30	3	Aust.
6							
2	In the right hind knee	260	0	20	10	3	Aust.
7							
2	At the root of the tail, the	261	0	4	50	5	Aust.
8	leading of four on the northern side						
2	The following on the same side	261	50	4	50	5	Aust.
9							
3	On the southern side, the	261	50	5	50	5	Aust.
0	leading one						
3	The following on the same side	262	50	6	30	5	Aust.
1							

All stars 31. Of the second magnitude 2. Of the third 9. Of the fourth 9. Of the fifth 8. Of the sixth 2. Nebulous 1.

CAPRICORNVS. — Constellatio XXXI.

[Margin: Capricornus]

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1	In the leading horn, the northern of three	270	40	7	30	3	Bor.
2	The middle one	271	0	6	40	6	Bor.
3	The southern of the three	270	40	5	0	3	Bor.
4	At the tip of the following horn	272	20	8	0	6	Bor.
5	In the mouth, the southern of three	272	20	0	45	6	Bor.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
6	Of the two remaining, the leading	272	0	1	45	6	Bor.
7	The following	272	10	1	30	6	Bor.
8	Above the right eye	270	30	0	40	5	Bor.
9	In the neck, the northern of two	275	0	4	50	6	Bor.
1 0	The southern	275	10	0	50	5	Aust.
1 1	In the right knee	275	0	6	30	4	Aust.
1 2	In the bent left knee	274	10	8	40	4	Aust.
1 3	In the left shoulder	280	0	7	40	4	Aust.
1 4	Under the belly, the leading of two adjacent stars	283	30	6	50	4	Aust.
1 5	The following	283	40	6	0	5	Aust.
1 6	In the middle of the body, the following of three	282	0	4	15	5	Aust.
1 7	Of the remaining leading stars, the southern	280	0	4	0	5	Aust.
1 8	The northern of them	280	0	2	50	5	Aust.
1 9	In the back, the foremost of two	280	0	0	0	4	Eclip.
2 0	The following	284	20	0	50	4	Aust.
2 1	In the southern spine, the preceding of two	286	40	4	45	4	Aust.
2 2	The following	288	20	4	30	4	Aust.
2 3	At the root of the tail, the leading of two	288	40	2	10	3	Aust.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
2 4	The following	289	40	2	0	3	Aust.
2 5	In the northern part of the tail, the leading of four	290	10	2	20	4	Bor.
2 6	Of the three remaining, the southern	292	0	5	0	5	Bor.
2 7	The middle one	291	0	2	50	5	Bor.
2 8	The northern, at the very tip of the tail	292	0	4	20	5	Bor.

All stars 28. Of the third magnitude 4. Of the fourth 9. Of the fifth 9. Of the sixth 6.

AQVARIVS. — Constellatio XXXII.

[Margin: Aquarius]

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1	In the head	293	40	15	45	5	Bor.
2	In the right shoulder, the brighter	299	40	11	0	3	Bor.
3	The fainter	298	30	9	40	5	Bor.
4	In the left shoulder	290	0	8	50	3	Bor.
5	Under the armpit	290	40	6	15	3	Bor.
6	Under the left hand, in the garment, the following of three	280	0	5	30	3	Bor.
7	The middle one	279	30	8	0	4	Bor.
8	The leading of three	278	0	8	30	3	Bor.
9	In the right arm	302	50	8	45	3	Bor.
1 0	In the right hand, the northern	303	0	10	45	3	Bor.
1 1	Of the two remaining, the southern, leading	305	20	9	0	3	Bor.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1 2	The one that follows	306	40	8	30	3	Bor.
1 3	On the urn, the leading of two adjacent	299	30	3	0	4	Bor.
1 4	The following	300	20	2	10	5	Bor.
1 5	In the right haunch	302	0	0	50	4	Aust.
1 6	In the left haunch, the southern of two	295	0	1	40	4	Aust.
1 7	The more northern	295	30	4	0	6	Aust.
1 8	In the right shin, the southern	305	0	7	30	3	Aust.
1 9	The northern	304	40	5	0	4	Aust.
2 0	In the left hip	301	0	5	40	5	Aust.
2 1	In the left shin, the southern of two	300	40	10	0	5	Aust.
2 2	The northern, below the knee	302	10	9	0	5	Aust.
2 3	In the pouring of the water, the first from the hand	308	20	2	0	4	Bor.
2 4	The more southern following	308	10	0	10	4	Aust.
2 5	The one following, at the first bend of the water	311	0	1	10	4	Aust.
2 6	The one following it	313	20	0	30	4	Aust.
2 7	In the second bend, the southern	313	50	1	40	4	Aust.
2	Of the two following, the	312	30	3	30	4	Aust.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
8	northern						
2	The southern	312	50	4	10	4	Aust.
9							
3	Drawn off toward the south	314	10	8	15	5	Aust.
0							
3	After it, the leading of two	316	0	11	0	5	Aust.
1	joined stars						
3	The following	316	30	10	50	5	Aust.
2							
3	At the third bend of the water,	315	0	14	0	5	Aust.
3	the northern of three						
3	The middle one	316	0	14	45	5	Aust.
4							
3	The following of three	316	30	15	40	5	Aust.
5							
3	Of three following in like	310	20	14	10	4	Aust.
6	arrangement, the northern						
3	The middle one	310	50	15	0	4	Aust.
7							
3	The southern of the three	311	40	15	45	4	Aust.
8							
3	At the last bend, the leading of	305	10	14	50	4	Aust.
9	three						
4	Of the two following, the	306	0	15	20	4	Aust.
0	southern						
4	The northern	306	30	14	0	4	Aust.
1							
4	The last of the water, and in the	300	20	23	0	1	Aust.
2	mouth of the Southern Fish						

All stars 42. Of the first magnitude 1. Of the third 9. Of the fourth 18. Of the fifth 13. Of the sixth 1.

INFORMES CIRCA AQVARIVM. (Unformed stars around the Water-Bearer)

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1	Of three following the bend of the water, the leading	320	0	15	30	4	Aust.
2	Of the two remaining, the northern	323	0	14	20	4	Aust.
3	The southern of them	322	10	18	15	4	Aust.

PISCES. — Constellatio XXXIII.

[Margin: Pisces]

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1	In the mouth of the leading fish	325	0	9	15	4	Bor.
2	In the back of the head, the southern of two	317	30	7	30	4	Bor.
3	The northern	319	20	9	20	4	Bor.
4	In the back, the foremost of two	321	30	9	30	4	Bor.
5	The one that follows	324	0	7	30	4	Bor.
6	In the belly, the leading	319	20	4	30	4	Bor.
7	The following	323	0	2	30	4	Bor.
8	In the tail of the same fish	329	20	6	20	4	Bor.
9	On its cord, the first from the tail	334	20	5	45	6	Bor.
10	The one that follows	336	20	2	45	6	Bor.
11	After it, the leading of three bright stars	340	30	2	15	4	Bor.
12	The middle one	343	50	1	10	4	Bor.
13	The following	346	20	1	20	4	Aust.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
1 4	At the bend, the northern of two small stars	345	40	2	0	6	Aust.
1 5	The southern	346	20	5	0	6	Aust.
1 6	After the bend, the leading of three	350	20	2	20	4	Aust.
1 7	The middle one	352	0	4	40	4	Aust.
1 8	The following	354	0	7	45	4	Aust.
1 9	At the knot of both cords	356	0	8	30	3	Aust.
2 0	On the northern cord, the leading from the knot	354	0	4	20	4	Bor.
2 1	The southern of three after it	353	30	1	30	5	Bor.
2 2	The middle one	353	40	5	20	3	Bor.
2 3	The northern of three, and it is at the tip of the tail	353	50	9	0	4	Bor.
2 4	In the mouth of the following fish, the northern of two	355	20	21	45	5	Bor.
2 5	The southern	355	0	21	30	5	Bor.
2 6	In the head, the following of three small stars	352	0	20	0	6	Bor.
2 7	The middle one	351	0	19	50	6	Bor.
2 8	The foremost of three	350	20	23	0	6	Bor.
2 9	In the southern spine, the leading of three, near the left elbow of Andromeda	349	0	14	20	4	Bor.

#	Form	Long. °	'	Lat. °	'	Ma g.	Hemis .
3 0	The middle one	349	40	13	0	4	Bor.
3 1	The following of three	351	0	12	0	4	Bor.

(Pisces continues on the following folio; the foot of the page carries the catchword "32 In".)

Table of the Fixed Stars (*Tabula Stellarum*) — continued

Column headers throughout: **Forma Stellarum** (the form/description of the star) | **Longit. G. | M.** (longitude, degrees | minutes) | **Latit. G. | M.** (latitude, degrees | minutes) | **Magnitudo** (magnitude). Longitudes are absolute ecliptic longitudes (0–360°). In this southern section the latitude-hemisphere label (Bor./Aust.) is not printed in the magnitude column as it was in the zodiacal tables; the northern/southern position is instead given in the descriptive text (Borea / Australis) where relevant.

PISCES — conclusion (Constellatio XXXIII)

Forms of the stars (Pisces, stars 32–34):

N o.	Position	Longit.	Latit.	Mag.
32	In the belly, of the two, the northern one	355° 30'	17° 0'	4 (Bor.)
33	The one more to the south	352° 40'	15° 20'	4 (Bor.)
34	On the following spine, near the tail	353° 20'	11° 40'	4 (Bor.)

All stars 34. Of the third magnitude 2. Of the fourth 22. Of the fifth 3. Of the sixth 7.

Unformed stars around Pisces (Informes circa Pisces)

N

o.	Position	Longit.	Latit.	Mag.
1	In the quadrilateral below the leading Fish, of the northern side, the one that goes before	324° 30'	2° 40'	4 (Aust.)
2	The one that follows	325° 45'	2° 30'	4 (Aust.)
3	Of the southern side, the leading one	324° 0'	5° 50'	4 (Aust.)
4	The following one	325° 40'	5° 20'	4 (Aust.)

All stars 4, of magnitude: of the fourth 4.

And so, in the Zodiac the stars are 346 in all: of the first magnitude 5, of the second 9, of the third 64, of the fourth 132, of the fifth 106, of the sixth 27; nebulous 3. Also the lock of hair which we said above is called Berenice's Hair [*coma Berenices*], [reckoned] outside this number by Conon the Mathematician [Conon of Samos]. Bright 1, faint 2.

THIRD PART OF THE TABLE

Third part of the table, comprising the names of all the constellations that incline from the Zodiac toward its southern pole, together with the number, order, longitudes, latitudes, and magnitudes of the stars.

CETUS [the Whale / Sea-monster] — Constellatio XXXIV

[Margin: Cetus.]

No	Position	Longit.	Latit.	Mag
.	.	.	.	.
1	At the tip of the snout	11° 0'	7° 45'	4
2	In the jaw, the following of three	11° 0'	11° 20'	3
3	The middle one, in the middle of the mouth	6° 0'	11° 30'	3
4	The leading of three, at the knee [in genu]	3° 50'	14° 0'	3
5	In the eye	4° 0'	8° 10'	4

No .	Position	Longit.	Latit.	Mag .
6	In the mane, the northern one	5° 30'	6° 20'	4
7	In the mane, the leading one	1° 0'	4° 10'	4
8	In the breast, the northern of the four leading ones	355° 20'	24° 30'	4
9	The southern one	356° 40'	28° 0'	4
10	The northern of the following ones	0° 0'	25° 10'	4
11	The southern one	0° 20'	27° 30'	3
12	In the body, the middle of three	345° 20'	25° 20'	3
13	The southern one	346° 20'	30° 30'	4
14	The northern of the three	348° 20'	20° 30'	3
15	Toward the tail, the following of two	343° 0'	15° 20'	3
16	The leading one	338° 20'	15° 40'	3
17	In the tail, of the following ones of the quadrilateral, the northern	335° 0'	11° 40'	5
18	The southern one	334° 0'	13° 40'	5
19	Of the remaining leading ones, the northern	332° 40'	13° 0'	5
20	The southern one	332° 20'	14° 0'	5
21	At the northern end of the tail	327° 40'	9° 30'	3
22	At the southern end of the tail	329° 0'	20° 20'	3

All stars 22. Of the third magnitude 10. Of the fourth 8. Of the fifth 4.

ORION — Constellatio XXXV

[Margin: Orion.]

No .	Position	Longit.	Latit.	Mag .
1	In the head, nebulous	50° 20'	16° 30'	Neb
2	In the right shoulder, bright and reddish [Betelgeuse]	55° 20'	17° 0'	1

No .	Position	Longit.	Latit.	Mag .
3	In the left shoulder	46° 40'	17° 30'	2
4	The one that follows it	48° 20'	18° 0'	4
5	In the right elbow	57° 40'	14° 30'	4
6	In the right forearm	59° 40'	11° 50'	6
7	In the right hand, the following of the four southern ones	59° 50'	10° 40'	4
8	The leading one	59° 29'	9° 45'	4
9	Of the northern side, the following one	60° 40'	8° 15'	6
10	The leading one of the same side	60° 0'	8° 15'	6
11	In the club [in colorobo], the leading of two	55° 0'	3° 45'	5
12	The following one	57° 40'	3° 15'	5
13	In the back, of the four in a straight line, the following one	50° 50'	19° 40'	4
14	The second toward the west	49° 40'	20° 0'	6
15	The third toward the west	48° 40'	20° 20'	6
16	The fourth in order toward the west	47° 30'	20° 40'	5
17	In the shield, the northernmost of nine	43° 50'	8° 0'	4
18	The second	42° 50'	8° 10'	4
19	The third	41° 20'	10° 15'	4
20	The fourth	39° 40'	12° 50'	4
21	The fifth	38° 30'	14° 15'	4
22	The sixth	37° 50'	15° 50'	3
23	The seventh	38° 10'	17° 10'	3
24	The eighth	38° 40'	20° 20'	3
25	The remaining one of these, the southernmost	39° 40'	21° 30'	3
26	In the belt, the leading of the three bright ones	48° 40'	24° 10'	2
27	The middle one	50° 40'	24° 50'	2

No.	Position	Longit.	Latit.	Mag.
28	The following of the three, in a straight line	51° 40'	25° 30'	2
29	In the hilt of the sword	47° 10'	25° 50'	3
30	In the sword, the northern of three	50° 10'	28° 40'	4
31	The middle one	50° 0'	29° 30'	3
32	The southern one	50° 20'	29° 50'	3
33	At the end of the sword, the following of two	51° 0'	30° 30'	4
34	The leading one	48° 20'	30° 50'	4
35	In the left foot, bright, and shared with the River [Rigel]	42° 30'	31° 30'	1
36	In the left shin	44° 20'	30° 15'	4
37	In the left heel	46° 40'	31° 10'	4
38	In the right knee	53° 30'	33° 30'	3

All stars 38. Of the first magnitude 2. Of the second 4. Of the third 8. Of the fourth 15. Of the fifth 3. Of the sixth 5. Nebulous 1.

FLUVIUS, or ERIDANUS, or the NILE [the River] — Constellatio XXXVI

[Margin: Eridanus.]

No.	Position	Longit.	Latit.	Mag.
1	The one at Orion's left foot, at the beginning of the River	41° 40'	31° 50'	4
2	At the bend, near Orion's leg, the northernmost	42° 10'	28° 15'	4
3	After this, the following of two	41° 20'	29° 50'	4
4	The one that goes before	38° 0'	28° 15'	4
5	Then, of two, the following	36° 30'	25° 50'	4

No.	Position	Longit.	Latit.	Ma g.
	one			
6	The one that precedes	33° 30'	25° 20'	4
7	After these, the following of three	29° 40'	26° 0'	4
8	The middle one	29° [?]'	27° 0'	4
9	The leading of three	26° 10'	27° 50'	4
10	After a gap, the following of four	20° 20'	32° 50'	3
11	The one that goes before it	18° 0'	31° 0'	4
12	The third to the west	17° 30'	28° 50'	3
13	The westernmost of all four	15° 30'	28° 0'	3
14	Again in like manner, the following of four	10° 30'	25° 30'	3
15	The one west of it	8° 10'	23° 50'	4
16	The one still west of this	5° 30'	23° 10'	3
17	The one that goes before these four	3° 50'	23° 15'	4
18	The one that, at the winding of the River, touches the breast of Cetus	358° 30'	32° 10'	4
19	The one that follows it	359° 20'	34° 50'	4
20	The leading of the three following	2° 10'	38° 30'	4
21	The middle one	7° 10'	38° 10'	4
22	The following of three	10° 50'	30° 0'	5
23	In the quadrilateral, the northern of the two leading ones	14° 40'	41° 30'	4
24	The southern one	14° 50'	42° 30'	4
25	Of the following side, the leading one	15° 30'	43° 20'	4
26	The following of those four	18° 0'	43° 20'	4

No.	Position	Longit.	Latit.	Ma g.
27	Toward the east, the northern of the two joined together	27° 30'	50° 20'	4
28	The one more to the south	28° 20'	51° 45'	4
26 [recte 29]	At the bend, the following of two	21° 30'	53° 50'	4
30	The leading one	19° 10'	53° 10'	4
31	In the remaining stretch, the following of three	11° 10'	53° 0'	4
32	The middle one	8° 10'	53° 30'	4
33	The leading of three	5° 10'	52° 0'	4
34	At the end of the River	353° 30'	53° 30'	1

All stars 34. Of the first magnitude 1. Of the third 5. Of the fourth 27. Of the fifth 1.

LEPUS [the Hare] — Constellatio XXXVII

[Margin: Lepus.]

No	Position	Longit.	Latit.	Mag
.	.	.	.	.
1	In the ears, of the leading ones of the quadrilateral, the northern	43° 0'	35° 0'	5
2	The southern one	43° 10'	36° 30'	5
3	Of the following side, the northern one	44° 40'	35° 40'	5
4	The southern one	44° 40'	36° 40'	5
5	On the mount [in monte]	42° 30'	39° 40'	4
6	At the end of the left forefoot	39° 30'	45° 15'	4
7	In the middle of the body	48° 0'	41° 30'	3
8	Under the belly	48° 10'	44° 20'	3
9	In the hind feet, the more northern of two	54° 20'	44° 0'	4
10	The one more to the south	52° 20'	45° 50'	4

No	Position	Longit.	Latit.	Mag
.				.
11	In the loin	53° 20'	38° 20'	4
12	At the tip of the tail	56° 0'	38° 10'	4

All stars 12. Of the third magnitude 2. Of the fourth 6. Of the fifth 4.

CANIS MAIOR [the Greater Dog] — Constellatio XXXVIII

[Margin: Canis maior.]

No	Position	Longit.	Latit.	Mag
.				.
1	In the mouth, the most brilliant, called the Dog[-star], Candens [Sirius]	71° 0'	39° 10'	1
2	In the ears	73° 0'	35° 0'	4
3	In the head	74° 40'	36° 30'	5
4	In the neck, the northern of two	76° 40'	37° 45'	4
5	The southern one	78° 40'	40° 0'	4
6	In the breast	73° 50'	42° 30'	5
7	In the right knee, the northern of two	69° 30'	41° 15'	5
8	The southern one	69° 20'	42° 30'	5
9	At the end of the forefoot	64° 20'	41° 20'	3
10	In the left knee, the leading of two	68° 0'	46° 30'	5
11	The following one	69° 30'	45° 50'	5
12	In the left shoulder, the following of two	78° 0'	46° 0'	4
13	The one that goes before	75° 0'	47° 0'	5
14	At the top of the left thigh	80° 0'	48° 45'	3
15	Under the belly, between the thighs	77° 0'	51° 30'	3
16	In the ham of the right leg	86° 20'	55° 10'	4
17	At the end of that same foot	63° 0'	53° 45'	3
18	At the tip of the tail	85° 30'	50° 30'	3

All stars 18. Of the first magnitude 1. Of the third 5. Of the fourth 5. Of the fifth 7.

Unformed stars around the Dog (Informes circa Canem)

No .	Position	Longit.	Latit.	Mag .
1	To the north, at the crown of the Dog	72° 50'	25° 13'	4
2	Under the hind feet, on a straight line, the southern one	63° 20'	61° 30'	4
3	The one more to the north	64° 40'	58° 45'	4
4	The one still more northern than this	66° 20'	57° 0'	4
5	The remaining one of those four, the northernmost	67° 30'	56° 0'	4
6	Toward the west, almost in a straight line, the leading of three	50° 20'	55° 30'	4
7	The middle one	51° 40'	57° 40'	4
8	The following of three	55° 40'	59° 30'	4
9	Beneath these, the following of two bright ones	52° 20'	59° 40'	2
10	The leading one	49° 20'	57° 40'	2
11	The remaining one, more southern than those mentioned above	45° 30'	59° 30'	4

All stars 11. Of the second magnitude 2. Of the fourth 9.

PROCYON, or CANIS MINOR [the Lesser Dog], also called ANTECANIS — Constellatio XXXIX

[Margin: Canis minor.]

No .	Position	Longit.	Latit.	Mag .
1	In the neck	78° 20'	14° 0'	4
2	In the thigh, shining, Procyon, or the Dog [Procyon]	82° 30'	16° 10'	1

All stars 2. Of the first magnitude 1. Of the fourth 1.

ARGUS, or the SHIP [Argo Navis] — Constellatio XXXX

[Margin: Nauis.]

No				Mag
.	Position	Longit.	Latit.	.
1	At the stern of the ship, the leading of two	93° 40'	42° 40'	5
2	The following one	97° 40'	43° 20'	3

Table of the Stars (*Tabula Stellarum*) — Southern Constellations (continued)

Column headers throughout (verbatim): FORMÆ STELLARVM (Configurations of the stars) | **Longit. G. | M.** (Longitude, degrees | minutes) | **Latit. G. | M.** (Latitude, degrees | minutes) | **Magnitudo** (Magnitude). Latitudes in this southern section are southern latitudes. A [*] at the start of a description marks a star flagged with a marginal asterisk in the source (an editorial mark keyed to Clavius's commentary).

Argo / The Ship (*Navis*) — Constellatio XXXX (continued from stars 1–2)

N						Ma
o.	Star description	Long °	Long '	Lat °	Lat '	g.
3	Of the two on the poop, the northern	92	10	45	0	4
4	The one more to the south	92	10	46	0	4
5	Preceding the two	88	40	45	30	4
6	Shining in the middle of the shield	89	40	47	15	4
7	Of the three below the shield, the preceding	88	50	49	45	4
8	The following	92	40	49	50	4
9	The middle of the three	91	40	49	15	4

N o.	Star description	Long °	Long '	Lat °	Lat '	Ma g.
1 0	At the end of the rudder	97	20	49	50	4
1 1	Of the two in the keel of the poop, the northern	87	20	53	0	4
1 2	[*] The southern	87	20	58	40	3
1 3	In the base of the poop, the northern	93	30	55	30	5
1 4	Of the three on the same base, the preceding	95	30	58	30	5
1 5	The middle	96	40	57	15	4
1 6	The following	99	50	57	45	4
1 7	The bright one following, on the cross-bench	104	30	58	20	2
1 8	Of the two faint ones below it, the preceding	101	30	60	0	5
1 9	[*] The following	104	20	59	20	5
2 0	[*] Of the two above the said bright one, the preceding	106	30	56	40	5
2 1	The following	107	40	57	0	5
2 2	Of the three at the little shields and mast-step, the northern	119	0	51	30	4
2 3	[*] The middle	119	30	55	40	4
2 4	The southern of the three	117	20	55	10	4
2 5	Of the two joined below these, the northern	122	30	60	0	4
2	The more southern	122	20	61	11	4

N o.	Star description	Long °	Long '	Lat °	Lat '	Ma g.
6						
2 7	Of the two in the middle of the mast, the southern	113	30	51	30	4
2 8	The northern	112	40	49	40	4
2 9	Of the two at the top of the sail, the preceding	111	20	43	20	4
3 0	The following	112	20	43	30	4
3 1	Below the third, which follows the shield	98	30	54	30	2
3 2	In the section of the decking	100	50	51	15	2
3 3	Among the oars, in the keel	95	0	63	0	4
3 4	The faint one following it	102	20	64	30	6
3 5	The bright one following it, on the decking	113	20	63	50	2
3 6	Shining more to the south, within the keel	121	50	69	40	2
3 7	Of the three following it, the leading	128	30	65	40	3
3 8	The middle	134	40	65	50	3
3 9	The following	139	20	65	50	2
4 0	Of the two following toward the section, the preceding	144	20	62	50	3
4 1	The following	151	20	62	15	3
4 2	On the northern and leading tiller, the one that goes before	57	20	65	50	4

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
4 3	The one that follows	73	30	65	40	3
4 4	The one preceding on the remaining tiller, Canopus	70	30	75	0	1
4 5	The remaining one, following it	82	20	71	50	3

Summary (verbatim): *Omnes stellæ 45. Primæ magnit. 1. Secundæ 6. Tertiæ 8. Quartæ 22. Quintæ 7. Sextæ 1.* — "All stars: 45. Of first magnitude 1, second 6, third 8, fourth 22, fifth 7, sixth 1." (Magnitude tally of stars 3–45 as transcribed is self-consistent: the missing 2 counts belong to stars 1–2 of the prior page, one third-magnitude and one fifth-magnitude.)

Hydra / The Water-Snake — Constellatio XLI

Margin: Hydra.

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
1	Of the five in the head, of the two preceding in the nostrils, the southern	97	20	15	0	4
2	The northern of the two, and in the eye	98	40	13	40	4
3	Of the two following, the northern, and in the back of the head	99	0	11	30	4
4	The southern of them, and in the open mouth	98	50	14	45	4
5	The one following all these, in the cheek	100	50	12	15	4
6	Of the two in the extension of the neck, the preceding	103	40	11	50	5
7	[*] The following	106	40	13	40	4
8	Of the three at the bend of the neck, the middle	111	40	15	20	4

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
9	Following this	114	0	14	50	4
1 0	[*] The most southern	111	40	17	10	4
1 1	Of the two adjacent to the south, the faint one; and the northern	112	30	19	45	6
1 2	The bright one of them, following	113	20	20	30	2
1 3	Of the three after the bend of the neck, the leading	119	20	26	30	4
1 4	The following	124	30	23	15	4
1 5	The middle of them	122	0	26	0	4
1 6	Of three in a straight line, the preceding	131	20	24	30	3
1 7	The middle	133	20	23	0	4
1 8	The following	136	20	22	10	3
1 9	Of the two below the base of the Bowl (Crater), the northern	144	50	25	45	4
2 0	The southern	145	40	30	10	4
2 1	After these, in the triangle, the preceding	155	30	31	20	4
2 2	The southern of them	157	50	34	10	4
2 3	The following of the same three	159	30	31	40	3
2 4	[*] After the Raven (Corvus), nearest to the tail	173	20	13	40	4
2	[*] At the tip of the tail	186	50	17	40	4

N						Ma
o.	Star description	Long °	Long ′	Lat °	Lat ′	g.
5						

Summary (verbatim): *Omnes stellæ 25. Secundæ magnit. 1. Tertiæ 3. Quartæ 19. Quintæ 1. Sextæ 1.* — "All stars: 25. Of second magnitude 1, third 3, fourth 19, fifth 1, sixth 1." (Transcribed tally matches exactly.)

Unformed stars around Hydra (*Informes circa Hydram*)

N						Ma
o.	Star description	Long °	Long ′	Lat °	Lat ′	g.
1	[*] From the head, to the south	95	13	13	0	3
2	[*] Following those which are in the neck	124	20	16	0	3

(No magnitude-summary line is printed for these two unformed stars.)

Crater / The Bowl, or Cup, or Urn (*Sive Patera, vel Urna*) — Constellatio XLII

Margin: Crater.

N						Ma
o.	Star description	Long °	Long ′	Lat °	Lat ′	g.
1	At the base of the Bowl, also shared with Hydra	139	40	23	0	4
2	Of the two in the middle of the Bowl, the southern	146	0	19	30	4
3	The northern of them	143	30	18	0	4
4	On the southern circumference of the rim	150	20	18	30	4
5	On the northern edge	142	40	13	40	4
6	On the southern handle	152	30	16	30	4
7	On the northern handle	145	0	11	50	4

Summary (verbatim): *Omnes stellæ 7. Quartæ magnitudinis.* — "All stars: 7. Of fourth magnitude." (All seven transcribed as magnitude 4.)

Corvus / The Raven — Constellatio XLIII

Margin: Corvus.

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
1	In the beak, also shared with Hydra	158	40	21	30	3
2	In the neck	157	40	19	40	3
3	In the breast	160	0	18	10	5
4	In the right wing, and the leading one	160	50	14	50	3
5	Of the two in the following wing, the leading	160	0	12	30	3
6	The following	161	20	11	45	4
7	In the tip of the foot, shared with Hydra	163	50	18	10	3

Summary (verbatim): *Omnes stellæ 7. Tertiæ magnit. 5. Quartæ 1. Quintæ 1.* — "All stars: 7. Of third magnitude 5, fourth 1, fifth 1." (Transcribed tally matches exactly.)

Centaurus / The Centaur — Constellatio XLIV

Margin: Centaurus.

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
1	Of the four in the head, the most southern	183	50	21	40	5
2	The one more to the north	183	20	18	50	5
3	Of the two in the middle, the preceding	182	30	20	30	4
4	The following, and the remaining of the four	183	20	20	0	5
5	In the left shoulder, and the leading one	179	30	25	40	3
6	In the right shoulder	189	0	22	30	3

N o.	Star description	Long °	Long '	Lat °	Lat '	Ma g.
7	In the left upper arm	182	30	27	30	4
8	Of the four in the shield, of the two preceding, the northern	191	30	22	20	4
9	The southern	192	30	23	45	4
1 0	Of the remaining two, which are at the top of the shield	195	20	18	15	4
1 1	The one more to the south	196	50	20	50	4
1 2	Of the three in the right side, the preceding	186	40	28	20	4
1 3	The middle	187	20	29	20	4
1 4	The following	188	30	28	0	4
1 5	In the right arm	189	40	26	3 [?]	4
1 6	In the right elbow	196	10	25	15	3
1 7	In the tip of the right hand	200	50	24	0	4
1 8	Shining at the emergence of the human body	191	20	33	30	3
1 9	Of the two faint ones, the following	191	0	31	0	5
2 0	The preceding	189	50	30	20	5
2 1	Along the line of the back	185	30	33	50	5
2 2	Preceding this, on the horse's back	182	20	37	30	5
2 3	Of the three in the loins, the following	179	10	40	0	3
2	[*] The middle	178	20	40	20	4

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
4						
2 5	The leading of the three	176	0	41	0	5
2 6	Of the two adjacent in the right haunch, the preceding	176	0	46	10	3
2 7	[*] The following	176	40	46	45	4
2 8	In the breast, below the horse's flank	191	40	40	45	4
2 9	[*] Of the two below the belly, the preceding	189	40	43	0	2
3 0	[*] The following	191	0	43	45	3
3 1	In the hollow of the right foot	183	20	51	10	2
3 2	[*] In its calf	188	40	51	40	2
3 3	In the hollow of the left foot	179	40	55	10	4
3 4	[*] Below its muscle	184	30	55	40	2
3 5	[*] In the top of the right fore- foot	211	40	41	10	1
3 6	In the left knee	197	30	45	20	2
3 7	[*] On the outside, below the right thigh	188	0	49	10	4

Summary (verbatim): *Omnes stellæ 37. Primæ magnit. 1. Secundæ 5. Tertiæ 7. Quartæ 16. Quintæ 8.* — "All stars: 37. Of first magnitude 1, second 5, third 7, fourth 16, fifth 8." (Transcribed tally matches exactly.)

The Beast of the Centaur, or the Wolf (*Bestia Centauri, sive Lupus*) — Constellatio XLV

Margin: Lupus.

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
1	In the top of the hind foot, toward the Centaur's hand	201	20	24	50	3
2	[*] In the hollow of the same foot	199	10	29	10	3
3	Of the two in the shoulder, the preceding	204	20	21	15	4
4	The following	207	30	21	0	4
5	In the middle of the body	206	20	25	10	4
6	In the belly	203	30	27	0	5
7	In the haunch	204	10	29	0	5
8	Of the two along the haunch, the northern	208	0	28	30	5
9	The southern	207	0	30	0	5
1 0	In the top of the loin	208	40	33	10	5
1 1	Of the three at the tip of the tail, the southern	195	20	31	20	5
1 2	The middle	195	10	30	0	4
1 3	The northern of the three	196	20	29	20	4
1 4	[*] Of the two in the neck, the southern	212	10	17	0	4
1 5	The northern	212	40	15	20	4
1 6	Of the two in the open jaws, the preceding	209	0	13	30	4
1	The following	210	0	12	50	4

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
7						
1 8	[*] Of the two in the fore foot, the more southern	200	40	11	30	4
1 9	[*] The one more to the north	199	50	10	0	4

Summary (verbatim): *Omnes stellæ 19. Tertiæ magnit. 2. Quartæ 11. Quintæ 6.* — "All stars: 19. Of third magnitude 2, fourth 11, fifth 6." (Transcribed tally matches exactly.)

The Hearth, or Censer, or Altar (*Lar, sive Thuribulum, seu Ara*) — Constellatio XLVI

Margin: Ara.

N o.	Star description	Long °	Long ′	Lat °	Lat ′	Ma g.
1	Of the two in the base, the northern	231	0	22	40	5
2	The southern	233	40	25	45	4
3	In the middle of the small altar	229	30	26	30	4
4	Of the three in the fire-pan, the northern	224	0	30	20	5
5	Of the remaining two adjacent, the southern	228	30	34	10	4
6	The northern	228	20	33	20	4
7	In the middle of the flame	224	10	34	10	4

Summary (verbatim): *Omnes stellæ 7. Quartæ magnit. 5. Quintæ 2.* — "All stars: 7. Of fourth magnitude 5, fifth 2." (Transcribed tally matches exactly.)

(The catalogue continues with Corona Australis and Piscis Austrinus; the southern-region total and the grand total of 1022 do not appear on these pages.)

TABLE OF THE STARS [FORMÆ STELLARVM]

Column headers (verbatim): **Longit. G.** | **M.** | **Latit. G.** | **M.** | **Magnitudo**
(Longitude in degrees and minutes | Latitude in degrees and minutes | Magnitude).

THE SOUTHERN CROWN, WHICH IS ALSO THE WHEEL OF IXION.
Constellation 47. [CORONA AVSTRINA, QVÆ ET ROTA IXIONIS.
Constellatio XLVII.]

[Margin: Corona Austrina (The Southern Crown).]

N			M		M Magnitud
o.	Description	Longit. G.	. Latit. G.	. e	
1	<i>Quæ ad ambitum Australem foris præcedit</i> — The one on the outside that leads toward the southern edge	242	3 21 0	3 4 0

number 316 in all: of the first magnitude 7, of the second 18, of the third 60, of the fourth 168, of the fifth 53, of the sixth 9, and 1 nebulous. [omnes 316. Primæ magnit. 7. Secundæ 18. Tertiæ 60. Quartæ 168. Quintæ 53. Sextæ 9. Neb. 1.]

IN THE WHOLE FIRMAMENT, MOREOVER, ALL THE STARS, [IN TOTO AVTEM FIRMAMENTO STELLAE OMNES,]

besides the three in the lock of hair, number **1022**, as was said above. [præter tres in cincinno. 1022. vt supra dictum est.]

[Margin: That there are no stars near the Antarctic pole. (Iuxta polum Antarcticum nullas esse stellas.)]

From all of this it is plainly established that near the Antarctic pole there are no stars, since the nearest of all to that pole is star 34, beneath the muscle of the Centaur's left foot, which is 28°39' distant from the Antarctic pole — for its declination, as we shall show a little later, amounts to 61°21'. For if those who have sailed from Portugal [Lusitania] and the other provinces of Spain to the Indies report truly, the star nearest the pole — the one they watch to steer the ship's course across the Ocean — is about 30° from the Antarctic pole, as they themselves observed with instruments. Hence it will be a fable, what is commonly said, that near the Antarctic pole there are very bright stars forming the shape of a cross — unless we take this to mean the stars in the Centaur, of which nos. 29, 31, 33, and 34 form a figure like a cross, and are all of the second magnitude.

THE USE OF THE PRECEDING TABLE. [VSUS PRAECEDENTIS TABVLAE.]

[Margin: The use of the preceding table of stars. (Vsus præcedentis tabulæ stellarum.)]

From the table set out above, three things are known about each individual star: longitude, latitude, and magnitude. For if you take any star in its own constellation, you will have at once, in the same line: first the degrees and minutes of its longitude; then the degrees and minutes of its latitude; and finally its magnitude.

EXAMPLE. In the 26th constellation, namely Leo, I take the 27th star, which is at the end of the tail [Denebola]. In the same line, then, I find the longitude of this star to be $137^{\circ}30'$, its latitude $11^{\circ}50'$, and finally that the star itself is of the first magnitude — and so for the rest.

[Margin: The longitudes of the stars in the preceding table begin from the first star of Aries. (Longitudines stellarum in præcedenti tabula incipiunt à prima stella Arietis.)]

But this longitude (like all the others contained in the table above) is to be understood not from the beginning of Aries ♈ of the *primum mobile*, but from the first star of the constellation Aries ♈, which is located in the right horn, so that relative to it all the others lie farther to the east. For Nicolaus Copernicus [Copernicus] did not compute the positions of all the stars from the beginning of Aries ♈ of the *primum mobile* — as Ptolemy and all other astronomers were accustomed to number the positions of the stars — but from the first star of Aries.

For since the fixed stars always keep the same longitude reckoned from the first star of Aries, but not from the beginning of Aries ♈ of the *primum mobile* — that is, from that common intersection of the Zodiac with the Equator which is usually called the beginning of Aries ♈ — because from this point they always move gradually toward the eastern signs, as we showed above: therefore Copernicus preferred to refer the longitudes of the stars to the first star of Aries rather than to the beginning of Aries ♈ of the *primum mobile*, so that, just as their latitudes always remain the same, so too their longitudes should undergo no variation.

[Margin: What the true longitudes of the stars are, and how they are to be investigated. (Vera longitudes stellarum quid & quomodo inuestigentur.)]

But if anyone wishes to know the distances of the individual stars from the vernal equinox — that is, from the beginning of Aries Υ of the *primum mobile* (these distances being in fact called the true longitudes of the stars), in the manner of Ptolemy and the other astronomers — he will reach the desired end without much labor by this method. First let the true position of the first star of Aries be ascertained, or (what is the same thing) the true longitude of that star. Then let the longitude of any star be taken from the table above, and to it let the true longitude of the first star of Aries be added. For the resulting sum, if it is less than 360° , will at once indicate the distance of the proposed star from the beginning of Aries Υ of the *primum mobile*; but if it exceeds 360° , the number left over, after 360° has been cast off, will give the said distance.

EXAMPLE. According to the observations of Peter Apian [Petrus Apianus], who examined the true positions of the fixed stars in the year 1532, the first star of Aries has moved eastward from the beginning of Aries Υ of the *primum mobile* by $26^\circ 38'$. If, then, I wish to know how far Spica $\mathfrak{M}$ [in Virgo] has moved from that same beginning, I take from the table above, in the constellation Virgo $\mathfrak{M}$ (which is the 27th constellation), the distance of the said star from the first star of Aries Υ , namely $170^\circ 0'$; to this I add the $26^\circ 38'$ by which the first star of Aries Υ has moved from the vernal equinox, and $197^\circ 38'$ results. And so great is the true longitude of that star which they call Spica $\mathfrak{M}$.

Likewise, if one should wish to inquire how far distant from the vernal equinox is that star which lies in the navel of Pegasus and in the head of Andromeda [Alpheratz], I take from the 19th constellation, which is Pegasus — or from the 20th, which is Andromeda — the distance of the said star from the first star of Aries Υ , namely $341^\circ 10'$; to this I add $26^\circ 38'$, and $367^\circ 48'$ results, from which, if 360° be cast off, $7^\circ 48'$ remain. So great, then, is the true longitude of the proposed star. And so for the rest.

But it must not be passed over that Nicolaus Copernicus, an exact observer of the stars, found in the year 1525 that the first star of Aries Υ had moved from the vernal equinox not only by $26^\circ 38'$, as Apian holds, but by $27^\circ 21'$. Therefore, if you prefer to trust his observations rather than Apian's, you will find, by the preceding procedure, the longitude of Spica $\mathfrak{M}$ — that is, its distance from the beginning of Aries Υ of the *primum mobile* — to be $197^\circ 21'$, and the longitude of the head of Andromeda to comprise $8^\circ 31'$. But since the stars gradually advance from West to East, more minutes must be added for the present time. For from the year 1525 up to the Jubilee year 1575 — when at Rome we constructed, as accurately as we could, an astronomical globe according to this table — the fixed

stars have advanced by about 26'. Therefore, to the longitudes found in the preceding table, 27°47' must be added so that the true longitudes may be obtained. This is what we ourselves carried out on that globe. By this reckoning Spica ♏ will be distant from the beginning of Aries ♈ by 197°47', while the head of Andromeda will be 8°57' from the same beginning. For the year 1600, 28°6' must be added; for by so great a space will the first star of Aries ♈ then be elongated from the vernal equinox, according to the Prussian Tables [Tabulae Prutenicae] drawn from Copernicus's teaching. But what must be added at other times, both before and after the Nativity of the Lord, you will learn from the scholium to Proposition 11, Book 2, of our *Astrolabe* [Astrolabium].

[Margin: In what sign and degree of the Ecliptic any given star is found. (In quo signo, & gradu Ecliptica quavis stella reperiatur.)]

From this, too, you will easily discover in what sign of the Zodiac and in what degree any given star is found. For if the degrees of the true longitude that has been found are divided by 30, the whole signs by which the star is removed from the vernal equinox will at once appear in the quotient; and the remaining number of degrees and minutes is then to be assigned to the following sign.

EXAMPLE. The longitude of Spica ♏ was found to be 197°47' (for we now follow the observation of Copernicus as the truer one, with 26' still added, as we said, for the year 1575). I divide 197 by 30, and the quotient is 6, with 17°47' remaining. Therefore Spica ♏ has moved from the beginning of Aries ♈ of the *primum mobile* by six whole signs, and it is in the 17th degree and 47th minute of the seventh sign, namely Libra ♎. I therefore declare that at this time the true position of Spica ♏ is at 17°47' of Libra ♎. By the same reasoning the true position of the head of Andromeda will be found at 8°57' of Aries ♈. And in the same way you will investigate all the positions of the fixed stars, whether according to the observations of Apian, or of Nicolaus Copernicus, or of anyone else, and so on.

ON INVESTIGATING THE DECLINATIONS OF THE STARS. [DE STELLARVM DECLINATIONIBVS INVESTIGANDIS.]

[Margin: In what way the declinations of the stars are investigated. (Declinationes stellarum quo pacto inuestigentur.)]

Since the fixed stars, on account of that very slow motion from West to East, continually change their declinations from the Equator, I think it worthwhile to teach briefly here by what method the declinations of the stars — whose longitudes and latitudes are known — may be found from the sines [ex sinibus

[?]]. For this matter is of extraordinary usefulness among astronomers, especially in the construction of instruments. But although we can accomplish what is proposed in many ways, as we showed in the scholium to Canon 3, Book 3, of the *Astrolabe*, Number 10, I have preferred here to explain only that method which Pedro Nunes [Petrus Nonius] set forth in his little book *On Twilights* [De crepusculis], and which we demonstrated more clearly in the scholium to Canon 15, Book 3, of the *Astrolabe*, Number 6. The method is as follows.

Let it be arranged that: as the square of the whole sine [the radius] is to the rectangle contained under the sine of the maximum declination of the Ecliptic [the obliquity] and the sine of the complement of the proposed star's latitude, so is the versed sine of the star's longitude — reckoned from the beginning of Cancer ☿ if the star's latitude is northern, or from the beginning of Capricorn ♑ if the star's latitude is southern — to a fourth number. (This longitude is to be counted from Cancer ☿ according to the succession of the signs if the star lies in the descending semicircle of the Ecliptic — that is, if its true longitude from the beginning of Aries ♈ is greater than 90° but less than 270° — but against the succession of the signs if the star lies in the ascending semicircle of the Ecliptic — that is, if its true longitude from the beginning of Aries ♈ is less than 90° or greater than 270° . For by this rule the star's longitude computed from the beginning of Cancer ☿ will always be less than a semicircle. In the contrary manner the longitude is to be counted from the beginning of Capricorn ♑: for if the star lies in the descending semicircle of the Ecliptic, the longitude from the beginning of Capricorn ♑ is to be computed against the succession of the signs, but if in the ascending semicircle, according to the succession of the signs. For in this way, again, the star's longitude computed from the beginning of Capricorn ♑ will always come out less than a semicircle.)

For a number will be found from which, by this technique, we shall determine the star's declination. Let the number found be compared with the sine of the complement of the difference between the maximum declination of the Ecliptic and the complement of the star's latitude. For if the number found is equal to that sine of the complement, the star will have no declination but will lie on the Equator. But if it is less, then subtracting this from that, there will remain the sine of the star's declination, of the same denomination as the latitude — that is, northern if the star's latitude is northern, southern if it is southern. If, finally, the number found is greater than that sine of the complement, then subtracting this from that, the remainder will be the sine of the star's declination, of the contrary denomination to the latitude — that is, northern if the star has southern latitude, southern if it has northern. The matter will become clearer by a few examples.

[Margin: The declination of Arcturus. (Declinatio Arcturi.)]

Let the declination of Arcturus be found — the star that is unformed near Boötes, that is, in constellation 5. Since this star has in the table a longitude of $170^{\circ}20'$, we shall add $27^{\circ}47'$ to make its true longitude from the beginning of Aries Υ $198^{\circ}7'$. Since this is greater than 90° but less than 270° , the said star will lie in the descending semicircle of the Ecliptic, and its longitude must be reckoned from the beginning of Cancer $\mathfrak{C}$ (since it has northern latitude) according to the succession of the signs; and this longitude, if 90° be subtracted from its true longitude, will be found to contain $108^{\circ}7'$, whose versed sine will be 131095, the whole sine being taken as 100000. The northern latitude of the same star is $31^{\circ}30'$, and its complement $58^{\circ}30'$. The difference, too, between the maximum declination of the Ecliptic — that is, $23^{\circ}30'$ — and the complement of the star's latitude — that is, $58^{\circ}30'$ — is $35^{\circ}0'$, and the sine of the complement of this difference is 81915.

Therefore, let it be set up thus: as 10000000000, the square of the whole sine, is to 3399816736, the rectangle contained under 39874 (the right sine of the maximum declination of the Ecliptic) and 85264 (the sine of the complement of the proposed star's latitude), so is 131095 (the versed sine of the star's longitude from Cancer $\mathfrak{C}$, according to the succession of the signs) to a fourth number. (That is: following the rule of proportions which they call the Rule of Three, we multiply the said rectangle — which is obtained by multiplying the sine of the maximum declination of the Ecliptic by the sine of the complement of the star's latitude — by the versed sine of the star's longitude; that is, we multiply the second number of the Rule of Three into the third, and divide the product by the square of the whole sine, that is, by the first number of the Rule of Three — which is done most easily if the ten right-hand figures are cast off from the product.) By this, the number 44569 will be found. Since it is less than 81915 — the sine of the complement of the difference between the maximum declination of the Ecliptic and the complement of the star's latitude — we shall subtract it from 81915, the sine of the complement of the said difference, and there will remain 37346, the sine of the northern declination of Arcturus, to which, in the table of sines, corresponds an arc of $21^{\circ}56'$. So great, then, is the declination of Arcturus from the Equator toward the North.

[Margin: The declination of Capella [Hircus]. (Declinatio Hirci.)]

Let the declination that Capella [Hircus, "the Goat"] has be inquired into next — the brightest star on the left shoulder of Auriga, and the third in constellation 12. The longitude of this star has in the table $48^{\circ}20'$; and if $27^{\circ}47'$ be added to it, its true longitude from the beginning of Aries Υ will be assembled as $76^{\circ}7'$. Since this

is less than 90° , the given star will lie in the ascending semicircle of the Ecliptic, and its longitude must be reckoned from Cancer $\mathfrak{C}$ (since its latitude is northern) against the succession of the signs; and this longitude, if its true longitude be subtracted from 90° , will comprise $13^\circ 53'$, whose versed sine will be 2921. The northern latitude of the same star is $22^\circ 30'$, and its complement $67^\circ 30'$. The difference, too, between $23^\circ 30'$, the maximum declination of the Ecliptic, and $67^\circ 30'$, the complement of the star's latitude, comprises $44^\circ 0'$; and the sine of the complement of this difference is 71933. Therefore, let it be set up thus: as 10000000000, the square of the whole sine, is to 3683839238, the rectangle comprised under 39874 (the right sine of the maximum declination of the Ecliptic) and 92387 (the sine of the complement of the given star's latitude), so is 2921 (the versed sine of the star's longitude from Cancer $\mathfrak{C}$, against the succession of the signs) to a fourth number— ...this number 1076 will be found. Since it is smaller than 71933 — the sine of the complement of the difference between the maximum declination of the ecliptic and the complement of the star's latitude — we subtract it from 71933, and there remains 70857, the sine of the northern declination of Hircus [Capella]. To this in the table of sines correspond 45 degrees 7 minutes, for the declination of Hircus from the equator toward the North.

[Second star of Aquarius — declination]

[Margin: The declination of the 2nd star of Aquarius, which is placed in the right shoulder, and is of the 3rd magnitude.]

AGAIN, let the declination be investigated of the star that is placed in the right shoulder of $\approx$ [Aquarius], which is the second [star] in the constellation Aquarius and is of magnitude 3. Its longitude in the table is 299 degrees 40 minutes. If we add to this 27 degrees 47 minutes, its true longitude from the beginning of Υ [Aries] comes to 327 degrees 27 minutes. Since this is greater than 270 degrees, the star will lie in the ascending semicircle of the ecliptic, and its longitude must be reckoned from $\mathfrak{C}$ [Cancer] (because it has northern latitude), against the succession of the signs. If this true longitude is subtracted from 360 degrees, and 90 degrees are added to the remainder, we obtain 122 degrees 33 minutes, whose versed sine is 153803. The northern latitude of the same star is 11 degrees 0 minutes, and its complement is 79 degrees 0 minutes. Moreover, the difference between 23 degrees 30 minutes of the maximum declination of the ecliptic and 79 degrees 0 minutes, the complement of the star's latitude, amounts to 55 degrees 30 minutes, and the sine of the complement of this difference is 56640.

Therefore, if the proportion is set up — as 10000000000, the square of the whole sine, is to 3914111588, the rectangle contained under 39874 (the right sine of the

maximum declination of the ecliptic) and 98162 (the sine of the complement of the star's latitude), so is 153803 (the versed sine of the star's longitude from ♋ [Cancer], against the succession of the signs) to a fourth — this number 60200 will be found. Since it is greater than 56640 (the sine of the complement of the difference between the maximum declination of the ecliptic and the complement of the star's latitude), we take away from it 56640, the sine of the complement of the said difference, and there remains 3560, the sine of the southern declination of the said star. To this in the table of sines correspond 2 degrees 2 minutes, for the declination of the given star from the equator toward the South.

[34th star of Centaurus — declination]

[Margin: The declination of the 34th star of Centaurus, which is under the muscle of the left foot, and is of the 2nd magnitude.]

LASTLY, let it be investigated how great a declination the 34th star in Centaurus has — the one that is most southern, lies under the muscle of the left foot, and is of magnitude 2. Its longitude in the table is 184 degrees 30 minutes. If we add to it 27 degrees 47 minutes, its true longitude from the beginning of ♈ [Aries] is made up to 212 degrees 17 minutes. Since this is greater than 90 degrees but less than 270 degrees, the star will lie in the descending semicircle of the ecliptic, and its longitude must be reckoned from ♎ [Capricorn] (because it has southern latitude), against the succession of the signs. If its true longitude is taken from 270 degrees, there remains 57 degrees 43 minutes, whose versed sine is 46590. The southern latitude of the same star is 55 degrees 40 minutes, and its complement is 34 degrees 20 minutes. Accordingly, the difference between 23 degrees 30 minutes of the maximum declination of the ecliptic and 34 degrees 20 minutes, the complement of the star's latitude, amounts to 10 degrees 50 minutes, and the sine of the complement of this difference is 98217.

Therefore, if the proportion is set up — as 10000000000, the square of the whole sine, is to 2248893600, the rectangle contained under 39874 (the right sine of the maximum declination of the ecliptic) and 56400 (the sine of the complement of the star's latitude), so is 46590 (the versed sine of the star's longitude from ♎ [Capricorn], against the succession of the signs) to a fourth — this number 10459 will be found. Since it is smaller than 98217 (the sine of the complement of the difference between the maximum declination of the ecliptic and the complement of the star's latitude), we subtract it from 98217, the sine of the complement of the said difference, and there remains 87758, the sine of the southern declination of the proposed star. To this in the table of sines correspond 61 degrees 21 minutes, for the declination of the said star from the equator toward the South.

From these examples I judge that the precept we have handed down, by which the declinations of the stars may be investigated, can be sufficiently grasped. Other methods of computing the same declinations of the stars, no less easy, you will find in Book 3 of the *Astrolabe*, in the scholium to Canon 3, No. 10.

DE QUANTITATE STELLARUM. [On the size of the stars]

[Margin: The proportions of the diameters of the stars to the diameter of the earth.]

Now that the number of the stars, which are distributed into six differences of magnitude, has been established, and the method by which their declinations are investigated has been explained, we must next set forth the size of these same stars in each difference of magnitude. This we shall accomplish most conveniently by inserting here certain tables, in which are contained both the proportions of the diameters of the stars — the fixed as well as the wandering — to the diameter of the earth, and the proportions of the sizes of those same stars to the size of the earth. In these tables we have followed Francesco Maurolico [Francesco Maurolico], the Abbot, in the Appendix of his *Dialogues on Cosmography*.

Proportions of the diameters of all the stars to the diameter of the earth.

The diameter of...	has to the diameter of the earth the proportion, as
any star of the 1st magnitude	19 to 4
any star of the 2nd magnitude	269 to 60
any star of the 3rd magnitude	25 to 6
any star of the 4th magnitude	19 to 5
any star of the 5th magnitude	119 to 36
any star of the 6th magnitude	21 to 8
♄ Saturn	9 to 2
♃ Jupiter	32 to 7
♂ Mars	7 to 6
☉ the Sun	11 to 2
♀ Venus	3 to 10
☿ Mercury	1 to 28
☾ the Moon	5 to 17

The diameter of...	has to the diameter of the earth the proportion, as
☉ the Sun (to the diameter of ☾ the Moon)	187 to 10

THEREFORE, if the individual antecedent terms of these proportions are divided by the individual consequent terms, it will become clear how many times the diameter of any given star contains the diameter of the earth — that is, when the star's diameter exceeds the earth's diameter, as is the case with the diameters of all the heavenly bodies except the diameters of Venus, Mercury, and the Moon. Or else it will show how many times the diameter of the earth contains the diameter of the star — that is, when the star's diameter is exceeded by the earth's diameter, as with the diameters of the three lower planets; for here the consequent terms must be divided by the antecedent terms. But all of this may be examined in the table set out below.

How many times the diameter of any star contains the diameter of the earth, or the diameter of the earth contains the diameter of the star.

[Margin: How many times the diameter of any star contains the diameter of the earth, or the reverse.]

The diameter of...	contains diameters (of the earth, or of the star, as noted)
any star of the 1st magnitude contains earth-diameters	4 $\frac{3}{4}$
any star of the 2nd magnitude contains earth-diameters	4 $\frac{29}{60}$
any star of the 3rd magnitude contains earth-diameters	4 $\frac{1}{6}$
any star of the 4th magnitude contains earth-diameters	3 $\frac{4}{5}$
any star of the 5th magnitude contains earth-diameters	3 $\frac{11}{36}$
any star of the 6th magnitude contains earth-diameters	2 $\frac{5}{8}$
♄ Saturn contains earth-diameters	4 $\frac{1}{2}$
♃ Jupiter contains earth-diameters	4 $\frac{4}{7}$

The diameter of...	contains diameters (of the earth, or of the star, as noted)
♂ Mars contains earth-diameters	1 1/6
☉ the Sun contains earth-diameters	5 1/2
the earth contains ♀ Venus-diameters	3 1/3
the earth contains ☿ Mercury-diameters	28
the earth contains ♃ Moon-diameters	3 2/5
☉ the Sun contains ♃ Moon-diameters	18 7/10

[a] Since spheres have to one another the triplicate proportion of their diameters, it will not be difficult for anyone even moderately versed in arithmetic to gather from the preceding table all the proportions that the sizes of the stars have to the size of the earth, as appears in the following table, in which the said proportions are contained in whole and least numbers.

[Margin: a. 18. duod. (i.e. Euclid, *Elements* XII.18: spheres are in the triplicate ratio of their diameters.)]

Proportions of the sizes of all the stars to the size of the earth.

[Margin: The proportions of the sizes of the stars to the size of the earth.]

Any star of...	has to the earth the proportion, as
the 1st magnitude	6859 to 64
the 2nd magnitude	19465109 to 216000
the 3rd magnitude	15625 to 216
the 4th magnitude	6859 to 125
the 5th magnitude	1685159 to 46656
the 6th magnitude	9261 to 512
Saturn stands to the earth, as	729 to 8
Jupiter stands to the earth, as	32768 to 343
Mars stands to the earth, as	343 to 216
the Sun stands to the earth, as	1331 to 8
Venus stands to the earth, as	27 to 1000
Mercury stands to the earth, as	1 to 21952
the Moon stands to the earth, as	125 to 4913

Any star of...	has to the earth the proportion, as
the Sun stands to the Moon, as	6539203 to 1000

AND IF the antecedent terms of all these proportions are divided by the consequent terms, it will be manifest how many times the size of any heavenly body contains the size of the earth within itself — excepting the three lower planets. For in their case the consequent terms must be divided by the antecedent terms, so that it may be known how many times the size of the earth comprehends the size of each of them, as is plain in the following table.

How many times the size of any star contains the size of the earth; or the size of the earth contains the size of the star.

... contains sizes	number
Any star of the 1st magnitude contains within itself earth-sizes	107 $\frac{11}{64}$ — or 107 $\frac{1}{6}$
Any star of the 2nd magnitude contains within itself earth-sizes	90 $\frac{25109}{216000}$ — or 90 $\frac{1}{8}$
Any star of the 3rd magnitude contains within itself earth-sizes	72 $\frac{73}{216}$ — or 72 $\frac{1}{3}$
Any star of the 4th magnitude contains within itself earth-sizes	54 $\frac{109}{125}$ — or 54 [?]
Any star of the 5th magnitude contains within itself earth-sizes	36 $\frac{5543}{46656}$ — or 36 $\frac{1}{8}$
Any star of the 6th magnitude contains within itself earth-sizes	18 $\frac{45}{512}$ — or 18 [?]
Saturn contains within itself earth-sizes	91 $\frac{1}{8}$
Jupiter contains within itself earth-sizes	95 $\frac{183}{343}$ — or 95 $\frac{1}{2}$
Mars contains within itself earth-sizes	1 $\frac{127}{216}$ — or 1 [?]
the Sun contains within itself earth-sizes	166 $\frac{3}{8}$
the earth contains within itself Venus-sizes	37 $\frac{1}{27}$
the earth contains within itself Mercury-sizes	21952

... contains sizes	number
the earth contains within itself Moon-sizes	39 38/125 [?] — or 39 1/5
the Sun contains within itself Moon-sizes	6539 203/1000 — or 6539 [1/5?]

The former numbers of this table correspond precisely to the numbers of the preceding tables; the latter do not, but fall somewhat short of the truth. They have nevertheless been included, because being smaller they are more easily grasped.

[Margin: The Sun is the greatest among the stars, and Mercury the smallest. How many stars of the 1st magnitude would be required to fill the whole Firmament.]

FROM ALL these tables, then, it is quite plainly evident that the Sun is the greatest among all the heavenly bodies of the world, and Mercury the smallest; and likewise that all the stars, both fixed and wandering, are greater than the earth itself, with only three planets excepted — Venus, Mercury, and the Moon; for these indeed are smaller than the earth.

AND IF some curious person should wish to know how many stars would be required, in any given difference of magnitude, to fill the whole concave surface of the Firmament so that they touch one another, he will easily attain this partly from what we have here said about the proportions of the diameters of the stars and of the earth, and partly from what we shall write at the end of this chapter. For since the diameter of the concave [surface] of the Firmament contains 22612 1/2 diameters of the earth, and the diameter of any star of the first magnitude contains 4 3/4 diameters of the earth: if the proportion is set up, as 4 3/4 is to 1, so is 22612 1/2 to a fourth, there will be found in the diameter of the concave Firmament 4760 diameters of one star of the first magnitude, and a little more. And if we multiply this diameter by 3 1/7, the circumference of the greatest circle in the concave of the Firmament will contain 14960 diameters of one star of the first magnitude. If we multiply that circumference by the diameter — namely by 4760 — we shall find that the concave surface of the Firmament contains 71209600 square diameters of one star of the first magnitude. Within these, that same number of stars of the first magnitude, touching one another, can be drawn. From this it also appears that those are deceived who think that there are in reality more stars in the Firmament than the children of Israel, on account of the words of Scripture cited above. For since at the Exodus from Egypt there were

numbered 603550 of the children of Israel above 21 years of age — those, namely, who went forth to war, as is clear from chapter 1 of [the Book of] Numbers...

number. Some scholars rightly conclude that, if children and women too are counted, their number was more than 2,000,000. Who, then, can doubt that over so many centuries of years there were far more than 71,209,600? Therefore, since in fact the stars are far fewer — because between any two of them a great space is interposed, and there are not a few vast spaces in the heaven in which no star at all appears, so that they in no way touch one another — it is clear that the stars in the firmament are far fewer than the children of Israel. By the same reasoning one finds the number of stars that could fill any firmament whatsoever.

[Margin: Which stars Alfraganus is speaking of.]

Alfraganus [al-Farghānī], then, in the argument our author brought forward to confirm the second part of the fourth conclusion — namely that the earth stands as a point when compared with the firmament — means the smallest stars perceptible to sight, that is, those which we, along with other astronomers, have called stars of the sixth magnitude, each of which is more than eighteen times larger than the earth. Therefore one may conclude with full right that the earth is as a point in relation to the heaven, since a star that is so much larger than the earth is itself reckoned as a point when compared with the heaven.

[Margin: How the earth stands when compared with the individual heavens.]

It will not be out of place here to explain briefly how the earth stands when compared with each of the celestial spheres in turn. For it should not be reckoned of imperceptible size in relation to every heaven. It must therefore be held as most certain that the earth is of imperceptible size if it is compared with the heaven of Jupiter, of Saturn, of the firmament, and the other higher heavens — as all the arguments already adduced clearly confirm. But in relation to the heaven of Mars and of the Sun it is indeed of some size, though not of such size as to be of any importance, as is clearer than daylight from those arguments which we set out, drawn from shadows and from the instruments of mathematicians. For those observations were made especially on the Sun. Finally, if it is compared with the heaven of Venus, of Mercury, and of the Moon, it must now be reckoned altogether of notable size, especially in relation to the lunar sphere. For since the body of the Moon, in relation to the sphere in which it exists, presents a perceptible size and mass, as is manifest to the senses, how could the earth — which is far larger than the lunar body — be said to have no notable mass and size in relation to the heaven of the Moon? All this will be clearer from this

common opinion of the astronomers, who assert that if someone stationed in the lunar sphere were to look at the earth, it would appear to him three times larger, and a little more, than the Moon appears to us here from the earth; that from the sphere of the Sun the earth, seen, would be judged twice as large as Venus appears to us from there; that from the heaven of Mars the earth, if it shone, would be reckoned equal to one of the smallest stars, of the kind comprised in the sixth magnitude; and finally that from the higher heavens, especially from the firmament, it would in no way be discerned, but would be altogether like an imperceptible point.

[Margin: That the earth is smaller than the Sun, but larger than the Moon.]

But since what we have affirmed about the size of the heavenly bodies in relation to the size of the earth may perhaps seem astonishing to someone, we shall now briefly show that the earth — although it appears to us endowed with an enormous mass — is much smaller than the body of the Sun, while the Moon, on the contrary — although the senses judge it to be the same size as the Sun — is far smaller than the earth itself. But the extremely subtle arguments by which the most skilled astronomers establish all this geometrically we omit entirely, since they belong to a higher order of study than can be explained here and pertain to the *Theorics of the Planets*. Anyone gripped by a desire for them must seek them from Ptolemy, the supreme master of these arts, and from other astronomers. That the Sun, then, is far larger than the earth can be made evident from the arguments of the writers on optics [Perspectiui].

For if the Sun were equal to the earth, the earth's shadow would be projected uniformly, in the manner of a cylinder, to infinity. But if the Sun were smaller than the earth, the earth's projected shadow would forever grow to infinity — the former of which is demonstrated most clearly by Witelo [Vitellio] in the *Perspectiva*, Book 2, proposition 26, and the latter in proposition 28.

Consequently, on a clear night some fixed stars would always be hidden — those, namely, that would lie in the earth's shadow — or at least would not have as much brightness as the other stars that are then illuminated by the Sun; and by the same reasoning [some would be hidden] when Mars, Jupiter, and Saturn are set diametrically opposite the Sun — which has never been observed. The Sun, therefore, will be much larger than the earth. For thus it comes about that the earth's shadow is projected lengthwise in the shape of a pyramid, or rather a cone, and ends in an indivisible point, so that it does not reach the fixed stars or the said planets at all — as the same Witelo demonstrates in proposition 27 of the same book. Hence it is no wonder that neither any fixed stars nor those higher

planets suffer any loss of light, even though they face the Sun from directly opposite.

That the Moon, however, is much smaller than the earth can now be deduced demonstratively from what has been said. For since it has been shown that the earth's shadow is conical, so that it always grows narrower and finally ends in a point, the shadow must necessarily have a diameter smaller than the earth's diameter. Therefore, since the whole Moon is sometimes hidden within that shadow — and for a long stretch of time, as appears in its eclipses — who does not see that its diameter is smaller than the shadow's diameter, and consequently far smaller still than the earth's diameter? Since, then, the Moon is much smaller than the earth and yet appears to us so large, it is clear that it is very near to us — so that the distance from the earth's surface to its center is altogether perceptible and appreciable when compared with the distance from the earth's surface to the heaven of the Moon. Therefore Ptolemy and Johannes Regiomontanus rightly prescribe (*Almagest* IV.1) that the true place of the Moon [☽] should be investigated by means of lunar eclipses, and not by instruments. For, they say, since we exist on the earth's surface, a great and perceptible error will befall us if we wish to hunt for the true place of the Moon by instruments, on account of its excessive nearness — which would not happen at all if we were placed at the center of the earth.

[Margin: A digression on that new star which appeared in 1572 and vanished in 1574, and on other new stars.]

This is the place to remind me that, since I have spoken of all the stars conveniently perceived by sight, I should also say something (for many weighty and learned men have demanded my opinion on the matter) about that new star which appeared in the year 1572 in the constellation of Cassiopeia and vanished in the year 1574. That star, indeed, appeared at first of such magnitude and splendor that it outshone the star Venus; but after some months it was so diminished that it was judged equal to the pole star, or to any other star of the third magnitude; and thereafter, right to the end, it grew ever more diminished. A thing truly to be marveled at, very like a portent, and one that exercised the minds of many.

[Margin: The first opinion on the new star.]

For some — though few — thought that this was not a new star, but one of those thirteen ancient stars that astronomers have always observed in Cassiopeia, and that it then appeared larger than usual because of an exhalation interposed in the

highest region of the air between it and our sight; and that thus it came about that most people believed it to have been new.

[Margin: The second opinion on the new star.]

Others, however, judged that this star was some very small one in the firmament, of the number of those that lie outside the six magnitudes and generally hide themselves because of their smallness, so that they do not...

[Margin: The third opinion on the new star.]

appear, and therefore, as we said above, are not counted by astronomers among the number of the stars; but that on account of the interposed exhalation it then appeared of such magnitude that it was reckoned new by almost everyone. Others, finally, judged that this star was a comet in the highest region of the air.

[Margin: Refutation of the first opinion.]

But none of these opinions seems to me to be true. That this star was not one of those thirteen noted in Cassiopeia I consider more certain than certainty itself. For Francesco Maurolico [Maurolycus], Abbot of Messina, most experienced in the contemplation of the stars (seeing that he had spent sixty whole years in that study), in Sicily; and very many other astronomers, both in the two Germanies and in Spain and France, who had more than once counted those thirteen stars of Cassiopeia — at that very time when this new one appeared, noticed in Cassiopeia, besides those thirteen, this new one of which we are speaking, so that they now understood there to be not thirteen stars, as of old, but fourteen in Cassiopeia. Of this fact I myself am also a witness, who at Rome in December of the year 1573, besides that new star (diminished, however, so that it seemed the equal of a star of the third magnitude), saw thirteen others in Cassiopeia; and indeed not I alone at Rome, but several others together with me, to whom I was pointing out the newly-risen star, observed it repeatedly.

[Margin: What figure the new star made with the stars of Cassiopeia.]

But it is astonishing that the authors of this opinion, alone among all astronomers, should have seen that it was an old star yet not have seen the star itself — so that one might easily suspect that they were not very diligent in observing this star, and that, relying on the authority of the ancients rather than on new observation, they had grown accustomed to hold that that star did not differ from the others, evidently so as not to concede anything new in the heaven. This is apparent even from the following: that the new star, together with three other stars of Cassiopeia which are of the third magnitude — I mean the second,

which is seen in her breast; the fourth, which is above the chair at the hips; and the twelfth, which is situated at the mid-ascent of the chair — formed that figure which geometers call a rhombus; whereas the eleventh star of Cassiopeia, which is of the fourth magnitude — and which the authors of this opinion suppose to have appeared new because it seemed larger on account of the interposed vapors (as they think) — perpetually forms that figure which geometers call a trapezium, such that it is less distant from the fourth star than the twelfth is from the second, whereas the new star, by the consensus of all who observed it, was equally distant from the fourth as the twelfth is from the second, as is clear from the adjoining figure.

Diagram. A small woodcut (set in the left margin/text column) showing two configurations of printed star-glyphs (asterisks) with adjacent catalog numerals, illustrating the argument of the surrounding text: the rhombus formed by the new star with Cassiopeia stars 2, 4, and 12, versus the trapezium formed by star 11 with the same three stars. The exact geometric placement of the glyphs is not fully resolvable at this resolution.

- Upper cluster: an asterisk labeled "NOVA" (the new star), an asterisk labeled "11", an asterisk labeled "4", plus additional unlabeled asterisks [layout uncertain — ?]
- Lower cluster: an asterisk labeled "12", an asterisk labeled "2", plus additional asterisks [layout uncertain — ?]

Furthermore, if that interposed exhalation was so great, and by its interposition in both Germanies, Spain, France, Italy, Sicily, and perhaps other regions, that eleventh star of Cassiopeia appeared larger than it really is, how can it be that for the same reason the remaining neighboring stars did not likewise appear larger, but of exactly the same magnitude at which they were always seen and are seen today? Someone will perhaps say that the exhalation was so placed that it was interposed only between our sight and that one star, but not between our sight and the others. But even granting that this could happen in one region, it certainly could not in many, so widely separated by intervals, as is clear from the observed difference. It is therefore clear — to me it is certainly established — that the star of which we are treating could not have been one of those thirteen which are seen daily in Cassiopeia.

[Margin: Refutation of the second opinion.]

And this latter argument that I have brought forward refutes the second opinion as well. For if, on account of an exhalation (as they suppose), that little star,

which otherwise cannot be seen, presented itself to be seen with such great magnitude, then surely for the same reason the eleventh star of Cassiopeia — to pass over the others in silence — near which that new star was observed, would have shown itself much larger; whereas at that time it was seen by all as of the same magnitude, that is, the fourth, at which it was of course seen both before and after, and is even now seen.

[Margin: Refutation of the third opinion.]

That the new star was also not a comet in the highest region of the air we shall make evident as follows. Skilled astronomers everywhere noted that this star held the same position among the fixed stars — namely the position that the figure above shows — so that they all placed it near that point where the Colure of the Equinoxes intersects the Arctic Circle, and reported it to be distant from the Arctic pole by about $23\frac{1}{2}$ degrees, and from the Equator by about $66\frac{1}{2}$ degrees, detecting almost no parallax [*aspectus varietas*] in it at such various places. Since this is so, who can doubt that it obtained its place not in the highest region of the air, where the other comets are generated, but above the Moon? For never is one and the same comet seen from different regions in exactly the same place when it is compared with the stars; since, on account of its nearness (as is agreed among astronomers), it undergoes no small variation of aspect [*parallax*]; indeed, even the Moon itself, according to all astronomers, is not without diversity of aspect, because it is very near the earth. Since, then, the new star was observed to have absolutely no diversity of aspect when observed in such various regions, this is surely an argument that it was higher than the Moon, and therefore was in no way a comet — unless we are also to say that comets are generated in the aethereal region.

[Margin: The commentator's opinion on the new star.]

So then, to say briefly what I think: I judge that this star, whatever it was, existed in the firmament, where the fixed stars are. For that it appeared in the aethereal region and not in the elementary one is established from what we adduced a little earlier in the refutation of the third opinion — that of those who made it a comet existing in the highest region of the air — precisely because no diversity of aspect was detected in it. For by the same argument philosophers and astronomers refute Aristotle's opinion about the Milky Way, which he said was continually generated in the highest region of the air from vapors and exhalations raised and drawn to that region by the force of the stars that are seen in the milky circle.

[Margin: That the new star was in the firmament.]

For since everywhere on earth the milky way is seen drawn through the same stars of the firmament — Cassiopeia, Cygnus, Aquila, Sagittarius, Gemini, and others, as we shall explain more fully in the second chapter — there can be no doubt that it is much higher than the highest region of the air, and situated in the firmament itself, because it has no diversity of aspect, which it certainly would have if it were placed in the air, as Aristotle wished. Now, that I may believe that this new star existed in the firmament and not in any other celestial sphere, I am led especially by this argument: that neither I, nor any astronomer at all, so far as I know, detected in it any [motion] other than the one we observe in the fixed stars...

For it retained a constant motion throughout, and the same position among the other fixed stars, for the whole two years (for it lasted about that long). But if it had been in the sphere of some planet — since that sphere certainly has a motion foreign to the fixed stars — undoubtedly the star itself would have had the same motion and course; but astronomers found that the case was otherwise. And this same argument evidently establishes, still more, that the star did not exist in the elementary region: because there it could by no means have kept always the same position and distance with respect to the fixed stars. Since this is so, I am persuaded either that the star was then created by God, the Best and Greatest, in the eighth heaven, to portend something great (of what sort it may be is still unknown), or else that comets can indeed be generated in the heaven itself, just as in the air, though this happens more rarely — which not a few of the ancient philosophers openly admit, and many of the more recent adduce authorities and histories to convince us that stars of this kind have often arisen in the heaven at long intervals of time, some to signify one thing, others another. If this is true, let the Peripatetics see how they can defend Aristotle's opinion about the matter of the heaven.

For it will perhaps have to be said that the heaven is not a certain fifth essence [Quinta essentia], but a mutable body, though less corruptible than these lower bodies — which indeed, before Aristotle, Plato held, along with many other philosophers; and after Christ not a few taught it plainly, among them Saint Ambrose, Basil, Gregory of Nyssa [Gregorius Nissenus], and nearly all the other lights of the Church. Whatever the case may be (for I do not interpose my own opinion in so great a matter), it is enough for me at present to have demonstrated in a few words that the star of which we speak had its seat in the firmament. But whence it so suddenly came to be, what it portended, and why it vanished after two years — I judge that as yet no one but God knows.

[Margin: What Paulinus Pridianus writes about the new star.]

This should be established for everyone: that God has not deprived himself of the power of making stars; and therefore that he could then, and can now, if he wishes, create even innumerable ones. But why it was created chiefly at that time must be left to the hidden judgment of God — who does nothing in vain, but directs all things by supreme providence to their ends — until it be revealed to mortals. I shall add here the opinion of a certain Paulinus Pridianus, physician and astronomer, who observed this same new star at Antwerp. Then I shall also bring forward some passages excerpted word for word from the disputation of Francesco Maurolico, Abbot, which was sent to me from Sicily in past years — so that it may be manifest to all that astronomers, in regions separated even by a long interval, found the same position in our new star. Thus, then, did Paulinus Pridianus write in the year 1572, among other things:

"Now, by the admirable and truly awesome judgment of God, there is visible a bright and shining star which before this neither appeared nor was seen: in form, indeed, not differing from the other stars, but appearing greater in light, in splendor, and in mass as well, and seen brighter and more brilliant not only than the stars of the first magnitude, but even than the planets themselves — in no way yielding to the most luminous and brilliant star Venus. Which, besides this, seems also to stand in its own place, and to advance by no other than the daily motion, and to revolve together with the firmament — quite contrary to the nature of the other heavenly fires and fiery meteors [Meteoron], which are moved by some proper motion of their own. This new star is seen next to Cassiopeia, toward the North, [together] with the one that is in the breast of Cassiopeia herself, and another that is above the seat near the legs, and a third in the middle of the chair — so arranged and situated that it expresses the figure and form of a rhombus [Rhambus], of which figure the new star itself forms the upper angle, inclining toward the pole of the world, etc."

[Margin: What Maurolico said about the same new star.]

Maurolico, however, wrote about the same star thus, in the same year 1572: "This year an unusual sign, more marvelous than a comet, appeared — namely a remarkable star of surpassing splendor, in a place where no star had been marked. Nor does it seem to me to be a comet of the kind generated in the air, for it appears higher, and among the number of the fixed [non-wandering] stars. Perhaps, just as it began to shine, so it will cease — especially since certain philosophers, with whom Cardano [Cardanus] agrees, are of the opinion that comets, and new stars too, can be produced even in the heaven, from the

aggregation of splendor from the planets and the other stars. However that may be, I cannot marvel enough at this new blazing of a star in our time. For it is certain that it is not one of the number of the first-magnitude stars that are turned in the Ptolemaic and Alphonsine tables, and that have shone since the founding of the world, and are fifteen in number — which this new star so surpasses in splendor that henceforth they must be called of the second magnitude, if only this one endures. Observing this star here on the horizon of Messina, standing on the meridian at about the third hour of the night, I found its altitude to be 62 degrees. From this I conjectured that it is located as if at the summit of the Arctic Circle, so that here it is distant from my vertex [zenith] by 28 degrees, and consequently from the Equator by about $66\frac{1}{2}$ degrees — since the latitude of Messina is $38\frac{1}{2}$ degrees — and that it is situated at that point where the Colure of the Equinoxes cuts the Arctic Circle, or very close to that point, etc."

The same must be said of that new star which (as was written to me from Germany) appeared in the year 1600 in Cygnus, next to the one that shines in its breast, and still persists. Likewise of another, which was first seen in October of the year 1604, between the 17th and 18th degree of Sagittarius, having a northern latitude of about 2 degrees — although, by the time I was writing this, it had so diminished that it scarcely appeared. The same, I say, must be said. For each of these stars, on account of the same arguments, must be placed in the firmament, because each was found everywhere at the same distance from the other fixed stars, so that it admitted no diversity of aspect, and no motion other than the one we note in the fixed stars was observed in it. So much, then, be said about the fourth conclusion of our author.

THE EARTH IS IMMOBILE.

[Margin: That the earth does not move with rectilinear motion.]

That the earth is held immovably at the center of all things, since it is supremely heavy, its heaviness seems to prove thus. Every heavy thing naturally tends toward the center; the center, indeed, is the point in the middle of the firmament. The earth, therefore, since it is supremely heavy, naturally tends toward that point.

COMMENTARIVS.

The author has hitherto shown that the earth exists at the center of all the heavens and the elements, as the center of the whole universe. Now, in this fifth conclusion, he attempts to prove that it is so situated in the middle of the world that it is devoid of all local motion. He carries this out by two arguments, the first

of which is taken from the earth's heaviness. For since the earth is the heaviest of all bodies, it will be carried by its own nature, impeded nowhere, to the lowest place — namely, to the center of the world — and there it will rest.

[Lemma — Sacrobosco] Likewise, whatever moves away from the center rises toward the circumference of the heaven; but the earth would move away from the center. Therefore it would rise — which is dismissed as impossible.

COMMENTARIVS

He proves the same point from the absurdity that follows. In the preceding conclusion it was established, by very many phenomena, that the earth stands at the center of the world. If, then, it were moved from the center by local motion, it would certainly rise toward the circumference of the heaven — which conflicts with the phenomena and runs contrary to the nature of the earth's heaviness.

[Margin: That the earth is entirely immobile.]

But since the Author excluded from the earth only rectilinear local motion, and not circular motion, it will be necessary to confirm in a general way, from Ptolemy, Aristotle, and the rest of the astronomers and philosophers, that the earth is immobile. The argument runs as follows. If the earth did not remain immobile, it would move either by rectilinear or by circular motion.

It cannot be moved by rectilinear motion. Since it has been demonstrated above that it stands at the center of the world, then, if it were carried by rectilinear motion, it would withdraw from the center — and so we would fall into exactly the same absurdities that we said would follow if the earth were not set at the middle of the world. Moreover, if it moved rectilinearly, it would do so either naturally or by force. It will not move naturally in this way, since by its own nature it tends toward the lowest place, which is at the center of the Universe; yet it is certain that it rises in whatever direction it is driven by rectilinear motion. Nor can it be moved rectilinearly by force, since no body heavier than the earth is to be found, which could drive it from the center of the world by its own weight.

Again, if the earth were carried by rectilinear motion, it would necessarily move with the greatest velocity, since it is supremely heavy. Grant this, and who does not see that lighter things — such as tree-leaves, chaff, and all other bodies — would have to be left behind it in the air, since they could not keep pace with its most rapid motion, not being endowed with such great heaviness? But all of this is contradicted by common experience. For we see that bodies of this kind, unless

torn away by some wind or force, cling motionless to the earth's surface. The earth, therefore, is not carried by rectilinear motion.

That it is not moved by circular motion either, as many have supposed, can be confirmed as follows. If the earth moves in a circle, it will move either about the axis of the world — from East to West, or from West to East — or about some other axis. Suppose it is said to move about the axis of the world. Then the clouds, the birds, and everything that exists in the air would be seen to move in the opposite direction — namely toward the West, if the earth rolls toward the East, or toward the East, if the earth glides toward the West — because they could not keep pace with the earth's extremely rapid motion, given that it is completed within the space of 24 hours. Nor can it be said that the air is carried around at the same speed as the earth, since it is well known that the air surges now this way, now that, according as it is driven toward one quarter or another by the various winds, as daily experience teaches us.

Moreover, if the earth were spun about the axis of the world so fast as to complete a full circuit within the space of 24 hours — as certain people fancy — then all buildings would collapse and could by no means stand for long. That this is utterly false, no one fails to see. Nor is the reply of certain persons valid, who say that buildings do not collapse precisely because of the excessive speed of the motion — just as water held in a vessel does not spill out if the vessel is whirled around very fast. This reply, I say, is not valid, because the whole impetus of the water is directed toward the lower parts of the vessel, not toward its mouth; whereas the impetus imparted to buildings is directed toward the outermost parts of the earth, so that they could not possibly keep standing — just as water placed in a vessel would not stay put, however fast the vessel is whirled, if its mouth faced outward. By the same reasoning it would follow that a stone, or an arrow shot straight upward with great force, would not fall back to the same spot — as we observe happening aboard a ship moving very fast. All of which is absurd.

Again, if the earth were set in circular motion, that motion would be either natural or against nature. It cannot be natural. For since to a single simple body only one motion belongs naturally, and the earth by its own nature proceeds rectilinearly toward the center of the world whenever it finds itself outside it, it cannot be moved in a circle according to its own nature. Nor would it be spun around in a circle against nature — that is, by the motion of the heaven — because in that case the same part of the heaven would always stand over our zenith, and so the stars would neither rise nor set, which is absurd.

But suppose it is said that the earth moves about some other axis, one that cuts the axis of the world obliquely. Then, quite apart from our sliding back into nearly the same difficulties, it would follow that in one and the same city the altitude of the pole would vary from day to day, since that city, in following the earth's motion, would not trace a circle parallel to the pole. It would therefore now draw nearer to the pole, now be carried farther from it, and so would vary the pole's altitude — which is false. For we see, for example, that at Rome the Arctic pole permanently keeps the same elevation above the Horizon.

Let us conclude, then, with the common opinion of the astronomers and philosophers, that the earth is devoid of all local motion, whether rectilinear or circular, and that the heavens themselves are continually carried around it — especially because, once this is granted, all the phenomena are far more easily accounted for, and no difficulty follows from it.

The sacred scriptures also favor this view, affirming in very many places that the earth is immobile and testifying that the Sun and the other stars move. For we read in Psalm 103 [Vulg.; = Ps. 104]: "You who founded the earth upon its own firmness — it shall not be shaken for ever and ever." Likewise in Ecclesiastes, chapter 1: "The earth stands forever; the Sun rises and sets, and returns to its place, and there, being born anew, wheels through the South and bends toward the North." What could be said more plainly? A most clear testimony that the Sun moves is likewise furnished us by Psalm 18 [Vulg.; = Ps. 19], where we read: "In the sun he has set his tabernacle; and he himself, like a bridegroom coming forth from his bridal chamber, has rejoiced like a Giant to run his course — his going forth is from the highest heaven, and his circuit reaches even to its height, nor is there any who can hide himself from his heat." Again, it is recorded among the miracles that God once either drew the Sun back, or made it stand entirely still.

[Margin: The various opinions as to why the earth is immobile, and their refutation.]

Different thinkers have assigned different causes for this immobility of the earth at the center of the world. Some — among whom, on Aristotle's testimony in the second book of *On the Heavens* [*De Caelo* II], is Xenophon of Colophon [recte: Xenophanes of Colophon] — said that the earth is infinitely deep on its underside, and that for this reason it does not fall downward. But this opinion is false. First, because on this view the earth would not be round and spherical, the contrary of which we demonstrated above. Next, because, according to Aristotle in the third book of the *Physics* and the first of *On the Heavens*, and to other philosophers, no actual infinite exists. Third, because on this view the heaven could in no way

revolve, since it would be obstructed by that infinite depth of the earth; nor indeed does the heaven stand at an infinite distance from us, which is absurd.

Others thought — as did Thales of Miletus — that the earth floats upon the waters and is supported by them, so as not to fall. But this is ridiculous. For since water is much lighter than earth, how can it possibly support a heavier body — especially since we see, everywhere, parts of the earth sinking beneath the water?

Furthermore, such philosophers ought to be asked what the water itself rests upon, so as not to fall together with the earth; for water, being fluid, cannot stay in place unless it is supported upon some solid body.

Certain others affirmed — as did Anaxagoras and Democritus — that the earth has a very ample and broad shape, and that it therefore compresses the air, by which it is held up so as not to fall. But this too is a fabrication, and very like an old wives' tale. For the earth has a spherical shape, not a flat one, as we demonstrated above. Indeed, even if it did have such a form, it is still contrary to experience that broad bodies should be so held up in the air that they never fall at last. For although bodies of this kind descend only with difficulty on account of their breadth — since they can scarcely cut through the air — they are nonetheless seen to tend gradually downward.

Some, finally — as Anaximander of Miletus — coming nearer to the truth, testified that the earth rests at the middle for this reason: because it is placed at the middle of the world. For from this it comes about, they say, that the earth is either inclined to move toward every quarter of the heaven alike — since there is no greater reason why it should move toward one quarter rather than another — or else is attracted equally from all quarters of the heaven. And so, since it cannot be carried to all quarters at the same instant, it rests at the middle, or center, of the world. But this opinion too is mistaken. First, because if the earth were unmoved for this cause, it would be held at the middle of the Universe by force and not naturally. Next, because it is false that it is always inclined to move toward the quarters of the heaven, since on that view it would tend upward, which is repugnant to its nature. For we see the parts of the earth naturally descend with the greatest force, unless obstructed, and always withdraw from the heaven toward the center as far as they possibly can. By the same reasoning it is false that the earth is attracted by the heaven, since we see rather that the earth is drawn away from the heaven by its own nature. Third, because if the earth rested immobile at the center for this cause, then by the same reasoning it would be established that fire or air, placed at the center of the world, ought likewise to rest there — for there would be no greater reason for it to move toward one

quarter than another, since it would have an equal inclination toward all quarters of the heaven. Yet no philosopher has ever granted this.

[Margin: Why the earth rests at the middle.]

It must be said, therefore, that there is no other cause for the earth's resting at the middle of the world than its own heaviness. For from this it comes about that the earth always seeks to be in the lowest place — the place farthest from the heaven, namely the center of the whole Universe. Once it has taken possession of that place, it cannot naturally be torn away from it, because it would then have to rise against its own nature and inclination. For the same cause, all heavy bodies are naturally borne toward the center of the world with the greatest force, unless something obstructs them — so that if the whole earth were bored through from one side to the other, and some heavy body fell into that hole, it would reach only the center with the greatest force, and not the other side, because there it would begin to rise. At the outset, on account of the impetus of its motion, it would swing back and forth for a while; but as the impetus of the motion gradually slackened, it would come to rest at the middle. Of this immobility of the earth Manilius too writes elegantly, thus:

Nor need the nature of the hanging earth seem wondrous to you, since the World itself hangs and sets its footprints on no floor beneath. This is plain from its very motion, from its flying course: since suspended Phoebus [the Sun] goes his way and turns his course now here, now there, and keeps his nimble turning-posts within the aether; since the Moon and Stars flit through the empty reaches of the world — the earth too, imitating these airy laws, hangs suspended. It is the earth, then, that has been allotted the middle hollow of the air, and is lifted up equally from the whole depth, not stretched flat over broad expanses, but built into a globe that rises equally on every side and equally falls away. This is the face of Nature...

[Margin: Why the antipodes do not fall.]

From what we have said, that common argument of Lactantius Firmianus [Lactantius] and of the crowd against the antipodes is easily resolved. They say that if there were antipodes — that is, men set opposite to us — they could not keep their footing there, but would fall. It can be resolved, I say, because the antipodes, by their own heaviness, always tend toward the center of the world, just as we do. Indeed, if they could not keep their footing, they would fall *into the heaven* — that is, into the higher place — which is against the nature and

inclination of heavy things. It is no wonder, then, that they do not fall; rather, it would be a great wonder if they did fall into the heaven.

DE AMBITV TERRÆ

[*Lemma — Sacrobosco*] On the authority of the philosophers Ambrose, Theodosius, Macrobius, and Eratosthenes, the circumference of the whole globe of the earth is determined to contain 252,000 stadia, with 700 stadia to be assigned to each of the 360 parts of the Zodiac.

[Margin: The circumference of the earth according to Macrobius and Eratosthenes.]

COMMENTARIVS

This is the sixth and last conclusion: namely, that the earth has, in its circumference, a fixed and determinate magnitude, and is not of infinite depth, as some falsely supposed. He confirms it in the following way. On the opinion of Ambrose, Theodosius, Macrobius (for these three names do not denote three Authors, as some would have it, but signify only one) in the commentaries he published on the *Dream of Scipio*, book 1, and on the opinion of Eratosthenes, the whole circumference of the earth contains 252,000 stadia — for the reason that 700 stadia correspond to one degree of the earth out of the 360. The magnitude of the earth, therefore, is known and determinate.

[Margin: The circumference of the earth must be taken with respect to a great circle. 25. tertij [i.e. a cross-reference, prop. 25 of book 3 (?)].]

This circumference of the terrestrial globe must be taken not with respect to just any circle drawn on the earth, but according to a great circle of the earth — one, that is, which has the same center as the earth, such as the Meridian circle, the Equinoctial [the Equator], the Horizon, or any other great circle drawn on the earth's surface. In the same way, the thickness or depth of the earth, or of any spherical body, must be determined with respect to its diameter — which is the greatest line in a circle or sphere, since it passes through the center — and not by other lines, which can be varied in a thousand ways.

[*Lemma — Sacrobosco*] Take an Astrolabe or a Quadrant; and by the brightness of a star at night, having sighted the pole through both holes of the alidade [mediclinium], note the number of degrees at which the alidade comes to rest. Then let the surveyor [Cosmimeter] proceed due North from the South, until, by the brightness of another night's star, and the pole having been sighted as before,

the alidade comes to rest one degree higher. After this, measure the distance of this journey, and 700 stadia will be found. Then, assigning that many stadia to each of the 360 degrees, the circumference of the terrestrial globe will be found.

COMMENTARIVS

The Author had assumed as settled and certain that 700 stadia correspond to one degree of the terrestrial globe, and hence that all 360 degrees — that is, the whole circumference of the earth — amount to 252,000 stadia. Someone might deny this; indeed the crowd, and many others too who wish to seem learned, think it impossible for the earth's circumference to be measured, on the grounds that, because of the many obstacles — inaccessible crags, valleys, rivers, lakes, the Ocean, the Mediterranean Sea, and so on — the whole cannot be traveled around. He therefore prescribes the method the Astronomers used, and which anyone, if he likes, will be able to use in measuring the earth's circumference. For it will be enough if one measures accurately and carefully the length of journey that corresponds to one degree of the earth's globe, rather than the whole circuit. Since the earth is spherical, as has been demonstrated, then from any known part of the circumference that bears a known proportion to the whole, we will easily arrive, by the rule of proportions, at knowledge of the earth's entire circumference. The method he hands down is clear in the text and quite easy for anyone even moderately versed in Mathematical instruments, especially the astrolabe and Quadrant. Only this must be understood about it: that the pole can in no way be sighted through the Astrolabe or the Quadrant. For the pole star, which we observe near the pole, is not the true pole, but traces a circle around the true pole at a distance of nearly $3\frac{1}{4}$ degrees from it. The altitude of the pole must therefore be sought by another method — but how this ought to be done is not the place here, for it belongs to the treatment of the use of the Astrolabe or Quadrant, on which subject we will nonetheless say something when we come to discuss the Meridian circle.

[Margin: It is enough if the interval of one degree on the earth is investigated, so that the whole circumference may be obtained.]

Nor indeed is it necessary to walk out or measure a whole degree in order to have the earth's entire circumference; it will suffice to measure the length of half a degree, or of a third of one degree, or finally of any portion at all whose proportion to a whole degree is known. For from such a known portion, by the benefit of the rule of proportions, we will easily derive the whole circumference. For example, since 175 stadia are found to correspond to a quarter of one degree, 1,440 such quarter-parts — that is, the whole circumference of the earth — will

contain 252,000 stadia, as before. By the same reasoning, if 350 stadia correspond to half a degree, they will correspond, for the whole circumference (which consists of 720 half-parts), again to 252,000 stadia. And so for the rest.

[Margin: It is enough if the space of some half degree on the earth, or a third of one degree, is measured, so that the whole circumference may be known.]

VIAE AD INVESTIGANDVM AMBITVM TERRÆ COMMODIORES, quam ea, quæ ab Auctore tradita est

[Lemma heading — Ways of investigating the circumference of the earth more convenient than the one handed down by the Author]

But since it is a laborious and difficult task to proceed straight along the Meridian circle toward the North or the South until an altitude of the pole greater by one degree is found, the same measure of the terrestrial circumference will perhaps be obtained more conveniently by the following method. Mark two cities situated under the same Meridian; and once the elevations of the pole for each have been carefully ascertained, subtract the smaller elevation — the one the more southerly city has — from the greater, which the more northerly city has. What remains will show the distance between the two cities in terms of degrees; and once this has been measured in stadia or some other unit, you will easily be led, by the rule of proportions, to knowledge of the terrestrial circumference.

[Margin: Various ways by which the circumference of the earth may be explored.]

EXAMPLE. Mark two cities under one and the same Meridian, of which the more southerly has, say, a pole-altitude of 10 degrees, while the pole-altitude of the more northerly is 12 degrees 30 minutes. If, then, the smaller altitude is subtracted from the greater, the distance between the two cities will be 2 degrees 30 minutes. On the Author's opinion, if Eratosthenes and Macrobius had measured this distance, it would contain 1,750 stadia. Accordingly, the 360 degrees of the whole circumference will comprise 252,000 stadia. By the same reasoning, if the length of the journey between any two cities whatever — even if they do not lie under the same Meridian — is known, the magnitude of the whole terrestrial circumference can be found through the doctrine of spherical triangles, provided that the pole-altitude and the longitude (which is reckoned from the West) of each city have been ascertained. For from the pole-altitude and the longitude of each place, the number of degrees of the great circle measuring the distance traveled will be known. Therefore it will not be unknown how many stadia or miles are to be assigned to one degree — and from this the whole

circumference will be worked out. But because this way of measuring the earth's circumference is more obscure and belongs to Cosmography, we deliberately pass it over.

Now suppose someone wishes to explore how great the earth's circumference is from East to West, or vice versa. The Author taught only how to observe it from one pole to the other — that is, from North to South, or vice versa — although from this too the earth's circumference from East or West is established, since, because of the earth's roundness, it is exactly equal to the circumference from pole to pole. He will be able to accomplish this by the following technique. Mark two cities situated under the Equinoctial circle, and observe carefully, in each city, the hour at which some eclipse of the Moon began. For once it is known by how many hours earlier the lunar eclipse began in one city than in the other, the degrees of the Equator lying between them will also be known; for to each hour there correspond 15 degrees of the Equinoctial circle, as has been said elsewhere. The extent of those degrees having thus been measured, easily — by the rule of proportions — into knowledge of the whole circumference...

we shall arrive at the rule.

Example. Suppose the beginning of one and the same lunar eclipse is observed in an eastern city at the tenth hour plus a third of an hour after noon, but in a more westerly city at the ninth hour after noon. Therefore the more easterly city had its noon a full hour and a third of an hour earlier than the more westerly one. The interval lying between the two accordingly contains 20 degrees; and if anyone were to measure it, he would find, according to the authors already cited, that it contains 14,000 stadia, and so would conclude that the whole circumference of the earth contains 252,000 stadia.

[Margin: Posidonius's very easy method for investigating the earth's circumference.]

We can also investigate the earth's circumference most easily by means of some fixed star, such as Spica in ♍ [Virgo], or any other. For if two places lying under the same meridian are taken on the earth, whose road-distance apart is known by exploration, and if at each place the meridian altitude of the chosen and known star is observed, then the difference of the altitudes will be the number of degrees of the meridian lying between the two places. Since it is therefore known how many stadia correspond to those degrees, the number of stadia owed to the whole circumference of the terrestrial globe can in no way remain unknown. This method of investigating the earth's circumference is the one I most approve;

for it does not require, at any place, a knowledge of the pole's altitude or of the longitude — which cannot be had except by long-continued observation — nor in this matter should too much trust be placed in tables that record the latitudes and longitudes of cities. That Posidonius [Posidonius] used this very method of measuring the earth is reported by Franciscus Maurolycus [Francesco Maurolico] in his *Cosmographical Dialogues* [*Dialogi Cosmographici*], from which we have also taken the two following methods, of which the first was familiar to Eratosthenes, while the other was devised by Maurolycus himself.

[Margin: Eratosthenes's method for investigating the earth's circumference.]

Eratosthenes proceeded by roughly this method in tracing out the earth's circumference. At Alexandria he set up a gnomon on the horizon at right angles. Then, while the Sun stood at the beginning of ♋ [Cancer], he perceived that two rays were cast at the time of midday: one passing through the city of Syene [Syene, i.e. Aswan] (which is more southerly than Alexandria, and on very nearly the same meridian as Alexandria), a ray that ran straight toward the center of the world, since Syene lies directly under the Tropic of ♋ [Cancer]; the other passing over the vertex of the said gnomon. And thus, from the proportion of the gnomon to its shadow, he found by a geometrical route the space between Alexandria and Syene.

To make this clearer: let there be a circle described on the earth through Alexandria and Syene, in which A is the site of Alexandria, B the site of Syene; let AD be the style erected at Alexandria; let FBC be the ray of the Sun passing through Syene toward the center of the world; let EDG be the ray passing over the vertex of the gnomon and casting the shadow AG toward the north; and let the gnomon AD be understood to be produced as far as the center C.

Diagram. A woodcut of Eratosthenes's construction. At the top is the Sun, inscribed **SOL**, emitting rays downward. Below, near the small hatched disc of the earth, are the gnomon and its shadow; two long rays descend from the Sun. Readable labels:

- SOL (top): the Sun.
- E (upper left): origin, on the solar side, of the ray EDG that grazes the gnomon's vertex.
- F (upper right): origin, on the solar side, of the ray FBC passing through Syene.
- D (below E): the vertex of the gnomon (style).
- G (lower left, on the earth's surface): the tip of the shadow AG.

- A (surface, center): Alexandria, the foot of the gnomon.
- B (surface, right of A): Syene.
- C (at the center of the earth-disc): the center of the world.

Since, then, in the triangle ADG the arc AG can, without error, be taken for the straight line — if it be compared with the whole circumference — and since angle A is a right angle and the two sides AD, AG are known (AD indeed by [measurement], and AG by some measure, or certainly from those things which have been demonstrated by us in book 5 of our *Gnomonics*, proposition 1, where we showed by what reasoning the proportion of the style to its erect shadow may be known from the known altitude of the Sun): the angle ADG will also be known, by the doctrine of triangles (as we demonstrated in our work on triangles). For since the sides AD, AG are known, [Margin (a): *Elements* I.47] their squares will also be known; and since these are equal to the square on DG, the square on the straight line DG will likewise be known, and so DG itself will be known. And because, if DG be set as the whole sine, the straight line AG is the sine of angle ADG (as we demonstrated in the treatment of sines): if it be arranged that, as DG (in the terms in which it is thus far known) is to the whole sine, so AG (in the terms in which it is known, in parts of the shadow) is to something else, then AG will become known in the terms in which it is the sine of angle ADG; and hence, from the table of sines, the angle ADG will be known; and consequently also the alternate angle ACB, [Margin (b): *Elements* I.29] which is equal to it, because the rays FBC, EDG are very nearly parallel, on account of the exceedingly small distance of Syene from Alexandria when it is compared with the Sun. Therefore the arc AB, subtended by angle C, will also be known — namely the space intercepted between Alexandria and Syene. This method of Eratosthenes is reported a little differently by Cleomedes [Cleomedes] than by Maurolycus. By this method Eratosthenes found (if the author who reports the earth's circumference according to the opinion of Eratosthenes has reported truly) the arc AB to be $8\frac{1}{4}$ [?] degrees, and the road-distance to comprise $6183\frac{1}{3}$ stadia. Whence by the rule of proportions he concluded that 252,000 stadia are owed to the whole circumference of the earth, over its 360 degrees.

Franciscus Maurolycus, Abbot, devised this method of tracing out the earth's circumference. Let BCD be a circle of the earth, on which let some very high mountain be chosen (he himself judged Mount Etna [Mount Etna] in Sicily suitable for this business), whose height AB is made known by the precepts for measuring heights. Then, from A, the summit of the mountain, by the precepts for measuring distances, one must measure that whole expanse of sea or land (provided there be no mountains in the way) that is thence visible, such that the

visual ray AC touches the earth's surface at the point C. Let the space seen be BC, which, even though it be curved and not flat, nevertheless differs from a flat line by no perceptible difference, because the arc BC is exceedingly small when compared with the whole circumference of the earth. These things being duly performed, we shall set up the geometrical reasoning thus. I conceive four straight lines: the first is AB, the height of the mountain assumed; the second, the visual ray AC; the third, AD, which is composed of the mountain's height and the earth's diameter; the fourth, finally, BC, the interval seen — for it can, without error, be taken for a straight line, as has been said. Since, then, the straight lines AB, BC are known, their squares will also be known; [Margin (c): *Elements* I.47] and since these are equal to the square on AC, the square on AC will also be known. But the square on AC (since AC touches the circle) [Margin (d): *Elements* III.36 (printed citation number unclear)] is equal to the rectangle contained by DA, AB. Therefore the rectangle under DA, AB will be known; and AB, the mountain's height, is known. Hence the line AD will also be known, if indeed the known rectangle contained by AB, AD is divided by the line AB. For the quotient number will give the line AD; and if from it AB, the mountain's height, be subtracted, the earth's diameter BD will be left...

Diagram. A woodcut of Maurolycus's mountain construction: a circle (the earth) with a diameter drawn vertically, the mountain's summit above it, and the visual ray drawn as a dashed line to the point of tangency. Readable labels:

- A (top, above the circle): the summit of the mountain.
- E (just below A, on the visual ray): point on the line of sight.
- C (upper left, on the circle): the point where the visual ray AC touches the surface.
- B (upper middle, on the circle): the foot of the mountain.
- F (center of the circle): the center of the earth.
- D (bottom of the circle): the far end of the diameter.

the earth's diameter BD will be left. Therefore from the diameter BD — following what Archimedes [Archimedes] demonstrated in his little book *On the Measurement of the Circle*, as is established from the corollary of proposition 2, book 4 of the *Practical Geometry* [*Geometria Practica*] — the whole circumference of the earth will be known. Which was the thing proposed.

But since the arc BC is not a straight line — especially when the mountain is so high that a space of 200 or 300 miles can be seen (in which case the arc BC, according to the circumference fixed by Ptolemy [Ptolemy], would contain 3

degrees 11 minutes, or 4 degrees 40 minutes), and therefore the tangent line AC is not correctly gathered from the sides AB, BC — and add to this that, by the problems of books 2 and 3 of our *Practical Geometry*, only the perpendicular BE is found, in the plane to which the mountain stands perpendicular: in the *Practical Geometry* we have reduced this method of Maurolycus to a better procedure by several routes, one of which is this.

[Margin: Maurolycus's method is corrected.]

Once the angle A has been found, by means of a quadrant or a geometric square — when the visual ray, passing through the sight [dioptra], touches the circle of the earth or of the sea (which is done most reliably when the Sun or some other star is observed through the sight as it rises or sets) — and once the line FC has been drawn, [Margin (a): *Elements* III.18] which will be perpendicular to AC: the angle F at the center, which is the complement of angle A, will also be known. And since, once the line FE has been drawn, the two sides EC, CF are equal to the two sides EB, BF and contain equal right angles, [Margin (b): *Elements* I.4] the angles at F will be equal. So, since the whole angle BFC is known, as we said just now, the angle BFE, being its half, will also be known, and hence its complement BEF will not be unknown. Therefore in triangle ABE, from the angles A, E and the side AB, BE will be found (by proposition 4 on right-angled triangles) in parts of the mountain's known height AB. And in the same way, in triangle BEF, from the angles E, F and the known side BE, the radius BF will be found in parts of the side BE — that is, in parts of the mountain's height AB. Hence the whole diameter BD will become known; and from it the earth's circumference will be found, from those things which Archimedes and we ourselves demonstrated in the corollary of proposition 2, book 4 of the *Practical Geometry*.

Now all the aforesaid methods of investigating the earth's circumference — except the last, which we demonstrated just now from Maurolycus — rest upon this geometrical conclusion:

If there be two or more circles described about the same center, and if from the center two straight lines be drawn to the circumference of the greatest circle, then the arcs of all the circles comprehended between the said straight lines will be similar to one another.

[Margin: Straight lines going out from one point cut all the circles described from that point as center into similar arcs.]

COMMENTARIVS.

This conclusion, since it is of the greatest service to astronomers and to geometers, we shall try to demonstrate briefly here. Let there be, about the center E, the circles described ACBD, FHGI, KMLN, and from the center E let the straight lines EC, ED be drawn. If these make one straight line, it is certain that all the circles are cut by them into similar arcs, namely into semicircles. Again, let two straight lines EA, ED be drawn from the same center E, making a right angle AED. It is then evident that the arcs AD, FI, KN are similar, since they are quadrants of the circles. For if the straight lines AE, DE be produced as far as B, C, there will be four right angles at E, [Margin (c): *Elements* III.26] and therefore the arcs AD, DB, BC, CA will be equal. In the same way the arcs FI, IG, GH, HF will be equal; likewise the arcs KN, NL, LM, MK. Hence each of them will be a quadrant of its own circle. Finally, let the straight lines ED, EO be drawn, making the angle DEO, not a right angle. I say that even now the arcs DO, IP, NQ are similar — that is, that DO is such a part of the quadrant DA as the arc IP is of the quadrant IF, and as the arc NQ is of the quadrant NK. [Margin (d): *Elements* VI.33] For since, as the angle DEO is to the angle DEA, so is the arc DO to the arc DA, and the arc IP to the arc IF, and the arc NQ to the arc NK, it is manifest that the aforesaid arcs are similar to one another, since they have the same proportion.

[Margin: Another demonstration.]

This can also be gathered by the following reasoning. Just as the [equal angles at the center subtend equal] circumferences, so (by the 2nd corollary of the last proposition of book [six]) the arc DO is to the whole circumference DACB, and the arc IP to the circumference [IFHG], and the arc NQ to the circumference NKML. Therefore the arcs DO, IP, NQ are similar, since they have the same proportion.

Diagram. A woodcut of three concentric circles about a common center E, with a horizontal diameter, a vertical diameter, and an oblique radius drawn to the upper right. The outer circle is lettered ACBD, the middle FHGI, and the inner KMLN. Readable labels:

- E (center).
- A (top, outer circle); B (bottom, outer circle); C (left, outer circle); D (right, outer circle).
- F (top, middle circle); G (bottom, middle circle).
- K (top, inner circle); L (bottom, inner circle); M (left, inner circle).
- O (upper right, on the outer circle, at the end of the oblique radius EO); P (upper right, where the oblique radius crosses the middle circle).

The remaining letters of the middle circle (H, I), of the inner circle (N), and the point Q on the inner circle where the oblique radius crosses it fall in the crowded central region and could not be placed with certainty. (more than two labels unresolved).

Another demonstration, without proportions, can prove the same theorem in this way. From the center E of the circles ABCD, FGHI, let two straight lines EA, EB be drawn. I say that the arcs AB, FG are similar to one another. For, the straight lines AE, BE being produced as far as C, D, let the straight lines BC, GH be drawn; let also, in the arcs AB, FG, the points K, L be taken at random, to which let the straight lines AK, BK, FL, GL be drawn. Since, then, the angles E, G, H of triangle EGH are equal to the angles E, B, C of triangle EBC [Margin (e): *Elements* I.32] (because both these and those are equal to two right angles): if the common angle E be taken away, the two angles G, H will be equal to the two angles B, C. [Margin (f): *Elements* I.5] But both these two and those two are equal to one another, because the straight lines EG, EH are equal to one another, as are the straight lines EB, EC, by the definition of the circle. Therefore the angle EHG will be equal to the angle ECB. Again, [Margin (g): *Elements* III.22] since in the quadrilateral FLGH the two opposite angles FHG, GLF are equal to two right angles; likewise the two opposite angles ACB, BKA in the quadrilateral AKBC: when the equals FHG, ACB are removed, the remaining angles BKA, GLF will be equal; and therefore, by the definition, the arcs AB, FG will be similar to one another. Which was to be demonstrated.

Diagram. A woodcut of two concentric circles about the center E, with radii drawn and chords forming two similar figures. Readable labels:

- A (top); C (bottom); B (left); D (right) — endpoints of the two diameters through E.
- E (center).
- F (inner circle, near A); G (inner circle, near the left, toward B); H (inner circle, lower right); I (inner circle, right of E).
- K (outer circle, upper left); L (inner circle, upper left).

This theorem having been demonstrated, all the aforesaid methods hold good. For it will come about that, when in the heaven a variation of one degree (or of several) has occurred, on the earth a variation of just as many degrees will likewise have occurred. For if, from the extremities of those celestial degrees, two straight lines be conceived as drawn to the center of the world, they will necessarily intercept just as many degrees also on the surface of the earth, by what has just been demonstrated, as is clear in this figure here adjoined. And the

same reasoning holds for any celestial space whatever: for the said lines will always comprehend a similar space on the earth. This, indeed, was assumed as most certain in all the aforesaid methods; otherwise nothing at all could have been concluded by them, as is plain.

Diagram. A woodcut showing an outer circle (the heaven) enclosing a smaller hatched disc at its center (the earth). Two straight lines are drawn from two points on the outer circle, converging to a point at the center, forming a narrow triangular wedge — illustrating that equal celestial arcs correspond to equal terrestrial arcs. No letter labels are present.

From these things, moreover, by the rule of the circle and the diameter, the diameter of the earth can be found thus. Take away the twenty-second part from the circumference of the earth, and the third part of the remainder — that is, 80,181 stadia, and a half, and a third of a stadium — will be the diameter, or thickness, of the terrestrial globe.

COMMENTARIVS.

After the Author has explained how great the circumference of the terrestrial globe is, and by what method it ought to be traced out, he now teaches by what art, from the known circumference of the earth, its depth — that is, the diameter of that same earth — may be known. For he says that if the twenty-second part be taken away from the whole terrestrial circumference (which part will be had in the quotient number, if the circumference is divided by 22) — namely, if from 252,000 stadia there be subtracted 11,454 $\frac{6}{11}$ stadia — then the third part of the remaining number (namely of 240,545 $\frac{5}{11}$ stadia; which part likewise the quotient number will offer, if the said remaining number be divided by 3), that is, 80,181 $\frac{9}{11}$ [?] stadia — or, as he himself says, 80,181, and a half, and roughly a third part — will be the whole depth, or diameter, of the terrestrial globe, by the rule of the circle and the diameter.

[Margin: How the earth's diameter is derived from its known circumference.]

Now this rule is taken from the little book of Archimedes *On the Measurement of the Circle*, in which Archimedes demonstrated (as we too have done in the *Practical Geometry*, book 4, proposition 2) that the proportion of the circumference of any circle to its diameter is roughly triple-and-one-seventh, such as is 22 to 7. So that, if the circumference of some circle be cut into 22 equal parts, its diameter will contain roughly 7 such parts; and conversely, if the diameter of some circle be divided into seven equal parts, its circumference will comprehend 22 such parts. Whence, if the diameter of some circle be taken three

times and a seventh part added, a straight line will be produced roughly equal to the circle's circumference. All of which may be seen in this figure here set forth.

[Margin: What the proportion of any circle to its diameter is.]

Diagram. A woodcut of a circle whose horizontal diameter is extended to the left as a straight line marked with tick divisions — representing the circumference straightened out and shown to be three-and-one-seventh times the diameter (the 22-to-7 ratio). No letter labels are present.

Since these things are so, it is evident that if from the circumference of the circle — namely from 22 — the twenty-second part (that is, unity) be taken away, then the third part of the remaining number, that is of 21 — namely 7 — is the diameter of the circle. From which the Author's rule is manifest, which prescribes that from the terrestrial circumference the diameter, or depth, of the earth be explored.

*RULE, BY WHICH THE DIAMETER IS FOUND FROM THE
CIRCUMFERENCE, AND THE CIRCUMFERENCE FROM THE DIAMETER.*

From this same proportion of the circumference of a circle to its diameter — which, namely, they have as 22 to 7 — other writers elicit this rule, much more convenient than the rule of our author, for inquiring the diameter from the known circumference, or conversely for finding the circumference from the known diameter, as we gathered in the corollary of proposition 2, book 4 of the *Practical Geometry*. The first part of the rule, by which the diameter is derived from the known circumference, is this.

Let the circumference be divided by $3 \frac{1}{7}$ — namely by the denominator of the triple-and-one-seventh proportion which, as we have said, the circumference has to the diameter according to Archimedes: the number coming out in such a division will be the diameter of the circle. Thus, if the circumference of some circle, comprising 1540 palms, be divided by $3 \frac{1}{7}$, there will result 490 palms for the magnitude of the diameter. This rule can also be stated thus: let the circumference be multiplied by 7, and let the product be divided by 22, and the diameter will be found. For since the proportion of the circumference of any circle to its diameter is, as Archimedes demonstrated, [22 to 7]: it comes about that if the number of the rule of proportions be multiplied by 7 — namely by the second number of that same rule — and the product be divided by the first number, that is by 22, then the diameter is found as the fourth number of the rule of proportions. As in the preceding example: if the circumference 1540 be multiplied by 7 and the product divided by 22, the diameter 490 will be found, as

before. By this reasoning, if we multiply the earth's circumference according to Eratosthenes — namely 252,000 stadia — by 7, there will be produced 1,764,000; which divided by 22 yields 80,181, that is 80,181 $\frac{18}{22}$, for the diameter of the earth, just as before according to the Author's rule. The latter part of the rule, by which in turn the circumference is elicited from the known diameter, stands thus.

[Margin: How the circle's diameter is elicited from its known circumference.]

Let the diameter be multiplied by $3\frac{1}{7}$ — namely by the denominator of the triple-and-one-seventh proportion which, according to Archimedes, the circumference has to the diameter. For the product number will at once indicate the circumference. Thus, if the diameter of some circle, having 490 palms, be multiplied by $3\frac{1}{7}$, a circumference of 1540 palms will be found. This rule too can be stated in this way: let the diameter be multiplied by 22, and let the product number be divided by 7, and the quantity of the circumference will result. For since, as was demonstrated by Archimedes, the proportion which is 22 to 7 is the proportion of the circumference of any circle to its diameter...

[Margin: How the circle's circumference is found from its known diameter.]

By conversion, there will be the same ratio, 7 to 22, as of the diameter to the circumference. Therefore, if the diameter — that is, the third number of the rule of proportions — is multiplied by 22 (namely by the second number of the same rule), and the resulting number is divided by the first number, that is, by 7, the fourth number of the same rule is found: the circumference of the circle. As in the next example: if the diameter 490 is multiplied by 22, and the resulting number is divided by 7, the circumference 1540 is found, as before. This twofold precept is contained in the following verses:

Circuitus circi per septem multiplicetur, Per duo viginti productum deinde secato: Hinc numerus, Quotiens qui dicitur, est diametrus. Per duo viginti si multiplices diametrum, Per septemque seces numerum, qui prodijt inde: Circuitum circi Quotiens numerus tibi reddet.

Multiply the circumference of the circle by seven, then divide the product by twenty-two: the number that results, called the quotient, is the diameter. If you multiply the diameter by twenty-two, and divide by seven the number that comes out, the quotient will give you back the circumference of the circle.

From this it is easy to understand the method that Francesco Maurolico [Francesco Maurolico] used in investigating the circumference of the terrestrial

globe. For he first learned by a geometrical procedure the size of the earth's diameter, and from this he then, according to this ratio of diameter to circumference demonstrated by Archimedes [Archimedes], hunted out the circumference of the greatest circle described through the earth's center.

[Margin: From the foregoing rules the circumference is found from a known diameter greater than it truly is, and the diameter from a known circumference smaller than it truly is.]

The circumference of any circle does not, however, stand to its diameter precisely in the ratio that 22 has to 7, but in a slightly smaller one. For as Archimedes most acutely demonstrated in his booklet *On the Measurement of the Circle* [*De dimensione circuli*], the circumference of any circle has to its diameter a ratio smaller than triple-and-one-seventh [tripla sesquiseptima, i.e. $3 \frac{1}{7}$] — or (what is the same) triple-and-ten-seventieths [$3 \frac{10}{70}$] — but greater than triple-and-ten-seventy-firsts [$3 \frac{10}{71}$]. Thus, if the diameter is taken three times together with a seventh part of it, that is, with $3 \frac{1}{7}$, a line slightly greater than the circumference is produced; whereas if the diameter is taken with $3 \frac{10}{71}$, a line slightly smaller than the circumference is produced. So the true ratio of circumference to diameter lies (though it remains hidden) between the two whose denominators are $3 \frac{1}{7}$ and $3 \frac{10}{71}$.

Common practice among practitioners has nonetheless prevailed, so that the former ratio — namely triple-and-one-seventh — is used as though it were the true one, rather than the ratio whose denominator is $3 \frac{10}{71}$. For they take the diameter three times with a seventh part of it, in order to yield a straight line equal to the circumference, since it falls only a little short of the truth, and since the calculation is easier with $3 \frac{1}{7}$ than with $3 \frac{10}{71}$. For that reason we too may use the same ratio, provided we remember — from the demonstrations above — that from a known diameter the circumference is found slightly larger, and from a known circumference the diameter slightly smaller, than it truly is. For since, according to Archimedes, the ratio of circumference to diameter is smaller than triple-and-one-seventh — that is, than 22 to 7 — if the diameter is 7, the circumference is slightly less than 22. [Margin a: (Euclid, Elements) V.8] For a number smaller than 22 has a smaller ratio to 7 than 22 has to 7. Hence, since by the rule above, if the diameter is 7 the circumference is found to be 22, it is plain that the circumference is found from a known diameter larger than it really is. Again it follows that, if the circumference is 22, the diameter is slightly larger than 7. [Margin b: (Euclid, Elements) V.8] For 22 has a smaller ratio to a number larger than 7 than it has to 7. Therefore, since by the rule above, if the

circumference is 22 the diameter is found to be 7, it is clear that the diameter is found from a known circumference smaller than it really is.

All these rules, and many more bearing on the same subject, we have demonstrated in Book 4 of the *Practical Geometry* [*Geometria practica*].

Rules by which may be found the area of the greatest circle on the terrestrial globe (or in any sphere whatever), the convex surface of the same terrestrial globe (or of any sphere whatever), and indeed the entire solidity as well

So far, drawing on approved authorities, we have reviewed various methods by which the earth's circumference is investigated, and we have set out precepts by which, from a known circumference, the diameter is found, and conversely, from a known diameter, the circumference. Now I shall present other precepts by which, from the diameter and circumference of the earth — or of any other sphere — the area of the greatest circle on the earth (or another sphere) is to be found; and from this area, the convex surface of the same earth or sphere; and finally, from this convex surface, the entire solidity of the whole earth or another sphere. For in this way it will come about that the earth's magnitude is made known in every respect — not merely as to its circumference, which is what our Author accomplished in this place.

[Margin: By what art the area of any circle is found.]

As to the first, then: if the radius [semidiameter] of any circle is multiplied by half of the circumference (or perimeter) of the circle, the area (or surface) of the circle enclosed within the circumference is produced. For example, if the circumference of some circle is 132 and the diameter 42: if we multiply 21, half the diameter, by 66, half the circumference, this number, 1386, is produced for the area of the circle. This we demonstrated in Book 7 of the *Practical Geometry*, in the treatment of isoperimetric figures, proposition 4, in which it is established that the rectangle contained by the radius of any circle and half of its circumference is equal to the circle. Thus, if the radius of the earth — namely 40090 $\frac{7}{22}$ stadia according to Eratosthenes [Eratosthenes] — is multiplied by half the circumference — that is, according to Eratosthenes, by 126000 stadia — the area of the greatest circle on the earth is produced: 5,051,454,545 $\frac{5}{11}$ stadia. That is, the plane surface of the greatest circle on the earth will comprise as many squares, each of which encloses one stadium on each of its sides, as there are units in the said number. For the areas of plane figures are measured by the

squares of the lines by which the sides, or perimeters, of those figures are usually measured.

By another method the area of a circle will be found from its circumference, even when the diameter is not known, in this way. Let the whole circumference be multiplied by itself, and the resulting number divided by $12\frac{4}{7}$. The quotient will give the area. For example, if the circumference of a circle is 44 palms, let 44 be multiplied by itself, and the resulting number, 1936, divided by $12\frac{4}{7}$; the quotient, 154, will be the number of square palms that the surface of the given circle contains, as we demonstrated in Book 4 of the *Practical Geometry*, chapter 7.

[Margin: By what route the convex surface of any sphere is found.]

As to the second: if the area of the greatest circle in a sphere is multiplied by 4, the entire convex surface of the sphere is produced. For example, given a sphere whose greatest circle has a perimeter of 132 and a diameter of 42, by the first rule the area of the greatest circle is 1386, as was said; and if this is multiplied by 4, the convex surface of that sphere at once arises: 5544. This was most clearly demonstrated by Archimedes in Book 1 of *On the Sphere and the Cylinder* [*De sphaera et cylindro*], proposition 31, in which it is concluded that the convex surface of any sphere is quadruple the greatest circle in the sphere. Thus, if the area of the greatest circle on the earth — which contains, as we said, 5,051,454,545 $\frac{5}{11}$ square stadia — is multiplied by 4, the whole convex surface of the terrestrial globe will be found: 20,205,818,181 $\frac{9}{11}$ square stadia. The same convex surface can nonetheless be found more easily, even if we do not have the area of the greatest circle, in this way.

[Margin: By what reasoning the solidity of a sphere is found.]

Let the whole diameter be multiplied by the whole circumference of the greatest circle. The resulting number will give the convex surface of the sphere. For example, if the earth's diameter — containing 80181 $\frac{9}{22}$ stadia — is multiplied by the whole perimeter, namely by 252000 stadia, the convex surface of the earth is produced: 20,205,818,181 $\frac{9}{11}$ square stadia, as before. We shall demonstrate this as follows. The rectangle contained by the diameter of the sphere and the circumference of the greatest circle is similar to the rectangle contained by the radius of the sphere and the semicircumference of the greatest circle, because the sides of the former have a double ratio to the sides of the latter, and therefore, by permutation, the sides of the former have the same ratio to one another as the sides of the latter. [Margin a: (Euclid, Elements) VI.20] Hence the former will have

to the latter the doubled ratio of the corresponding [homologous] sides. Since, then, the homologous sides have a double ratio, that rectangle will have to this one a quadruple ratio, which is the duplicate of the double ratio — as appears in these numbers: 1, 2, 4. But this rectangle, contained by the radius and the semicircumference of the greatest circle, is equal to the area of the greatest circle in the sphere, as we demonstrated in the *Practical Geometry*, proposition 4, in the treatment of isoperimetric figures. Therefore that rectangle contained by the whole diameter and the whole circumference is quadruple the greatest circle in the sphere; and consequently it is equal to the convex surface of the sphere, since this too is quadruple the same greatest circle, as Archimedes demonstrated in Book 1 of *On the Sphere and the Cylinder*, proposition 31.

[Margin: By what reasoning the solidity of a sphere is found.]

Now, to come to the third: the entire solidity of the sphere is produced if the radius of the sphere is multiplied by a third part of the sphere's perimeter, or of the convex surface of the sphere. For the solid rectangle [rectangular solid] contained by the radius of the sphere and a third part of the sphere's perimeter is equal to the sphere itself, as we demonstrated in the treatment of isoperimetric figures, proposition 16. By this reasoning, if the radius of the earth — 40090 $\frac{7}{22}$ stadia — is multiplied by a third part of the convex surface — namely by 6,735,272,727 $\frac{7}{11}$ stadia — the solidity of the earth is produced: 270,023,206,611,570 $\frac{7}{33}$ cubic stadia. That is, the solidity of the earth will comprise as many cubes, each of which encloses one stadium on each of its sides, as there are units in the said number. For the volumes of solid figures are measured by the cubes of the lines by whose squares the perimeters, or convex surfaces, of those figures are usually measured.

By another method the solidity of a sphere will be found from its greatest circle, even if its convex surface is unknown, in this way. Let the greatest circle [i.e. its area] be multiplied by two-thirds of the whole diameter. The resulting number will be the solidity of the sphere, as we demonstrated in Book 5 of the *Practical Geometry*, proposition 7. For example, if some sphere has a diameter of 14 palms and it is multiplied by $3\frac{1}{7}$, the circumference of the greatest circle, 44, is found; half of this, 22, if multiplied by the radius 7, produces the area of the greatest circle, 154; and if we multiply this by two-thirds of the diameter — that is, by $9\frac{1}{3}$ — the solidity of the same sphere is produced: 1437 $\frac{1}{3}$ cubic palms.

All these rules, and many more relating to the same matter, have been demonstrated by us in Books 4 and 5 of the *Practical Geometry*.

On the various measures of mathematicians

But in order that the earth's circumference may be had not only in stadia, but also in paces, miles, leagues, and other measures, we must enumerate the measures that mathematicians — especially geometers — use. For mathematicians, lest confusion should arise from the diversity of measures in various regions (since nearly every region has more or less its own measures), usefully devised certain measures that would be held fixed and settled among all nations. The principal measures are contained in the table below.

[Margin: The various measures used among geometers.]

Measure	Contains	or	amount
Barleycorn (granum hordei) — the smallest of all measures, and the starting point			
Finger (digitus) — has grains arranged by their width	4 grains		
Palm (palmus) — contains digits	4	or grains	16
Foot (pes) — contains palms	4	or digits	16
Small cubit (cubitus parvus), according to Vitruvius [Vitruvius] — contains feet	1 1/2	or palms	6
Common cubit (cubitus communis) — embraces feet	4	or palms	16
[Note: This common cubit is not found among the ancients, but was perhaps added by more recent writers, because it is the same as the common ell (ulna); for in some provinces the ell and the cubit are taken as the same thing.]			
Great cubit (cubitus magnus) — consists of feet	9	or palms	36
[Note: This great cubit too was perhaps added by more recent writers, on account of Origen			

Measure	Contains	or	amount
<i>[Origen], though it is found in no other writer.]</i>			
Simple pace of the first kind (passus simplex primæ differentiæ) — has feet	2	or palms	8
Double pace of the first kind — has feet	4	or palms	16
Simple pace of the second kind — contains feet	2 1/2	or palms	10
Double pace of the second kind, called the geometric [pace] — has feet	5	or palms	20
Simple pace of the third kind — has feet	3	or palms	12
Double pace of the third kind — consists of feet	6	or palms	24
Common ell (ulna communis) — embraces feet	4	or palms	16
Rustic ell (ulna agrestis) — consists of feet	6	or palms	24
Perch (pertica) — comprises feet	10	or palms	40
Stadium — has geometric paces	125	or feet	625
Mile (milliarium) — contains stadia	8	or geom. paces	1000
Gallic or Spanish league (leuca Gallica sive Hispanica) — contains miles	1 1/2	or geom. paces	1500
Common German league (leuca Germanica communis) — has miles	4	or geom. paces	4000
Swabian league (leuca Suevica), the greatest of all — has miles	5	or geom. paces	5000

However, the value of these measures is to be understood only with respect to length. So, for example, eight stadia in length make one mile in length, and four digits in length make one palm in length, and so on — but not with respect to

area. For eight square stadia are not equivalent to one square mile, since the square of one mile comprises 64 square stadia; this is because the square of eight (the number of stadia that make one mile) is 64. Likewise one square palm will contain 16 square digits, because the square of four (four digits making a palm) is 16, and so on. I say this so that you may not be surprised that the stadia comprised in the whole convex surface of the earth cannot be reduced to miles by dividing by 8, but by 64.

[Margin: How the aforementioned measures are to be understood.]

From these it will be easy for anyone not wholly destitute of the precepts of arithmetic to convert any measure into another. For if a smaller measure is to be changed into a greater, the number of the smaller measure must be divided by the number by which the smaller is contained in the greater. For example, if 46000 paces are to be reduced to miles, they must be divided by 1000, since 1000 paces make one mile, and 46 miles result. Likewise, since 8 stadia make a mile, from 252000 stadia are produced 31500 miles. By the same reasoning, since 20000 palms make a mile, in 560000 palms are contained 28 miles, and so on. But if some greater measure is to be converted into a smaller, the number of the greater measure must be multiplied by the number according to which the smaller is contained in the greater. For example, if I wish to know how many paces are made from 46 miles, I multiply 46 by 1000 (for the pace is contained that many times in a mile), and I produce 46000 paces; and so for the rest.

Various opinions of authors on determining the earth's circumference

Although all the methods adduced above, by which the circumference of the terrestrial globe is investigated, rest on geometrical demonstrations, the terrestrial distance corresponding to a like celestial interval nevertheless cannot be measured with perfect exactness — because of the obstacles of mountains or valleys and the like, or also because one rarely travels by a straight route from one place to another, but rather the routes are always winding. And although Maurolico's demonstration does not require that we traverse any distance, it is still quite difficult to discern exactly and precisely, by a visual ray, that point of contact on the earth's surface. Hence it has come about that different practitioners, having measured the circumference of the globe composed of earth and water, have not found it to be of the same magnitude, but differ greatly among themselves in determining the quantity of that circumference. It has

seemed good to review their opinions here, so that from them we may choose the one that comes closer to the truth.

[Margin: Why various authors have found different values for the earth's circumference.]

Aristotle [Aristotle], then, near the end of Book 2 of *On the Heavens* [*De caelo*], reports the opinion of certain ancients who asserted that the earth's circumference contains 400000 stadia, which make 50000 miles. Thus, according to this view, to one terrestrial degree there would correspond 1111 $\frac{1}{9}$ stadia [?], or 138 $\frac{8}{9}$ [?] miles; the earth's diameter would be 127272 $\frac{8}{11}$ stadia, or 15909 $\frac{1}{11}$ miles; and the radius 63636 $\frac{4}{11}$ stadia, or 7954 $\frac{6}{11}$ miles. But because this opinion attributes more than is fair to the earth's magnitude, and conflicts too much with the observations of more recent men, it is rejected by all.

[Margin: The earth's circumference according to Aristotle.]

Hipparchus [Hipparchus], on the testimony of Pliny [Pliny the Elder], assigned to the earth's circumference 277000 stadia, that is, 34625 miles; so that the space of one degree comprises 769 $\frac{7}{9}$ [?] stadia, or 96 $\frac{2}{6}$ [?] miles. Thus for Hipparchus the earth's diameter will be 88136 $\frac{4}{11}$ stadia, or 11017 $\frac{1}{11}$ miles; and the radius will contain 44068 $\frac{2}{11}$ stadia, or 5508 $\frac{4}{11}$ miles. But for the same reason as the previous one, this opinion is exploded by the astronomers.

[Margin: The earth's circumference according to Hipparchus.]

Eratosthenes [Eratosthenes], as is found in Macrobius [Macrobius], Book 1 of *On the Dream of Scipio* [*In Somnium Scipionis*], assigned to the earth's circumference 252000 stadia, which make 31500 miles. For he had found that in one degree of the earth 700 stadia are contained, that is, 87 $\frac{1}{2}$ miles. Hence the earth's diameter will have 80181 $\frac{9}{11}$ stadia, or 10022 $\frac{2}{11}$ miles; and in the radius there will be 40090 $\frac{9}{22}$ stadia, or 5011 $\frac{1}{22}$ miles. If, however, we are to believe Cleomedes [Cleomedes], Eratosthenes said that only 250000 stadia are contained in the whole circumference of the earth. Yet the astronomers of our time do not embrace this opinion either, because they find the earth's circumference smaller than Eratosthenes did.

[Margin: The earth's circumference according to Eratosthenes.]

Ptolemy [Ptolemy] affirms that the whole circumference of the terrestrial globe contains 180000 stadia, that is, 22500 miles — so that to one degree on the earth there correspond 500 stadia, or 62 $\frac{1}{2}$ miles. By this reckoning the [length] of the earth's diameter...

[Margin: The earth's circumference according to Ptolemy.]

the length will comprise 57,272 $\frac{8}{11}$ stadia, or 7159 $\frac{1}{11}$ miles. The semidiameter will be 28,636 $\frac{4}{11}$ stadia, or 3579 $\frac{6}{11}$ miles. And the whole convex surface of the earth will comprise 10,309,090,909 $\frac{1}{11}$ stadia, or 161,079,545 $\frac{5}{11}$ miles.

[Margin: The earth's circumference according to Alfraganus [al-Farghānī], Almaeon, and Thebith [Thābit ibn Qurra].]

ALFRAGANUS [al-Farghānī], Almaeon, Thebitius [Thābit ibn Qurra], and — on Alfraganus's authority — very many learned men assign to the earth's circumference 163,200 stadia, or 20,400 miles. For they allot to each single degree only 453 $\frac{1}{3}$ stadia, that is, 56 $\frac{2}{3}$ miles. Accordingly, on these authors' reckoning, the earth's diameter will contain 51,927 $\frac{3}{11}$ stadia, or 6490 $\frac{10}{11}$ miles; its semidiameter will amount to 25,963 $\frac{7}{11}$ [?] stadia, and to 3245 $\frac{5}{11}$ [?] miles; and the convex surface will be 8,474,530,909 $\frac{1}{11}$ stadia, or 132,414,545 $\frac{5}{11}$ miles.

[Margin: The earth's circumference according to Fernel of Amiens [Jean Fernel].]

FERNEL of Amiens [Jean Fernel], in his *Cosmotheoria*, holds that the earth's circumference comprises 196,114 $\frac{8}{25}$ stadia, or 24,514 $\frac{29}{100}$ [?] miles. For he says that he found one degree on the earth to correspond to 544 [?]/500 stadia, or 68 [?]/4000 miles. On this view, then, the earth's diameter will be 62,400 $\frac{2}{275}$ [?] stadia, or 7800 $\frac{3}{2200}$ [?] miles; the semidiameter, 31,200 $\frac{3}{500}$ stadia, or 3900 $\frac{3}{4400}$ miles; and the convex surface of the earth will on this reckoning contain 12,237,535,707 [?]/[?] stadia, or 191,211,495 $\frac{217143}{880000}$ miles.

[Margin: The earth's circumference according to the more recent navigators.]

The MODERNS, finally — experts in astronomical matters who have more than once sailed across the whole ocean — testify that the entire circuit of the earth comprises 152,640 stadia, or 19,080 miles. For they say that a single degree at sea corresponds to only 424 stadia, that is, 53 miles. And so, if this is true, the length of the earth's diameter will be 48,567 $\frac{3}{11}$ [?] stadia; in miles, 6070 $\frac{10}{11}$. The semidiameter will be 24,283 $\frac{7}{11}$ stadia, or 3035 $\frac{5}{11}$ miles. Finally the convex surface of the earth will comprise 7,413,308,509 $\frac{1}{11}$ stadia, or 115,832,945 $\frac{5}{11}$ miles.

These, then, are the seven opinions of any weight concerning the size of the earth's circuit. Of them the first three are rejected by everyone as altogether false, while the latter four are probable, and each has its own defenders. [Margin: Ptolemy's opinion on the earth's circumference is the common one.] For the schools of astronomers generally embrace Ptolemy's view as the truer — and it is

the one we shall follow in what follows, so as not to seem to depart from the common path. Others rather adhere to Alfraganus's opinion, because after Ptolemy many learned men, as Alfraganus reports, confirmed it; hence perhaps the moderns' opinion, which departs but little from Alfraganus, will prove the truer. Finally, a few seem to incline to the opinion of Fernel of Amiens.

There are also some who try to reconcile all the said opinions. For they say that the aforementioned authors did not use the same measure, but that those who set the earth's circuit larger assumed smaller paces, while those who said it was smaller used larger paces. Hence the discrepancy among these astronomers will not be as great as it seems. But anyone who considers the matter more carefully will readily see that no agreement can be found among all the opinions, even though between two or three some measure of agreement may be found.

So that you may have all the aforementioned opinions before your eyes, I have appended the following little tables, in which, according to each view, are set out the earth's circuit, the size of one terrestrial degree, the diameter of the earth, and its semidiameter; and, following the latter four opinions as well, the convex surface of the earth — all this both in stadia and in miles.

The earth's circumference contains, as each holds — *Ambitus terrae continet, vt vult*

Author	Stadia	Milliaria (miles)
Aristoteles [Aristotle]	400,000	50,000
Hipparchus	277,000	34,625
Eratosthenes	252,000	31,500
Ptolemaeus [Ptolemy]	180,000	22,500

THE DISTANCES OF THE HEAVENS FROM THE EARTH, THEIR THICKNESSES, AND THEIR CIRCUMFERENCES — *DISTANTIÆ COELORVM A TERRA, CRASSITVDINESQVE, & Ambitus eorundem*

Since we have spoken of the size of the earth — both as regards the circuit of the greatest circle described upon it, and as regards its diameter, its semidiameter, and its convex surface — it will not be out of place to indicate briefly here also the semidiameters, that is, the distances from the center of the world, of all the heavens, together with their thicknesses and their circuits, or circumferences. This I shall carry out in three tables: the first of which contains the semidiameters of all the heavens; the second, their thicknesses; and the third, finally, the circumferences of the same in their greatest circles, both along the concave and along the convex [surface]. From the precepts given above, anyone who wishes can readily work out, should he desire it, both the concave and the convex surfaces — indeed even the solid volumes — of these heavens. In these tables I have followed almost throughout Francesco Maurolico [Franciscus Maurolycus] in the appendix to his *Dialogues on Cosmography*.

The semidiameters of the heavens, both along the concave and along the convex — *Semidiametri coelorum tam secundum concauum, quam secundum conuexum*

Each row gives the value first in terrestrial semidiameters (*semidiametros terrae*), then "or in miles" (*vel milliaria*).

Boundary	Terrestrial semidiameters	Or miles
Semidiameter of the concave of ☾ [Moon] contains	33 7/10	120,630 15/22
Semidiameter of the convex of ☾ [Moon], and concave of ☿ [Mercury]	64 1/6	229,687 1/2
Semidiameter of the convex	167 2/3	600,167 14/33

Boundary	Terrestrial semidiameters	Or miles
of ☿ [Mercury], and concave of ♀ [Venus]		
Semidiameter of the convex of ♀ [Venus], or concave of ☉ [Sun]	1121 7/20	4,013,923 7/22
Semidiameter of the convex of ☉ [Sun], or concave of ♂ [Mars]	1216 1/12	4,353,025 25/44
Semidiameter of the convex of ♂ [Mars], or concave of ♃ [Jupiter]	8853 3/4	31,692,400 25/44
Semidiameter of the convex of ♃ [Jupiter], or concave of ♄ [Saturn]	14,378 1/3	51,467,897 8/11
Semidiameter of the convex of ♄ [Saturn], or concave of the Firmament, according to Alfraganus	22,612 1/2	80,942,471 13/22
Semidiameter of the convex of the Firmament, according to Alfraganus	45,225	161,884,943 2/11

The thicknesses of the heavens — *Crassitudines coelorum*

These are obtained if the semidiameters extended to the concave of each heaven are subtracted from the semidiameters extended to the convex of the same. Each row gives the thickness first in terrestrial semidiameters, then "or in miles."

Heaven	Terrestrial semidiameters	Or miles
Thickness of the heaven of ☾ [Moon]	31 7/15 [?]	109,056 9/11
Thickness of the heaven of ☿ [Mercury]	103 1/2	370,479 61/66
Thickness of the heaven of ♀ [Venus]	953 41/60 [?]	3,413,755 59/66 [?]

Heaven	Terrestrial semidiameters	Or miles
Thickness of the heaven of ☉ [Sun]	94 11/15 [?]	339,102 1/4
Thickness of the heaven of ♂ [Mars]	7637 2/3	27,339,375
Thickness of the heaven of ♃ [Jupiter]	5524 7/12	19,775,497 7/44
Thickness of the heaven of ♄ [Saturn]	8234 1/6	29,474,573 10/22
Thickness of the Firmament, from Alfraganus	22,612 1/2	80,942,471 13/22

The circumferences of the heavens, both concave and convex, reduced to miles — *Ambitus coelorum tam secundum concauum, quam secundum conuexum ad milliaria reducti*

Circle	Miles
Circumference of the concave of ☾ [Moon]	758,250
Circumference of the convex of ☾ [Moon], or concave of ☿ [Mercury]	1,443,750
Circumference of the convex of ☿ [Mercury], or concave of ♀ [Venus]	3,772,500
Circumference of the convex of ♀ [Venus], or concave of ☉ [Sun]	25,230,375
Circumference of the convex of ☉ [Sun], or concave of ♂ [Mars]	27,361,875
Circumference of the convex of ♂ [Mars], or concave of ♃ [Jupiter]	199,209,375
Circumference of the convex of ♃ [Jupiter], or concave of ♄ [Saturn]	323,512,500
Circumference of the convex of ♄ [Saturn], or concave of the Firmament	508,781,250
Circumference of the convex of the Firmament	1,017,562,500

[Margin: By what method the distances and thicknesses of the heavens, and the magnitudes of the stars, may be investigated.]

The untrained crowd is often not a little astonished at how astronomers have gathered the distances of the heavens, and hence also determined their thicknesses and circumferences, together with the magnitudes of the stars. Many even of those who wish to be reckoned mathematicians do the same, since they see that this could not have been done by the altimeter's scale, or by the other instruments with which surveyors [Geometrae] usually measure the distances of places. For every use of instruments fails when a distance as great as that at which those heavenly bodies stand from us has to be investigated — seeing that instruments of this kind are scarcely fit to measure fifty miles, even from some very lofty mountain, let alone the hundred and sixty millions of miles and more at which the convex surface of the Firmament is said to lie from the center of the earth. So that they may cease to wonder, then, let them know that all these things were investigated by skilled astronomers through the motions of the planets; and by what method this can be done, I shall explain briefly here.

First, then, they investigated the Moon's distance when it is closest to the earth — that is, the semidiameter of the concave surface of the lunar orb in relation to the earth's semidiameter — by means of what Ptolemy demonstrated in Book 5 of the *Almagest*, through the parallax [diuersitatem aspectus] of that same Moon, which he teaches how to investigate in that same book.

[Margin: How the Moon's distance from the earth's center is to be investigated.]

He applied virtually this same technique to investigating the Moon's distance from the earth's center when it is nearest to us. Let AB be a greatest circle on the earth, about C, the center of the world. In the same plane let there be a circle in the Moon's heaven passing through its center E, running along DE. Finally, let a vertical circle in the Firmament pass through the zenith F and, going through the Moon's center, be FG.

Diagram. A lunar-parallax construction. About the center C (the earth, drawn as a small hatched globe) two large concentric circles are drawn: a middle circle representing the Moon's heaven and an outer circle representing the Firmament. A vertical diameter runs from F at the top down through the center to B. Straight lines drawn from C and from A (a point on the earth's globe just above C) pass through E (the Moon's center, on the middle circle) and strike the outer circle at the points G, H, I on the upper right.

- F (top, on outer circle): the zenith
- D (upper, on the middle/lunar circle)

- g (upper right, on outer circle): G, the Moon's true place (printed as lowercase *g*)
- H (right, on outer circle, below g): the Moon's apparent place
- I (right, on outer circle, below H)
- E (center-right, on the lunar circle): the Moon's center
- A (just above center, on the earth's globe)
- C (center): the world's center (the earth)
- B (lower right, on the earth's globe, on the vertical diameter)

Now draw the straight line CF through C, the world's center, and through the zenith F; and through E, the Moon's center, draw the straight lines CEG and AEH. Then G will be the Moon's true place, H its apparent place, and GH the parallax. And since the earth is of imperceptible size in relation to the Firmament, if CI is drawn parallel to AH, the arc HI will be of no perceptible size with respect to the Firmament; and therefore the arc GI can be taken for the parallax, since HI adds nothing perceptible to the arc GH. Consequently, once the parallax is known, the angle GCI [note a] — and therefore also its alternate angle AEC — will be known. The angle ACG is also known, since the Moon's true distance from the zenith is known, namely the arc FG. (This too will become known if the parallax GH is subtracted from the arc FH, known by observation.) [note b] Therefore the remaining angle CAE too will be known, out of the two right angles [to which the triangle's angles sum]. Since, then, all three angles of triangle ACE are known, together with the side AC, [note c] if we set up the proportion:

As the sine of angle E (the parallax) is to the side AC (taken as 1), so is the sine of angle A to another quantity,

then CE will be produced — the Moon's distance from the earth's center, in the parts of which the earth's semidiameter AC is 1 — which was the thing proposed.

[Margin, note a: 29 of the first (book).] [Margin, note b: 32 of the first (book).]

[Margin, note c: 10 of the *Triangles, rectilinear* (i.e. of Regiomontanus, *De triangulis*).]

Next they explored the eccentricities of all the planets — that is, how far the centers of the eccentric orbs, on which the planets are carried from west to east, are distant from the world's center — as was demonstrated by Ptolemy in the *Almagest*.

Third, with remarkable ingenuity they hunted out the thicknesses of the eccentrics in terms of the diameter of the epicycles, as Ptolemy taught in the same

Almagest. From all these they concluded the distances of the heavens — that is, their semidiameters — in the following way.

Let ABC be the heaven of any planet, in which the eccentric is IMO and its deferents are ABCL and FEDK; let G be the center of the world and H the center of the eccentric. Let CF (or AD) be the thickness of the whole heaven; CL (or KD) the greatest thickness of the deferent orbs of the augment [maxima crassities orbium augem[?] deferentium]; and finally AK (or FL) the thickness of the eccentric orb, which is exhibited by the diameter of the solar body AK, or of the epicycle FL. Before all else it must be demonstrated that the thickness CL (or KD) is double the eccentricity GH — that is, of the distance of the eccentric's center H from the world's center G — which will become clear as follows. Cut off GN equal to GH. And since the semidiameters GA, GC are equal, when the equals GH, GN are removed, HA and NC will also be equal. Since, then, HC exceeds NC by the straight line HN — which is double the eccentricity GH — the same HC will also exceed HA (that is, HL, namely the semidiameter of the eccentric) by the straight line HN. But HC exceeds this same HL by the thickness CL. Therefore the thickness CL is equal to double the eccentricity — that is, to the straight line HN — which was to be shown.

Diagram. A woodcut of a planet's heaven with its eccentric and deferent orbs, shown as a broad shaded (dark) annulus enclosing a lighter inner region. A vertical diameter runs from A at the top down to C at the bottom. Two small circles (the planetary/solar body in two positions) sit on this axis: one at the top marked with an *i* (drawn with radiating rays, like a small sun) just below A, and one near the bottom marked with an *o*. The center of the world G lies on the axis at mid-height, with the eccentric's center H just above it.

- A (top, on the outer deferent)
- *i* (small rayed circle just below A): the center I of the solar/planetary body at its apogee
- M (left, on the eccentric circle)
- [label reading like "P" or "R" [?], below the sun-circle, on the axis]
- D (upper middle, on the axis)
- H (center, the eccentric's center)
- E (left of center)
- G (center, the world's center)
- N (below G, on the axis)
- F (lower middle, on the axis)

- o (small circle near the bottom): the center O of the epicycle at its perigee
- B (lower left)
- L (bottom center)
- C (very bottom of the axis)

[The point K named in the text (deferent FEDK, thickness KD) falls on the right side of the figure and is not legible on the scan.]

And this demonstration holds also in the heaven of Mercury, in which four eccentrics enclose the eccentric orb that carries the epicycle, provided the denser parts are placed together so as to make up the whole thickness of the heaven, the eccentric aside. Thus, once the amount of the eccentricity relative to the earth's semidiameter is known, if it is doubled, the thickness CL is produced; and if to this is added the thickness of the eccentric FL — that is, the diameter of the epicycle, or of the solar body in the heaven of the Sun — the whole thickness of the heaven will be composed.

By this same method, moreover, the eccentricity and the semidiameter of any epicycle become known, in the parts of the earth's semidiameter. From H, the center of the eccentric, let the eccentric circle IMO be described, through I, the center of the Sun, or through O, the center of the epicycle. And since in the Moon's heaven the eccentricity GH is known in the parts of which the semidiameter of the eccentric circle HI (or HO) contains 60; and since FO is also known in the same parts; GF too will be known in the same parts. Since, then, GF is also known in parts of the earth's semidiameter, as far as the concave surface of the Moon: if we set up the proportion — as GF, insofar as it is known in parts of the semidiameter HO, is to GF known in parts of the earth's semidiameter, so GH, known in parts of the semidiameter HO, is to another quantity — then GH will be made known in parts of the earth's semidiameter. And thus the eccentricity of the Moon is now known in parts of the earth's semidiameter. Again, if we set up — as GF, known in parts of the semidiameter HO, is to GF known in parts of the earth's semidiameter, so FL, the diameter of the Moon's epicycle, insofar as it is known in parts of the semidiameter HO, is to another quantity — then FL will be found in relation to the earth's semidiameter. From which it comes about that the whole thickness of the Moon's heaven is known in parts of the earth's semidiameter, which was proposed. Hence too the line GC will be made known — that is, the semidiameter of the Moon's convex surface — in the same parts of the earth's semidiameter.

Now if ABC is taken for the heaven of Mercury, its thickness CF will be known in the same way, in parts of the earth's semidiameter, from GF, the semidiameter of

the concave surface, known in the same parts; and consequently GC, the semidiameter of Mercury's convex sphere, will also be known. And in this manner the thickness and the semidiameters of the heavens will be known, in order, for the remaining planets, up to the Firmament — whose thickness cannot be known by a geometrical route. Nevertheless, since it surrounds and contains all the other heavenly bodies and the elements, it pleased the astronomers, and especially al-Farghānī [Alphragano], to assign to it a thickness as great as its distance from the world's center — which is not incredible. For since the Moon's heaven, which contains the sphere of the elements, has a thickness nearly as great as its distance from the earth's center is found to be, why should this be denied to the Firmament, the noblest of the heavens, which encloses and surrounds not only the elements but even all the orbs of the planets? But however the matter may stand, it is highly reasonable that at least the Firmament, together with the ninth, tenth, and eleventh heaven, be of a thickness as great as the distance from the earth's center at which the concave surface of the Firmament stands: so that what we shall say a little below about the speed of the Firmament's motion may be understood of the speed of the prime mover, or eleventh heaven, in case the Firmament does not have so great a thickness.

Now, from the distances of the heavens investigated in the way we have described, and from the diameters of the planets and of the other stars, known through instruments, we shall arrive at knowledge of the magnitude of the stars, by this method. From the doubled distance of any star, the diameter becomes known of that greatest circle whose circumference passes through the star's center. Then from this diameter it is drawn out how many earth-diameters the circumference of that circle comprises, by means of what Archimedes demonstrated about the ratio of the circumference of any circle to its diameter, as I set out at length a little earlier. Again, from this circumference we shall learn how many earth-diameters the star's diameter contains. Finally, once this ratio of the star's diameter to the earth's diameter is known — since spheres have the triplicate ratio of their diameters, as Euclid demonstrated in *Elements* XII.18 — if the triplicate of that ratio is taken, it will be known how many times the star itself contains the globe composed of earth and sea. For example: the greatest distance of the Sun from the earth contains 1216 earth-semidiameters, that is, 608 diameters; and this distance doubled gives 1216 diameters, comprised in the total diameter of the Sun's heaven. Therefore the circumference of the Sun's heaven, along its greatest circle, will contain nearly 3822 earth-diameters. And accordingly the half-degree which the diameter of the solar body is found by the astronomers' instruments to occupy will comprise about $5\frac{1}{2}$ earth-diameters, so that the ratio of the Sun's diameter to the earth's diameter is roughly $5\frac{1}{2}$ to 1.

Hence, since the ratio $166\frac{3}{8}$ to 1 is the triplicate of the ratio $5\frac{1}{2}$ to 1 — as appears in these numbers: 1, $5\frac{1}{2}$, $30\frac{1}{4}$, $166\frac{3}{8}$ — the solar body will contain the earth's globe 166 times, and moreover three eighth-parts of it. And the same reasoning applies to the other planets and stars.

But this too must not be passed over: that Ptolemy, by another route — namely through eclipses — also investigated the ratio of the bodies of the Sun and Moon to the globe composed of earth and sea.

Moreover, this too must be carefully observed: that the distances, thicknesses, and magnitudes of the heavens and stars, found in the way we have prescribed — although they are immense and in a way surpass human belief — are nevertheless the smallest that they could be. This is because the astronomers place the eccentric orb of each celestial orb touching the convex and concave surface of that heaven itself at only a single point; likewise the epicycle of each planet, and the solar body, touching also the convex and concave surface of the eccentric orb at only a single point, as appears in the figure above, where the eccentric IMO touches the convex surface of the heaven at point A and the concave at point F. Likewise both the Sun and the epicycle fill the entire thickness of the eccentric. But it is credible that God, Best and Greatest, made those celestial orbs denser, so that no eccentric orb touches the convex and concave surface of the heaven, but is immersed within the heaven's thickness; nor does the epicycle or the Sun reach the convex and concave surface of the eccentric, but is immersed within its thickness too. This granted, it is certain that the distances, thicknesses, and magnitudes of the heavens and stars are far greater than have been found by the astronomers. We have therefore only demonstrated in what way all these things can be gathered from the motions themselves. For although perhaps the thickness and distance created by God is greater, we can in no way come to know it through the motions — just as neither could the thickness of the Moon's fourth orb, which is concentric and is called the bearer of the head and tail of the Dragon [caput & caudam Draconis, the lunar nodes], be traced out from motion; and for this reason no mention is made of it, as if it did not exist in the nature of things — although it is certain that it is solid, and that on this account the heaven of Mercury is farther from the earth than has been detected by the astronomers.

From these things it is established that any point of the Firmament situated on the Equator traverses, each hour, $42398437\frac{1}{2}$ miles; since, evidently, in 24 hours it completes 1017562500 miles. From which it comes about that the speed of the Firmament's motion can scarcely be grasped in thought — which antiquity

supposed to be the prime mover, as Aristotle too affirmed. For the space which any point of the Equator traverses on the convex surface of the Firmament in one hour is so great that one could scarcely traverse it in 2904 years, even if daily, without any interruption, one covered 40 miles. This seems incredible. For the motion of that point is swifter than the motion of some arrow or bird which, in the span of time in which a single Angelic Salutation [the Hail Mary] is recited, would traverse 176660 miles — that is, would circle the whole earth from east to west under the Equator more than seven times, since the earth's circumference of 22500 miles is contained in this number 176660 more than seven times: a speed that exceeds the grasp of human intellect. Anyone will easily persuade himself that this is so, if he considers attentively that in a quarter of an hour one can scarcely recite 60 Angelic Salutations, and thus 240 in one hour. For hence it follows that the time in which a single Angelic Salutation is recited is $1/240$ of an hour; and it is established that a point of the Equator traverses 176660 miles on the convex surface of the Firmament in $1/240$ of an hour, since in one hour it completes 42398437½ miles, as we have said. Therefore it is necessary that the arrow or bird likewise traverse 176660 miles — that is, circle the earth more than seven times — in the span of one Angelic Salutation, if it is to keep pace with the motion of the Firmament. Or (if you prefer) so great is the speed of the motion of that point of the Firmament in one hour as would be that of some arrow or bird which circled the whole earth from east to west under the Equator, in one hour, one thousand eight hundred and eighty-four times [*millies, octingenties, octogies, & quater* = 1884]; because the earth's circumference, comprising 22500 miles, is contained in the 42398437½ miles (which are traversed in one hour by that point of the Equator) as many times as there are units in this number 1884, and more — a speed that can hardly be conceived.

[Margin: How many miles in one hour any point whatever of the Equator traverses in the Firmament.] [Margin: The wondrous speed of the Firmament.]

[Margin: That the circle described by the polar star is of such magnitude that the whole sphere of the Sun, placed within it, does not touch it.]

Again, from what we have said it will be permissible to gather that the polar star, which in our time is distant from the Arctic pole by nearly $3\frac{1}{2}$ degrees, describes a circle whose diameter is much greater than the diameter of the whole heaven of the Sun — so much so that the entire sphere of the Sun, placed within that circle, would not touch it: which seems utterly incredible, since the polar star scarcely appears to change its place. This is gathered as follows. Since the semidiameter of the convex Firmament contains 45225 earth-semidiameters, if

we set up the proportion — as the whole sine 100000 is to 45225, the semidiameter of the Firmament, so is 12208, the chord of the 7 degrees by which the diameter of the said circle of the polar star is subtended, to the sought quantity — the said chord, or diameter of that star-circle, will be found to contain 5521 earth-semidiameters. Since, then, the diameter of the convex sphere of the Sun comprises only 2432 earth-semidiameters and a little more, it is clear that the diameter of the Sun's sphere does not amount to half the diameter of the said circle. Therefore, since circles have the duplicate ratio of their diameters [note a] — namely that which the squares of the diameters have — the greatest circle in the sphere of the Sun will be less than $\frac{1}{4}$ of the said circle. From which it follows that the sphere of the Sun, placed within that circle, can in no way touch the said circle.

[Margin, note a: 2 of the twelfth (i.e. *Elements* XII.2).]

A DIGRESSION ON THE NUMBER OF THE SAND

[Margin: That the number of the sand is, according to some, infinite; but according to others finite indeed, yet surpassing every given number.]

[Margin: Archimedes' proposition in the book *On the Number of the Sand*.]

In Archimedes' time (as he himself relates in his book *On the Number of the Sand* [the *Sand-Reckoner*, *Arenarius*]) some thought the number of the sand — not only of that contained around Syracuse and the rest of Sicily, but also of that contained in every region, both habitable and uninhabitable — to be infinite. Others, indeed, did not say that the number of the sand was infinite, since an infinite cannot be given, but they believed that no determinate number could be given that would exceed it or equal its multitude; on the contrary, rather, that any number proposed and determined would be surpassed by that number of the sand. Hence Archimedes relates that those who held this opinion, if they were to conceive in their mind such a heap of sand as there would be if the whole earth — with the sea in it filled up, and all the hollows leveled up to the summits of the highest mountains — and if they then devised some further multiple of this same heap, would without any doubt suppose that its multitude far and greatly surpassed all numbers. Archimedes refutes the error of all these geometrically, and indeed most acutely, in the book which he entitled *On the Number of the Sand*, seeking a number that would not only exceed the multitude of the sand which, filling the earth on every side (as we said), would be equal to it, but would also equal in magnitude the sand that would fill the world itself (the world too being posited much larger than it really is). And this is Archimedes' proposition in

his book *On the Number of the Sand*, where first, by a certain subtle reasoning, he demonstrates by what route the distance of the Sun from the earth is to be investigated — an angle having first been found that is smaller than the angle which two straight lines, going out from the center of vision and touching the Sun, contain; on which matter consult his writings, and the *Commentaries* of Federico Commandino [Federici Commandini].

We, therefore, following in the footsteps of Archimedes, shall likewise inquire into a number that is far greater than the number of even the tiniest sand-grains that would fill the whole world up to the Firmament. For many have urged me to explain this matter here. This I have done the more gladly because I know it will be most delightful to many; and especially because this business is not entirely foreign to our undertaking, since we have adduced here many things concerning the distances and magnitudes of the heavens, from which we can with little trouble gather what we have proposed. And so that our discussion may turn out more illustrious and more admirable, let us posit that the whole world, up to the Firmament, is far greater than has been detected by the astronomers; likewise, that the sand-grains filling the whole universe are much smaller than are found anywhere. For if it be demonstrated by us that the number we have found is greater than the number of sand-grains — smaller than any that exist — filling a world greater than this world of ours: it will be clear that the same number is much greater than the number of even the tiniest sand-grains existing in the nature of things which would fill the whole world, up to the Firmament, as far as it has been detected by the astronomers. Let these things, then, be laid down by us in order.

I. That the earth's diameter is much less than 10000 miles. Although this is most true — since, according to Ptolemy and the more common opinion of astronomers, the earth's diameter contains only 7159 $\frac{1}{11}$ miles, as we said above — nevertheless, in order that the reckoning may be made easier, and that we may make the world larger than it really is, let us set it at 10000 miles.

II. That the diameter of the concave Firmament is far less than 100000 earth-diameters. Although this is true — since, according to al-Farghānī [Aphraganum], that diameter comprises only 45225 earth-diameters — let us nevertheless take it to contain 100000 earth-diameters, for the reason adduced before. And since we assumed the earth's diameter to comprise 10000 miles (though it is much less), the diameter of the concave Firmament will contain fewer miles than 1000000000. But for the said reason let us posit that it comprises 1000000000 miles.

[Margin: By what method the number of the tiny sand-grains filling the whole world, up to the concave surface of the Firmament, may be investigated.]

III. That a little sphere equal to a single grain of poppy is not greater than 10000 sand-grains, however minute. This anyone will readily grant, since the intellect can scarcely grasp that a single poppy-grain could be divided into 10000 equal particles: for sand-grains so tiny have nowhere been seen. But in order that the demonstration may be made more admirable, and that more sand-grains may be contained in the world, let us posit that that little sphere comprises 10000 sand-grains.

IIII. That the diameter of a poppy-grain is not less than the fortieth part of one geometric digit [finger-breadth]. That this is so, Archimedes found by experiment; he says that he discovered that 35 poppy-grains placed in a single straight line and touching one another exceed the length of a geometric digit — so that a single poppy-grain is greater than $1/35$ of a digit. From which it follows that a single poppy-grain is much greater than $1/40$ of a digit, and not less. But let us posit that it is $1/40$ of a digit, so that the demonstration may be made more evident, although poppy-grains so minute are not found.

V. That a mile is far less than 100000 digits. For since four digits make a palm, and four palms a foot, and five feet a geometric pace, and a thousand geometric paces a mile, it comes about that 80000 digits compose one mile. Therefore a mile is much less than 100000 digits. But let us posit, so that the demonstration may be made easier, that 100000 digits make one mile.

*(Conclusion of the Digressio de arenæ numero — the Sand-Reckoner digression — completing CAPVT PRIMVM.)**

Therefore, since we have taken the diameter of a grain of poppy to be $1/40$ of a digit (although it is in fact much larger), so that 40 grains of poppy make up a digit, a sphere whose diameter equals a digit will have to a grain of poppy — whose diameter equals $1/40$ of a digit — the ratio of 64,000 to 1, ^a inasmuch as spheres stand in the triplicate ratio of their diameters. This is clear from the four numbers set alongside, which are in continued proportion in the ratio of 40, that is, in the ratio of a digit to $1/40$ of a digit; so that a sphere having a diameter equal to a digit contains 64,000 grains of poppy.

[Margin (numerals set beside the paragraph, in continued proportion): $1 \cdot 40 \cdot 1600 \cdot 64000$]

[Margin: 18. duod. — i.e. Euclid, *Elements* XII.18 (spheres are to one another in the triplicate ratio of their diameters)]

Consequently, since we have established that one grain of poppy contains 10,000 sand-grains, the same sphere with a diameter equal to a digit will comprise 640,000,000 sand-grains. Indeed this number will be much greater than the number of sand-grains that are enclosed in a sphere having a diameter equal to a digit, because both fewer than 40 grains of poppy make up a digit, and the sand-grains are larger than would allow 10,000 of them to make a single grain of poppy. Nevertheless, so that the computation may proceed more conveniently, let us suppose that a sphere whose diameter equals a digit contains not merely 640,000,000 but 1,000,000,000 sand-grains.

Next, since we have taken 100,000 digits to constitute one mile (although a mile is much less than that), a sphere having a diameter equal to a mile will have to a sphere whose diameter equals a digit the ratio of 1,000,000,000,000,000 to 1 [i.e. 10^{15}], ^b because spheres stand in the triplicate ratio of their diameters. This is evident in these four numbers, which are continued proportionals in the ratio of 100,000 digits, that is, in the ratio of one mile to 1.

[Margin: 18. duod.]

[Margin (numerals set beside the paragraph, in continued proportion): $1 \cdot 100000 \cdot 100000000000 [10^{10}] \cdot 10000000000000000 [10^{15}]$]

Since, then, a sphere having a diameter equal to a digit has been posited to contain 1,000,000,000 sand-grains — although it holds far fewer, as has been shown — a sphere whose diameter equals a mile will contain all these sand-grains to the number of 1,000,000,000,000,000,000,000,000 [10^{24}]. Indeed this number is much greater than the number of sand-grains contained in a sphere having a diameter equal to a mile, because both fewer than 1,000,000,000 sand-grains fill a sphere whose diameter equals a digit, and fewer than 100,000 digits make up a mile. Nevertheless, for the reason stated just above, let us accept that 1,000,000,000,000,000,000,000,000 [10^{24}] sand-grains fill a sphere whose diameter equals a mile.

Finally, since we have posited that the diameter of the concave of the Firmament comprises 1,000,000,000 miles (although it is in reality much smaller), a sphere whose diameter equals the diameter of the concave of the Firmament will have to a sphere whose diameter equals a mile the ratio of [10^{27}] to 1, ^c because spheres have the triplicate ratio of their diameters, as is plain in these four numbers,

which are in continued proportion in the ratio of 1,000,000,000 miles — that is, in the ratio of the diameter of the concave of the Firmament to 1.

[Margin: 18. duod.]

[Margin (numerals set beside the paragraph, in continued proportion): $1 \cdot 1000000000 [10^9] \cdot 1000000000000000000 [10^{18}] \cdot [10^{27}]$]

Hence, since a sphere having a diameter equal to a mile has been posited to contain $[10^{24}]$ sand-grains — although it in fact encloses far fewer, as we have demonstrated — a sphere comprised within the concave of the Firmament and precisely reaching it [?] will contain sand-grains to a number that is far greater than the number of sand-grains contained in the whole world all the way to the concave of the Firmament.

[Number line, full width: 1 followed by a long string of zeros — the grand total, which the note beside it identifies as having 51 ciphers after the initial 1, i.e. 10^{51} .]

[Margin, in italic: *Qui numerus maior sit numero arenularum, quarum 10000. grano papaueris æquales sint, replentium totum mundum, vsque ad concauum Firmamenti.* — "How much this number exceeds the number of sand-grains — of which 10,000 equal one grain of poppy — that would fill the entire world, up to the concave of the Firmament."]

which fill a sphere whose diameter equals a digit [?]; the miles, of which each contains 100,000,000 [?] within the diameter of the concave of the Firmament ... the number that fills [the world], which of course, after the figure 1, has 51 ciphers, being far ... those that fill it up to the concave of the Firmament, even though the sand-grains ... equal to a grain of poppy.

It is therefore clearly established from what has been said that we could determine for certain how many sand-grains could fill the entire world, if only it were ascertained to us how many sand-grains equal a grain of poppy, how many grains of poppy make up a digit, and finally how many miles — each of which contains 80,000 digits — are comprised within the diameter of the concave of the Firmament. But since these things are as yet unknown and uncertain, we have assumed (following Archimedes [Archimedes] in this) a diameter of the world much greater than it really is according to skilled astronomers; likewise we have posited that more sand-grains equal a grain of poppy than really do, and that more grains of poppy make up a digit than truly do — precisely so that by this reckoning a greater number of sand-grains might arise, one which will assuredly be far greater, as we have said, than the number of sand actually able to be

comprised within the concave of the Firmament. This, indeed, seems incredible to many.

Primi Capitis Finis. [End of the First Chapter.]

CHAPTER TWO

On the circles out of which the material sphere is composed, and by which the supercelestial sphere — the one that the material sphere represents — is understood to be composed.

(Sacrobosco's lemma, in italic:)

Now of these circles some are greater and some smaller, as is evident to the senses. A circle in the sphere is called great when, drawn on the surface of the sphere, it divides the sphere into two equal parts about its center. A small circle is one which, drawn on the surface of the sphere, does not divide it into two equal parts, but into unequal portions. Among the great circles, we must speak first of the Equinoctial.

[Margin: *Maior circulus, & minor in sphæra quid.* — "What a great and a small circle in the sphere are."]

COMMENTARIVS

The Author set out, in the first chapter, the principles and foundations of the whole of Astronomy. Now, in this second chapter, he explains those ten primary circles out of which the material sphere is composed, and by which the celestial sphere — for whose sake this material sphere is constructed — is understood to be composed; namely because without these circles the causes of the celestial appearances can in no way be given — such appearances as the risings and settings of the signs, the risings and settings of the stars, the variation of days and nights in different regions, and so forth. This chapter may not inaptly be divided into three parts. For in the first the Author treats the circles of the sphere in general; in the second he discusses these same circles individually, explaining the name, function, and use of each; and in the third, finally, he adds that in the world five Zones are constituted out of these circles.

[Margin: *Argumentum secundi cap. eiusdemque diuisio.* — "The subject of the second chapter and its division."]

In the first part, then, he divides all the circles of the sphere into greater and smaller — which are called by others "greatest" (maximi) and "not greatest" — whose definitions are clearly given in the text. Of the greater, or greatest, circles, our Author in this second chapter explains only six, namely the Equinoctial circle, the Zodiac, the Colure of the Solstices, the Colure of the Equinoxes, the Meridian, and the Horizon; and of the smaller, or not-greatest, circles, he declares only four, namely the Tropic of Cancer [♋], the Tropic of Capricorn [♐], the Arctic circle, and the Antarctic circle. These ten circles of the sphere we did indeed set out briefly in the first chapter; but now, together with the Author, more will have to be said of them.

[Margin: *Auctor 10. tantum circulos sphærae considerat.* — "The Author considers only ten circles of the sphere."]

The Astronomers, however, in order to attain a perfect knowledge of the celestial motions, devised many others besides those ten primary circles, some greatest and some not greatest. Among the greatest, the foremost place is held by those that now follow. The VERTICAL circles, which are drawn through the vertex of any given place to the individual points of the Horizon. The HORARY (hour) circles, which cut the whole heaven into 24 hours; and these are of three kinds. For either they divide the heaven into 24 [unequal] hours ... through the poles of the world; or into 24 equal hours, beginning from the Meridian, in which way they proceed along parallel circles, one of which is always the greatest of those that appear and the other the greatest of those that are hidden; or, finally, into 24 unequal hours — namely when they neither proceed through the poles of the world nor touch the said parallels, but divide all the segments of the parallels above the Horizon, and likewise those below the Horizon, into 12 equal parts. But since, as we demonstrated in Book 1 of the *Astrolabe*, Lemma 39, there are no greatest circles that divide all the semidiurnal arcs into 12 equal parts, only two kinds of horary circles will have to be established. Of this variety of hours, however, we shall say more in the third chapter, when we deal with natural and artificial days. The circles of the celestial HOUSES, which cut the whole heaven into 12 parts, called the celestial houses. The circles of POSITION, which are defined as passing through the common intersections of the Horizon and the Meridian, and also through the center of each star. The circles of DECLINATION, which are drawn through the poles of the world and the individual points of the Equator. The circles of LATITUDE, which are described through the poles of the Zodiac and the individual points of the Ecliptic. Finally, very many other circles are found among the Astronomers. For, to pass over the greatest, there are considered to be almost infinitely many not-greatest circles. For every greatest

circle has its own parallels: as the Horizon has parallel circles described about the vertex of the head, which are commonly called circles of altitude; the Equator has parallel circles described about the poles of the world, of which kind are those which the individual stars and planets, or any points of the heaven whatever, describe daily by the diurnal motion. The Zodiac too has its own parallels described about the poles of the Zodiac, of which kind are those which the individual stars and planets, or any points of the heaven, trace out by the proper motion of the eighth Sphere from West to East. And the same is to be said of the other greatest circles. But of all these circles we must treat in another place: for it will now be enough for us to expound in this second chapter those first ten circles, which are called primary, since these properly belong to the sphere.

[Margin: *Verticales circuli. Horarij circuli.* — "Vertical circles. Horary circles."]

[Margin: *Circuli domorum cœlestium, & positionum. Circuli declinationum, & latitudinum.* — "Circles of the celestial houses, and of position. Circles of declination, and of latitude."]

Those circles in the sphere which share the same center as the sphere are called *greatest*, or *greater*, because, as Theodosius [Theodosius] demonstrates in Book 1, Proposition 6, the circles that are drawn through the center of the sphere are the greatest of all, so that none greater than they can be given — just as the line drawn through the center in any circle, namely the diameter, is the greatest of all. But those circles whose center is different from the center of the sphere are called *not-greatest*, or *smaller*, because, as Theodosius demonstrates in the place cited, circles that are not drawn through the center of the sphere are smaller than those that pass through the center of the sphere, and the farther they are from the center of the sphere, the smaller they become.

[Margin: *Maximi circuli & non maximi in sphæra cur sic dicti. 25. tertij.* — "Why the greatest and not-greatest circles in the sphere are so called. (III.25.)"]

Now, so that the things to be said about the celestial circles may be understood more perfectly, I shall bring forward a number of properties of the circles of the sphere — both of the greater and of the smaller — demonstrated by Theodosius in his *Elements of Spherics*. From these, indeed, much will have to be demonstrated in what follows.

I.

All the greatest circles of the sphere cut one another in half; and conversely, circles in the sphere that cut one another in half are the greatest. The first Theodosius demonstrates in Book 1, Proposition 11; the second in Proposition 12 of the same book.

[Margin: *Proprietates nonnullæ circularum in sphæra*. — "Certain properties of the circles in the sphere."]

II.

All the greatest circles of the sphere are equal to one another. This indeed is easily established from the equality of their diameters: for the diameter of any greatest circle is the same as the diameter of the sphere. Moreover, if one were greater than another, they would not both be greatest; for the smaller of them would not be greatest, since another greater than it is given.

III.

Not-greatest circles in the sphere that cut one another do not cut one another in half. For if they were to cut one another in half, they would themselves — by Proposition 17 of Book 1 of Theodosius — be greatest circles, which is contrary to the hypothesis. It is possible, however, for one of them sometimes to be divided in half; but when this happens, the other will by no means be cut in half, unless both circles are greatest.

III.

Among the not-greatest circles of the sphere, only those are equal to one another which are equally distant from the center of the sphere; and conversely, not-greatest circles equal to one another are equally distant from the center of the sphere. Both are demonstrated by Theodosius in Book 1, Proposition 6.

V.

Every greatest circle in the sphere passing through the poles of another circle — whether greatest or not-greatest — divides it in half and at right angles. And conversely, a circle in the sphere dividing another circle in half and at right angles is a greatest circle, and it passes through the poles of that other. The former Theodosius demonstrates in Book 1, Proposition 15; the latter we have demonstrated in the scholium of the same proposition, Theorem 3.

Diagram. A large woodcut armillary sphere set into the text between propositions V and VI, showing the great and small circles of the sphere with the small terrestrial globe at the center. The graduated meridian ring and horizon

ring carry degree-scales numbered 10, 20, 30, 40, 50, 60, 70, 80, 90 (repeating by quadrant). The oblique ecliptic band bears the zodiacal signs with 10°/20°/30° subdivisions.

- POLVS SEPTENTRIONALIS (top, radiating from a star): North Pole
- ARCTICVS (upper region, small circle): Arctic Circle
- TROPICVS ÆSTIVVS (upper oblique circle; printed "TROP·ICVS ESTIVVS"): Summer Tropic (Tropic of Cancer)
- ÆQVINOCTIALIS (central great circle; printed "...VINOCTIALIS," with "ÆQ" abbreviated): Equinoctial (Equator)
- ORIZON (central horizontal ring; printed "ORIZON"): Horizon
- Ecliptic/zodiac band signs, reading along the band: ARIES, TAVRVS [♉], GEMINI [♊] ... PISCES [♐], AQVARIVS [♑], each with degree graduations 10 · 20 · 30
- TROPICVS HIEMALIS (lower oblique circle): Winter Tropic (Tropic of Capricorn)
- ANTARCTICVS (lower region, small circle; printed "ANTARC·TICVS"): Antarctic Circle
- POLVS AVSTRALIS (bottom, radiating from a star): South Pole
- (center): small globe of the Earth

VI.

Every greatest circle in the sphere, through whose poles another greatest circle in the sphere passes, passes in turn through the poles of that other. This we have demonstrated in Theorem 1 of the scholium on Proposition 15, Book 1, of Theodosius.

VII.

A greatest circle in the sphere which touches some not-greatest circle will also touch another not-greatest circle equal and parallel to it. This indeed Theodosius shows in Book 2, Proposition 6.

VIII.

A greatest circle in the sphere cutting not-greatest circles not through their poles — that is, obliquely — cuts them into unequal parts, yet in such a way that the alternate segments of equal and parallel circles are equal to one another. This is clear from Proposition 19, Book 2, of Theodosius.

IX.

When three greatest circles in the sphere cut one another mutually at right angles, the two poles of each of them will lie precisely on the common intersections of the circumferences of the other two. And conversely, when there are greatest circles in the sphere such that the two poles of any one of them are found on the common intersections of the other two, they will cut one another mutually at right angles. Both of these can easily be deduced from Theodosius, or from the properties already adduced — namely from the fifth and the sixth.

An example of each you also have in the material sphere. For if the Equator, the Meridian, and the Horizon [so ...]

so arranged that they cut one another at right angles (which happens only when each pole of the world lies precisely on the horizon, as occurs in the right sphere), you will see that the poles of the Equator lie at the common intersections of the Meridian and the Horizon; the poles of the Meridian, at the common intersections of the Equator and the Horizon; and finally the poles of the Horizon, at the common intersections of the Equator and the Meridian, and so on. I have cited these propositions of Theodosius [Theodosius] in accordance with the Greek exemplar — the same one by which I earlier published Theodosius, together with the treatise on triangles and on sines — where I relegated to the scholia those propositions that the Arabs added.

[Margin: How Proclus divides the circles of the sphere.]

Proclus [Proclus], in the *Sphere* that he composed, set up a different division of the circles of the sphere. For he does not divide those primary circles into greatest and not-greatest, but into equidistant (or parallel) circles, into oblique ones, and into those drawn through the poles of the world. He calls "equidistant" those circles whose poles are the same as the poles of the world; of this kind are five circles in the sphere — namely the Equator, the Tropic of Cancer ☿ [Cancer], the Tropic of Capricorn ♄ [Capricorn], the Arctic Circle, and the Antarctic Circle. For these circles are equidistant among themselves, as is established from proposition 2 of book 2 of Theodosius (*Spherics* II.2). He calls "oblique" those which cut the parallel circles they intersect at unequal and oblique angles; such, in his view, are the Zodiac and the Milky Way, to which must be added any oblique Horizon. Finally, he says that those are "drawn through the poles of the world" which divide the parallel (or equidistant) circles at right angles and into two halves; and these are three in number: the Colure of the Solstices, the Colure of the Equinoxes, and the Meridian, to which the right Horizon can be joined.

Diagram. An armillary sphere representing the material sphere with its ten primary circles, referred to just below as the "figure set out above" (*supra proposita figura*). A small terrestrial globe is drawn at the center. A graduated meridian ring runs through the two poles, marked with degree numbers in ascending-then-descending quadrants (10, 20, 30, 40, 50, 60, 70, 80, 90, 80, 70, 60, 50, 40, 30, 20, 10). Readable labels:

- POLVS SEPTENTRIONALIS (North Pole) — upper left, at the top of the meridian ring
- POLVS AVSTRALIS (South Pole) — lower right
- ARCTICVS (Arctic Circle)
- TROPICVS ÆSTIVVS (Summer Tropic; "ÆSTIVVS" = of summer) — upper zone
- ÆQVINOCTIALIS (Equator) — the central ring
- ORIZON (Horizon; spelled without initial H)
- TROPICVS HIEMALIS (Winter Tropic)
- ANTARCTICVS (Antarctic Circle)
- Zodiac band (oblique), with signs and degree scales (10, 20, 30 within each):
ARIES ♈, TAVRVS ♉ [Taurus], GEMINI ♊ [Gemini]
- On the opposite side of the zodiac band: AQVARIVS ♊ [Aquarius], PISCES ♋ [Pisces] [?]

[Margin: Another division of the circles of the sphere.]

Some others divide the celestial circles on a different principle. For they say that some circles are intrinsic, others extrinsic. The intrinsic ones are those conceived as wholly fixed in the heaven, so that they are carried around together with it; hence by some they are called movable — such are all the primary circles of the sphere except the Meridian and the Horizon. For these two are called extrinsic, because they are to be conceived in the heaven in such a way as always to keep a firm position, and in no way to revolve with the motion of the heaven, but always to remain in the same place. For this reason they have been called immovable by most writers.

An example of the ten circles of the sphere, which are called primary, you have in the figure set out above, which represents the material sphere.

ON THE EQUINOCTIAL CIRCLE

The equinoctial, then, is a certain circle dividing the sphere into two equal parts, equidistant from each pole according to every part of itself.

COMMENTARY

[Margin: What the Equinoctial circle is.]

Having completed the first part of this chapter, he now proceeds to the second, in which the individual circles are discussed one by one. He treats first of the greatest circles, then of the not-greatest; and among the greatest he explains the Equinoctial first, because knowledge of it is easier and nearly all the rest are explained through it. The Equinoctial is also the noblest of all circles, since it is the measure — as will presently be said — of the noblest motion, namely that of the primum mobile; for it moves with the most uniform motion. Hence this circle stands, when compared with the other celestial circles, just as the primum mobile does when compared with the other celestial [orbs

orbs]. For this reason the philosophers placed the prime mover — that is, God, the best and greatest — in the Equinoctial circle, as in his proper seat.

He defines the Equinoctial circle, saying that it is the circle which in the material sphere is called Equinoctial, which divides the sphere into two equal parts and is equidistant from each pole according to every part of itself. And this circle, by the same reasoning, must be conceived in the heaven as placed midway between the two poles of the world.

[Margin: How the Equinoctial circle is conceived to be described in the heaven.]

Some indeed conceive it to be described as follows. From the center of the world, through the center of the Sun while it is at the beginning of Aries ♈ [Aries] or Libra ♎ [Libra], they imagine a straight line drawn, which in the space of 24 hours would describe the Equinoctial circle. But since the Sun never completes an entire circle — because it does not return to the same point, on account of its proper motion, which it has from west to east — it will perhaps be better said that the Equator is described by a straight line extended from the center of the world to the beginning of Aries ♈ or Libra ♎ of the primum mobile. For from the revolution of this line there will be described, in a natural day, a greatest and perfect circle, always at right angles to the axis of the world and equidistant on every side from the poles of the world — all of which are required for the equinoctial circle.

[Margin: Where, above all, the circles of the sphere are to be conceived in the heaven.]

Now all the celestial circles — and hence the Equinoctial too — are to be conceived in the primum mobile, which is what the material sphere chiefly

represents for us. It makes little difference whether we understand them as on the concave or on the convex surface of the primum mobile. Yet because we, enclosed within the heaven and existing at its center, look upon the concave surface of the heaven, we are in a way compelled to consider the celestial circles on that same concave surface of the primum mobile; just as, because we are outside the material sphere, we are obliged in a way to mark those circles on its outermost or convex surface. This is also done on the cosmographical and astronomical globe. And since, of the ten primary circles of the sphere, the Meridian and the Horizon are wholly immovable in every region — so that, even if the first heaven is perpetually and unceasingly carried around, these two circles are nonetheless conceived as entirely unmoved and fixed, while the other eight are movable, inasmuch as they are continually revolved with the primum mobile — it will not be inappropriate if we consider these eight movable circles on the convex surface of the primum mobile, and those two on the concave surface of the immovable Empyrean heaven, beneath which the primum mobile and the whole world are placed. For thus it will come about that the other, movable circles are perpetually carried around within these immovable ones; just as in the material sphere too we see the Meridian and the Horizon standing out above the other circles, so that, while these others move without ceasing, those two remain wholly unmoved.

And it is called the equinoctial because, when the Sun passes through it (which happens twice a year, namely at the beginning of Aries and at the beginning of Libra), there is equinox over the whole earth. Hence it is also called the equator of day and night, because it equalizes the artificial day with the night. And it is to be understood that the first motion is called the motion of the primum mobile — that is, of the ninth sphere or outermost heaven — which goes from east through west, returning again to the east; and this is also called rational motion, by analogy with the motion of reason that is in the microcosm, that is, in man, namely when consideration proceeds from the Creator, through creatures, back into the Creator, coming to rest there. The second motion is that of the firmament and the planets, contrary to this one, going from west through east and returning again to the west; and this motion is called irrational or sensual, by analogy with the motion of the microcosm, which goes from corruptible things to the Creator and then returns again to corruptible things. It is therefore called the girdle of the first motion, because it girds or divides the primum mobile — namely the ninth sphere — into two equal parts, equidistant from the poles of the world.

[Margin: Why the Equinoctial circle is so called; likewise why it is called the Equator and the girdle of the primum mobile.]

He explains in this place the names and functions of the Equinoctial circle, teaching that it is called Equinoctial because, when the Sun passes through it — namely at the beginning of Aries ♈ and Libra ♎ — it produces equinox over the whole earth, that is, it makes the artificial day equal to the artificial night.

For the same reason he says it is called the Equator of day and night. Likewise, that it is named the girdle of the first motion, because it divides the first motion into two equal parts. For since a motion is divided in accordance with the division of the movable body, as the philosophers hold, the Equator will assuredly divide the motion of the primum mobile, seeing that it also divides the primum mobile itself into two halves. For the sake of this point he repeats that twofold motion of the heavens — namely from east to west, and from west to east — as is clear in the text.

The Greeks call this circle ἰσημερινόν [Greek: ἰσημερινός (isēmerinos), "equinoctial," literally "of equal day"], that is, "equidial," because the day is equal to the night. Hence, just as the Latins name it from the day, so it pleased the Greeks to give it a name from the night. By Ptolemy [Ptolemy] it is called the Line, Circle, or orb of the Equation of Day. By Alfraganus [al-Farghānī], the Circle of the Equinox. Most writers also hold that it is called by these names not because the Sun, when in it, produces equinox everywhere, but because in the right sphere, which lies beneath it, the nights never exceed the length of the artificial days, but the days are perpetually equal to the nights, wherever the Sun may be, as we shall explain in chapter 3. The Equinoctial circle is also sometimes called by astronomers the greatest of the parallels. For they call "parallel circles" those which the stars and the individual points of the heaven describe in the diurnal motion, of all which the greatest, as is established, is the Equator.

[Margin: How it is to be understood that equinox occurs twice a year over the whole earth.]

As for what is commonly said — that over the whole earth equinox occurs twice a year, namely when the Sun is at the beginning of Aries ♈ and Libra ♎ — this must be understood of places where the alternation of day and night occurs within the space of 24 hours, that is, where the Equinoctial circle intersects the Horizon and is intersected by it. I have said this in order to exclude from this universal proposition those regions that lie directly beneath the poles of the world. For in those regions the day — which is only a single one in the whole year — lasts six months, and the night as many, as will be established near the end of chapter 3. Or else that common proposition must be understood negatively, as if it were said that the day is not unequal to the night — which is indeed true even

under the poles, when the Sun is in the Equinoctial circle, because then the day is not unequal to the night.

[Margin: Why, when the Sun is in the Equator, equinox occurs.]

In all those regions in which the Equator and the Horizon intersect one another, that equinox occurs while the Sun tarries in the Equator can easily be demonstrated on this principle. Since each circle — the Equator, that is, and the Horizon — is a greatest circle, each bisects the other, by proposition 11 of book 1 of Theodosius (*Spherics* I.11), as was said above. Therefore in any region whatever where these two circles cut one another, one half of the Equator will be above the Horizon and the other below. Since, then, the Sun is carried uniformly from east to west, it comes about that it spends as much time above the hemisphere — which delay makes the artificial day — as below the hemisphere, which delay constitutes the artificial night.

[Margin: Why the pole that always appears to us is called Septentrional, Arctic, and Boreal; and the opposite one, Antarctic, Meridional, and Austral.]

Hence it must be noted that the pole of the world which always appears to us is called the Septentrional, Arctic, or Boreal pole. It is called Septentrional from Septentrio, that is, from the Lesser Bear, which is named from septem ("seven") and trio ("a plough-ox"), because the seven stars that are in the Bear move slowly, after the manner of an ox, being near the pole. Or those seven stars are called Septentriones, as if "seven teriones," from the fact that they tread the parts around the pole. It is called Arctic from ἄρκτος [Greek: ἄρκτος (arktos), "bear"], which means "bear"; for it is next to the Greater Bear. It is called Boreal because it is in that quarter from which Boreas comes. The opposite pole is called Antarctic, as if placed over against the Arctic. It is also called Meridional, because it is on the side of the south. It is likewise called Austral, because it is in that quarter from which Auster comes. These two points, fixed in the firmament, are called the poles of the world, because they bound the axis of the sphere, and about them the world is turned — of which one always appears to us, while the other is always hidden. Hence Virgil [Virgil], Georgics I:

This summit is ever high above us; but the other, beneath our feet, black
Styx and the deep shades behold.

COMMENTARY

He here declares the poles of the Equinoctial circle, from which he had said the Equinoctial circle itself is equally distant. But all these matters are clear in the

text. It remains for me to explain the manifold use, the functions, and the utilities on account of which astronomers devised the Equinoctial circle in the heaven.

THE FUNCTIONS OF THE EQUINOCTIAL CIRCLE

I.

[Margin: The Equator is the measure and rule of the first motion.]

It is the measure and rule of the first motion. For it shows that the primum mobile revolves in the space of 24 hours, since in each hour 15 degrees of the Equinoctial circle described in the primum mobile are raised uniformly above the Horizon, as the observations of astronomers teach.

II.

[Margin: The Equator measures time.]

It measures time. For from one revolution of the Equinoctial circle, with the addition of a small part corresponding to that portion of the Zodiac which meanwhile the Sun completes by its proper motion toward the east, the natural day is constituted, as will be said in chapter 3. From the rising of 15 degrees of it we know that a whole hour has passed; and finally, from the ascension of a single degree, we perceive that 4 minutes of an hour have elapsed.

III.

[Margin: The Equator reduces to regularity the irregularity of the Zodiac's motion from east to west.]

It directs, as a most certain rule and canon, the irregularity of the motion of the Zodiac from east to west, which the Zodiac has on account of its oblique position. For, as will be established from chapter 3, equal parts of the Zodiac ascend unequally above any Horizon whatever, whether right or oblique. Hence this whole inequality is, by a wonderful device, reduced by astronomers to equality through the uniform motion of the Equinoctial circle, so that from the neighboring arcs of the Equinoctial circle we come to know the times of the rising and setting of all the arcs of the Zodiac.

IIII.

[Margin: The Equator produces the equinoxes.]

It distinguishes the equinoxes. For it divides the Zodiac circle obliquely at two points, namely at the beginning of Aries ♈ and Libra ♎, at which, when the Sun arrives by its proper motion, it makes the spaces of day and night equal. Hence these points too are called equinoctial by astronomers. Manilius [Manilius] the poet elegantly describes them, saying:

Libra and Aries render night and day equal.

On what days of the year the two equinoxes formerly occurred, and on what days they occur at the present time, we shall disclose when we treat of the Colures.

V.

[Margin: The Equator is the terminus from which declinations are numbered. — What declination is. — The Equator separates the northern part of the heaven from the southern.]

It is the terminus from which all the declinations of the points of the Ecliptic, and of the stars, take their beginning. For declination is the distance of a star, or of a point of the Ecliptic, from the Equator toward either of the poles of the world. But by what means this distance, or declination, is to be taken and measured, we shall say when we treat of the Ecliptic.

VI.

[Margin: Which is the northern part of the heaven and which the southern. — Which stars or signs are called northern or southern.]

It indicates which part of the heaven is called Septentrional or Boreal, and which Austral or Meridional. For that part which lies between the Septentrional (or Arctic) pole and the Equinoctial circle is called Septentrional; while the remaining part, which is placed between the same Equinoctial circle and the Austral (or Antarctic) pole, is called Meridional. From this it can easily be perceived which stars, or which constellations or signs, are called Septentrional or Austral; likewise when the planets are called Septentrional and when Austral. For whenever they are in that part of the heaven which we have said is called Septentrional, they are called Septentrional; and when they are in that which we have named Austral, they are called Austral. Hence while the Sun moves from the beginning of Aries ♈ up to the beginning of Libra ♎, it is called Septentrional; but while it moves from the beginning of Libra ♎ to the beginning [of Aries...

the beginning of Aries (♈), it is customarily called the Meridional, or Southern, part. Astronomers do, however, take "northern part" in another sense as well, as I

shall explain when I treat of the uses of the ecliptic. But this is the principal sense of "northern part" and "southern part" among authorities. Indeed, among cosmographers too the Equator, traced upon the earth, divides the whole earth into a Boreal (northern) and an Austral (southern) part.

[Margin: The Equator, on the earth, divides the whole earth into a Boreal and an Austral part.]

VII.

The Equator fixes for us the length, or quantity, of the artificial day and night in any region of the terrestrial globe and at any time of year. For in any region and at any time of year the artificial day is as long as the arc of the equinoctial circle that ascends above the hemisphere while the Sun lingers above that same hemisphere. This arc of the Equator is determined in the following way, using a material sphere properly and accurately constructed. Set the material sphere in its proper position — that is, at the due elevation of the pole — and place the degree of the ecliptic in which the Sun stands on the given day upon the horizon on the eastern side, and carefully mark the point of the Equator that then stands on the horizon on that same side. Then rotate the sphere until that same degree of the ecliptic reaches the western side, and until that point of the Equator, about half a degree further on, is again found on the horizon — while on the eastern side [that first point] is seen to touch the horizon precisely and exactly. This done, count the degrees of the equinoctial circle lying between those two points, beginning from the first point and proceeding toward the east. For the said degrees of the Equator will yield the diurnal arc in question — that is, the arc which, together with the Sun, while it lingers in the upper hemisphere, emerges above the horizon. Therefore, if the aforesaid arc is divided by 15, the hours contained in that day will at once result, provided you remember that the degrees which perhaps remain over from the division each comprise four minutes of an hour.

[Margin: The Equator indicates the length of the artificial day and night.]

[Margin: How great the artificial day is, and how it is determined from the material sphere.]

EXAMPLE. With the Sun at the beginning of Cancer (♋), if the material sphere is so set that 42 degrees of the meridian are intercepted between the Arctic pole and the horizon — that being the number of degrees by which the Arctic pole is raised above the horizon at Rome — and the first degree of Cancer (♋) is placed on the horizon both on the eastern and on the western side, and the two points on the

Equator are marked, the diurnal arc will be found to comprise about 226 degrees 6 minutes. Reduced to hours by dividing by 15, this shows that the artificial day at Rome on 22 June — when, that is, the Sun is at the beginning of Cancer (♋) — amounts to 15 hours and about 4 minutes. From the known length of the artificial day, the length of the artificial night is easily found. For if you subtract the artificial day from 24 hours — that is, from the whole natural day — the artificial night remains. On this reckoning, if 15 hours and 4 minutes are taken from 24 hours, the night at Rome on 22 June will comprise 8 hours and 56 minutes. Anyone may, however, if he wishes, derive the length of the night by the same procedure by which we have said the length of the day is to be investigated.

[Margin: How great the elevation of the pole at Rome is.]

VIII.

The Equator is wonderfully serviceable to cosmographers and geographers. For without the equinoctial circle no complete description of the earth is possible, nor can any city be set in its proper place on the terrestrial globe or on a map of the world. It is by reference to the equinoctial circle that both the longitude and the latitude of cities are determined, as I shall explain more clearly when I have treated of the meridian circle, which is likewise required for that task.

[Margin: The Equator is useful to cosmographers.]

Besides the many functions already mentioned, the equinoctial circle has still other functions and uses among astronomers, which for brevity's sake I think it best to pass over now. In their proper places, when the matter requires it, they will be explained much more conveniently. Let it now suffice to have set out its principal functions.

Since, however, in the seventh function of the Equator it was necessary to reduce degrees and minutes of the equinoctial circle to hours and minutes of hours, I have judged it useful to set out here two tables. By the first, the degrees, minutes, seconds, and thirds of the equinoctial circle are reduced with the greatest ease to hours, minutes, seconds, and thirds of hours; by the second, conversely, hours, minutes, seconds, and thirds of hours are transformed with equal ease into degrees, minutes, seconds, and thirds of the equinoctial circle. For although either operation can be carried out by division, the said tables accomplish the same thing much more expeditiously.

CONVERSION of the degrees, minutes, and seconds of the Equator into hours, minutes, seconds, and thirds.

The table is printed in three parallel column-groups, each headed **G.** (degrees) **H.** (hours) **M.** (minutes); the argument runs 1–30 in the first group, 31–60 in the second, and by tens 70–360 in the third. The two footer rows give the alternate sexagesimal reading (see parsing note).

THE USE OF THE TWO PRECEDING TABLES.

[Margin: By what method degrees and minutes are reduced to hours from the following tables, and conversely.]

If degrees are to be converted into hours, take the degrees in the first table under the heading **G**, and the two columns immediately following will show the hours and minutes of hours due to the degrees taken. Thus you see that to 4 degrees correspond 16 minutes of an hour; likewise to 27 degrees, 1 hour 48 minutes; likewise to 45 degrees, 3 hours 0 minutes; likewise to 250 degrees, 16 hours 40 minutes; and so on. But if the number of degrees is not found exactly in the said table, take the nearest smaller number with its corresponding hours and minutes; then take the remaining degrees again with their corresponding hours and minutes; and finally join the latter hours and minutes to the former. For example, if you wish to know how many hours correspond to 215 degrees, take the 14 hours corresponding to 210 degrees; then take the 20 minutes corresponding to the remaining 5 degrees; and thus to 215 degrees are due 14 hours 20 minutes. And so for the rest.

If, however, minutes or seconds of degrees are to be converted into hours, take the minutes or seconds of degrees above the headings **M** or **S**, and the two columns immediately following will show the minutes, seconds, or thirds of hours, as the letters placed at the foot of the table indicate. On this reckoning you

see that to 56 minutes of a degree correspond 3 minutes 44 seconds of an hour; likewise that to 25 seconds of a degree are due 1 second 40 thirds of an hour.

In just the same way, from the latter table hours, minutes, seconds, and thirds of hours are reduced to degrees, minutes, seconds, and thirds of the equinoctial circle.

But if anyone should be unwilling to use tables of this kind, degrees, minutes, and so forth may be reduced to hours, minutes, seconds, and so forth — and, conversely, hours, minutes, and so forth to degrees, minutes, and so forth — in this way. Multiply the degrees, minutes, seconds, and so forth by 4; for the resulting numbers will give the next-smaller parts of time. Thus the product from degrees will give minutes of hours, the product from minutes of degrees will give seconds of hours, and so on. EXAMPLE. If 9 degrees 40 minutes 20 seconds are multiplied by 4, there result 0 hours 36 minutes 160 seconds 80 thirds — that is, 0 hours 38 minutes 41 seconds 20 thirds. Again, if 20 degrees 40 minutes are multiplied by 4, there are produced 0 hours 80 minutes 160 seconds — that is, 1 hour 22 minutes 40 seconds. And so for the rest.

[Margin: In what manner hours and minutes are made from degrees and minutes, and conversely how degrees and minutes are made from hours and minutes.]

Now, on the other hand, if hours, minutes, and so forth are divided by 4, the next-larger parts of the Equator are produced. Thus from thirds of hours are produced seconds of degrees; from seconds of hours, minutes of degrees; from hours, finally, degrees; while from minutes of hours are produced "parts" of one part of the Equator, each of which comprises 60 degrees, just as one degree comprises 60 minutes. EXAMPLE. If 0 hours 38 minutes 41 seconds 20 thirds are divided by 4, there are produced 0 parts (each of which comprises 60 degrees), $9\frac{1}{2}$ degrees, $10\frac{1}{4}$ minutes, 5 seconds — that is, 0 parts, 9 degrees, 40 minutes, 20 seconds. For $\frac{1}{2}$ degree makes 30 minutes, which together with the 10 minutes make 40 minutes; likewise $\frac{1}{4}$ minute makes 15 seconds, which together with the 5 seconds make 20 seconds. Again, if 1 hour 22 minutes 40 seconds are divided by 4, there result $\frac{1}{4}$ part (of those each of which comprises 60 degrees), $5\frac{1}{2}$ degrees, 10 minutes — that is, 20 degrees; because $\frac{1}{4}$ part (of those each of which contains 60 degrees) makes 15 degrees, which together with the 5 degrees make 20 degrees; likewise $\frac{1}{2}$ degree makes 30 minutes, which together with the 10 minutes make 40 minutes. And so for the rest.

It is also a pleasant thing to know that when we wish to divide degrees, minutes, seconds, and so forth — or even hours — by 6, that is, to take the sixth part, this is done most briefly by appending a cipher, that is, by multiplying by 10. For by this means are generated the next-smaller parts, which are one sixth of the parts we wished to divide by 6: thus from degrees come minutes, from minutes seconds, and so on. Accordingly the sixth part of 9 degrees, or hours, will be 90 minutes — that is, 1 degree, or 1 hour, and 30 minutes besides.

I should also like to append here a further, fourfold table, very useful in astronomical matters. By the first, degrees, minutes, seconds, thirds, and so forth of the Equator are converted into minutes, seconds, and thirds of Days. By the second, minutes, seconds, thirds, and so forth of Days are converted into degrees, minutes, seconds, thirds, and so forth of the Equator. By the third, hours, minutes, seconds, thirds, and so forth are converted into minutes, seconds, thirds, and so forth of Days. By the fourth, finally, minutes, seconds, thirds, and so forth of Days are transformed into hours, minutes, seconds, thirds, and so forth. The use of all of them is the same as that of the two preceding tables.

These, then, are the tables that follow.

Conversion tables (concluding the Equator)

The two facing pages present the promised "fourfold" (*quadruplex*) conversion tables — reference tables that convert between arc of the Equator (or time) and fractions of a day, each printed within a decorative woodcut border. Each table has a left panel (converting *into* days) and a right panel (converting *out of* days). Both panels carry, beneath the numeric columns, a **unit-shift key** (rows of abbreviations G./M./S./T./Q. = *Gradus/Minuta/Secunda/Tertia/Quarta*, or H./D. = *Horæ/Dies*): the same digits serve at successively finer sexagesimal levels by reading the column headings shifted down one place.

Table 1 (printed p. 130) — Equator ↔ Days

Left panel — heading: *Conversio Graduum, Minutorum, Secundorum, Tertiorum, &c. Aequatoris in Minuta, Secunda, Tertia, &c. Dierum.* ("Conversion of Degrees, Minutes, Seconds, Thirds, etc. of the Equator into Minutes, Seconds, Thirds, etc. of Days.")

Columns: **G.** (degrees of the Equator) | **M. dierū** (minutes of days) | **S. dierū** (seconds of days). Each degree = 10 seconds-of-a-day.

ON THE ZODIAC CIRCLE

(DE ZODIACO CIRCULO)

[Margin: What the Zodiac is.]

There is another circle in the sphere which cuts the Equinoctial and is cut by it into two equal parts; and one half of it inclines toward the North, the other toward the South.

COMMENTARY

After his treatment of the Equator, the author takes up the Zodiac in the second place, because knowledge of the remaining circles depends on an understanding

of this one. In describing the Zodiac circle, then, he says that it is the greatest circle in the sphere — one that cuts the Equinoctial circle and is cut by it into two equal parts, of which one inclines toward the North, the other toward the South.

[Margin: The distance of the poles of the Zodiac from the poles of the world.]

As for the poles of this circle, we said in chapter 1 — when we were dealing generally with the circles of the sphere — that they are removed from the poles of the world by a fourth part of a quadrant, plus a ninetieth of one quadrant; that is, by $23\frac{1}{2}$ degrees. From this it follows that the midpoint of each of its two halves is exactly the same distance from the Equator, the one inclining toward the North, the other toward the South.

[Margin: Why the Zodiac was devised by astronomers.]

Astronomers devised this circle among the celestial orbs chiefly on account of the motion of the planets. For they observed through daily experience that the Sun, the Moon, and the other planets, by their own proper motions from West to East, depart from the Equinoctial circle — now toward the North, now toward the southern region — and this by a certain fixed and determinate distance and elongation, which of course amounts to 23 degrees 30 minutes, especially if we are speaking of the Sun (for the other planets vary this distance somewhat). Next, that these same bodies return and approach the Equinoctial circle again, and always keep the same path, as we established in chapter 1 by many proofs when we were discussing the motions of the heavens. Again, by the clearest indications they discovered — as we showed in the same place — that the Firmament, together with all the fixed stars, moves from West to East about poles that are distant $23\frac{1}{2}$ degrees from the poles of the world.

[Margin: Anaximander the first discoverer of the Zodiac.]

Hence they marked out in the heaven a greatest circle, which they called the Zodiac, to be the path of all the planets and the belt of the second motion — that of the fixed stars as well — just as the Equator is the belt of the first motion. Pliny [Pliny the Elder] reports that the first discoverer of the Zodiac was Anaximander [Anaximander of Miletus].

[Margin: That the Zodiac makes various angles with any horizon.]

Although the Zodiac is fixed in the heaven and is everywhere the same, it nevertheless does not always make the same angles, whether with the right horizon or with the oblique; rather, it continually changes and varies them. For now it forms more upright angles, now more oblique ones, adapting itself to each

horizon according to the varying inclination it has toward that horizon. From this arises the whole non-uniformity — the irregularity — in the rising and setting of the signs, as we shall explain in chapter 3.

[Margin: Whence the Zodiac is so called.]

AND this circle is called the Zodiac, from Ζωή [Greek: zōē, "life"], which means life, because it is in accordance with the motion of the planets beneath it that all life exists in the lower things. Or it is called from Ζώδιον [Greek: zōdion, "living creature," "little figure" — a sign of the zodiac], which means animal; for, since it is divided into 12 equal parts, each part is called a Sign and has its own particular name taken from the name of some animal, on account of some property shared alike by the sign itself and the animal. Or it is so called on account of the arrangement of the fixed stars in those parts after the manner of animals of this kind.

COMMENTARY

He gives a twofold reason why this circle is called the Zodiac. It may be, no doubt, from Ζωή [Greek: zōē, "life"], that is, life, because on account of the continuous motion of the planets beneath this circle all these lower things possess life, as Aristotle relates in many places throughout his works. Or it may be from Ζώδιον [Greek: zōdion, "living creature," "little figure" — a sign of the zodiac], which means animal, because this circle is divided by the astrologers into 12 equal parts, each of which — with one exception — receives the name of some animal. And these 12 parts are called Signs, of which we shall speak presently.

[Margin: Why the signs of the Zodiac are named after animals.]

As for why these Signs are named after particular animals, he assigns a twofold cause here as well. The first is that (as the judicial astrologers maintain) those constellations possess virtues or properties shared in common with the animals from which they take their name; that is, because in these lower regions they produce effects that conform to animals of that kind. For example: The first Sign is called Aries, because, just as the Ram is a hot-blooded animal, so too the Sun, present in that part of the sky which is called Aries, begins to put forth its heat and to warm these lower regions. The second Sign is called Taurus, because, just as the Bull is stronger than the Ram, so too the Sun, once established in the sign of Taurus, exerts greater force than it did in Aries; or else because, with the Sun in Taurus, the toil of the oxen — that is, of the bulls — begins to appear, namely the standing crops. The third Sign took its name from the Twins [Gemini], because, as the Sun runs its course through it, the heat in these lower regions is in a way

doubled. The fourth is called Cancer, because, when the Sun reaches Cancer, it begins to move backward in the manner of a crab and to withdraw from us. The fifth is called Leo, for, just as the Lion is the strongest of animals, so too the Sun, present in Leo, brings on the greatest dryness and heat. The sixth Sign is called Virgo, because the Sun, present in it, is in a way barren, and produces nothing anew, but only brings to maturity what has already been produced. The seventh is named Libra, because, when the Sun is in it, the days and nights are weighed out and made equal as though on a balance or some pair of scales. The eighth is called Scorpio, for, just as the Scorpion stings and wounds with its tail, so too, while the Sun lingers in this Sign, the cold spells are wont to injure and sting the unwary. The ninth is called Sagittarius, because, when the Sun is in it, hailstorms and rains are hurled down upon us like arrows. The tenth is called Capricorn, because, just as the goat is forever raising itself up toward trees and foliage, so too the Sun, when it reaches this sign, begins to climb back up toward us again. The eleventh is called Aquarius, because, when the Sun is in that Sign, the waters of the rains tend to be abundant. Finally, the twelfth takes its name from the fishes [Pisces], because, while the Sun tarries in Pisces, the rains become so frequent that all things seem to swim about like fish. But all these things are to be understood of the region [inhabited zone] which, from the Equator...

tilts from the Equator toward the North. For those stars that dwell in the southern part experience the exact opposite of these.

The SECOND cause is that the stars lying in that part of the Zodiac which is called, for example, Scorpius reproduce the image or figure of a Scorpion. Likewise the stars set in that part which takes its name from Sagittarius express, in a manner, a man shooting an arrow from a taut bow — and so with the rest.

But if NEITHER of these explanations satisfies, we can say that these twelve parts obtained the aforesaid animal-names for this reason: since throughout the whole Firmament there are found 48 constellations or images (of which we spoke in chapter 1, where we listed their names and their individual stars one by one), twelve of them are contained within the Zodiac — namely Aries, Taurus, Gemini, and so on. Hence the astronomers gave these same names to the 12 parts into which the Zodiac is divided. But since the same difficulty seems to remain — namely why those 48 celestial images were furnished with such names — it must be said that the ancients imposed names of this kind on the constellations (whatever the judicial astrologers may say) in memory of certain illustrious men, or else of some fable or history. Thus one constellation is called Hercules [Hercules], in memory of Hercules; another Argo [Argonavis], on account of the

first ship, by which men entrusted themselves to the waves of the sea; and so forth. Nevertheless it cannot be denied that those who imposed these names had great regard for the figures which the stars form. For in memory of the Crown of Ariadne [Ariadne] they called that constellation the Crown, which presents the likeness of a certain crown — and so it must be said of the rest.

[Margin: Why the ancients gave the constellations those names, about which above.]

FROM this it is clear that, if we take account of the 12 signs or constellations comprehended in the Zodiac, this name properly belongs to the Zodiac of the Firmament, in which such constellations exist, and not to the Zodiac of the primum mobile, since there no trace of such images exists. But if anyone prefers the Zodiac to be named from Ζωή [Greek: ζῳή (zōē, "life")], rather than from Ζώδιον [Greek: ζῳδιον (zōdion, "living creature")], he will rightly be able to say that this name was first imposed on the Zodiac of the primum mobile. For it is on account of the motion of the planets beneath the Zodiac of the primum mobile that all these lower things have life, as the Philosophers assert.

[Margin: To which Zodiac this name better applies.]

[Lemma.] *This circle is called in Latin Signifer [the Sign-bearer], because it carries the Signs, or because it is divided into them. By Aristotle [Aristotle], in book 2 of On Generation and Corruption, it is called the oblique circle, where he says that according to the approach and recession of the Sun along the oblique circle, generations and corruptions come to pass in lower things.*

COMMENTARY

HE brings in two other names by which the circle of the Zodiac is usually called by the astronomers, saying that it is called by the Latins Signifer, either because it carries the 12 aforesaid Signs, or indeed because it is divided into them — an appellation very familiar to the poets. For so Claudian [Claudian] calls it in the epigram he composed on the sphere of Archimedes [Archimedes], where he speaks thus:

[Margin: Other names of the Zodiac.]

Percurrit proprium mentitus signifer annum, Et simulata nouo Cynthia mense redit.

The counterfeit sign-bearer runs through its own year, and a feigned Cynthia [the Moon] returns with each new month.

Lucan [Lucan] too names it thus in book 3, writing:

*Aethiopumque solum, quod non premeretur ab vlla Signiferi regione poli,
ni poplite lapsa Vltima curuati procederet vngula Tauri.*

And the land of the Ethiopians, which would be pressed by no region of the sign-bearing pole, did not — its knee slipping — the last hoof of the curved Bull reach out over it.

THEN he says that the Zodiac is called the oblique circle by Aristotle in book 2 of On Generation and Corruption; and by this name too many astronomers have been accustomed to call it. This circle is called oblique, first because it cuts the Equator and the Colure of the equinoxes at oblique angles; and second because, if it is compared with the parallel circles, it holds an oblique position in the sphere, since it is not equally removed from the poles of the world with respect to all its parts, but one half of it inclines toward the South and the other toward the North. Hence it comes about that the Sun and the other planets, which are perpetually moved beneath the Zodiac, sometimes approach nearer to us — namely when they are in the half toward the North — and sometimes recede farther from us, namely when they traverse the remaining half, which inclines toward the South.

[Margin: Why the Zodiac has an oblique position in the sphere.]

BUT if anyone should ask the cause why Nature has assigned this obliquity to the path of the Sun and of the other planets, the answer must be given, with the Philosophers, that it was done for two chief reasons. The first is the alternation of the seasons; for on account of the motion of the Sun beneath this oblique circle there arise Spring, then Summer, afterward Autumn, and last Winter, as we shall soon say. Likewise, in the oblique sphere, by the same motion of the Sun beneath the Zodiac, it comes about that sometimes the artificial days are equal to the nights, sometimes the artificial days exceed the nights, and sometimes, finally, the artificial days are surpassed by the nights, as will be established more clearly than daylight in chapter 3. For if the Zodiac which the Sun traverses by its own motion were not oblique, there would never be any variety of seasons in any region whatever, because the Sun would always keep the same distance from the top of the head [zenith]. The second cause is the diversity and variety of effects; for on account of the obliquity of the Zodiac the Sun and the other planets, as has been said, now approach nearer to us, now stand farther from us — and from this alternation arises the whole diversity in effects. For if the Zodiac were not oblique, the same effects would always be produced, since the planets would perpetually keep the same nearness and remoteness.

[Lemma.] *But the NAMES of the Signs, their arrangement, and their number are set out in these verses:*

*Sunt Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libraque, Scorpius,
Arcitenens, Caper, Amphora, Pisces.*

They are the Ram, the Bull, the Twins, the Crab, the Lion, the Virgin, the Balance, the Scorpion, the Archer (Arcitenens), the Goat (Caper), the Urn (Amphora), the Fishes.

[Margin: The names of the 12 signs of the Zodiac, and their order.]

COMMENTARY

SINCE the Author had said that the Zodiac is divided by the astronomers into 12 equal parts, which are called Signs, he now explains in two verses how these twelve Signs are named, and in what order they stand to one another in the Zodiac. This we too did long ago in chapter 1, when we were treating of the motions of the heavens, where we also set down the characters by which they are usually designated by the astronomers; and we now repeat these same characters here, for the benefit of students, so that they may cling more firmly to the memory. There are, then, 12 celestial signs endowed with these names, and they have this order among themselves, and they are usually expressed by such characters. Now each

♈	♉	♊	♋	♌	♍
Aries	Taurus	Gemini	Cancer	Leo	Virgo
♎	♏	♐	♑	♒	♓
Libra	Scorpius	Sagittarius	Capricornus	Aquarius	Pisces

higher sign corresponds to the one lower and opposite to it through the diameter in the Zodiac, as Aries to Libra, Taurus to Scorpio, Gemini to Sagittarius, and so on.

MOREOVER, among the astronomers a sign is customarily taken in two ways. In one way, for the sixth part of the whole Zodiac — in which sense it is called a Physical or natural sign, because a circle is, as it were, naturally divided into 6 equal parts without any artifice applied, by the very same spreading of the legs of the compass with which the circle was described, as is clear from the corollary of proposition 15 of book 4 of Euclid [Euclid, *Elements* IV.15, corollary]. Such signs the astronomers are accustomed to use in composing tables of the motions, as may be seen in Alfonso, King of Spain [Alfonso X of Castile], and others who

composed tables. In the other way, a sign is taken for the twelfth part of the Zodiac, or (what is the same) for the halved part of a physical or natural sign, and is called a common sign, because the astronomers are accustomed to use it — and it is in this signification that our Author here too has taken the sign. Now these parts of the Zodiac are perhaps called signs because through them are designated the motions of all the heavenly bodies, or also because they designate the various seasons of the year, as we shall soon say.

[Margin: The twofold sense of "sign." What a physical sign is. What a common sign is.]

THESE same twelve celestial signs Manilius [Manilius] describes most elegantly in twelve verses, in which he also expresses their order and names, and in what manner they are usually depicted by the astronomers on the celestial globe. These are the verses:

*Aurato princeps ARIES in vellere fulgens Respicit admirans aduersum
surgere TAVRVM Summisso vultu GEMINOS, & fronte vocantem: Quos
sequitur CANCER: Cancrum LEO: VIRGO Leone, Aequato tum LIBRA die
cum tempore noctis Attrahit ardenti fulgentem SCORPION astro, In cuius
caudam contentum dirigit arcum. MIXTVS EQVO, volucrem missurus
iamque sagittam Tum venit angusto CAPRICORNVS sidere flexus. Post
hunc inflexam diffundit AQVARIVS vrnas PISCIBVS assuetas auide
subeuntibus vndas, Quos Aries tangit claudentes vltima signa.*

First, the Ram, gleaming in his golden fleece, looks back, marveling to see the Bull rise opposite — the Bull, with lowered face and brow, summoning the Twins; whom the Crab follows; the Crab the Lion; the Lion the Virgin. Then the Balance, the day made equal with the time of night, draws in the Scorpion, blazing with its burning star, at whose tail [the Archer] aims his drawn bow. Mingled with a horse, and now about to loose the winged arrow, then comes Capricorn, coiled in his narrow constellation. After him Aquarius pours out his tilted urn for the Fishes, who eagerly draw beneath their accustomed waters, whom the Ram touches, closing the last of the signs.

WHICH verses indeed most beautifully explain the figures of the twelve Signs of the Zodiac, which are usually depicted on the celestial globe.

CONCERNING the NAMES of these twelve signs we spoke above — namely why these names were attributed to them by the astronomers. It must now be said concerning their number and order: namely why the astronomers established

only 12 signs in the Zodiac, not more nor fewer; and why they chose to take the beginning from Aries rather than from another sign, since in a circle there is properly no beginning, but one may take the beginning from any point whatever without distinction. For although all these things depend on the will and judgment of the astronomers, yet it must be believed that they were not established by them without reason. As for what pertains to the number of the signs, then, certain reasons are brought forward by the astronomers which show that the Zodiac was very fittingly divided into 12 signs. The first is this. Since there are four elements, from which all things are generated — namely Fire, Air, Water, and Earth — and since each one possesses three chief terms — namely a beginning, a middle, and an end — and since generable things are first generated, then conserved, and finally, thirdly, corrupted: if we multiply the ternary of these terms

[Margin: Why the Zodiac is divided into 12 signs.]

by the quaternary number of the elements, we shall produce the number twelve. Not without reason, therefore, ought the number of the signs in the Zodiac to be such that the individual elements, according to the aforesaid threefold term, should each obtain three signs. And thus the astronomers assigned to Fire Aries, Leo, and Sagittarius, because these three signs are hot and dry (as the judicial astrologers assert), just as Fire is. To Air they assigned Gemini, Libra, and Aquarius, for these three signs are hot and moist, like Air. To Water they ascribed Cancer, Scorpio, and Pisces, because these three signs are cold and moist, like water. To Earth, finally, they granted Taurus, Virgo, and Capricorn, because these three signs are cold and dry, like Earth.

[Margin: Which signs are called fiery and choleric; which earthy and melancholic; which airy and sanguine; and which watery and phlegmatic.]

But so that it may easily be held in memory which signs pertain to each element, four fingers on the hand are to be taken, of which the first should represent Fire, the second Earth, the third Air, the fourth Water; and then all the signs are to be reckoned upon them in that order in which we listed them above. So it will come about that the three signs falling above the first finger are assigned to Fire, and are called Fiery, on account of their heat and dryness — hence also Choleric. Those which fall above the second finger pertain to Earth, and are called earthy, on account of their coldness and dryness; hence too they are called Melancholic. Those next, which fall above the third finger, are ascribed to Air, since they are hot and moist, and are called Airy and Sanguine. Those finally which are set upon

the fourth finger are given to Water, on account of coldness and moisture, and are called Watery and Phlegmatic. All this may be viewed in this formula:

IGNIS	TERRA	AER	AQVA
♈	♉	♊	♋
♌	♍	♎	♏
♐	♑	♒	♓
IGNEA	TERREA	AEREA	AQVEA
CHOLERICA	MELANCHOLICA	SANGVINEA	PHLEGMATICA

The SECOND reason is of this sort. Since the Sun, in the space of a whole year, runs through the entire Zodiac, and distinguishes the intervals and boundaries of the seasons, it seemed to the astronomers most consonant with reason to divide the Zodiac into as many equal parts as there are notable varieties of seasons produced by the Sun's motion in the Zodiac. Now the perceptible diversities of the seasons are twelve. Rightly, therefore, were just so many Signs established in the Zodiac. For in the year there are four sufficiently common and principal parts — namely Spring, Summer, Autumn, and Winter — which do not behave in the same way in their complexions and qualities. For Spring is moist and hot; Summer hot and dry; Autumn dry and cold; Winter, finally, cold and moist — as not only the Philosophers but also the Physicians assert. Since, therefore, these four seasons are produced by the oblique motion of the Sun beneath the Zodiac (on account of which the Sun now approaches nearest to us, now is farthest from us, now behaves in an intermediate way), the whole Zodiac has been divided by the astronomers into 4 parts or quadrants, corresponding to the aforesaid four seasons of the year. The first Quadrant, corresponding to the season of Spring, takes its beginning from the first degree of ♈ [Aries], and has its end at the extremity of ♊ [Gemini], or the first degree of ♋ [Cancer]. The second Quadrant, in which the Sun, being present, produces Summer, begins from the first degree of ♋ [Cancer], and ends at the end of ♍ [Virgo], or the first degree of ♎ [Libra]. The beginning of the third Quadrant is set at the first degree of ♎ [Libra], and its term at the end of ♐ [Sagittarius], or the first degree of ♑ [Capricorn]; and this Quadrant corresponds to Autumn. The fourth Quadrant, finally, in which, while the Sun tarries, Winter is produced, takes its beginning from the first degree of ♑ [Capricorn], and has its end at the last degree of ♓ [Pisces].

But since in each of these seasons three further manifest diversities are discerned — for the Beginning, Middle, and End of each of them are not of exactly the same complexion, yet they have something in common with the complexions of the neighboring seasons. Hence, although Spring is hot and moist, yet not every part

of it is equally hot and moist. For its Beginning, on account of its nearness to the past winter, which is also moist and not hot, is more moist than hot; the Middle is temperately moist and hot; the End, finally, on account of the nearness of the coming summer, which is also hot but not moist, turns out more hot than moist. And the same reasoning is to be applied to the remaining three seasons of the year. Therefore, by the best counsel, the astronomers distributed each Quadrant of the Zodiac into three other equal parts, which should be the three mansions of the Sun in the three parts of each of these four seasons. From which it results that there are twelve Signs of the Zodiac.

[Margin: The qualities of the four seasons of the year. — To which seasons of the year the Quadrants of the Zodiac correspond.]

Moreover, so that all the Signs which correspond to the beginning, middle, and extremity of each of the aforesaid four seasons of the year may be ready at hand, all the Signs are to be numbered on three fingers, the beginning being made from ♈ [Aries], in such a way that four Signs fall above each finger. So it will come about that the 4 Signs of the first finger correspond to the beginnings of the four seasons — the first to the beginning of Spring, the second to the beginning of Summer, the third to the beginning of Autumn, the fourth finally to the beginning of Winter — which Signs are usually called Movable [Mobilia]. For in them occurs the change of one season into another. So too, in the same order, the four Signs of the second finger will correspond to the middle parts of those same seasons; hence they are called Fixed [Fixa], because in them the complexion of each season is firm and fixed. Finally, by the same reasoning, the four Signs on the last finger will indicate the extreme parts of those same seasons — which indeed are called Common [Communia], because, since they are the extremes of those seasons, each season has something in common with the qualities of the seasons following. All this is set before the eyes in the following formula:

[Margin: Which are the Movable, Fixed, and Common Signs.]

	INITIVM	MEDIVM	FINIS
VERIS	♈	♉	♊
ÆSTATIS	♋	♌	♍
AVTVMNI	♎	♏	♐
HYEMIS	♑	♒	♓
	MOBILIA	FIXA	COMMVNIA

The THIRD reason is this. Of the 48 images of heaven — the constellations, that is, which the astrologers formed out of the 1022 fixed stars of the Firmament, of which we indeed spoke in chapter 1 (whose histories or fables, if you desire to know them more fully, you must consult Hyginus [Hyginus], or Johannes Stöffler [Johannes Stöffler] on the Sphere of Proclus, or also Alessandro Piccolomini [Alessandro Piccolomini] in his little work on the fixed stars) — only 12 are included in the Zodiac, namely Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libra, Scorpius, Sagittarius, Capricornus, Aquarius, and Pisces, as was said in chapter 1. For which reason the astronomers wished to distribute the Zodiac into just as many equal parts, so that they might be called by the same names.

Commentary on Chapter II of the *Sphere* — On the Zodiac Circle (continued)

A FOURTH reason can be of this kind. It has been observed that in the space of a single year the Moon commonly comes into conjunction with the Sun under the Zodiac twelve times, and stands in opposition to it just as often — that is, twelve new moons occur in the course of a year, and as many full moons, even though the Moon runs through the whole Zodiac thirteen times in the space of one year. This is why it was decided to cut the Zodiac into exactly that many parts, and not into more or fewer; for it is precisely from this varying aspect of the Moon to the Sun that the intervals of time are distinguished. Thus the time that elapses from one conjunction to the next is called a *month*; the time contained between conjunction and opposition, and again from opposition to conjunction, makes up half a month; and the time that falls midway between conjunction (or opposition) and quadrature — when, that is, the Moon appears exactly half-full — makes a week [*hebdomada*], or seven-day span.

[Margin]

A FIFTH and final reason is drawn from the worth of the number twelve. For twelve is the first of all numbers to possess a half, a third, a quarter, a sixth, and a twelfth part — all of which are needed in the Zodiac: partly so that it may conveniently be divided into 12 parts, answering to the 12 varieties of the seasons, and into 4 quadrants, which produce spring, summer, autumn, and winter; and partly, above all, so that all the aspects of the stars treated in the *Theorics of the Planets* can be represented. For by the half-part of the Zodiac is designated the diametral aspect, or opposition of the stars; by the third part, the trine aspect; by the quarter, the square; and by the sixth, finally, the sextile aspect

is marked. It is clear, therefore, that the astronomers were not without reason when they divided the Zodiac into the 12 aforesaid celestial signs.

[Margin]

Now the reasons that moved the astronomers to take the beginning of the Zodiac from the first point of **Aries**, rather than from any other point, are chiefly three. The first is Ptolemy's [Ptolemy]: namely that, when the Sun stands at the beginning of Aries — that is, when the vernal equinox occurs — there begins the season most suited to the generation of things, for then all things grow green and flower. But when the Sun enters the first degree of **Libra** — that is, when the autumnal equinox occurs — there begins a season wholly contrary to the former, and more suited to the corruption of things; for then the leaves begin to fall from the trees, and everything to grow cold in some degree, as experience confirms. Not without reason, therefore, did the astronomers choose the first point of Aries out of all the points of the Zodiac to be the beginning of the whole Zodiac. There is a further consideration: when the Sun enters the sign of Aries, spring begins, the moist season, which corresponds most closely to the first age of living creatures. Then, as the Sun passes under the sign of **Cancer**, summer begins, the hot season, suited to the second age of creatures. Afterwards, when the Sun reaches the sign of **Libra**, autumn begins, the dry season, which agrees with the third age of creatures. And finally, when the Sun is in the sign of **Capricorn**, winter begins — that is, the cold season — which befits and answers to the fourth and last age of creatures.

[Margin]

For authors are accustomed to divide the life of living creatures into four principal ages. In the first, they say, moisture predominates, as we see in children; in the second, heat, as experience shows in youths and adolescents; in the third, dryness, as we observe in men now established in their full maturity; and in the fourth, finally, coldness, as is plain in the aged. This reasoning of Ptolemy's, however, holds and has force only for the regions that lie back from the equator toward the north. For if it were put to those who live beyond the equinoctial circle toward the south, it would have no weight. Indeed, it would prove that in the Zodiac the beginning ought to be taken from the first point of **Libra**. For just as with us, when the Sun stands in Aries it is spring, so with them it is spring when the Sun stands in Libra; and just as with us summer begins when the Sun is in Cancer, so with them summer comes when the Sun enters the sign of Capricorn. In short, everything that happens to us under any given signs must of necessity happen to them under the opposite signs — as can easily be

seen on a material sphere. Yet this reasoning is not on that account to be lightly esteemed. For one thing, Ptolemy and the other astronomers who gave these signs their names and established their order lived in regions that bend away from the equator toward the north, so that it is no wonder they had regard to this northern part of the sphere, in which they observed the courses of the stars. For another, this northern part is worthier and nobler than the southern, as the very structure and arrangement of the universe sufficiently shows.

[Margin]

For to anyone rising above whatever horizon, the eastern part lies to the right, and the southern to the left; and the northern part is the right-hand part, since it is always to the right of the Sun as it rises, while the southern lies to its left. This can also be established from the fact that the northern quarter of the heavens is adorned with far more stars near the Arctic pole than the southern, since near the Antarctic pole no stars at all exist, as was said above.

[Margin]

A SECOND reason is this. Since in the Zodiac there are four principal points, called *cardinal*, by which the whole Zodiac is distributed into four quadrants — each of which answers to one of the four parts of the year, namely spring, summer, autumn, and winter, as has been said — these points are: the beginning of Aries, the beginning of Cancer, the beginning of Libra, and the beginning of Capricorn. Of these, two, namely the beginning of Aries and of Libra, are called *equinoctial*; and two, namely the beginning of Cancer and of Capricorn, *solstitial*. Not unjustly, and not by any rashness, did the astronomers determine that a beginning must be made from one of these. Therefore, of them all they had to select the noblest, namely the first point of Aries. For this point is nobler than the two solstitial points. When the Sun stands at either of the solstitial points it describes the shortest parallels [of the day], and produces the greatest inequality of the days and nights, that is, of the artificial [days]; and hence those points are of less excellence. But when the Sun is at the equinoctial points it describes the greatest parallel, makes the day equal to the night, produces the most temperate climate, and — what deserves careful notice — is visible in all parts of the world in the space of 24 hours, even under the poles of the world, which can happen at no other point of the Zodiac. Likewise the first point of Aries is nobler than the beginning of Aquarius, for this reason: that when the Sun stands in it, it produces spring in the northern part [of the earth], and enters the signs that decline from the equator toward the north — that is, toward the northern part of the heavens, which is nobler than the southern, as we have said.

[Margin]

A LAST reason properly belongs to certain astronomers, who hold that it best accords with reason that the beginning in the Zodiac be taken where the Sun stood at the beginning of the world when it was created. And it is indeed probable, they say, that the world was fashioned with the Sun holding the first point of Aries — inasmuch as, in the Law of Moses, God commanded that at the time when the Sun enters the sign of Aries the Jews should take the beginning of the year, and celebrate the solemnity of the Passover; whereas before they had, with the Egyptians, begun the year from autumn. In this opinion are many holy Doctors, such as Eusebius in the *Chronicle*; Cyril in *Catechesis* 14; St. Leo, Sermon 9 on the Passion [St. Leo the Great]; [the commentary] on Exodus; St. John Damascene, book 2, chapter 7 [John of Damascus]; Isidore, *Etymologies* book 5, the chapter on the divisions of time [Isidore of Seville]; the Venerable Bede, in his book *On Reckoning* [Bede]; Strabus [Walahfrid Strabo] on Exodus 12; Rabanus [Rabanus Maurus] in the same place; the *Historia Scholastica*, chapter 25, on the History of Exodus; the interlinear Gloss —

— the interlinear Gloss on chapter 35 [recte: Genesis]; the Gloss on Genesis at the word "*in spring*"; and most others: to whom the school of theologians now almost commonly assents, on the ground that at that season of the year, when the Sun enters the sign of Aries, Christ the eternal Son of God took on human flesh, and by his most holy Passion redeemed the world. It seems probable, then, they say, that the world was created at the same season in which it was also redeemed.

I know that almost all the Hebrews, the Egyptians, and some of the ecclesiastical Doctors as well hold that the world was made around the time of autumn, on the ground that plants and trees were brought forth already bearing ripe fruit — as is clear from the forbidden apple offered to our first parents — which happens only around autumn. This may also be gathered, they argue, from the fact that God, in memory of the benefit by which he had freed the Hebrews from the servitude of Egypt, commanded that the year thenceforth be begun from that same season, namely from spring — the time at which he had conferred so great a benefit upon them — and no longer from autumn, from which (as they interpret it) the world was created.

But these arguments are not altogether firm. To the first it can be replied that God created the earthly Paradise, in which the first parents were placed, together with all its fruits, even though it was then springtime. Nor indeed does that argument hold which some allege — that the fruits were then created ripe because otherwise the trees would not naturally have produced them ripe in due course;

for on this reasoning all fruits ought to be ripe at the same season, namely in autumn, as they themselves maintain, which we nevertheless see does not happen. And so, although all the trees were created in springtime, natures of such a kind were nevertheless implanted in them by God that they should afterwards bring forth their fruits each at its proper season. It could also be said that the fruits were then ripe only in Paradise, which was not liable or subject to the qualities and variations of the seasons — but outside Paradise, by no means. To the second argument it can be answered that God willed the Jews, having abandoned the error of the Egyptians, to begin the year afresh from the springtime, at which the world had been created, and at which it pleased him to free them from so hard a servitude. But whatever be the case concerning the time at which the world was created, everyone is free, for all I care, to hold what he pleases: to me, at any rate, it seems more probable that it began in springtime, when, that is, the Sun stood at the beginning of Aries.

Virgil seems to feel the same, in book 2 of the *Georgics* [Virgil, *Georgics* II], where he sings thus:

*Non alios prima crescentis origine mundi Illuxisse dies, aliumue habuisse
tenorem Crediderim. Ver illud erat, Ver magnus agebat Orbis, & hybernis
parcebant flatibus Euri, Cum primum lucem pecudes hausere, virumq;
Ferrea progenies duris caput extulit armis, [recte: aruis] Immissæq; feræ
sylvæ, & sidera cælo.*

(I would not believe that other days shone forth at the first origin of the growing world, or that it kept another course. That was spring; the great world was keeping spring, and the east winds spared their wintry blasts, when the first cattle drank in the light, and the iron race of men raised its head from the hard fields, and wild beasts were let loose into the forests, and stars into the sky.)

It is clear, then, that no point of the Zodiac could more fitly furnish a beginning to the Zodiac than the first point of Aries.

SOMEONE will perhaps raise a doubt: since all the astronomers, for the reasons explained, begin the year when the Sun enters the beginning of Aries, why do the ancients in our calendars — and we too, together with the Roman Church — begin not from that same point but rather from the winter solstice, which once fell around the beginning of January; that is, we take the beginning of the year when the Sun enters the first degree of Capricorn? To this it can be briefly replied that it seemed more convenient to the ancients to fix the beginning of the year at the winter solstice than at the vernal equinox, because that point of the solstice —

which is the beginning of Capricorn — is the end of the descending [semicircle] and the beginning of the ascending semicircle. (The descending semicircle is called the half of the Zodiac from the beginning of Cancer, through Libra, up to the beginning of Capricorn, because in it the Sun descends from the zenith of our head; the ascending semicircle is called the other half of the Zodiac, from the beginning of Capricorn through Aries to the beginning of Cancer, because in it the Sun again ascends toward the zenith of our head — this, of course, being understood of the northern habitation. For exactly the contrary would have to be said in the southern habitation.)

[Margin]

It is the end of the withdrawal of the Sun and the beginning of its return toward us; it is the end of the shortening of the days and the beginning of their lengthening; it is the end of the lengthening of the nights and the beginning of their shortening — with respect to the northern part, which is worthier than the southern, and which the founders of the year inhabited. All this will be made plain in chapter 3. This same doubt — why, that is, the ancients chose to begin the year from the winter solstice rather than from the vernal equinox — Janus resolves in Ovid, *Fasti* book 1 [Ovid, *Fasti* I], where Ovid asks Janus why the beginning of the year is not set at the vernal equinox, when, that is, all things flower and grow green, in these verses:

*Dic age, frigoribus quare nouus incipit annus, Qui melius per ver
incipiendus erat? Omnia tunc florent, tunc est noua temporis ætas: Et noua
de grauido palmite gemma tumet. Et modo formatis operitur frondibus
arbor: Prodit & in summum seminis herba solum. Et tepidum volucres
concentibus aera mulcent: Ludit & in pratis, luxuriatq; pecus. Tunc blandi
Soles, ignotaq; venit hirundo, Et luteum celsa sub trabe fingit opus. Tunc
patitur cultus ager, & renouatur aratro. Hæc nouitas anni iure vocanda
fuit. Quæsieram multis, non multis ille moratus Contulit in versus sic sua
verba duos. BRVMA noui prima est, veterisq; nouissima Solis: Principium
capiunt Phœbus, & annus idem.*

(Come, tell me: why does the new year begin in the cold, when it would better have begun with spring? Then all things flower, then is the fresh age of the season, then the new bud swells on the teeming vine-shoot; then the tree is clothed with newly formed leaves, and the blade of the seed comes up to the surface of the soil; then the birds soothe the warm air with their harmonies, and the flock frolics and revels in the meadows. Then the sunshine is soft, and the swallow, till then unseen, arrives and builds its clay work beneath the lofty

rafter; then the tilled field bears the plough and is renewed by it. This freshness deserved by right to be called the year's beginning. — I had asked at length; without long delay he pressed his reply into two verses: "The winter solstice is the first of the new sun and the last of the old: Phoebus and the year alike take their beginning [there].")

WE Christians too can add another cause why the Church begins the year from the winter solstice: namely, because at that season the Savior of the world was born, to illuminate the darkness of men. And although the winter solstice does not fall exactly at the beginning of January, but on the 22nd day of December, even after the correction of the Calendar —

— the Church has nevertheless retained the ancient usage, so as to set the beginning of the year, with Julius Caesar, on the first day of January. This, then, is the reason why in the Roman calendars the year begins from the Kalends of January, even though the astronomers, considering the other reasons already stated, begin their reckonings of the years from the vernal equinox, and end them at the same point.

MANY things would have to be said here about the various properties and names of the signs; but since they pertain more to the judicial astrologers, they must for the present be passed over. Only this must be explained: which signs are called the *houses* [*domus*] and *exaltations* of this or that planet — inasmuch as any planet standing in its own house exercises and displays its power most fully in these lower regions.

[Margin]

Now every planet has two signs assigned to it for a double house — the Sun and Moon excepted, to which single signs are assigned each for a single house. Thus the sign **Leo** is called the house of the **Sun**; for since Leo is a fiery sign, and coincides with summer, the Sun as it runs through it produces the greatest heat upon the earth. The sign **Cancer**, on the other hand, is called the house of the **Moon**; for since Cancer is a watery sign, the Moon standing in Cancer most fully moistens these lower things. The next two signs surrounding these, namely **Virgo** and **Gemini**, are called the houses of **Mercury**. Two others still adjacent, namely **Libra** and **Taurus**, are the houses of **Venus**. Two next in order, namely **Scorpio** and **Aries**, are the houses of **Mars**. Two more adjoining, namely **Sagittarius** and **Pisces**, are the houses of **Jupiter**. And the two remaining, which enclose all these, namely **Capricorn** and **Aquarius**, are called the houses of **Saturn**.

But although each of these five planets possesses two houses, yet of the two one is always the more principal and the other less so, in such a way that the planet does not have the same power in both houses. For Mercury has greater strength and virtue standing in Virgo than in Gemini; Venus greater in Taurus than in Libra; Mars greater in Scorpio than in Aries; Jupiter greater in Sagittarius than in Pisces; and Saturn, finally, exercises greater power in Aquarius than in Capricorn.

[Margin]

Again, the sign which is diametrically opposite to the house of some planet is called the *detriment* [*detrimentum*] of that planet. Thus, since the sign **Aquarius** is opposed by diameter to Leo, which is the house of the Sun, the sign Aquarius will be called the detriment of the **Sun**. Likewise each of the signs **Taurus** and **Libra** will be called the detriment of **Mars** [since they oppose his houses]; but the greater detriment will be the sign Taurus, because it is opposed to the sign Scorpio, which is the principal domicile of Mars. And so with the rest. The following table will set these houses before your eyes:

Planet	House
Sun	Leo
Moon	Cancer
Mercury	Virgo (principal); Gemini (less principal)
Venus	Libra (less principal); Taurus (principal)
Mars	Scorpio (principal); Aries (less principal)
Jupiter	Sagittarius (principal); Pisces (less principal)
Saturn	Capricorn (less principal); Aquarius (principal)

[Margin]

CERTAIN of the 12 signs are called the *exaltations* of the planets. Thus the sign **Aries** is called the exaltation of the **Sun**, because when the Sun enters the sign of Aries the days begin to grow longer than the nights, and the Sun's heat begins to gain increase in these lower regions. But when it enters the sign of **Libra**, the nights begin to exceed the length of the days, and the Sun's heat gradually to weaken; hence the sign Libra is called the *fall* [*casus*] of the Sun. For the sign that is diametrically opposite the sign which is the exaltation of some planet is always called the fall of that same planet. Next, the sign **Taurus** is the exaltation of the **Moon**, and the sign **Scorpio** [her] fall; [the sign Cancer is the exaltation of Jupiter, and] the sign Capricorn the fall of **Jupiter**. The sign **Virgo** is the exaltation of

Mercury, but the sign **Pisces** the fall of Mercury; [the sign Libra is the exaltation of Saturn, and the sign Aries] the fall of **Saturn**. The sign **Capricorn** is the exaltation of **Mars**, and the sign **Cancer** the fall of Mars. The sign, finally, [Pisces is the exaltation of Venus, and Virgo her fall]. All of which are explained in the following table:

Planet	Exaltation	Fall
Moon	Taurus	Scorpio
Mercury	Virgo	Pisces
Venus	Pisces	Virgo
Sun	Aries	Libra
Mars	Capricorn	Cancer
Jupiter	Cancer	Capricorn
Saturn	Libra	Aries

[Margin]

EACH sign, moreover, is divided into 30 degrees; whence it is plain that in the whole Zodiac there are 360 degrees. According to the astronomers, again, each degree is divided into 60 minutes; each minute into 60 seconds; each second into 60 thirds; and so on in succession up to the tenth [order of division]. And just as the Zodiac is divided by the astronomers, so likewise every circle in the sphere, whether greater or lesser, is distributed into corresponding parts.

COMMENTARY.

Now that the Zodiac has been divided into the 12 common signs, [Sacrobosco] next divides the signs into further parts, teaching that each sign is distributed by astronomers into 30 equal parts, which are called Degrees [gradus]. [Margin: What a Degree is, and how many there are in the whole Zodiac according to longitude.] Since, then, 12 signs are contained in the whole Zodiac, if 12 is multiplied by 30 the result is 360 — which is exactly the number of degrees contained in the whole Zodiac. He then says that each degree is subdivided into 60 equal parts, called minutes [minuta]; each minute into 60 seconds [secunda]; each second into 60 thirds [tertia]; and so on always, proceeding by this sexagesimal division, until one reaches the tenths [decima]. For astronomers rarely go beyond the tenths. And just as the Zodiac is divided into 360 degrees, so too any other circle in the heavens — whether a great circle or not — is customarily distributed into the same number of degrees; and in the same way each degree is customarily divided into 60 minutes, each minute into 60 seconds,

and so forth. But this division of the Zodiac into 360 degrees, of each degree into 60 minutes, of each minute into 60 seconds, and so on, seems here to call for a somewhat fuller explanation. This particular division of the Zodiac is usually called division according to longitude.

Astronomers, then, observing that any circle can be cut by its primary and, in a way, natural division into 6 equal parts — by the very same span of the compass legs with which the circle is drawn, since the semidiameter of any circle is the side of the equilateral hexagon inscribed in it [Margin: a. 15 of the fifth [i.e. the inscribed-hexagon corollary; printed "quinti"]] — divided the whole Zodiac into 6 equal parts, which constitute the six physical, or natural, signs, as we said above. Then they divided each physical sign — that is, a sixth part of the whole Zodiac — into 60 equal parts, which they called Degrees, from the daily step-by-step advance, perhaps, of the Sun and the other planets through these parts. For the planets, as it were, walk through the Zodiac step by step (*gradatim*), passing through the said parts. From this it came about that the whole Zodiac contains 360 degrees. After this they again distributed each degree into 60 equal small parts, which they called minutes, and the minute into 60 seconds, the second into 60 thirds, and so on to infinity — although astronomers very rarely reach the tenths, and much more rarely go beyond them. And they divided the Zodiac into these minutest particles so that they might attain the utmost precision in the place and motion of the Sun and the other planets.

They preferred to carry this out by a sexagesimal division rather than by another — though another would have been open to them — first, because the number six, among all the perfect numbers (which are of course constituted from all their aliquot parts), is the first, and has a certain affinity with the sexagesimal number, since it measures it exactly ten times; and second, because the sexagesimal number seemed more convenient and apt for this sectioning. For it has a half [*dimidiatam partem*], a third, a fourth, a fifth, and a sixth part, with which parts the ancients were content, in order to avoid trouble and tedium. The same number does indeed contain still other parts — namely a tenth, a twelfth, a fifteenth, a twentieth, and finally a thirtieth — but the ancient mathematicians did not take account of these.

Another reason can also be offered for why the whole Zodiac is cut into 360 degrees. Since from one conjunction of the Moon with the Sun to another — that is, from one new moon to the next — there intervene very nearly 30 days, namely the span of one month, it pleased the astronomers to divide each common sign into 30 parts, which are called degrees from the "step" (*gressu*) of the luminaries;

or else because the Sun uses up about 30 days to run through a whole common sign, completing, that is, roughly one degree on each single day. Hence it was fitting that so much space should be granted to a single degree, since the Sun, the most brilliant lamp of the world, advances in a natural day very nearly one degree. By this reasoning, just as the whole Zodiac corresponds to a whole year, and the individual signs to the individual months, so too the individual degrees will correspond, as it were, to the individual days in the Zodiac. From this it came about that the whole Zodiac comprises 360 degrees, while the physical sign comprises 60. Therefore, lest a variation of division breed confusion, the degree in turn was divided into 60 minutes, the minute into 60 seconds, and so on. [Margin: Why astronomers use the sexagesimal division.]

These, then, are the reasons that drove the astronomers to use the sexagesimal division in dividing the Zodiac; of which the strongest seems to be that both the number 360 and the number 60 have very many aliquot parts. The former has all these: 1, 2, 3, 4, 5, 6, 8, 9, 10, 12, 15, 18, 20, 24, 30, 36, 40, 45, 60, 72, 90, 120, 180. The latter has all these: 1, 2, 3, 4, 5, 6, 10, 12, 15, 20, 30. And if the numbers 360 and 60 themselves are added to these, and are arranged so that the halved portion, in which the smaller parts are contained, is set on the left, and the remaining halved portion, containing the larger parts, on the right — as has been done here — you see that they denominate each other in pairs, mutually. For 1 is $1/360$ of the number 360; but 360 makes $1/1$ of the same number 360. Likewise 5 constitutes $1/72$ of the same, while 72 yields $1/5$; and so on. So too 3 makes $1/20$ of the number 60, while 20 constitutes $1/3$ of the same number 60; and so on.

So that it may be known how many particles of each division make up one degree, or even the whole Zodiac, I have thought fit to append here two little tables. In the first, a whole degree is distributed into minutes, Seconds, Thirds, Fourths, Fifths, Sixths, Sevenths, Eighths, Ninths, and Tenths. In the second, the whole Zodiac is distributed according to longitude into degrees, Minutes, Seconds, and so on.

ONE DEGREE CONTAINS [Margin: How many Minutes, Seconds, Thirds, and so on one Degree contains.]

Minutes [Minuta]	60
Seconds [Secunda]	3600
Thirds [Tertia]	216000
Fourths [Quarta]	12960000
Fifths [Quinta]	777600000
Sixths [Sexta]	46656000000
Sevenths [Septima]	2799360000000
Eighths [Octava]	167961600000000
Ninths [Nona]	10077696000000000
Tenths [Decima]	604661760000000000

THE ZODIAC CONTAINS [Margin: How many Degrees, Minutes, Seconds, Thirds, and so on are contained in the whole Zodiac.]

Degrees [Gradus]	360
Minutes [Minuta]	21600

Seconds [Secunda]	1296000
Thirds [Tertia]	77760000
Fourths [Quarta]	4665600000
Fifths [Quinta]	279936000000
Sixths [Sexta]	16796160000000
Sevenths [Septima]	1007769600000000
Eighths [Octava]	60466176000000000
Ninths [Nona]	3627970560000000000
Tenths [Decima]	21767823360000000000

Anyone will be able to extend both of these little tables on his own to infinity. For if the Tenths are multiplied by 60, the Elevenths [Vndecima] will be had; and if these in turn are multiplied by 60, the Twelfths [Duodecima] will result; and so on.

The Latins, too, call any whole, or Total whatever — and thus a Degree — an *as* (Assem), and they divide it into twelve equal parts. Of these they call: eleven, the *deunx*; ten, the *dextans*; nine, the *dodrans*; eight, the *bes*; seven, the *septunx*; six — that is, the half part — the *semis* (Semissem); five, the *quincunx*; four, the *triens*; three, the *quadrans*; two, the *sextans*; and one, finally, the *uncia*. [Margin: The *as* and its parts.] Since the use of these terms is frequent among the ancients — especially in Pliny, Vitruvius, Columella, and other writers both ancient and more recent — I judge it will not be out of place if I set down a table in which, in the first place, are contained the names of the 12 parts of the *as*, or whole degree; in the second place, the Minutes that correspond to each of the 12 parts; and in the third place, the common fractions that express the value of those same parts.

A TABLE CONTAINING THE NAMES OF THE TWELVE PARTS OF THE AS, AND THEIR VALUE.

Name of part		Minutes	Whole degree (fractional value)
<i>As</i> , or <i>Assis</i>	minutes	60	(Whole degree — <i>Gradus integer</i>)
<i>Deunx</i>	minutes	55	55/60, or 11/12
<i>Dextans</i>	minutes	50	50/60, or 10/12, or 5/6
<i>Dodrans</i>	minutes	45	45/60, or 9/12, or 3/4

Name of part		Minutes	Whole degree (fractional value)
<i>Bes</i> , or <i>Bessis</i>	minutes	40	40/60, or 8/12, or 2/3
<i>Septunx</i>	minutes	35	35/60, or 7/12
<i>Semis</i> , or <i>Semissis</i>	minutes	30	30/60, or 6/12, or 1/2
<i>Quincunx</i>	minutes	25	25/60, or 5/12
<i>Triens</i>	minutes	20	20/60, or 4/12, or 1/3
<i>Quadrans</i>	minutes	15	15/60, or 3/12, or 1/4
<i>Sextans</i>	minutes	10	10/60, or 2/12, or 1/6
<i>Uncia</i>	minutes	5	5/60, or 1/12

Now, in whatever way the Zodiac is divided, in just the same way the Equinoctial circle, the Meridian, and finally any other circle of the sphere — whether a great circle or not — is customarily divided by astronomers; except that they called the degrees of the Equinoctial circle, because by a fixed and perpetual law they mark out the diurnal and nocturnal times and distribute these into equal hours, in Greek χρόνους [Greek: χρόνους (chronous, "times")], and in Latin *Tempora* ("Times"), so that they might be distinguished from the degrees of the Zodiac.

In the same manner, too, in which the degree is divided, the hour is also customarily distributed — and any whole whatever — namely, into 60 minutes; the minute into 60 seconds; and so on. Likewise it is divided into the *deunx*, *dextans*, *dodrans*, and so on. The ancients also subdivide the *uncia* into further small parts, which, in the interest of brevity, I here omit; anyone, however, will be able to grasp all these things more thoroughly from the book of [Guillaume] Budé [Budaëus] which he entitled *On the As and its parts* [*De Asse et partibus eius*].

[Lemma — Sacrobosco:] Since, moreover, every circle in the sphere except the Zodiac is understood, like a line, [to be] a circumference, the Zodiac alone is understood as a surface, having in its breadth twelve degrees — of which kind of degrees we have already spoken. From this it is clear that certain people speak falsely in Astrology when they say that the signs are square, unless, misusing the term, they should mean by "square" [quadratum] a rectangle [quadrangulum]. For a sign has 30 degrees in length, but 12 in breadth.

COMMENTARY.

Up to this point the Author has dealt with the division of the Zodiac according to longitude; here he now explains its magnitude, or its division according to

latitude. For the Zodiac, he says, has this property among the other circles of the sphere, peculiar to itself: that whereas all the others are conceived on the surface of the heaven as lines, or circumferences, indivisible with respect to latitude, the Zodiac alone is understood as a kind of surface having in its breadth 12 degrees throughout its whole circuit. And since we have said that each sign has 30 degrees in length, he concludes that certain people are deceived in Astrology when they say that the signs of the Zodiac are square — unless by the term "square" they mean a rectangle, which is a broader term applying both to the square and to a figure longer on one side. For on this reckoning every sign will be longer on one side, having on each longer side 30 degrees, and on the shorter 12. [Margin: Why the Zodiac is given breadth by the astronomers.]

Astronomers attributed this latitude to the Zodiac alone, among all the other circles, for two reasons. First, so that it could contain within itself the figures and names of the signs. Second, on account of the irregular motion of the planets beneath it. For although all the planets are carried perpetually beneath the Zodiac, they do not all move in the same way. The Sun, running through the middle of it, never inclines either to the right or to the left; but all the other planets deviate now to the north of the middle of the Zodiac, now to the south, so that this deviation, to either side from the middle of the Zodiac, embraces about 6 degrees. Hence it came about that the whole Zodiac obtains a latitude of 12 degrees.

But someone will object that Mars and Venus recede not only 6 degrees from the middle of the Zodiac — whether to the north or to the south — but sometimes nearly 8 degrees; and that therefore the latitude of the Zodiac ought rather to be 16 degrees, so that the planets should never be found straying outside the Zodiac. [Margin: Why the latitude of the Zodiac embraces 12 degrees rather than 16.] To this objection it must nonetheless be answered that it was for this reason that some, following [Regiomontanus] Ioan. Regiom., assigned 16 degrees of latitude to the Zodiac; but all other astronomers deny that this is necessary. For they say it is more consonant with reason that the Zodiac should be cut into 12 degrees of latitude, on the ground that the other planets never exceed this latitude; and that the fact that Mars and Venus sometimes deviate more than 6 degrees from the middle of the Zodiac happens very rarely, and only by reason of the magnitude of the epicycles they have — so that this deviation cannot be a sufficient cause for assigning 16 degrees of latitude to the Zodiac. There is also this: it seems fitting that, just as the whole Zodiac contains 12 signs in length, so too in breadth it should comprise the same number of parts, namely 12 degrees. And by parallel reasoning: just as one degree is a thirtieth part of one sign, so too the whole

latitude of the Zodiac would be a thirtieth part of the whole compass, or circuit, of the same Zodiac — such being the 12 degrees of latitude in relation to the 360 degrees of longitude. Finally, just as the compass of the whole Zodiac in longitude comprises 360 degrees, so too the same number of degrees would contain one sign in its whole area, or surface. For 12 multiplied by 30 makes 360 degrees — the area, that is, of a single sign.

[Lemma — Sacrobosco:] Now the line dividing the Zodiac around its circuit, in such a way that on one side of itself it leaves six degrees and on the other side another six, is called the Ecliptic line: because, when the Sun and Moon are directly beneath it, an eclipse of the Sun or of the Moon occurs. Of the Sun — as when there is a new moon and the Moon is interposed exactly between our sight and the solar body; of the Moon — as at full moon, when the Sun is diametrically opposite the Moon. Hence an eclipse of the Moon is nothing other than the interposition of the earth between the body of the Sun and the Moon.

COMMENTARY.

He explains in this place what the Ecliptic line is, saying that, since the Zodiac has 12 degrees in latitude, if a line is understood to cleave the whole circuit of the Zodiac through the middle of these 12 degrees, in such a way that six degrees are left on one side and as many on the other, that line will be called the Ecliptic, for the reason that, when the Moon is conjoined with the Sun while lying exactly beneath this line, an eclipse of the Sun occurs; and when it is opposed to the Sun across a diameter, lying on the same line, an eclipse of the Moon happens. Here too he declares in passing what an eclipse of the Moon is. All these things are clear in the text. But we shall say more about the eclipse both of the Sun and of the Moon in chapter 4. [Margin: What the Ecliptic line is, and why it is so called.] [Margin: What an eclipse of the Moon is.]

This Ecliptic line is called — since among approved Authorities it is used without qualification for the Zodiac, with no account taken of the latitude of the Zodiac — the "Way of the Sun" (Via Solis), because the Sun always travels beneath it by its own motion. For the same reason it is called the orbit of the Sun, the Solar Path, the Place of the Sun, the Plane of the Sun, the circle of the Sun, the Ecliptic place; and in Ptolemy the "circle through the middle of the living creatures" (i.e. of the zodiacal animals), the "circle of the signs"; and it is customarily called by various writers by other names of this kind. [Margin: The various names of the Ecliptic.]

The Ecliptic line is drawn in the heaven in this way. Let a straight line be conceived from the center of the earth, or of the whole world,

[Margin: How the ecliptic is conceived as described in the heavens.]

goes out from that point and passes through the center of the Sun's body all the way to the primum mobile. For from the Sun's annual motion from west to east a circle is described, whose circumference, lying in the primum mobile, is called the ecliptic line. For the Sun by its own motion always recedes from the equator in the same way and within the same limits, as we shall shortly explain. And if throughout the whole circuit of the zodiac six degrees are added on either side of this line — or, according to some, eight degrees — the entire circle of the zodiac will be constituted.

The Sun indeed always runs beneath the ecliptic, but all the other planets decline either toward the north or toward the south; and sometimes they too are beneath the ecliptic.

COMMENTARY

[Margin: The Sun always moves beneath the ecliptic, but the other planets do not.]

Here he teaches how the Sun and the other planets stand with respect to the ecliptic line already mentioned. He asserts that the Sun runs perpetually beneath the ecliptic, declining to neither side, whereas all the other planets deviate from it, now toward the north, now toward the south — and sometimes (namely when they are passing from north to south, or from south to north) they lie on the ecliptic itself.

[Margin: How it was discovered that the Sun always moves beneath the ecliptic, while the other planets do not.]

For astronomers have observed and noted that the Sun, in any given clime, rises and sets each year at the same point of the horizon whenever it stands in the same sign and degree of the zodiac — for instance in the first degree of ♋ [Cancer]. This can easily be observed from the shadow of some stylus fixed in a wall that faces the rising or the setting Sun. Likewise at midday they have observed that its meridian shadow is perpetually the same at fixed times of the year: at the summer solstice it has the same length every year, and so too at each equinox, and at the winter solstice. Thus at one summer solstice the meridian shadow has never been seen longer than at another summer solstice, nor at one equinox longer than at another, nor at one winter solstice longer than at another; and the same must be said of all the other times of the year, or points of the zodiac. By like reasoning astronomers have established that the Sun, when it

declines most from the equator — namely when it stands at the beginning of ♋ [Cancer] or ♑ [Capricorn] — is removed from it by a constant interval every year; and they observed the same when it stands at any other point of the zodiac. They therefore necessarily concluded that the Sun always keeps the same path or track by which it is carried from west to east by its own motion; and this track they called the ecliptic line, or the solar path, as has been said.

Hence it comes about that all affirm with one voice that the Sun always moves on the ecliptic line, so that its center never deviates from it either to the left or to the right — since its path is constant and always behaves in the same way. This line they named "ecliptic" because of the eclipses that occur beneath it. In all the other planets they have found the contrary. For the Moon, for example, at different times, while standing in the same degree of the zodiac, is not always seen to rise and set at the same point of the horizon, nor to cast a meridian shadow of the same length, nor to be removed from the equator by an equal amount, but now to stand farther from it and now nearer. The same they observed in the remaining five planets. They therefore rightly concluded that all the planets, the Sun alone excepted, wander here and there from the ecliptic, and do not always advance from west to east by the same road. Thus we see the Moon sometimes, when it stands at the beginning of ♋ [Cancer], recede from the equator by nearly 28 degrees, and sometimes by about 18 degrees. And so its meridian shadow must necessarily vary. The same has been observed at all the other points of the zodiac, not only in the Moon but also in the other planets. For all of them tend from west to east, not always along the ecliptic, but they wander now toward the north, now toward the south — that is, toward the meridian — with a variation that is wonderful, yet constant, and peculiar and proper to each.

[Margin: Which part of the zodiac is boreal and which austral; likewise which signs are boreal and which austral.]

The part of the zodiac that declines from the equator toward the north is called northern, or boreal, or arctic; and those signs that lie from the beginning of ♈ [Aries] to the end of ♍ [Virgo] are called northern or boreal signs. But the other part of the zodiac, which declines from the equator toward the south, is called southern, or austral, or antarctic; and the six signs that lie from the beginning of ♎ [Libra] to the end of ♓ [Pisces] are called southern or austral.

COMMENTARY

[Margin: When planets are boreal and when austral.]

Since in the sixth office of the equator we said that the whole heaven is divided by the equator into two hemispheres — the one that inclines toward the arctic pole being called northern, boreal, or arctic, and the other, looking toward the opposite pole, being called southern or austral — and since again one half of the zodiac declines from the equator into the northern hemisphere while the other declines into the southern, it follows that the former half is likewise called northern and the latter southern, and that the signs comprised in each half receive the same names, as the author here plainly explains. Therefore, since the first six signs — namely Aries, Taurus, Gemini, Cancer, Leo, and Virgo — are northern, and the latter six — namely Libra, Scorpio, Sagittarius, Capricorn, Aquarius, and Pisces — are southern, it comes about that planets running through the first six are called northern, while those dwelling in the latter six are called southern.

[Margin: First sense of "sign."]

But when it is said that the Sun is "in" Aries, or in some other sign, it must be understood that this preposition "in" is taken for "under," according to the sense in which we are now taking the word "sign."

COMMENTARY

[Margin: First sense of the zodiac.]

Being about to explain in what manner the Sun and the other planets — indeed even the fixed stars — are said to be in some sign, he introduces four senses of "sign" that are in use among astronomers. In the first sense a "sign" is a twelfth part of the surface of the zodiac — namely a quadrilateral 30 degrees in length and 12 degrees in breadth; and it is in this sense that we have hitherto spoken of a sign. This first sense of "sign" takes its origin from the first sense of "zodiac," in which the zodiac is taken for...

Diagram. A small woodcut set at the foot of the right-hand column, showing a fan- or sector-shaped figure containing several small star symbols, with a radiant sun-face at its lower apex — illustrating the wedge-like "sign" whose vertex lies toward the center. No letter-labels are legibly present on the figure.

that band or zone in the primum mobile, containing 360 degrees in its whole circuit, and 12 degrees in breadth. For if the zodiac in this sense be cut into 12 equal parts, there will be had the 12 signs in the first sense. And because in this way a sign is not in the orbs of the planets, nor even in the sphere of the fixed stars, but only in the primum mobile, the author teaches that when astronomers

say the Sun, or any other planet, is in such a sign — for example, in Aries — the preposition "in" is taken for "under"; so that the sense is: the Sun, or any other planet, is under the sign ♈ [Aries], in such a way that a straight line drawn from the center of the world through the center of the Sun, or of another planet, terminates in that sign in which the Sun or planet is said to be.

[Margin: When the Sun is to be understood as being in any sign in the first sense.]

In another signification, a "sign" is called a quadrilateral pyramid whose base is that surface which we have called the sign, and whose vertex is at the center of the earth. And according to this, properly speaking, we can say that the planets are in the signs.

COMMENTARY

[Margin: Second sense of "sign."]

In the second manner a "sign" is taken for a quadrilateral pyramid whose base is the sign in the first sense, and whose vertex is the center of the whole universe. This sign in the second sense likewise had its origin from the second sense of "zodiac," namely when astronomers take the zodiac not for that band or surface, but for the body or solid contained by the zodiac in the first sense and by two concave conical surfaces, each having its vertex at the center of the world, while their bases are two lesser circles equidistant from the ecliptic line and receding from it by 6 degrees. For in this way the zodiac will be divided into 12 quadrilateral pyramids, which constitute the 12 signs in the second sense. According to this sense of "sign" the author says it can properly be said that the planets are in the signs; for they will always be contained within one of the said 12 pyramids.

[Margin: Second sense of the zodiac.]

[Margin: The Sun is properly in the signs in the second sense.]

Diagram. A woodcut of a triangular wedge (quadrilateral pyramid) with its apex at the bottom, containing several small star symbols, a key-shaped object, and a crescent moon within the wedge — illustrating the "sign" as a pyramid whose base is the zodiacal surface above and whose vertex lies at the center of the earth below. No letter-labels are legibly present.

In the third manner a "sign" is spoken of so that there are understood six circles passing through the poles of the zodiac and through the beginnings of the 12 signs. These six circles divide the whole surface of the sphere into 12 parts, broad in the

middle but narrower toward the poles of the zodiac; and each such part is called a sign, and has its special name from the name of that sign which is intercepted between its two lines. And according to this sense, the stars that are near the poles, outside the zodiac, are said to be in the signs.

COMMENTARY

[Margin: Third sense of "sign."]

In the third sense a sign is also a certain surface, as in the first. For if there be described six great circles in the sphere passing through each pole of the zodiac and through the beginnings of the 12 signs in the first sense — so that the first passes through the beginning of ♈ [Aries] and ♎ [Libra]; the second through the beginning of ♉ [Taurus] and ♏ [Scorpio]; the third through the beginning of ♊ [Gemini] and ♐ [Sagittarius];

Diagram. A large circular celestial planisphere (woodcut). Great circles radiate from the center (the pole of the zodiac) dividing the disk into segments; the field is filled with zodiacal constellation figures and numerous small stars, illustrating the division of the whole surface of the heaven into 12 signs by the six circles through the poles of the zodiac. Individual constellation and point labels do not resolve legibly on the scan. [— peripheral labels not resolvable.]

the fourth through the beginning of ♋ [Cancer] and ♑ [Capricorn]; the fifth through the beginning of ♌ [Leo] and ♒ [Aquarius]; the sixth, finally, through the beginning of ♍ [Virgo] and ♓ [Pisces] — the whole surface of the heaven will be divided into 12 equal parts from one pole of the zodiac to the other, broader indeed in the middle, where the zodiac is, but narrower at the ends, namely near the poles of the zodiac, where all six of the aforesaid circles mutually intersect. These parts are called signs in the third sense, and are named after those signs of the first sense which are enclosed by the said circles, or which are found within the signs of the third sense; as the part in which the sign ♈ [Aries] of the first sense exists is called the sign ♈ [Aries], and so of the rest. These signs in the third sense also arise from the division of the zodiac in the third sense, namely when it is taken for the whole surface of the heaven, whether convex or concave. In this third manner all the stars, and all the points of the heaven, even those near the poles of the zodiac — the poles of the zodiac alone excepted, which can be referred equally well to all the signs — are said to be in some sign, that is, under some sign, even if the point of the heaven is not in the primum mobile.

[Margin: Third sense of the zodiac.]

[Margin: All points of the heaven are in some sign in the third sense.]

Now let a certain body be understood whose base is a sign, according to the sense in which we have just now last taken "sign," and whose apex is upon the axis of the zodiac. Such a body, then, in the fourth signification is called a sign; and according to this sense the whole world is divided into twelve equal parts, which are called signs. And thus whatever is in the world is in some sign.

[Margin: Fourth sense of "sign."]

COMMENTARY

Diagram. A half-circle (semicircular) woodcut set at the head of the left-hand column, containing small star symbols and a crescent moon — illustrating the "sign" of the fourth sense as a solid body bounded by two semicircular plane surfaces, with its base at the zodiacal surface and its apex on the axis of the zodiac. No letter-labels are legibly present.

[Margin: Fourth sense of the zodiac.]

In the fourth manner a "sign" is again taken for a certain body, as in the third sense. For if there be understood some body whose base is a sign in the third signification, and whose sides are the plane surfaces of two semicircles whose circumferences enclose the same sign, in such a way that the apex of the body lies on the axis of the zodiac, there will be had a sign in the fourth sense. For in the fourth sense the zodiac is taken for the whole solidity of the world. Hence, if the whole world be divided into 12 equal parts by circles that pass through the poles of the zodiac and the beginnings of the signs and mutually cut one another on the axis of the zodiac, there will result 12 signs in the fourth sense. Therefore, according to this sense of "sign," there will be nothing in the entire world that is not said to be in some sign — since these 12 signs constitute the whole universe as integral parts, so that there is no particle, however small, in the world that is found outside one of the said 12 signs.

[Margin: All things that are in the world are in some sign in the fourth sense.]

Some astronomers add two more senses to the four senses of "sign" and "zodiac," so that in a fifth manner the zodiac is called the ecliptic line alone — which is, as we have said, the circumference of the circle that the Sun describes by its own annual motion from west to east. Hence, if this circumference of the ecliptic be cut into 12 equal parts, there will be produced 12 signs in the fifth sense; so that a sign in the fifth signification is nothing other than a twelfth part of the ecliptic

line. Then in a sixth manner the zodiac is taken for the plane circular surface enclosed by the circumference of the ecliptic. Therefore, if from the signs in the fifth sense straight lines be dropped to the center of the world, the whole ecliptic circle will be divided into 12 sectors, or equal parts, which will give the signs in the sixth sense. And so a sign in the sixth signification is a sector of the ecliptic circle, being a twelfth part of that circle.

[Margin: Fifth sense of the zodiac and the sign.]

[Margin: Sixth sense of the zodiac and the sign.]

[Margin: How astronomers say that all things are in some sign.]

This so varied and manifold signification, or sense, of "zodiac" and "sign" was devised by the practitioners so that all things whatsoever that are in the world might in some way conveniently be said to be in some sign. Yet among the more expert astronomers the sign in the fifth sense suffices for all things to be said to be in some sign. For if through the poles of the zodiac and through any star or point in the world the surface of a great circle be understood to pass, that star or point will be said to be in that sign to which the circumference of the said circle reaches on the ecliptic line — as we shall teach more clearly when we treat of the latitude of the stars in the offices of the ecliptic line.

THE OFFICES OF THE ZODIAC, OR OF THE ECLIPTIC.

I.

[Margin: The ecliptic is the measure of the motion of the heaven from west to east.]

It is the rule and measure of the second motion, which is from west to east, just as the equator is the measure of the first motion, which is from east to west. For just as by the equinoctial circle we know how great is the diurnal motion of the stars, so too by the zodiac we learn in how much time the fixed stars and the planets, carried along the obliquity of the zodiac, complete their own proper motions from west to east. Likewise, just as the equator is the greatest circle described by the first, or diurnal, motion, and is the girdle dividing the first motion itself into equal halves and equally removed in all its parts from the two poles of the world, so also the zodiac is the greatest circle described by the second motion; and it is

the girdle of the second motion, dividing it in two and equally distant from the poles of the zodiac in all its parts.

II.

[Margin: The ecliptic is the cause of eclipses.]

Beneath the ecliptic occur the eclipses of the luminaries, namely of the Sun and of the Moon — from which it is called "ecliptic": so that whenever the Moon in conjunction with the Sun stands beneath the ecliptic, or at least near the ecliptic, an eclipse of the Sun occurs; but in opposition to the Sun, an eclipse of the Moon.

III.

[Margin: The ecliptic is the cause of the inequality of the days and of the changing of the seasons.]

The ecliptic, by its obliquity, is the cause of the inequality of the days and nights — indeed the origin of all the changing of the seasons of the year; whence, according to the philosophers, it is also the cause of generation and corruption.

IV.

[Margin: The ecliptic divides the heaven into a boreal and an austral hemisphere.]

It divides the whole heaven into two hemispheres, the one of which — that which lies between the ecliptic and the northern ecliptic pole — is called northern, while the other, placed between the ecliptic and the southern ecliptic pole, is named southern. For although, absolutely speaking, that part of the heaven placed between the arctic pole and the equator is called northern, and the rest southern — as we said above in the exposition of the offices of the equator — nevertheless it pleased the astronomers that the same heaven should also be divided by the ecliptic into a northern and a southern hemisphere, perhaps on account of the second motion from west to east. For thus it will come about that, just as one and the same star, moved by the primum mobile with the diurnal motion, is always in the same way northern or southern — so that on account of that motion it neither approaches the equator more nor recedes from it — so also the same star, moved from west to east by the second motion, is, in this latter manner, always northern or southern by the same reasoning. For on account of this motion no star whatever will ever be nearer to the ecliptic, or farther from it. Hence it has come about that astronomers sometimes divide the stars into northern and southern with regard to the ecliptic, and not to the equator, as is

plainly seen from the table of the fixed stars which we described in chapter 1. Hence also it comes about that planets existing in the sign ♋ [Cancer], which is the most northern, and in the other northern signs, are sometimes said in the tables of the ephemerides to be southern, because they deviate from the ecliptic toward the south, although they decline from the equator toward the north. Similarly, planets existing in the sign ♏ [Capricorn], which is the most southern, and also in the other southern signs, are...

[Margin: For what reason planets existing in boreal signs can be called austral, and boreal when they exist in austral signs.]

CAPVT SECVNDVM — On the Circles of the Sphere (continued)

On the Zodiac / Ecliptic — the Functions (Officia) of the Ecliptic (continued)

(continuation of the fourth function, from the preceding page)

are called Northern; namely because they run out northward from the Ecliptic, even though they bend southward away from the Equator, as is explained in the *Theorica of the Planets* [*Theorica Planetarum*]. On this reasoning the Sun can never be called Northern or Southern, because it never leaves the ecliptic path. The same must be said of the fixed stars and of the other planets, insofar as they may lie exactly under the Ecliptic.

Besides the two senses already described, astronomers understand the "Northern part" and the "Southern part" in yet another way. For the vertical circle properly so called — the one that passes through the vertex of the head, that is, through the Zenith of any given place, and through the common intersections of the Equator and the Horizon, and that stands perpendicular to the Horizon — likewise divides the whole heaven into two hemispheres. The one that extends from this vertical circle toward the North is called Septentrional; the other, which slopes toward the South, is called Meridional. It is in this sense that Ptolemy [Ptolemy] understands the Northern and Southern part in his little book *On the Analemma*, and all the astronomers who hand down the construction of sundials follow him. For this third sense of "Northern part" and "Southern part" is the most convenient for laying out sundials. And so by three circles — namely the Equator, the Zodiac, and the vertical circle properly so called — the sphere is

divided by astronomers, in three distinct ways, into a Boreal and an Austral hemisphere. I wished to alert the reader to this here, so that he may attentively consider, whenever writers make mention of these parts of the heaven, in which sense they mean the Septentrional or Meridional hemisphere. From this third sense it follows that the Sun, as it runs through the Boreal signs near its rising and setting, is called Septentrional, but for the rest of the day, before and after noon, is called Meridional. This, however, must be understood of a northern dwelling-place, where the pole's altitude is greater than $23\frac{1}{2}^{\circ}$. For where it is less, the Sun, when it is near Cancer [♋], will be Boreal — that is, Septentrional — the whole day long.

[Margin: The vertical circle properly so called cuts the heaven into a Boreal and an Austral hemisphere.]

[Margin: The heaven is divided into a Boreal and an Austral hemisphere in three ways: namely by the Equator, the Ecliptic, and the vertical circle.]

[Margin: How the Sun on the same day is both Boreal and Austral.]

V.

The Ecliptic is the boundary from which the latitudes of all the stars and points of the heaven are reckoned, just as the Equator bounds all the declinations of the heavenly bodies. For the latitude of stars differs from their declination in this: latitude is the distance from the Ecliptic, whereas declination is the distance from the Equator — although some writers, among whom is our own Author [Sacrobosco], occasionally call both distances "declination" without any distinction, though not without qualification. For they call latitude a "declination from the Ecliptic," and declination properly so called a "declination from the Equator." But it is better, with the other astronomers, to assign to each of these distances its own distinctive name.

[Margin: The Ecliptic is the boundary from which the latitudes of the heavenly bodies are computed.]

[Margin: What the latitude of a star is, and how it differs from declination.]

Each distance, moreover, is twofold, according as a given star recedes from the Ecliptic, or from the Equator, toward the North or toward the South. For if a star inclines from the Ecliptic toward the North, it is said to have northern latitude; but if it bends toward the South, it is declared to have southern latitude. In the same way, a star receding from the Equator toward the North has northern or

boreal declination; while one receding toward the south obtains southern or meridional declination.

[Margin: The northern and southern latitude and declination of stars, and by what method each is measured.]

Astronomers measure the latitude of any star by a great circle drawn through the poles of the Zodiac and through the center of the star; and this circle is commonly called the **circle of latitude**. Hence the latitude of a star is defined by astronomers as follows: the latitude of a star is the arc of the great circle passing through the poles of the Zodiac and through the center of the star, intercepted between the Ecliptic and the true place of the star. The degree of the Ecliptic through which the circle of latitude passes is called the degree of the star's longitude; for it is shown that this degree is intercepted between it and the beginning of Aries [γ], from which the longitude of any star must be taken, proceeding according to the succession of the signs — so that the longitude of a star is nothing other than the arc of the Ecliptic reckoned from the beginning of Aries up to the star's circle of latitude, following the order of the signs.

[Margin: The circle of latitude.]

[Margin: What the longitude of a star is.]

The declination of any star, on the other hand, is measured by a great circle passing through the poles of the world and through the center of the star; and this circle is customarily called the **circle of declination**. Accordingly, declination has come to be defined by astronomers as follows: the declination of a star, or of a degree of the Ecliptic, is the arc of the great circle passing through the poles of the world and through the center of the star — or through the proposed degree of the Ecliptic as it lies on that circle — intercepted between the Equator and the star, or the degree of the Ecliptic. Both latitude and declination can be at most 90° ; for no point of the heaven can recede farther from the Ecliptic, or from the Equator, than by a quadrant. Hence it comes about that the poles of the Zodiac have the greatest latitude, and the poles of the world the greatest declination; since the poles of any great circle are separated from its circumference by a quadrant, as we have demonstrated in the corollary to Proposition 16, Book I of [our commentary on] Theodosius [Theodosius].

[Margin: The circle of declination.]

[Margin: The various states of the stars with respect to latitude and declination.]

From what we have said about the latitude and declination of stars, it is gathered: **first**, that stars, or planets, sometimes have declination but no latitude — such as the stars that are found outside the Equator but are placed precisely under the Ecliptic, as the Sun is at all times except the two Equinoxes. **Secondly**, that stars sometimes have latitude but no declination, as are all the stars which, placed outside the Ecliptic, are set directly under the Equator. **Thirdly**, that stars sometimes lack both latitude and declination, as is the Sun at the time of the Equinoxes. **Fourthly**, that some stars have northern latitude and also northern declination; such as the stars which deviate from both the Ecliptic and the Equator toward the North. **Fifthly**, that some stars have both southern latitude and southern declination; such as the stars which recede toward the south from both the Ecliptic and the Equator. **Sixthly**, that some stars have northern latitude and southern declination; as are the stars placed between the Equator and that half of the Ecliptic which slopes to the south. **Seventhly**, that some stars have southern latitude and northern declination; such as the stars comprised between the Equator and the boreal half of the Zodiac.

In passing, it must also be noted here that those points of the Ecliptic which are equally distant from the Equinoctial points — where, that is, the Equator and the Ecliptic intersect one another — have equal declinations; that a point farther from either Equinoctial point has a greater declination; and finally, that the most remote point, namely the midpoint between the Equinoctial points, such as the beginning of Cancer [♋] and of Capricorn [♐], has the greatest declination. From this it follows that in the Ecliptic there are two non-declining points, namely the Equinoctial points themselves, and that everywhere four points decline equally from the Equator — two northern and two southern —

[Margin: Which points of the Ecliptic have equal declinations, and which greater or lesser.]

since there are always found four points equally distant from the two Equinoctial points. In the same way, points of the Ecliptic that have equal declinations will be equally distant from the Equinoctial points; a point that has a greater declination will be farther from the Equinoctial point; and the point that, finally, has the greatest declination will be farthest from the Equinoctial point. All these things can easily be demonstrated from the *Elements of Spherics* of Theodosius and from spherical triangles; and we have demonstrated them in Book I of [our commentary on] the *Astrolabe*, Lemma 49.

VI.

[Margin: The Ecliptic reveals the true places of the stars in the Zodiac, and what the true place of any star in the Zodiac is.]

The Ecliptic reveals the true places of the stars and planets in the Zodiac, so that, with the help of the Ecliptic, it is not difficult to know in which sign, and in which degree of the sign, any star or planet is located. For any heavenly body is said to be in that degree through which the body's circle of latitude passes; so that if it passes, for example, through 10° of Leo [♌], the body is said to be in 10° of Leo, and so on. From this it follows that those stars which lie in the same semicircle of latitude, intercepted between the two poles of the Zodiac, exist in one and the same degree of the Zodiac, even though one is at the extreme north and the other at the extreme south. Only to the poles of the Zodiac can no proper places in the Zodiac be assigned, since there is no greater reason why they should be said to be in this sign rather than in that; rather, they can be referred equally well to all.

VII.

[Margin: The Ecliptic indicates the true motions of the stars. What the true motion, and the line of true motion, of a star is.]

By the office of the Ecliptic astronomers investigate the true motions of the planets and of all the fixed stars. For the true motion of any heavenly body is the arc of the Ecliptic reckoned from the beginning of Aries [♈] up to the line of true motion, following the order of the signs, as is explained in the Theorica [of the Planets]. And the line of true motion is the one drawn from the center of the earth, through the center of the star, to the Ecliptic — or, if the body is not on the Ecliptic, the line extended up to the star's circle of latitude.

DE DVOBVS COLVRIS. [On the Two Colures]

There are, moreover, two other great circles in the sphere, which are called Colures; their function is to distinguish the Solstices and the Equinoxes. The word "Colure" comes from the Greek κῶλον [Greek: κῶλον (kōlon, "limb, member")], meaning "limb," and from [Greek: (?) — printed glyphs unresolved on the scan; the Latin gloss "bos silvester" indicates the standard form οὔρος (ouros, "wild ox")], meaning "wild ox." For just as the erect tail of a wild ox — which is one of its limbs — makes a semicircle and not a complete circle, so the Colure always appears to us incomplete, because only one half of it is visible while the other is hidden from us.

COMMENTARIVS.

In the third place, after the Zodiac, the author treats of the two Colures — because these two circles are intrinsic and mobile, whereas the other two, namely the Meridian and the Horizon, are extrinsic and immobile; and likewise because the two Colures are posited in the heaven in and of themselves, absolutely, whereas the other two are established in the heaven with regard to one's dwelling-place on earth. And those two [the Colures] remain always the same in every clime, whereas these [the Meridian and Horizon] necessarily change whenever the clime changes. Now the two Colures are great circles in the sphere, drawn through the poles of the world and through the four Cardinal points of the Zodiac, intersecting each other at spherical right angles at the poles themselves, and revolving together with the sphere. Their function, he says, is to distinguish the Solstices and Equinoxes — that is, to indicate at which points of the Ecliptic the Solstices and Equinoxes occur, as will be said shortly.

[Margin: What the Colures are.]

He then adduces the etymology of this name — namely, why these two circles are called Colures — which is utterly ridiculous and of no weight. For the proper and true etymology is that these circles are called "Colures" from the Greek word [Greek: κόλος (?) — printed glyphs faint on the scan (kolos, "docked, curtailed," i.e. mutilated and incomplete)], which means "docked" and "incomplete." For to those living in an oblique sphere these circles always appear docked and incomplete, so that all their parts can be seen neither at one and the same time, nor successively at different times.

[Margin: The true etymology of the Colures.]

For their arcs, lying opposite one another on either side near the poles of the world, are so disposed in any oblique sphere that those which stand above the Horizon near the elevated pole are perpetually presented to the eyes and are never removed or withdrawn from sight, while those opposite to them, near the pole depressed beneath the Horizon, are never brought into view but lie perpetually hidden. So much so, that the more oblique the sphere is, the greater are the arcs of these circles that are perpetually visible and perpetually hidden — whereas all the other movable circles in the heaven are so arranged that we either always see them whole and entire above the Horizon, as are the smaller circles near the visible pole, or else are never able to behold them at all, such as the smaller circles near the hidden pole, opposite to the former;

(page continues)

and, by the motion of the prime mover, there will likewise be no circle that is not seen in its entirety, successively, above the Horizon in the space of 24 hours. Hence, if those who dwell in the right sphere had assigned names to the celestial circles, they would have called none of them "Colures."

The solstitial Colure, therefore, in distinguishing the Solstices, passes through the poles of the world and through the poles of the Zodiac, and through the greatest declinations of the Sun — that is, through the first degrees of Cancer and Capricorn. Hence the first point of Cancer, where this Colure intersects the Zodiac, is called the point of the Summer Solstice; because when the Sun is in it, it is the Summer Solstice, and the Sun cannot approach any nearer to the Zenith. Now the Zenith is the point in the firmament placed directly above our heads. But the arc of the Colure intercepted between the point of the Summer Solstice and the equinoctial [point] is called the greatest declination of the Sun. And it is, according to Ptolemy [Ptolemy], 23 degrees and 51 minutes; but according to Almeon [al-Ma'mūn], 23 degrees and 33 minutes.

[Margin: The solstitial Colure.]

[Margin: What the Zenith of the head is.]

[Margin: The greatest declination of the Sun.]

Similarly, the first point of Capricorn, where the same Colure intersects the Zodiac on the other side, and the equinoctial [circle], is called the point of the Winter Solstice; and the arc of the Colure intercepted between that point and the equinoctial [circle] is called the other greatest declination of the Sun, and it is equal to the former...

COMMENTARIUS.

We said above that there are two Colures, the one of the solstices, the other of the equinoxes — which the author too intimated when he said that the function of these circles is to distinguish the Solstices and the Equinoxes. He therefore now explains each separately, beginning with the Colure of the solstices. He says, then, that this Colure distinguishes the solstices; that is, that the Colure of the solstices is the one described through the poles of the world and through the poles of the Zodiac, as well as through the greatest declinations of the Sun. Here he declares that the beginnings of Cancer [♋] and of Capricorn [♏] are the solstitial points — the former the point of the summer solstice, the latter of the winter solstice — since the Sun, when it is at the first point of Cancer, produces the summer solstice and cannot approach any nearer to the Zenith, that is, to the point of the sky set

above our head; whereas when it is at the beginning of Capricorn, it produces the winter solstice and cannot recede any farther from us. Likewise he declares that the two arcs of the solstitial Colure, intercepted between the said solstitial points and the Equator, are called the greatest declinations of the Sun, which are equal to one another, as we shall demonstrate below. But we shall say more about this greatest declination of the Sun, and about the solstice, in [the discussion of] the functions of these circles.

[Margin: What the point of the summer and of the winter solstice is.]

The other Colure passes through the poles of the world and through the first points of Aries and Libra, where the two Equinoxes are; whence it is called the Colure that distinguishes the Equinoxes. And these two Colures intersect each other over the poles of the world at spherical right angles. The signs of the solstices and of the equinoxes are shown by these verses:

These two make the solstice: Cancer, Capricorn. But Aries and Libra make the nights equal to the days.

[Margin: The Colure of the Equinoxes.]

COMMENTARIVS.

He teaches that the other Colure — the one that passes through the poles of the world and through the beginnings of Aries [γ] and Libra [♎] — is called the Colure of the Equinoxes, or the one that distinguishes the equinoxes; because the Sun, when it is at these points, makes the day equal to the night. And these two Colures, he says, intersect each other at the poles of the world at spherical right angles. Now a spherical angle is the one formed on the convex surface of the sphere by the intersection of the circumferences of two great circles. Hence, if one circle cuts another so that two equal angles are formed on either side, each is called a spherical right angle; but if unequal angles are formed, the greater is called a spherical obtuse angle, and the smaller a spherical acute angle. That the Colures intersect each other at the poles at right angles is evident from Proposition 15, Book I of Theodosius [Theodosius], and from the fifth property of the circles of the sphere cited above, since each passes through the poles of the other. For the beginnings of Aries and Libra — at which, of course, the Colure of the Equinoxes and the Equator intersect each other — are the poles of the solstitial Colure; while the points at which the solstitial Colure and the Equator intersect each other are the poles of the equinoctial Colure, as is clear from the definition of a pole.

[Margin: What a spherical angle is.]

OFFICIA VTRIVSQVE COLVRI. [The Functions of Each Colure]

I.

The two Colures point out four principal points in the Zodiac, which are called Cardinal, and at which, from the motion of the Sun, the greatest seasonal changes usually occur — namely Spring, Summer, Autumn, and Winter; such are the beginnings of Aries [γ], Cancer [♋], Libra [♎], and Capricorn [♏]. Hence the whole Zodiac too is cut by these same Colures, at the said four points, into four Quadrants corresponding to those four seasons of the year. Indeed the Equator as well is divided by them into four Quadrants — which is of the greatest use, as will be clear from Chapter 3, in determining the rising and setting of the signs. In the same way these same Colures divide all the parallel circles — that is, those equidistant from the Equator — into four Quadrants, as can easily be demonstrated from the spherical *Elements* of Theodosius.

[Margin: The two Colures indicate the four Cardinal points, and divide the Zodiac, the Equator, and all the parallels into four quadrants.]

II.

The solstitial Colure, which of course [divides] the Equator and all its parallels, and the Zodiac, or the Eclip...

cuts the ecliptic at right angles, by proposition 15 of Theodosius, book 1 [*Sphaerica* I.15]. Since it passes through the poles of these circles, it marks out two solstitial points, namely the first points of Cancer (♋) and Capricorn (♏).

[Margin: Why the first points of Cancer and Capricorn are called solstitial.]

These are not called solstitial because the Sun, when carried to them, halts and lingers there for a while — that is false, for the Sun never comes to rest in the Zodiac nor interrupts its course, as daily experience shows. Rather, they are so called because, while the Sun is near those points, for several days neither do the noon shadows change but stay the same length (as far as the senses can tell), nor are the lengths of day and night appreciably increased or diminished, so that the Sun seems in a way to stand still at those points. Or again, because when the Sun has reached one of them, it does not advance further but checks its course and turns back once more toward the opposite pole of the world; thus at those points the Sun, as regards its approach to and recession from one pole toward the other, seems in a way to stand still, since it is turning toward the opposite quarter of the

heavens. From this turning of the Sun the Greeks call these same points τροπικά [Greek: *tropika*, "turning-points," whence "tropics"].

[Margin: Why the first point of Cancer and of Capricorn are also called tropical.]

[Margin: What the solstice is.]

A solstice, then, will be nothing other than the end of the Sun's recession from the Equator and the beginning of its approach toward it. There are two solstices: the summer solstice, which occurs when the Sun is at the beginning of Cancer (♋) — speaking of the northern hemisphere, when of course it is summer; and the winter solstice, which happens when the Sun tarries at the beginning of Capricorn (♏), when of course winter is at hand. At the former the Sun stands nearest to the top of our head; at the latter it is farthest from it. Some also call the former the "solstice" absolutely and without qualification, but the latter the "midwinter" [Bruma]. So Ovid too named the winter solstice, in book 1 of the *Fasti*, when he said:

*Bruma noui prima est, veterisque nouissima Solis: Principium capiunt
Phœbus, & annus idem.*

[Midwinter is the first day of the new Sun and the last of the old: Phoebus and the year take their beginning together. — Ovid, *Fasti* I.]

III. The same solstitial colure divides the Zodiac, or ecliptic, into two semicircles. The one that runs from the beginning of Capricorn (♏), through Aries (♈), to the end of Gemini (♊) is called the Ascending semicircle; the other, running from the beginning of Cancer (♋), through Libra (♎), to the end of Sagittarius (♐), is called the Descending — reckoning, of course, from the standpoint of a northern dwelling, as we explained above when we discussed the order of the signs.

[Margin: The solstitial colure cuts the ecliptic into an ascending semicircle and a descending semicircle.]

IIII. The same circle sorts the twelve signs of the Zodiac into two classes. The first class contains six signs — Cancer (♋), Leo (♌), Virgo, Libra, Scorpio, Sagittarius [only the first two sign-glyphs, ♋ and ♌, are legible on the scan; the remaining four follow from the "six signs" count and the established zodiacal order] — which rise directly in the northern oblique sphere. The second class comprises the remaining six — Capricorn, Aquarius, Pisces, Aries, Taurus, Gemini [sign-glyphs not individually resolved on the scan] — which rise obliquely, as we shall set out in chapter 3.

[Margin: The solstitial colure divides the Zodiac into six signs that rise directly in the oblique sphere and six that rise obliquely.]

V. [?] Furthermore, this circle, in marking off the solstices, measures the Sun's maximum declinations. For when the Sun reaches this circle by its own motion from west to east — whether on the northern side, where the beginning of Cancer (♋) lies, or on the southern side, where the beginning of Capricorn (♐) lies — it declines farthest from the Equator. Hence at the aforesaid points it is said to have its maximum declination, since beyond them it no longer runs off toward the north or the south but turns back toward the Equator. This maximum declination is fixed by the solstitial colure: the Sun's maximum declination is exactly as great as the arc of the solstitial colure intercepted between the Equator and the point of either solstice.

[Margin: The solstitial circle measures the Sun's maximum declinations.]

This maximum declination of the Sun has been found to differ among astronomers at different periods, on account of the motion of libration of the tenth sphere, by which all the lower spheres are moved, as was said in chapter 1. Thus:

- **Ptolemy** found the Sun's maximum declination to comprise $23^{\circ} 51' 20''$ — nearly the value our author [Sacrobosco] asserted, following Ptolemy's opinion.
- **al-Battānī** [Mahometes Aratensis] found the same to be $23^{\circ} 35'$.
- **al-Zarqālī** [Arzahel the Spaniard] observed it to be $23^{\circ} 34'$.
- **al-Ma'mūn** [Almeon] found it to be $23^{\circ} 33'$, as the author reported.
- **Profatius the Jew** [Prophatius Iudaeus / Jacob ben Machir] reckoned it at $23^{\circ} 32'$.
- **Regiomontanus** [Ioannes Regiom.] asserted it to be $23^{\circ} 30'$.
- **Domenico Maria Novara** [Dominicus Maria the Italian] said it stood at $23^{\circ} 29'$.
- **Johannes Werner of Nuremberg** assigned it $23^{\circ} 28' 30''$.
- **Nicolaus Copernicus** declared it $23^{\circ} 28' 20''$.
- **Tycho Brahe** the Dane asserted it to be $23^{\circ} 31' 30''$.

[Margin: Various observations of the Sun's maximum declination, and which we think should be adopted.]

Copernicus, moreover, demonstrated that this maximum declination of the Sun has decreased by a regular motion, and will go on decreasing to $23^{\circ} 28'$ and no

further; thereafter it will increase again up to $23^{\circ} 52'$, so that the former is the maximum and the latter the minimum, and the difference between maximum and minimum amounts to 24 minutes.

Among all the aforesaid maxima of the Sun's declination, the common school of astronomers holds to the one that Regiomontanus, the foremost astronomer, observed — namely $23^{\circ} 30'$ — although it is quite probable that it may be only about $23^{\circ} 28'$ and a little more, as Copernicus put it. Nevertheless, so as not to seem to depart from the common view, in what follows we shall adopt $23^{\circ} 30'$, chiefly for this reason: that 2 minutes make no notable difference, and that 30 minutes are exactly half of one degree.

[Margin: By what method the Sun's maximum declination is to be investigated.]

The method by which astronomers observe the Sun's maximum declination — the principal one among several — is this. Around the summer solstice, that is, around 22 June, let the Sun's meridian altitude be observed with the greatest care until its maximum is found, for at that time the Sun has its greatest declination in summer. Then let the same be done around the winter solstice, until the Sun's least meridian altitude is found, for then the Sun declines farthest from the Equator toward the south. If, then, we subtract this least meridian altitude from that greatest one and halve the remaining degrees, we shall have the Sun's maximum declination on either side of the Equator;

for the maximum northern declination is equal to the maximum southern, as we shall shortly demonstrate — which the author also stated.

[Margin: An example, namely from Vienna in Austria.]

EXAMPLE. At Vienna, Regiomontanus found the Sun's greatest meridian altitude around the summer solstice to be $65^{\circ} 30'$; around the winter solstice he found the Sun's least meridian altitude to be $18^{\circ} 30'$. Subtracting the latter from the former leaves 47° , whose half gives the Sun's maximum declination as $23^{\circ} 30'$. Now, for measuring both meridian altitudes — the maximum and the minimum — the most suitable instrument is a quadrant of very great size, so that even the minutes of degrees can be marked on it, and on which a sighting-line [*linea fiduciae*, the alidade] turns about its center. For if this quadrant is set up in a plane parallel to the horizon, so that one of its sides answers directly to the meridian line and its center faces north, the said meridian altitudes will be found with the greatest ease. You will find the construction of this quadrant in Oronce Fine the Dauphinois [Orontius Delphinus / Finaeus], in the *Sphere* that he wrote.

Once the Sun's maximum declination is known, we shall arrive, by the doctrine of sines, at a knowledge of the declinations of all the points of the ecliptic.

[Margin: By what art the declinations of the points of the ecliptic are computed.]

For — as we demonstrated in the corollary to proposition 1, book 1, of our *Gnomonics* [*Gnomonices*], and elsewhere; likewise Regiomontanus in the *Epitome of the Almagest*, book 1, proposition 18; likewise Geber of Seville [Gebir Hispalensis / Jābir ibn Aflaḥ] in book 2; and Pedro Nunes the Portuguese [Petrus Nonius Lusitanus] in proposition 2 of the second part of *On Twilights* [*De Crepusculis*] — as the whole sine is to the sine of the maximum declination, so is the sine of the arc by which a given point of the ecliptic is distant from either of the equinoctial points to the sine of the declination of that same point.

Accordingly, following the rule of proportions, if the sine of the maximum declination is multiplied into the sine of the arc by which the given point of the ecliptic is distant from either equinoctial point, and the product is divided by the whole sine — which is done by striking off five figures at the right hand from the product, since we here take the whole sine to be 100000 parts — there results a sine whose arc, found from the table of sines, at once yields the declination of the point proposed.

EXAMPLE. Taking the Sun's maximum declination as $23^{\circ} 30'$, suppose we wish to investigate the declination of the 8th degree of Virgo (♍), which is distant 22° from the autumnal equinox. I therefore multiply the sine of the posited maximum declination, namely 39874, into the sine of the given distance — that is, of 22° , namely 37460 — and the number 1,493,680,040 is produced. Striking off five figures from the right side of this, there remains the sine 14936, to which the arc $8^{\circ} 35'$ corresponds in the table of sines. This, then, we shall say is the declination of the 8th degree of Virgo (♍). And so for the rest.

By this art we have computed the following table, in which are contained the declinations of all the degrees of the Zodiac, together with the twelfth-parts of degrees [i.e. in 5-minute steps, one-twelfth of a degree being $5'$]: so that the table is laid out by five minutes of a degree. But since — as we said above, at the end of the fifth function of the Equator — there are always found in the Zodiac four points that have equal declinations, it will be enough to compute the declinations of all the degrees and minutes of a single quadrant; for the points of the other three quadrants will readily be fitted to the parts of this quadrant, as may be seen on a material sphere and as will be plain in the following table.

THERE FOLLOWS A TABLE OF DECLINATIONS. [Sequitur tabula declinationum.]

DECLINATIONS OF THE POINTS OF THE ECLIPTIC FROM THE EQUATOR

[DECLINATIONES PVNCTORVM Eclipticae ab Æquatore.]

[Margin, left side (rotated): Degrees and minutes of the upper six signs (Gradus ac Minuta superiorum sex Signorum).] [Margin, right side (rotated): Degrees and minutes of the lower six signs (Gradus ac Minuta inferiorum sex Signorum).]

Column headings as printed: each data column carries a **top label** (read downward with the left "Signa" argument, 0°→30°) and a **bottom label** (read upward with the right "Signa" argument, 30°→0°). Values are degrees (G) and minutes (M) of declination. This page carries the top portion of the table only (argument 0° 0' through 4° 25'); the table continues onto the following page.

Signa (arg., G° M') — top ↓	♈ / ♈ (G° M')	♉ / ♉ (G° M')	♊ / ♊ (G° M')	Signa (arg., G° M') — bottom ↑
0° 0'	0° 0'	11° 30'	20° 12'	30° 0'
0° 5'	0° 2'	11° 32'	20° 13'	29° 55'
0° 10'	0° 4'	11° 34'	20° 14'	29° 50'

(Table continues on the following page; the left argument column advances by 5' steps and the complementary right argument column decreases by 5', their sum being 30° 0' in every row.)

Declination of the points of the ecliptic from the equator (continued)

Table of the declinations of the points of the ecliptic (DECLINATIONES PVNCTORVM ECLIPTICÆ AB ÆQVATORE), in steps of 5 minutes, computed for a greatest obliquity of 23°30'. This is the continuation of the table begun earlier; the present pages carry the argument from 4°30' through 19°20'.

Each declination column serves four zodiacal signs. Read **downward** with the left-hand argument column ("Degrees and minutes of the upper six signs" [*Gradus ac Minuta superiorum sex Signorum*], engraved vertically in the left margin), the three columns give the declination of ♈ Aries / ♎ Libra, ♉ Taurus / ♏ Scorpio, and ♊ Gemini / ♐ Sagittarius. Read **upward** with the right-hand argument column ("Degrees and minutes of the lower six signs" [*Gradus ac Minuta inferiorum sex Signorum*], engraved vertically in the right margin), the same three columns serve ♋ Pisces / ♍ Virgo, ♊ Aquarius / ♏ Leo, and ♉ Capricorn / ♎ Cancer (the sign glyphs repeated as foot-headers). The left and right argument values on any one row sum to 30°0'.

Table. Argument 4°30' – 9°25'.

Signa (upper six)	♈ Aries / ⚎ Libra	♉ Taurus / ♎ Scorpio	♊ Gemini / ♊ Sagittarius	Signa (lower six)

† Row 25 40, column $\varnothing$ $\mathbb{M}$, is printed **10 13**, which breaks the otherwise smoothly rising column (25 35 = 19 12; 25 45 = 19 15). Transcribed as printed; almost certainly a compositor slip for **19 13** (or 19 14). See Numerical impossibles.

USUS TABULÆ DECLINATIONVM — Use of the table of declinations

If the sign whose degrees' declinations you want is found in the **top** row of the table, take the degrees and minutes on the **left-hand** side of the table; but if the sign is set in the **bottom** row of the table, the degrees together with their minutes are to be taken on the **right-hand** side. Then, at once, where the sign and the degree you have taken meet in common, you will come upon the degrees and minutes of the declination.

Example. Suppose I wish to know how far the 17th degree of Scorpio $\mathbb{M}$ declines from the equator. In the left-hand part of the table, then, I take the 17th degree of Scorpio (for this sign is placed in the upper part of the table), and at the common corner beneath $\mathbb{M}$ I find 16°57'. This, therefore, I declare to be the declination of the 17th degree of Scorpio.

Again, suppose we must investigate how great a declination 23°40' of Cancer $\mathfrak{S}$ has. Since this sign is in the lower part of the table, in the right-hand part I find that to the said 23 degrees and 40 minutes, above the sign $\mathfrak{S}$, there answers 21°25'. And this is the declination sought.

But if the proposed minutes are not found in the aforesaid table, one must take the declinations of the next-greater and next-smaller minutes, and from their difference derive the proportional part. This part is to be **added** to the declination of the next-smaller minutes if the proposed sign is an **upper** one, but **subtracted** from that same declination of the next-smaller minutes if the sign is a **lower** one.

Example of both cases. I want the declination of 4°27' of Gemini $\mathbb{II}$. Since 27 minutes are not found in the said table, I take the difference of the declinations belonging to the 25 minutes and the 30 minutes of the fourth degree of Gemini; this difference amounts to 1 minute. By the rule of proportion I find that to the 2 minutes (by which 25 is exceeded by 27) there correspond $\frac{2}{5}$ of a minute — that is, 24 seconds — since to the 5 minutes (by which 25 is exceeded by 30) there corresponds the whole 1 minute of the difference. And because Gemini is an upper sign, these 24 seconds must be **added** to the declination of 4°25' Gemini, which is 21°5'. Thus the declination of 4°27' of Gemini will come to 21°5'24".

By the same reasoning I want the declination of $25^{\circ}32'$ of Capricorn ♑. Since the proposed sign is a lower one, I **subtract** the same proportional part — namely 24 seconds — from the declination of $25^{\circ}30'$ Capricorn, that is, from $21^{\circ}6'$; and there will remain the declination sought, $21^{\circ}5'36''$.

Moreover, the Sun's greatest **northern** declination is equal to its greatest **southern** declination, as the Author [Sacrobosco] stated; and this can readily be demonstrated as follows. Take some sphere in which the solstitial colure [Colurus Solstitiorum] is ABCD, the equator [Æquator] is AC, the Zodiac or ecliptic [Zodiacus sive Ecliptica] is FI, the Tropic of Cancer ☊ is FG, the Tropic of Capricorn ♑ is HI, and the Sun's greatest declinations are AF (northern) and CI (southern). Since, then, the semicircle ABC is equal to the semicircle FBI, once the common arc FBC is taken away, AF — the Sun's greatest northern declination — will be equal to the arc CI, that is, to the Sun's greatest southern declination. Which was the thing proposed.

[Margin: That the Sun's greatest northern declination is equal to the Sun's greatest southern declination.]

Diagram. A sphere shown with the solstitial colure as its bounding circle, seen edge-on so that the equator, ecliptic, and two tropics appear as chords. Per the accompanying text the construction is: solstitial colure = the whole circle ABCD; equator = diameter AC; ecliptic = diameter FI; Tropic of Cancer ☊ = chord FG; Tropic of Capricorn ♑ = chord HI; the Sun's greatest northern declination = arc AF, its greatest southern declination = arc CI. Labels legible in the woodcut:

- B (top of circle): one pole of the world
- D (bottom of circle): the other pole of the world
- A (right side, at equator level): equator endpoint on the colure
- F (upper right): ecliptic / Tropic-of-Cancer endpoint
- H (lower right): Tropic-of-Capricorn endpoint
- I (upper left): opposite ecliptic endpoint
- K (upper right, above F): point on the circle
- N (lower left): point on the circle
- M (lower right): point on the circle

[The equator's left endpoint C and the Cancer-tropic's left endpoint G are named in the text but did not resolve clearly on the left side of the leaf.]

VI.

(Section opens with a large display capital line reading SOLSTITIORVM; see QA.)**

The solstitial colure also **measures the distances of the poles of the Zodiac from the poles of the world**. For this distance is as great as the arc of the solstitial colure intercepted between the two poles — namely the pole of the world and the pole of the Zodiac. And these two distances of the poles of the Zodiac from the poles of the world are equal to the Sun's greatest declinations. For let the sphere be set up again, in which the poles of the world are B, D; the poles of the Zodiac are K, L; and the Sun's greatest declinations are AE, CH. Since, then, the quadrant AB is equal to the quadrant EK, once the common arc EB is removed, the arc AE (namely the greatest [solar declination]) will remain equal to the arc BK — that is, to the distance of one pole [of the Zodiac] from the other. By the same reasoning CH, the other greatest solar declination, will be equal to the arc DL, that is, to the distance of the pole of the Zodiac from the pole of the world — provided, of course, that the two quadrants CD, HL are taken. From this it is clear that the northern pole of the Zodiac is as far distant from the northern pole of the world as the southern pole of the Zodiac recedes from the southern pole of the world...

[Margin: The solstitial colure measures the distances of the poles of the Zodiac from the poles of the world. That the distances of the poles of the Zodiac from the poles of the world are equal to the Sun's greatest declinations.]

(The sentence continues into the following pages: "...the southern pole of the Zodiac [recedes from the southern pole of the world].")

Diagram. A second sphere, companion to the first, again seen edge-on. Per the text the construction is: poles of the world = B, D; poles of the Zodiac = K, L; the Sun's greatest declinations = arcs AE and CH; quadrants AB, EK, CD, HL; arcs BK and DL representing the pole-to-pole distances. Labels legible in the woodcut:

- B (top of circle): northern pole of the world
- D (bottom of circle): southern pole of the world
- K (upper right): a pole of the Zodiac
- L (lower left): the other pole of the Zodiac
- A (right side, at equator level): equator endpoint on the colure
- E (upper right): declination-arc endpoint (arc AE)
- H (left side, lower): declination-arc endpoint (arc CH)
- C (left side, at equator level): equator endpoint on the colure

- M (lower right): point on the circle
- G (right side, lower): point on the circle

[The peripheral point-letters of this lower figure are small and partly abraded; several positions (C, H, G) are uncertain — see QA]

of the zodiac, because each of these two distances is equal to the maximum declination of the Sun. This is shown as follows. Since the semicircles BCD and KHL are equal, then if the common arc KD is subtracted, there remain equal arcs BK and DL — that is, the distances of the poles of the zodiac from the poles of the world.

VII.

[Margin: The colure of the equinoxes marks out the two equinoctial points.]

The colure of the equinoxes — which cuts the equator at right angles but the ecliptic at oblique angles, since it passes through the poles of the equator and not through the poles of the ecliptic — marks out the two equinoctial points, namely the first point of Aries ♈ and of Libra ♎, at which the equinoxes occur, as has been said.

[Margin: The equinoxes and solstices shift their positions in the calendar.]

The equinoxes and solstices, however, have not always fallen at the same time of the year, but have continually shifted their positions toward the beginnings of the months in the calendar. For long ago Hipparchus [Hipparchus], in about the year 145 before Christ, found the vernal equinox to occur roughly around 23 March; the autumnal, around 26 September; the summer solstice fell then on about 24 June, and the winter around [day: ?] December. Ptolemy [Ptolemy], by contrast, in the year of the Lord 140, observed the vernal equinox to occur roughly around 22 March; the autumnal, at about 25 September; the summer solstice around [day: ?] June, and the winter around 23 December. And so I am utterly astonished that many who have recently written on the reform of the year should have wished so stubbornly to maintain that the vernal equinox ought to be brought back to 25 March, on the grounds — as they claim — that in the time of Christ, or of Julius Caesar [Julius Caesar], it fell on that day. For this is entirely false. Since in Ptolemy's time the vernal equinox anticipated its place in the calendar by one day in the span of 300 years — as he himself observed most carefully — it follows that in the 200 years or so that fell between Julius Caesar and Ptolemy it anticipated by only 16 hours, that is, $\frac{2}{3}$ of one day. Therefore, since Ptolemy found it roughly around 22 March, it must in Julius Caesar's time have fallen no later than 23

March. Gregory XIII [Gregory XIII], Supreme Pontiff, therefore acted more correctly when in the year 1582 he brought it back to 21 March, on which it fell in the time of the Council of Nicaea, that is, in the year 325. For in this way nothing at all had to be changed in the breviaries and missals, and the same Paschal terms remained which the holy Fathers established in the Council of Nicaea.

[Margin: The cause of the anticipation of the equinoxes and solstices in the calendar.]

The cause of this anticipation is that Julius Caesar, whom the Roman Church followed, assigned to the length of a single year more than was right. For he set the solar year at 365 days and 6 hours. Since in each year he was leaving out those six hours, which over four years made up a whole day, he decreed that every fourth year a whole day, composed of 24 hours, should be intercalated — the year he called bissextile, made up of 366 days. But the solar year is not so long; according to the reckoning of the Alphonsine [Alphonsine] tables it contains only 365 days, 5 hours, 49 minutes, 16 seconds. Thus the Roman year, which the Church uses, exceeds the true year according to the Alphonsine reckoning by 10 minutes of one hour and 44 seconds. Hence it comes about that, by those same minutes and seconds, whenever the Sun returns to the same equinoctial or solstitial point, the said 10 minutes and 44 seconds of one hour are lacking to complete the Roman year. It also follows that the equinoxes and solstices anticipate their places, since — the said minutes being wanting to complete the Roman year — in 400 years they run ahead of their places by nearly three whole days. Therefore, so that in future the equinoxes and solstices should not run further ahead of the days marked for them in the calendar, it was necessary (as Gregory XIII decreed) to omit three bissextiles in every 400 years — that is, to reckon three years which ought to be bissextile, namely of 366 days, as common years, of 365 days. For in this way it will come about that those three whole days are restored, and no anticipation of the annual motion of the Sun will be perceived, but the equinoxes and solstices will recur always on the same days of the year, returning fixed on their set days.

And had the calendar not been corrected, it would come about that in the span of 24,500 years the equinoxes and solstices would exchange their places with one another, so that spring would fall in September, autumn in March, the cold of winter in June, and the heats of summer in December — as we also see happened when Christ was born. Yet in the span of 49,000 years, by the opinion of the Alphonsines, both the solstices and the equinoxes would be restored to their former places. In our own time, before the restoration of the equinox to 21

March, the equinoxes and solstices had receded from the ancient positions noted in the time of Julius Caesar, toward the beginnings of the months, by nearly 12 days. For the vernal equinox fell on 11 March, the autumnal on 13 September; the summer solstice on 12 June, and the winter on 12 December. But after the restoration made by Gregory XIII, the equinoxes fall at this time on 21 March and 23 September, and the solstices on 22 June and [22] December.

[Margin: On what days the equinoxes and solstices used to fall before the correction of the calendar, and on what days they now fall after the correction.]

Since I have spoken of the days of the equinoxes and solstices after the correction of the calendar, it will not be out of place if I set out here a small table containing the Sun's entry into all the signs of the zodiac. For this matter is useful for many things in astronomical work. And although this can be known more accurately from ephemerides or astronomical tables, yet because we do not always have these at hand, we judge it better to know it, even in a rough-and-ready way, than to be wholly ignorant of it — especially since no notable error arises from it in the instruments of mathematicians, even if the Sun's entry into the signs of the zodiac is not known exactly, but it is sometimes reckoned to enter a day earlier, or a day later, than it truly does. For in a single day the Sun's declination does not increase perceptibly, as is clear from the preceding table. The same is to be understood of the degree in which the Sun is placed. For although, when the Sun is in some particular degree, one may take it to be in another very nearly — whether a little less or a little more — it makes no difference, for the reason just given. Nevertheless, a little later I shall set out a table for four years, from which the place of the Sun may be found each day with sufficient accuracy. Meanwhile the table promised here is as follows.

Ingressus Solis in 12. signa Zodiaci — The Sun's entry into the 12 signs of the zodiac.

♈ Aries	♉ Taurus	♊ Gemini	♋ Cancer	♌ Leo	♍ Virgo
21 March	21 April	22 May	22 June	23 July	23 August
♎ Libra	♏ Scorpio	♐ Sagittarius	♑ Capricorn	♒ Aquarius	♓ Pisces
23 September	24 October	23 November	22 December	21 January	19 February

[Margin: How to know in which degree of the zodiac the Sun stands on any given day. The Sun's entry into the signs, and in which degree it stands on any day; by what method this is learned by heart.]

From this you will easily find in which degree, more or less, the Sun is on any given day, by assigning one degree to each day. For example, since the Sun on 24 September is in the first degree of Libra ♎ , it will be in the 2nd degree of Libra on the 25th; on the 30th, in the 7th degree of Libra; and on 9 October it will stand in the 16th degree of Libra; and so on for the rest. For although by this method we may sometimes be off by one day from the true place of the Sun, no notable error will follow from it, as we have said.

Moreover, the Sun's entry into the 12 signs, and which degree, more or less, it occupies on any day, can most conveniently be known by these verses:

*Inclyta Laus Iustis Impenditur, Hæresis Horret Garrula, Grex Gratus
Faustos Gratatur Honores.*

[These twelve words correspond to the twelve months, January through December; the alphabetic position of each word's initial letter encodes the day of the sign-entry, as explained below.]

The meaning and use of these verses is as follows. The first word is assigned to January, the second to February, the third to March, and so on in order, the other words to the other months. Thus, to know on what day the Sun enters the sign proper to any month, and in what degree it stands on any given day, one must learn in order all 12 signs, as they are set down in these verses:

*Sunt Aries, Taurus, Gemini, Cancer, Leo, Virgo. Libraque, Scorpius,
Arcitenens, Caper, Amphora, Pisces.*

[*Arcitenens* ("the Archer") = Sagittarius; *Caper* ("the Goat") = Capricorn; *Amphora* ("the Water-jar") = Aquarius.]

For the Sun enters the first sign, that is, Aries, in the month of March; the second in April; and so on in order, so that in the twelfth month from March — which is February — the Sun enters the twelfth sign, namely Pisces. Once you know which sign the Sun enters in any given month, take the word of the first two verses corresponding to the given month. However many places the first letter of that word occupies in the alphabet, that many units are to be subtracted from 30, so as to leave the day on which the Sun enters the sign of that month.

Example. The Sun enters Libra — that is, the seventh sign — in the month of September, which is the seventh month from March. And since September corresponds to the ninth word, namely *Gratus* (because September is the ninth month from January), and its first letter, G, is the seventh in the alphabet, we subtract 7 from 30, leaving 23; therefore on 23 September the Sun enters Libra. Again, the Sun enters Pisces in the month of February, to which the second word, *Laus*, is due; and since the first letter, L, is the eleventh in the alphabet, if 11 be subtracted from 30, there remain 19. Therefore on 19 February the Sun enters the sign of Pisces. And so for the rest.

Now, to know which degree of the ecliptic the Sun holds on any given day of the year, add to the day of the month as many units as the place occupied in the alphabet by the first letter of the word corresponding to the given month. And if the resulting number is less than 30, it will indicate the degree of the sign of the preceding month; but if it is greater than 30, then, casting out 30, the remaining number gives the degree of the sign of the given month; if finally the resulting number is exactly 30, the Sun will be at the end of the preceding sign and at the beginning of the sign of the given month.

Example. I wish to know which degree of the ecliptic the Sun holds on 13 June. To this month, since it is the sixth from January, is due the sixth word, *Horret*, whose first letter, H, is the eighth in the alphabet. Adding, then, 8 to 13, we get 21, a number less than 30. Therefore on 13 June the Sun will be in the 21st degree of Gemini, which sign the Sun enters in the month of May. Again, if 27 June be proposed, adding 8 we get 35, a number greater than 30. Casting out 30, then, there remain 5; and so the Sun then occupies the 5th degree of Cancer, which it enters in the month of June. Finally, if 22 June be offered, adding 8 we get 30; the Sun will therefore then be at the end of Gemini and the beginning of Cancer. And the same reasoning holds for the rest.

In bissextile (leap) years, one degree is to be added to the place of the Sun so found after the feast of St. Matthias [Feb. 24], so that the Sun's place may be had more precisely. For example, on 27 September, to which the word *Gratus* is due, whose first letter, G, is the seventh: adding, then, 7 to 27, we get 34; and casting out 30, there remain 4. The Sun will therefore then be in the 4th degree of Libra, if it is a common year; but in a bissextile year, in the 5th degree.

Although by this method the true place of the Sun cannot be known altogether exactly — since the Sun does not traverse precisely one degree each day in the zodiac — yet scarcely an error of half a degree, or at most of one degree, will be committed. And so we reach the true place of the Sun, more or less, with such

certainty and assurance that we may safely use it in employing those clocks in which, to determine the hours, it is necessary to have the Sun's place in the zodiac known — as is also required for the use of the other instruments that astronomers employ.

[Margin: The Sun's place from tables.]

[Margin: How the bissextile years are distinguished from the common years.]

Since the use of the Sun's place in the zodiac is thoroughly necessary, and useful for very many observations, I should like here — so that the Sun's place may be had more exactly each day — to take from the Ephemerides of Giovanni Antonio Magini [Giovanni Antonio Magini] (as we also did in the scholium to Canon 2 of Book 3 of the *Astrolabe*) the Sun's place computed for four years for the several days of the year, namely for the year 1600, a bissextile, and the three common years following. For in these four years the whole variation of the Sun's place in the zodiac occurs, on account of the six hours neglected in the common years. But after very many years have passed, if these years are found no longer to agree with the true place of the Sun, four other years — one bissextile and three common — will have to be excerpted from the Ephemerides of that time. And since Magini computed the Sun's place even in seconds, we shall be content with minutes, taking one minute for any number of seconds greater than 30. And from these tables the true place of the Sun will be drawn much more surely than from any instrument — provided that it is sought, for a bissextile year, in the first table; for the first year after the bissextile, in the second; for the second year after the bissextile, in the third; and finally, for the third year after the bissextile, in the fourth.

You will discover with little trouble whether a given year is bissextile, or rather the first, second, or third after the bissextile, in this way. Reject from the proposed year all the thousands and hundreds; and from the remainder, which will be fewer than 100, [reject] the number 20 as many times as you can; then from the years that remain, which will be fewer than 20, reject 4 as many times as possible. For if after this last rejection nothing is left over, the given year will be bissextile; if 1 remains, it will be the first after the bissextile; if 2, the second; and if 3, the third. Thus, if the year 1654 be proposed: rejecting the 1600 years and all the 20s, from the remaining 54 years, and likewise all the 4s, from the remaining 14 years, there remain 2. You will say, therefore, that the year 1654 is a common year, and the second after the bissextile. But on this matter we have written more in the *Computus Ecclesiasticus* [Ecclesiastical Computation], where we also taught how, after the reform of the year, the centennial bissextile years

Commentary on Chapter II of the *Sphere* — Solar-position tables (continued)

These three pages carry, without intervening prose, the second, third, and fourth of the four annual solar-longitude tables ("Locus Solis in Zodiaco") — one for each year of the leap-year cycle. The first table of the set (Anno 1600) appeared in the preceding pages. Each table gives, for every day of the twelve months, the Sun's place in the zodiac in degrees (**G** = *gradus*) and minutes (**M** = *minuta*), with the

sign glyph printed at the start of each month and wherever the Sun crosses into a new sign (at 0°). The vertical rules at the outer edges are headed **Dies Mensium** ("Days of the months") — the day-number columns.

Sign glyphs: ♈ Aries, ♉ Taurus, ♊ Gemini, ♋ Cancer, ♌ Leo, ♍ Virgo, ♎ Libra, ♏ Scorpio, ♐ Sagittarius, ♑ Capricorn, ♒ Aquarius, ♓ Pisces. (The source prints Pisces as ⚹, Aquarius as a double-wave, Sagittarius as an arrow/cross; normalized here to the standard glyphs.)

Table — Locus Solis in Zodiaco Anno 1601, vel primo post bissextum

(The Sun's place in the zodiac, in the year 1601, or the first after a leap year)

January – June (degrees / minutes per day):

VIII.

[*Sacrobosco*] Likewise the Colure of the Equinoxes cuts the Ecliptic into two semicircles, namely the northern and the southern. These have been treated above.

[Margin: The Colure of the Equinoxes divides the Ecliptic into a northern and a southern semicircle.]

ON THE MERIDIAN [DE MERIDIANO]

[*Sacrobosco*] There are again two other great circles in the sphere, namely the Meridian and the Horizon. The Meridian is a circle passing through the poles of the world and through the zenith of our head. It is called the Meridian because, wherever a person may be and at whatever time of year, when the Sun—carried by the motion of the firmament—reaches his meridian, it is midday for him. For a like reason it is also called the circle of midday.

[Margin: What the Meridian is. Why the Meridian is so called, and why it is the circle of midday.]

COMMENTARY.

Having explained the four greater circles that are called intrinsic or mobile, he now treats the remaining two greater circles, which are called extrinsic or immobile, namely the Meridian and the Horizon. He sets out the Meridian first, because it is worthier and nobler: partly because it lies in the middle of the hemisphere, where the stars have their greatest elevations and powers, as we shall shortly say; and partly because astronomers begin the day from this circle, and not from the Horizon, as ordinary people are accustomed to do. He therefore defines the Meridian circle by saying that it passes through the poles of the world and through the zenith, or vertex, of the head—such as the circle in the material sphere that towers above all the rest and supports the axis of the world, about which the others turn. He then teaches that this circle is called "Meridian" from "midday" (*meridies*), because the Sun, brought to it by the motion of the first mobile at any time of year, produces midday, or noon. And for the same reason, he says, it is called the circle of midday, because it divides the artificial day into two equal parts.

Astronomers are also accustomed to call this circle the line of mid-heaven, or of midday; the royal cusp; the royal hinge (*cardo regius*); the beginning of the tenth celestial house; the mid-heaven; and by other names of this kind. This circle must be conceived as wholly immovable in the heavens and always fixed in the same place. For since it must necessarily pass through the vertex of the place whose

meridian it is called, and the vertex of that place does not change, if it were to move even a little it would depart from the vertex of the place, and so would neither divide the artificial day into two equal parts nor cut the Horizon at right angles—all of which are required in the Meridian.

[Margin: Other names for the Meridian.]

[*Sacrobosco*] And note that cities of which one lies nearer the East than another have different Meridians.

[Margin: Cities of which one lies farther east than another have different Meridians.]

COMMENTARY.

Since he had said that the Meridian passes through the zenith, or vertex, of the head—from which it follows that, just as not all places on Earth lie under the same point of the heavens, so too not all can have the same Meridian—he now teaches that Meridians vary in different cities, of which one is farther east than another.

From this it is clear that as many different Meridians must be conceived as there are zeniths, or vertical points, on some parallel circle running from East to West; yet all of them will intersect one another at the poles of the world. Hence by this reasoning one and the same city will contain several Meridians. For the more easterly a place is, the more easterly its Meridian will be, if we speak precisely and geometrically. But if we wish to consult the judgment of the senses, then within a space of about 300 stadia from East to West—which, on the authority of Proclus in his *Sphere*, amount to $37\frac{1}{2}$ Italian miles on the greatest circle and take up 36 minutes—scarcely any perceptible variation of the Meridian occurs. For within so large a space, he says, the vertical points begin to be perceptibly distinguished. Hence, since the whole Equator comprises 21,600 minutes, and each Meridian passes through two diametrically opposite points [Latin: *per duo minuta è diametro opposita*; *puncta* seems intended] [?], there will be 300 Meridians to be established in the whole circuit of the heavens. For in this way 36 minutes fall between any two nearest Meridians, and these make up $37\frac{1}{2}$ Italian miles, or 300 stadia, as Proclus holds. In this way, then, not only will one and the same city have the same Meridian, so far as the senses judge, but so too will two cities, or even more, provided that one is not more than 36 minutes farther east than another.

[Margin: By how great a space of the Earth from East to West the Meridians change with respect to the risings and settings of the stars.]

[Margin: How many Meridians are to be established, so far as the judgment of the senses.]

The cosmographers, following Ptolemy [Ptolemaeus], describe Meridian circles through the poles of the world and through the individual degrees of the Equator. So it comes about that there are 180 Meridians in all, since each one passes through two opposite degrees. The first Meridian passes through the Fortunate Isles, which are now called the Canaries and lie in the Western Ocean near Africa and Portugal [Lusitania], from which the longitudes of cities take their beginning among the cosmographers, as will be explained a little further on; the second through the first degree of the Equator, which follows the first Meridian as one proceeds toward the East; the third then through the second degree; and the rest in the same way in succession. On the cosmographical globe, however, and in the descriptions of the world that are usually called maps (*Mappae mundi*), the cosmographers draw only 12 Meridians, which divide the whole circuit of the Earth into 24 equal parts—perhaps for this reason, that 15 degrees, which make up one hour, may be intercepted between any two adjacent ones. For in this way it will easily be known by how many hours noon occurs sooner for one city than for another: for if one city is removed from another by three Meridians toward the East, it will have noon three hours earlier, and so on.

[Margin: How many Meridians there are according to Ptolemy and the cosmographers, and where they take their beginning.]

[Margin: On the cosmographical globe and on maps, 24 Meridians are drawn.]

[*Sacrobosco*] But the arc of the Equinoctial [Equator] intercepted between two Meridians is called the longitude of cities. And if two cities have the same Meridian, then they are equally distant from the East and from the West.

[Margin: What the longitude of cities is.]

COMMENTARY.

In passing, taking the occasion from the Meridian circle, he explains what the longitude of cities is, saying that it is the arc of the Equator intercepted between the two Meridians of two cities. This is to be understood only if the one Meridian passes through the Fortunate Isles, from which the longitude of cities is reckoned. For the arc between any two Meridians whatever is called the difference of longitudes. We shall say more about this a little later. But if two cities have the

same Meridian, they will be said to be equally distant from East and West, and to have the same longitude.

THE FUNCTIONS OF THE MERIDIAN [OFFICIA MERIDIANI]

I.

The Meridian circle determines the half-day and half-night time of the artificial day and night, by marking the points of noon and midnight. For the Meridian divides days and nights into equal spaces: it divides any day into the forenoon or morning part and into the afternoon or evening part; and it divides the night likewise into the hours that precede midnight and those that follow it.

[Margin: The Meridian determines the half-day and half-night time.]

II.

In it all the stars obtain the greatest altitude they can have, if you consider elevation above the Horizon; and they have their most intense vigor and power, since, when placed in it, they act upon these lower things through rays that make more nearly right, or less oblique, angles. We experience this more clearly than daylight in the case of the Sun, which, when set on the Meridian circle, more strongly heats and dries these lower regions and consumes their vapors than in any other part of the sky.

[Margin: On the Meridian the stars have their greatest altitudes and powers.]

III.

On it too is placed the zenith, or vertex, of each region, from which, by means of the Meridian, we shall easily measure the distances of the stars when they are set on the Meridian. In the same way we shall measure the intervals of all the parallel circles, both from our vertex and among themselves.

[Margin: The Meridian measures the distances of the stars from the vertex of the head, and of the parallels among themselves.]

III.

It shows us how great is the meridian altitude of the Sun and of the other stars—the altitude they have when placed on the Meridian circle—an operation of the greatest use among astronomers. For the meridian altitude of any star is the arc of the Meridian circle intercepted between the Horizon and the star set on the Meridian circle, provided that this arc does not exceed a quadrant, but is either

exactly a quadrant (as when the star stands at the vertex of the head) or certainly less than a quadrant (as when the star lies between the Horizon and the vertex).

[Margin: What the meridian altitude of the stars is, and by what method the Meridian measures it.]

V.

Astronomers place the beginning of the natural day—which is one complete revolution of the Sun—on the Meridian circle, and not, as ordinary people do, on the Horizon. For the beginnings of the day were various among various peoples and nations. The Babylonians, whom the Balearic Islands (called Majorca and Minorca) now imitate, began the day from one sunrise to the next; the Athenians, whom all Italians still follow, counted the day from one sunset to the next; the Egyptians and the Roman priests reckoned from one midnight to the next midnight, a custom that has remained in the Roman Church to this day; ordinary people, finally, reckon the day from sunrise to its setting; and astronomers, lastly, count the day from one midday to the next. Astronomers preferred to begin the day from the Meridian circle rather than from the Horizon because, as we shall teach in the third chapter, the Sun and stars always stand in the same way with respect to the Meridian in every region, but not with respect to the Horizon, which varies remarkably according to the greater or lesser elevation of the pole above the Horizon. Hence the natural days are rendered very unequal, as will be said in its place.

[Margin: The Meridian determines the beginning of the day for astronomers.]

[Margin: The various beginnings of the day among various peoples.]

[Margin: Why astronomers begin the day from the Meridian rather than from the Horizon.]

VI.

By means of the Meridian circle and the known meridian altitude of the Sun, the elevation of the pole in any region is found, together with the disposition or position of the sphere—without which scarcely any observation of astronomers is of any moment. For since a quadrant of the circle, that is, 90 degrees, lies between the zenith (the vertex of any region) and the Horizon, if, with the Sun standing at either of the equinoctial points, we subtract its meridian altitude from 90 degrees, there will remain the distance between the zenith and the Equinoctial circle. But this distance, as we shall demonstrate a little further on from the Author when he treats of the Horizon, is equal to the elevation of the pole—that is, to the arc of the

Meridian circle set between the raised pole of the world and the Horizon.

Therefore the elevation of the pole will be established from the known meridian altitude of the Sun at the time of the equinoxes. EXAMPLE. At Rome, at the time of the equinoxes, the meridian altitude of the Sun is found to be about 48 degrees; and when this is subtracted from a quadrant, about 42 degrees remain. This, then, will be the distance of the Roman vertex, or zenith, from the Equator, that is, the elevation of the pole at Rome.

[Margin: By the aid of the Meridian circle, the elevation of the pole is found at the time of the equinox.]

Now the meridian altitude of the Sun—indeed any altitude whatever, whether before or after noon—can be obtained in two ways. One way, most usual and easiest, is by some mathematical instrument, such as an astrolabe, a quadrant, a ring, and so on. The other way, more difficult but more certain, is by the shadow of some gnomon or stylus

[Margin: The meridian altitude of the Sun, or any other altitude, and by what method it is found.]

set perpendicular to the Horizon. For if at any time—say, for example, at noon—the shadow of the gnomon is equal to the gnomon itself (as happens at Venice, Milan, and Lyons at noon at the time of the equinoxes), the altitude of the Sun will be exactly 45 degrees, as we demonstrated with our astrolabe and in Book 3 of the *Practical Geometry*. But if the shadow is greater than the gnomon itself (as happens in Germany and other more northerly regions, where at noon at the time of the equinoxes it is greater than at 45 degrees), the altitude of the Sun will be less than 45 degrees. And if, finally, the shadow is smaller than the gnomon itself (as happens at Rome and in other regions that are less northerly than 45 degrees, at noon at the time of the equinox), the altitude of the Sun will be greater than 45 degrees. In what way the altitude of the Sun is to be derived from the known shadow and the gnomon, we demonstrated in Book 5 of the *Gnomonics*, Proposition 2. For now we shall be content with a simple rule and example. At Königsberg in Prussia [Mons Regius], at the time of the equinox, the shadow was found to be 16 of the units of which the gnomon is 12. I take the square of the shadow, namely 256, and add it to the square of the gnomon, namely 144, and make 400. By the square root of this number, namely by 20, I divide the product of the gnomon—namely of 12—multiplied into the whole sine, that is, into 100,000, which is 1,200,000; and there results 60,000 for the sine of the Sun's altitude, to which correspond about 36 degrees 52 minutes. When these are

subtracted from 90 degrees, there will remain the elevation of the pole in the said city, about 53 degrees 8 minutes.

More easily, the same altitude of the Sun will be investigated from the shadow by Problem 8 of our *Rectilinear Triangles*, set down in Lemma 53 of Book 1 of the *Astrolabe*, and in Book 1, Chapter 3, of the *Practical Geometry*. For if the length of the stylus, that is, 12, is multiplied into the whole sine, and the resulting number, 1,200,000, is divided by the length of the shadow, namely by 16, there will come out the Tangent of the Sun's altitude, 75,000, to which are owed about 36 degrees 52 minutes for the altitude of the Sun. Hence again its complement will give the altitude of the pole, about 53 degrees 8 minutes, as before.

MOREOVER, by this method the elevation of the pole is found only at the time of the equinox, from the meridian shadow of the Sun. For then, once the meridian altitude of the Sun is subtracted from a quadrant—that is, from 90 degrees—there remains the distance of the zenith from the Equator, which is indeed equal to the elevation of the pole. But if at any time of the year and on any day you wish to investigate the elevation of the pole from the meridian altitude of the Sun, it is necessary, from ephemerides or from elsewhere, to learn accurately the place of the Sun in the Ecliptic for the proposed day, and its declination from the table set out above. For the Sun's declination, if it is northern—as when the Sun is in the northern signs ♈ [Aries], ♉ [Taurus], ♊ [Gemini], ♋ [Cancer], ♌ [Leo], and ♍ [Virgo]—must be subtracted from the meridian altitude of the Sun, in order to obtain the altitude of the Equator, or (what is the same) the meridian altitude the Sun would have at the equinoxes: for when this is subtracted from 90 degrees, the elevation of the pole will remain.

[Margin: The finding of the elevation of the pole from the meridian altitude of the Sun outside the time of the equinox.]

For example, at Rome in the year 1569, on the 20th day of July, with the Sun at 6 degrees 40 minutes of ♌ Leo—which declines toward the North from the Equator by 18 degrees 39 minutes, as is evident from the table of declinations—I found at noon that the altitude of the Sun amounted to 66 degrees 39 minutes. From this I subtract the said declination, namely 18 degrees 39 minutes; there remain 48 degrees for the altitude of the Equator. When this is subtracted from 90 degrees, there remains the elevation of the pole, 42 degrees. But if the Sun's declination is southern—as when the Sun runs through the southern signs ♎ [Libra], ♏ [Scorpio], ♐ [Sagittarius], ♑ [Capricorn], ♒ [Aquarius], and ♓ [Pisces]—it must be added to the meridian altitude of the Sun, in order to find the altitude of the Equator; for when this is subtracted from 90 degrees, the elevation of the pole

will remain, as before. Thus at Rome, in the same year 1569, on the 21st day of November, with the Sun tarrying at 9 degrees 20 minutes of $\times^7$ Sagittarius—which departs from the Equator toward the South, as the table of declinations teaches, by 21 degrees 54 minutes—I found the meridian altitude of the Sun to be 26 degrees 6 minutes; and if to this is added the declination, say 21 degrees 54 minutes, the altitude of the Equator will be gathered as 48 degrees, from which again the elevation of the pole is found to be 42 degrees. Another method of finding the elevation of the pole from the Analemma on any day, even if the declination of the Sun is unknown, I have set down in the second scholium of Proposition 28 of Book 1 of the *Gnomonics*.

Now, in order that the elevation of the pole may be correctly found, the altitude of the Sun must be taken precisely at the point of noon—which will only then happen when the shadow of the gnomon is projected precisely onto the Meridian line. It will therefore not be out of place to indicate briefly by what art the Meridian line ought to be traced, since it is necessary for many observations of astronomers. On a plane, then, constructed level—that is, parallel to the Horizon—let many circles be described from the same center E, at which let a stylus or gnomon EF be erected at right angles. This will be the case when its tip F is equally distant from the circumference of any circle described in the proposed plane from center E. And it will be equally distant if it stands at an equal distance from at least three points of the circumference, as we demonstrated in Book 4 of the *Gnomonics*, Proposition 12. Next, before noon let the tip of the shadow be observed until it exactly touches the circumference of some circle—such as the shadow EG, whose tip falls precisely on the circumference of the third circle. Again, after noon let the tip of the shadow be marked until it falls precisely on the circumference of the same circle—such as the shadow EH.

[Margin: The Meridian line, by what art it is found.]

Diagram. A horizontal sundial layout for tracing the Meridian line, seen from above. Several concentric circles share a common center E, at which stands the vertical gnomon (stylus) whose tip is F. Two perpendicular diameters cross at E: the vertical one is the Meridian (noon) line, running from B at the top to D at the bottom; the horizontal one is the East–West line, running from A at the left to C at the right. Two shadow-tip points, G and H, are marked on the third circle, symmetrically placed to the lower right and lower left of center (the afternoon shadow EG and the forenoon shadow EH). The four cardinal words are engraved around the figure.

- MERIDIES (top): "Noon / South"

- B (top, on the Meridian line): upper endpoint of the noon line
- SEPTENTRIO (bottom, printed in mirror-reversed capitals): "North"
- D (bottom, on the Meridian line): lower endpoint of the noon line
- ORTVS (left): "East / sunrise"
- A (left, on the East–West line): eastern endpoint
- OCCASVS (right): "West / sunset"
- C (right, on the East–West line): western endpoint
- E (center): foot of the gnomon and common center of the circles
- F (above center, tip of the leaning stylus): apex of the gnomon EF
- G (lower right, on the third circle): tip of the afternoon shadow EG
- H (lower left, on the third circle): tip of the forenoon shadow EH

But in order that you may know at what hour after noon the tip of the shadow can touch the circumference of the same circle (so that you do not approach the Sun in vain), you must observe as many hours after noon as the hours before noon at which you marked the shadow. For if, say, at the third hour before noon the tip of the shadow touches precisely the circumference of some circle, it is necessary that at the third hour after noon the tip of the shadow reach the circumference of the same circle. This indeed you will know much more certainly by the following method. When the tip of the shadow falls before noon precisely on the circumference of some circle, let the altitude of the Sun be investigated with some instrument; and when this altitude has been carefully noted, then, when after noon the Sun obtains the same altitude, you may be perfectly assured that the tip of the shadow is touching the circumference of the same circle: for after noon the altitude of the Sun diminishes in the same proportion in which it increases before noon, and therefore, in whatever proportion the shadow of the gnomon decreases before noon, it must increase in the same proportion after noon, as can easily be demonstrated from the elements of spherics. And so, when these two points G and H—of which the former is distant before noon by the same interval as the latter is distant after noon—have been obtained with the utmost diligence, [the space between them is] to be divided

the arc GH will be bisected by the straight line BD, which is extended through the center E. For this line will be the meridian line, and if the shadow of the stylus is cast upon it, there is no doubt that noon is at hand. Therefore the straight line BD will be the common section of the horizon and the meridian circle. And if we cut this at right angles, the straight line AC will mark point A as the point of sunrise at the time of the equinox, and point C as the point of sunset, so that AC is the common section of the horizon and of the prime vertical properly so called. There

are indeed many other methods, no less reliable, for finding the meridian line — such as the one I set out by means of the analemma in the scholium to Proposition 23 of Book 1 of my *Gnomonics*, which in my judgment is the most reliable of all. But the method I have just explained is much quicker than all the others, and is more commonly used by astronomers.

Once the meridian line has been found on the said plane with so much labor, we shall discover countless other meridian lines on other planes with the greatest ease, in this way. Observe the moment of noon — that is, when the shadow of the gnomon falls exactly on the meridian line already found. If at that instant you hold up by hand, on any other plane, a fine thread with a plumb-weight, and mark its shadow on the plane at two points, then the straight line drawn through these two points will be a meridian line; for at noon the Sun's shadow produces it.

[Margin: By what technique, once one meridian line has been found, countless others may be found.]

Diagram. A horizontal sundial plane seen from above, used for finding the meridian line by equal gnomon-shadows. A set of concentric circles (the successive day-arcs traced by the shadow-tip) is centered on point E, where the gnomon (stylus) stands; a short wedge represents the gnomon and its shadow running from E toward F. Two perpendicular diameters divide the field into the four cardinal directions, each labeled in large type around the rim. The construction bisects the arc GH (the two points where the shadow, of equal length, touches one circle in the morning and afternoon) by the line BD through E, yielding the meridian.

- B (top): MERIDIES ["Noon" / south]
- D (bottom): SEPTENTRIO ["North"] (printed inverted at the foot of the figure)
- A (left): ORTVS ["Rising" / east] (printed vertically up the left side)
- C (right): OCCASVS ["Setting" / west] (printed vertically up the right side)
- E (center): base of the gnomon (unlabeled hub where the diameters cross)
- F (upper center): tip of the gnomon's shadow toward noon
- G (lower right): shadow-tip point on the day-arc (afternoon)
- H (lower left): shadow-tip point on the day-arc (morning)

VII.

In any oblique sphere this circle performs the same office that the right horizon performs in the right sphere. For however any point of the ecliptic, or

any star, is related to the right horizon, it must stand in exactly the same relation to the meridian of any given city, as regards rising and setting — that is, as regards its passage across the meridian; for both the meridian and the right horizon pass through both poles of the world.

[Margin: In every region the meridian serves as a right horizon.]

And it is for this reason that astronomers begin the natural day from the meridian circle, and not from the horizon. Since in their observations they require times as nearly equal as possible, they have noticed, by the surest evidence and demonstration, that the zodiac in its rising and setting admits far less variation with respect to the meridian than with respect to the oblique horizon. For the more oblique the horizon, the greater the variation seen in the rising and setting of the parts of the zodiac. But these matters will be better understood in chapter 3.

VIII.

The meridian circle has a notable use in cosmography, for by its office cosmographers measure the longitudes and latitudes of cities. To make this understood, a few things seem to me worth saying about the longitude and latitude of cities.

[Margin: The meridian measures the longitudes and latitudes of cities.]

Ptolemy, then — as is clear from Book 1, chapter 6 of his *Geography* [Ptolemy, *Geography* I.6], whom all cosmographers follow — seeing that the habitable earth extends farther from west to east than from north to south, calls the stretch of land from west to east "longitude," and that from north to south "latitude"; just as in any measurable thing whatever we are accustomed to call the greater distance its length, and to assign breadth to the lesser.

[Margin: Why Ptolemy calls the stretch of land from west to east "longitude," and that from north to south "latitude."]

Or else because, as he likewise says, the motion of the planets from west to east is longer than from north to south. For the latter is confined between the two tropics alone, whose distance amounts to 47 degrees, whereas the former embraces 360 degrees.

Now there are two kinds of East, and of West: the absolute and the relative.

[Margin: What the absolute East is. What the absolute West is. What the relative East and West are.]

The absolute East is called the limit of the habitable earth on the eastern side — such as, for Ptolemy, the region of the Sinae, which today is called Mangi, once subject to the King of the Tartars but now to the most powerful King of the Sinae [China]. For as one proceeds from west to east, immediately beyond that region one meets the sea. The absolute West is called the limit of the earth on the western side, of which kind are the Fortunate Isles, which lie in the west beyond the outermost shores of Europe and Africa. The relative East and West are taken with regard to any particular place of habitation, or horizon; in this way every city is said to have its own East and its own West. And in this latter sense every meridian is said to be equally distant from East and West; for the Sun spends as much time from rising to noon as from noon to setting — or because, in all regions on the equator, however the heaven revolves, there are 90 degrees between the horizon and the meridian.

But it is in the former sense that geographers take the longitude of the earth, so that the longitude of any city is said to be its distance from the West — that is, from the Fortunate Isles — toward the East; and it is usually defined as follows.

[Margin: What the longitude of cities is.]

The longitude of a city, or of any place, is the arc of the equator intercepted between the meridian of the said city or place and the meridian of the Fortunate Isles; or the arc of the parallel passing through the place, intercepted between those same two meridians. For this arc of the parallel is entirely similar to that arc of the equator, as is clear from Proposition 10 of Book 2 of Theodosius [*Spherics* II.10]. For since all circles running from north to south are carried by the motion of the heavens from east to west, the starting-point of longitude could not be taken from any of them; instead one had to resort to the meridian drawn through the most westerly islands then known — namely the Fortunate Isles — which are therefore said to be located in the absolute West. By the same reasoning that region of Mangi, because it is the most easterly, is said to occupy the absolute East. From which it is manifest that the longitude of any city cannot be measured without the meridian. For however many degrees the arc of the equator (or of the parallel) contains that is placed between the prime meridian — which passes through the Fortunate Isles — and the meridian of the city itself, so great is said to be its longitude. Thus the longitude of Rome is about 36 degrees 30 minutes. But the arc of the equator, or of the parallel of any city, lying between its

own meridian and the meridian of some other city — one that does not pass through the Fortunate Isles, or Canaries — is called the difference of longitudes.

[Margin: What difference of longitude is.]

The starting-point of latitude is set at the equator, because it in no way moves from north to south, or the reverse, but always keeps the same position with respect to the earth; so that any city is said to have as much latitude as it recedes from the equator, whether toward the north or toward the south — which we measure along the meridian. For the latitude of any city is the arc of the meridian enclosed between the equator and the parallel of the said city.

[Margin: What the latitude of cities is.]

On this reckoning Rome is said to have a latitude of about 42 degrees. But the arc of the meridian placed between the two parallels of two cities, neither of which lies on the equator, is called the difference of latitudes.

[Margin: What difference of latitude is.]

Therefore, just as the longitudes of the stars are reckoned from Aries toward the eastern signs, and their declinations from the equator toward one or the other pole, so too the longitudes of cities are counted from the meridian passing through the Canary (or Fortunate) Isles toward the eastern regions, while their latitudes are counted from the equator toward whichever pole. Hence, like the declinations of the stars, the latitudes of cities too will be twofold — northern, of course, and southern — according as they recede from the equator toward the north (the Bear), or toward the south.

[Margin: The latitude of cities is twofold: northern or southern.]

On this reckoning, places on the earth situated under the equator will have no latitude, while those set directly under the poles will be allotted a latitude of 90 degrees. Likewise, places whose zeniths lie on the same parallel, or on equal parallels, will obtain the same latitude.

[Margin: Which cities have the same latitude or longitude.]

Hence it comes about that our Antipodes have the same latitude as we do, though of a different name; for ours is northern, theirs southern. Again, cities placed under the same semicircle of the meridian that passes through the Fortunate Isles — the semicircle contained between the poles of the world, under which the said isles lie — will have no longitude at all; but those situated under the opposite semicircle will possess a longitude of 180 degrees. By the same reasoning, cities

placed under one and the same semicircle of any meridian, intercepted between the two poles, will have the same longitude; whereas those set under different semicircles of the same meridian will have a longitudinal difference of 180 degrees.

All this will be easily understood from some cosmographical globe, on which the great circles drawn through the poles indicate the longitudes of cities, while the circles equidistant from the equator indicate their latitudes; or else, at any rate, from some universal world-map, on which a straight line divided into degrees and drawn from pole to pole down the middle of the map represents the prime meridian, while the other curved lines drawn to either side of it (which indeed signify meridians; and the straight lines parallel to the equator, extended from left to right — which on some maps are curved) represent the parallels, that is, the latitudes of cities. From these it will readily appear which cities have the same longitude or latitude, or a different one, and by how much.

The philosophers, however — as is established in Aristotle, *On the Heavens*, Book 2, chapter 2 [*De Caelo* II.2] — speak otherwise about the longitude and latitude of the whole world. For, taking into account the differences of position that they conceive in the heaven, they call the East the right of the heaven, the West the left; the southern (or Antarctic) pole the upper, and the northern pole the lower.

[Margin: How the philosophers reckon longitude and latitude in the universe.]

For they imagine a man extended along the axis of the world, whose head is set at the Antarctic pole, his feet at the Arctic, his right hand in the East, and his left in the West. So, just as any man's length is taken from head to foot, or the reverse, while his breadth is taken from right to left, or the contrary, it follows that they measure the length of the world from pole to pole, but its breadth from east to west. But the cosmographers, considering the earth (as we said) as it is inhabited, define latitude from the equator toward the poles, and longitude from west to east.

The longitudes of cities can be found most reliably from eclipses of the Moon, although there are other methods, as we have taught in our *Cosmography*.

[Margin: The longitudes of cities are found most reliably from eclipses of the Moon.]

For if it is known that the beginning of an eclipse occurred two hours later at one city than at the Fortunate Isles, it clearly follows that this city lies 30 degrees to the east of the said isles; because that fact is proof that noon reached that city two

hours earlier. This must be understood of hours reckoned from noon, and not from sunset, unless the city lies under the parallel of the Fortunate Isles — and so for the rest. But the latitudes of cities are the same as the elevations of the pole. Hence, once the elevation of the pole has been found in any city, its latitude will be had. And since a knowledge of the longitudes, and no less of the latitudes, of cities is useful for many purposes, I judge that I shall do a welcome service to students if I set out the longitudes and latitudes of the principal cities in the following table. In it, so that any city may be found more easily, I have followed the order of the alphabet.

I have taken both the longitudes and the latitudes for the most part from Ptolemy's *Geography*; in a very few cities, whose longitudes and latitudes were known to me from the observations of other astronomers, I do not agree with Ptolemy. For, as I warned above, the tables of longitudes and latitudes are not to be trusted in every respect: often the longitude and latitude are found greater or less by one degree or another. So it is expedient that everyone, in the place where he is, should investigate the longitude and latitude before turning to other observations.

TABLE

Containing the longitudes and latitudes of the principal cities, and of other places.

Of the principal cities and other places.

Longitude and latitude are each given in degrees (G. = *gradus*) and minutes (M. = *minuta*). Southern latitudes are marked "Aust." (*Australis*, south) in the source and flagged **S** below; all others are northern.

Table of the longitudes and latitudes of cities (continued) — letters B–I

Continuation of the TABVLA continens Longitudines, Latitudinesque civitatum begun under letter A in the previous pages. Column banner on each page: **CIVITATVM PRÆCIPVARVM aliorumque locorum** — "Of the principal cities and other places." The two paired number columns are headed **Longit. G. | M.** (Longitude: degrees | minutes) and **Latit. G. | M.** (Latitude: degrees | minutes). Longitudes are reckoned eastward from the first meridian through the Canaries; the abbreviation **Aust. / Austr.** (*Australis*) marks a southern-hemisphere / New World location. Place-names are transcribed as printed (long-s resolved to s); the vernacular or alternative name printed after a comma is the source's own gloss.

The single row-rules that break the columns every few entries are typographic spacing only; the meaningful divisions are the alphabetical section letters (B, C, ...), given below as sub-headings.

CAPVT SECVNDVM (continued)

TABLE OF THE LONGITUDES AND LATITUDES OF THE PRINCIPAL CITIES AND OTHER PLACES (continued)

Table caption (repeated at the head of each page): **CIVITATVM PRÆCIPVARVM aliorumque locorum** — "Of the principal cities and other places." Column headings: **Longit. G. | M.** = Longitude in degrees and minutes; **Latit. G. | M.** = Latitude in degrees and minutes.

The gazetteer continues in strict alphabetical order. This portion runs from the tail of letter **I** through letter **S** (the letter **K** has no entries — the sequence passes directly from **I** to **L**). Longitudes are reckoned eastward from the first meridian through the Canaries, so New-World and Pacific places carry longitudes greater than 180°; these are transcribed exactly as printed.

How the Distance of Two Cities from Each Other Is to Be Investigated, When the Longitude and Latitude of Each Has Been Ascertained

Although it properly belongs to Cosmography to teach the method by which the intervals of travel between any cities whatever ought to be determined, I nevertheless thought it would not be unwelcome to explain this very matter here in a few words. Now all distances on the earth are measured — just as on any other globe or sphere — along great circles, as we showed in the *Cosmography*; so much so that the distance of one place from another is said to be as great as the arc of the great circle drawn through both places. For this arc of the great circle is the shortest of all the curved lines that can be drawn from one place to another on the convex surface of the earth. Therefore, to inquire into the distance of two places from one another is nothing other than to find out how many degrees, or

minutes, or miles the said arc comprehends. [Margin: The distances of places on the earth are measured along a great circle.]

[Margin: How the distance of places on the earth is investigated when each place is northern, or [each] southern, and the longitude of both is the same.] **When, therefore, two cities have the same longitude** — that is, are situated under the same meridian-semicircle running between the two poles of the world — and each declines either to the north or to the south, then the smaller latitude is to be subtracted from the greater, so that the difference of latitudes is obtained. For if you convert this difference into miles, assigning $62\frac{1}{2}$ miles to each degree and $1\frac{1}{24}$ miles to each minute, you will have the interval between those cities.

EXAMPLE. Rome and Salzburg [Salisburgum] in Germany have nearly the same longitude. Subtracting the latitude of Rome, namely $41^{\circ}56'$, from the latitude of Salzburg, namely $47^{\circ}40'$, the difference of latitudes is found to be $5^{\circ}44'$; and this, reduced to miles, yields $358\frac{1}{3}$ miles — the distance, that is, of the city of Rome from Salzburg.

LIKEWISE, Genoa [Genua] and Frankfurt am Main [Francofordia ad Mœnum], that most noble emporium of Germany, are set under the same meridian-semicircle, and the difference of their latitudes amounts to $6^{\circ}40'$, which yields about 376 miles. So great, then, shall I declare the distance of the one city from the other to be.

[Margin: When places have the same longitude, but one is northern and the other southern.] **But if two places have indeed the same longitude, yet the latitude of the one is northern and that of the other southern**, then the latitude of the one must be added to the latitude of the other in order to obtain their distance.

EXAMPLE. Constantinople and the Cape of Good Hope [Caput bonæ spei] are of nearly the same longitude, and Constantinople has a northern latitude of about 43° . The Cape of Good Hope, however, declines to the south by about 35° , which, added to the latitude of Constantinople, makes 78° , that is, 4875 miles. So great is the length of the journey between Constantinople and the Cape of Good Hope.

[Margin: When the difference of the longitudes of the places amounts to 180° , and each is northern or [each] southern.] **If two cities are located under different semicircles of the same meridian** — which happens only when the difference of their longitudes amounts to 180° — then, if each has a latitude either northern or southern, the sum of the latitudes, subtracted from the semicircle, leaves their distance. EXAMPLE. Granada [Granata] in Spain and the city of Quinsay in the province of Mangi beyond China lie, as it were, under the same meridian, but under different semicircles, and each has a northern latitude — the former

indeed $37^{\circ}50'$, the latter $37^{\circ}40'$. If, therefore, the sum of the two latitudes, namely $75^{\circ}30'$, is subtracted from the semicircle, that is, from 180° , there remains as the distance between the said cities $104^{\circ}30'$, that is, 6500 miles.

But if two places lie under different semicircles of the same meridian, and one has receded from the Equator toward the north, the other toward the south, then the difference of latitudes is to be subtracted from the semicircle, so as to obtain the space lying between them. EXAMPLE. Cantoon, the most noble harbor of China, and the mouths of the Silver River [Ostia fluvii argentei], which the Spaniards call *Rio della Plata*, in Peru, lie nearly on different semicircles of the same meridian; and the latitude of Cantoon is northern, about 19° , while the mouths of the Silver River have a southern latitude of about 36° . The difference of latitudes is about 17° , which, subtracted from 180° (that is, from the semicircle), leaves 163° ; and these amount to $10197\frac{1}{2}$ [?] miles. So great, then, is the distance between Cantoon and the mouths of the Silver River.

From this it follows that, if of two cities lying under different semicircles of the meridian the northern latitude of the one is equal to the southern latitude of the other (or the reverse), then the one is distant from the other by precisely a semicircle; for evidently the difference of latitudes is nothing, and so nothing is subtracted from the semicircle. It is also clear that the direct route between two places lying under different semicircles of the same meridian runs by way of one of the poles, that is, along the meridian circle that passes through both places. This too, moreover, is to be noted here in passing: that if, of two cities whose difference of longitudes contains exactly a quadrant — that is, 90° — the one lies under the Equator while the other has any latitude whatever, whether northern or southern, and however great it may be, then the one is distant from the other by precisely the space of one quadrant. And all these things can easily be shown from the *Spherics* of Theodosius [Theodosius of Bithynia], and demonstrated more clearly than light upon the material sphere.

[Margin: Which cities are distant from one another by a semicircle. — Which cities differ by a quadrant. — When cities are situated under the Equator. — When cities have both a different latitude and a different longitude.] **When, finally, two cities have neither the same longitude, nor a difference of longitudes amounting to 180°** (that is, are set neither under the same meridian-semicircle nor under different semicircles of the same meridian), and neither lacks latitude (that is, neither is placed under the Equator), then the difference of longitudes will reveal their distance, provided it is not greater than a semicircle;

otherwise this difference, subtracted from the whole circle, will give the desired distance. For then the route must be reckoned by way of the Equinoctial circle.

[Margin: By what technique, with the aid of the compass [circinus], the distances of places are found.] **When, at last, two places are situated in none of the aforesaid ways** — whether one lies under the Equator and the other not, or neither does, and whatever latitudes they may have — we shall determine their travel-distance by a device of **Francesco Maurolico, the Abbot** [Francisci Maurolyci Abbatis], namely with the help only of a compass, in this manner. Let a circle A B C D be described from center E; and let, first, the difference of longitudes of the two places — the arc A B — be less than a semicircle, and from the points A and B let two diameters, AEC and BED, be drawn. Let there then be placed the latitude of place A equal to the arc AF, and the latitude of place B equal to the arc BG; and let there be dropped to their respective diameters the perpendiculars FH and GI. After this, to the drawn straight line HI let there be erected from H and from I, on the same side, the perpendiculars HK and IL, each equal to its own — that is, HK equal to the straight line HF, and IL equal to the straight line IG. For the straight line joining the points K and L will be the chord of the arc of the distance of the one place from the other. Therefore, if by Proposition 1 of Book 4 of Euclid you fit into the circle a straight line DN equal to the straight line KL, the arc DN will be the distance between the two given places. Whence, once it is known how many degrees the arc DN contains, the [distance...]

[The geometric construction (circle ABCD with center E; diameters AEC, BED; points F, G, H, I, K, L, N) is described in the text but no figure is printed on this page; the accompanying diagram falls on the following page.]

[Continues from the previous page, mid-construction: how to find the distance between two cities from their coordinates.]

we shall arrive at the distance sought, by assigning 62½ miles to each degree. This rule is to be understood for the case when both places recede from the Equator toward the same quarter — either both to the north or both to the south. For if one of them, namely A, inclines to the south while the other, B, inclines to the north, then perpendiculars must be drawn from the points H and I to the line HI, on opposite sides — such as IL and HM — yet again in such a way that IL is equal to the line IG, and HM to the line HF. For the straight line LM joining the points L and M will again be the chord of the arc of the distance of one place from the other. And so, if a line DO equal to LM be fitted into the circle, the arc DO will be the distance of the two proposed places.

Next, let the difference of longitudes be the arc ABD, greater than a semicircle (for when this difference is a semicircle, it has been said above by what method the distance of the places is to be found); and from the points A and D let the diameters AEC and DEB be drawn. Then let the latitude of place A be set equal to the arc AF, and the latitude of place D equal to the arc DR; and let the perpendiculars FH and RQ be dropped to their respective diameters. After this, to the drawn line QH, on the same side — if both places are northern, or both southern — let perpendiculars QT and HS be drawn, equal respectively to the perpendiculars QR and HF: that is, QT equal to QR, and HS equal to HF. For the line joining the points T and S will be the chord of the arc of the distance of one place from the other. Hence if a line DP equal to TS be fitted into the circle, the arc DP will be the distance of the proposed places, as before.

But if place A is, for example, northern and D southern, perpendiculars must be drawn from Q and H to QH, again on opposite sides — such as QT and HV — yet so that QT is equal to QR, and HV to HF. For the line TV will be the chord of the arc of the distance of one place from the other; and therefore, if a line DX equal to TV be fitted into the circle, the arc DX will be the distance of the proposed places.

The demonstration of this operation — which is indeed most beautiful and most brief — cannot escape anyone even moderately versed in the doctrine of sines, who has examined the matter more carefully on some material sphere. For the circle ABCD will represent the Equator; the diameters AC and BD, the common sections of the Equator with the Meridians of the proposed places; and the points H and I, in the plane of the Equator, will be those on which the right sines of the latitudes of the said places fall. Hence if from the points H and I perpendiculars be raised to the plane of the Equator, these will be the very right sines of the latitudes; they will reach the places themselves on the surface of the sphere, and will be wholly equal to the lines HK and IL, as is evident. Therefore the line KL will be equal to the chord of the arc that lies between the said places; for the lines HK and IL are equal to the right sines of the latitudes.

These same precepts serve for finding the distance between any two stars of the Firmament, provided that in place of the Meridian one takes the circle of the longitude of the stars, which of course passes through the poles of the Ecliptic, as is clear.

We have given another geometrical method, no less subtle and pleasing, in the *Astrolabe*, book 3, in the scholium to Canon 15, no. 4. But of these matters, and of the longitude and latitude of cities, we have said more in the *Cosmography*; it is enough to have touched on these few points here.

Diagram. A large circle (representing the Equator) inscribed with two diameters and a dense network of chords and perpendiculars — the construction for finding the road-distance of two places from their longitudes and latitudes. Around and within the circle the following labels are legible; because the figure is crowded and several interior letters overlap the ruled lines, a few readings are flagged and the whole figure is marked a

- P (top of circle)
- O (top, just left of P)
- G (upper left)
- X (upper left, below G)
- C (upper right)
- N (right, below C)
- D (right end of the horizontal diameter)
- T (far right, below D, at the rim/outside)
- R (lower right)
- H (lower centre, interior)
- A (lower-left centre)
- M (lower left, at the rim/outside)
- S (bottom, outside the circle)
- B (far left, left end of the horizontal diameter)
- F (left edge, above B)
- V (centre-left, interior)
- L (upper centre, interior)
- I [?] (left-centre interior; could be the numeral 1)
- E (centre of the circle)
- K (centre, right of E)
- Q [?] (centre-right, near D; the glyph resembles G but the text's construction calls for point Q)

The main pairs of lines named in the text are the diameters AEC and DEB; the perpendiculars FH and RQ dropped to the diameters; the perpendiculars QT, HS (or QT, HV in the mixed case); the chords LM, TS, TV; and the fitted arcs DO, DP, DX.

But by far the most convenient and easiest way of all is by means of a cosmographical globe, if one is at hand, accurately drawn. For if with a bent compass the distance of one place from the other is taken upon it, and this is

transferred to the Equinoctial circle, at once the degrees between the legs of the compass will indicate the distance of one place from the other.

[Margin: How the road-interval between two places may be found from the sines.]

Yet it will not be out of place to bring forward here, out of all the methods, the one that Pedro Nunes [Petrus Nonius] demonstrated in book 2 of the *Art of Navigation*, and which we have demonstrated more clearly in the scholium to Canon 15, book 3, of our *Astrolabe*, no. 6. It is of this kind. When the two given places are both northern or both southern: let it be arranged that, as the square of the whole sine [radius] is to the rectangle contained under the sines of the complements of the latitudes of the places, so is the versed sine of the difference of longitudes of those same places — which difference, if it exceeds a semicircle, must be subtracted from the whole circle, and the versed sine of the remainder taken, as being that of the shorter difference of longitudes, that is, of the shorter distance between the Meridians of the given places — to a fourth quantity. For a number will be found, from which we shall determine the distance of the places by this device.

Compare the number found with the sine of the complement of the difference of the latitudes of the given places. For if the number found is equal to the sine of that complement of the difference of the latitudes of the given places, the distance of the places will comprise a quadrant of the greatest circle. But if it is smaller, then, when this is subtracted from that, there will remain the sine of the complement of the distance of the places; and so, if this complement be taken away from the quadrant, the remainder will be the distance of the places. If, finally, the number found is greater than the sine of the complement of the difference of the latitudes of the given places, then, when this is subtracted from that, the remainder will be a sine whose arc, added to the quadrant, will give the road-distance of the proposed places.

But when one place is northern and the other southern, one must take the place diametrically opposite to one of them, having the same latitude though on the opposite side, so that one may have two places of the same denomination — both northern, that is, or both southern. Then one must investigate, as we have taught, the road-interval between these two places of the same denomination, provided that in place of the difference of longitudes of the given places one takes what remains when that difference is subtracted from a semicircle, so as to have the difference of longitudes of those two places of the same denomination. For if this road-interval is subtracted from the semicircle, the known distance of the given

places — of which one is northern and the other southern — will remain. But let us set out some examples, to make the matter clearer.

Let the road-distance be explored between **Rome**, whose longitude is $36^{\circ} 30'$ and whose latitude is $41^{\circ} 56'$ north, and **Constantinople**, whose longitude comprises $56^{\circ} 0'$ and whose latitude is likewise $43^{\circ} 5'$ north. Let it be arranged that, as 10,000,000,000 (the square of the whole sine) is to 5,433,294,112 (the rectangle contained under 74392, the sine of the complement of the latitude $41^{\circ} 56'$, and 73036, the sine of the complement of the latitude $43^{\circ} 5'$), so is 5736, the versed sine of the difference of longitudes, which comprises $19^{\circ} 30'$, to a fourth; and there will be found here roughly the number 3116.

[Margin]

Since this is smaller than 99979 — the sine of the complement of the difference of the latitudes of the given places, which comprises $1^{\circ} 9'$ — we shall subtract it from 99979, the sine of the complement of the difference of the latitudes of the places, and there will remain 96863, for the sine of the complement of the distance of the given places. This complement, then, will contain $75^{\circ} 37'$, and so the distance will comprise $14^{\circ} 23'$ — that is, 898 $\frac{23}{24}$ Italian miles — assigning to each degree $62\frac{1}{2}$ miles and to each minute $1\frac{1}{24}$ miles.

Again, let the road-distance be investigated between **Rome** and **Malacca**, in the Golden Chersonese, whose longitude is $161^{\circ} 0'$, and whose latitude, being likewise northern as Rome's is, is $2^{\circ} 0'$. Let it be arranged that, as 10,000,000,000 (the square of the whole sine) is to 7,434,662,088 (the rectangle contained under 74392, the sine of the complement of Rome's latitude, which is $41^{\circ} 56'$, and 99939, the sine of the complement of Malacca's latitude, which is $2^{\circ} 0'$), so is 156640, the versed sine of the difference of longitudes, which comprises $124^{\circ} 30'$, to a fourth; and there will be found here roughly the number 116456. From this — since it is greater than 76679, the sine of the complement of the difference of the latitudes of the places, which is $39^{\circ} 56'$ — we shall subtract 76679, the sine of the complement of the difference of the latitudes; and there will remain the sine 39777, whose arc, $23^{\circ} 26'$, added to the quadrant makes $113^{\circ} 26'$ — that is, 7089 $\frac{7}{12}$ Italian miles — for the distance between Rome and Malacca in the Golden Chersonese.

Let the road-distance also be inquired into between **Rome** and **Mexico** [City], in the West Indies, whose longitude Giuseppe Moletti [Ioseph Moletius], in the new table of New Spain in his commentaries on Ptolemy's *Geography*, puts at about $272^{\circ} 30'$, and its latitude at $20^{\circ} 20'$ north (as Rome's latitude too is northern) —

although others make its longitude and latitude otherwise. Let it be arranged that, as 10,000,000,000 is to 6,975,589,056 (the rectangle contained under 74392, the sine of the complement of Rome's latitude, which is $41^{\circ} 56'$, and 93768, the sine of the complement of Mexico's latitude, which is set at $20^{\circ} 20'$), so is 158778, the versed sine of the difference of longitudes (which is $234^{\circ} 0'$; and since this exceeds a semicircle, it must be subtracted from the whole circle, so that $126^{\circ} 0'$ remain for the shorter difference of longitudes — namely the shorter distance between the Meridians of the proposed places — whose versed sine is 158778), to a fourth; and there will be found here nearly the number 1,110,757. From this — since it is greater than 92977, the sine of the complement of the difference of the latitudes of the places, which comprises $21^{\circ} 36'$ — we shall subtract 92977, the sine of the complement of the difference of the latitudes; and there will remain the sine 17780, whose arc, about $10^{\circ} 15'$, added to the quadrant makes $100^{\circ} 15'$ — that is, 6265 $\frac{5}{8}$ Italian miles — for the distance between Rome and Mexico in the West Indies.

Lastly, let the road-distance be proposed for investigation between **Rome** and **Cusco**, the capital of the province of Peru in the West Indies — a most noble and most wealthy province — whose longitude Giuseppe Moletti, in his new table of the New World, sets at about $305^{\circ} 40'$, and its latitude at about $18^{\circ} 40'$ south, although other writers judge otherwise. And since Rome inclines to the north and Cusco to the south, we shall take a northern place diametrically opposite to Cusco — one that has, of course, a northern latitude of $18^{\circ} 40'$. Then the difference of longitudes of Rome and Cusco, which is $269^{\circ} 10'$ and exceeds a semicircle, we shall subtract from the whole circle, and there will remain the shorter difference of longitudes — that is, the shorter distance between the Meridians of the given places — of $80^{\circ} 50'$. This in turn we shall subtract from the semicircle, so as to have the difference of longitude between Rome and that place opposite to Cusco — that is, the distance between the Meridian of Rome and the Meridian of the said place — of $99^{\circ} 10'$.

With this laid down, if it be arranged that, as 10,000,000,000 (the square of the whole sine) is to 7,047,823,688 (the rectangle contained under 74392, the sine of the complement of Rome's latitude, which is $41^{\circ} 56'$, and 94739, the sine of the complement of the latitude of the place set opposite to Cusco, which is $18^{\circ} 40'$), so is 115930, the versed sine of the difference of longitudes (which we said comprises $99^{\circ} 10'$), to a fourth; there will be found here approximately the number 81705. Since this is smaller than 91867 — the sine of the complement of the difference of the latitudes of the given places, which comprises $23^{\circ} 16'$ — we shall subtract it from 91867, the sine of the complement of the difference of the

latitudes, and there will remain 10162, for the sine of the complement of the distance of Rome from that place which is set opposite to Cusco. This complement, in the table of sines, is $5^{\circ} 50'$; therefore the distance itself will comprise $84^{\circ} 10'$, and if we take this from the semicircle, there will remain the distance between Rome and Cusco of $95^{\circ} 50'$.

DE HORIZONTE. [On the Horizon]

The Horizon, however, is the circle dividing the lower hemisphere from the upper. From this it is called the Horizon, that is, the boundary of sight. It is also called the circle of the hemisphere, for the same reason.

COMMENTARIVS. [Commentary]

In the last place among the great circles he treats of the Horizon, which he says, in the sphere, to be that circle — understand, that greatest circle — which divides the lower hemisphere from the upper. For although any great circle divides the sphere into two equal hemispheres, still, in a special sense and simply, the part of the sky that is seen (or not seen) is customarily called a "hemisphere"; and into these parts no great circle other than the Horizon divides the heaven — except when it performs the office of a Horizon, as the Equator does with respect to those who dwell beneath the poles of the world.

He then teaches that this circle is called "Horizon," as it were the "boundary of sight," from the Greek verb ὁρίζομαι [Greek: horizomai, "I bound/determine"], which means "I determine," because it separates the seen part of the sky from the unseen. For the same reason he says that it is also called "the circle of the hemisphere" — on account, that is, of the seen and the unseen hemisphere. This circle is also commonly called the "ring [gyrus] of the hemisphere," and by the Latins *Finitor* or *Finiens* (the bounder).

[Margin: What the horizon is, and why it is so called.]

The Horizon in the heaven, moreover, must be conceived as entirely immobile, just like the Meridian. For it must necessarily stand at right angles to the Meridian in every clime; and it is plain that the Horizon could not always be at right angles to the Meridian, if it moved while the latter remained immobile. From this it follows that there are as many Horizons from east to west as we said above there are Meridians — if we follow the judgment of sense, namely 300. For the Meridian and the Horizon follow one another mutually, so that when one is changed the other is necessarily changed too — so that it is surprising why

Proclus [Proclus], in his *Sphere*, maintained that the Meridian changes sensibly within a space of

[Margin: There are as many Horizons from east to west as there are Meridians.]

[Margin: The Horizon must be conceived as immobile.]

[Margin: Various names of the Horizon.]

[Top]

300 stadia, which make $37\frac{1}{2}$ miles, as we said above; but the Horizon within a space of 400 stadia, which make 50 miles — unless perhaps he understands the change of Horizons not from east to west, but from north to south. For Horizons change not only from east to west, like the Meridians, but also from pole to pole, so that it is utterly impossible — if we wish to speak geometrically — for two cities on earth to be able to have the same Horizon, whether the one is removed from the other toward east or west, or toward north or south. Yet very many cities — namely all those that have the same longitude, or even those whose difference of longitude amounts to a semicircle, that is 180 degrees — can obtain the same Meridian, even speaking geometrically.

Since this is so, perhaps Proclus meant that the Meridian, and consequently the Horizon, varies sensibly from east to west over a space of 300 stadia — which of course pertains to the rising and setting of the stars — but that the Horizon undergoes a sensible variation from pole to pole, which pertains to the elevation of the pole, over a space of 400 stadia. For one and the same elevation of the pole can serve for so great a space on the earth, as the sundials show. Nevertheless, however we speak, no fixed law can be prescribed either in the change of Meridians or of Horizons. For near the Equator a change of one or two degrees in the elevation of the pole — arising from the change of Horizons from pole to pole — introduces no sensible error as regards the increase and decrease of days and nights and the variety of shadows. But near the poles a change of only one degree induces the greatest difference in the phenomena of the astronomers. And you will say the same, in a certain proportion, of the Meridians, which change from east to west. But all this can be demonstrated geometrically from the Spherics of Theodosius [Theodosius] and Menelaus [Menelaus], and the calculus of sines teaches the same most certainly.

Proclus, Albertus Magnus [Albertus Magnus], and most other writers set up a twofold Horizon. For they say that one is grasped by reason, which they call the

Rational or Natural; the other is grasped by sense, which they call the Sensible or Apparent.

[Margin: What the rational horizon is.]

The Rational is the one that divides the whole heaven into two equal hemispheres and separates the seen part from the unseen; its poles on the sphere are the vertex of the head, or Zenith, and the opposite point, which they call the Nadir; and its centre is the same as the centre of the earth. For what is commonly said — that the Horizon of which the astronomers dispute is a flat circular surface resting upon the surface of the earth and touching the heaven all around, so that it divides it into two equal parts — is to be understood only according to the judgment of the senses. For geometrically speaking, such a surface does not bisect the heaven, since it does not pass through its centre. Yet because the distance from the surface of the earth to its centre is not so great as to bring it about that an eye set upon the globe of the earth — other obstacles, namely mountains and valleys, being removed — should fail to see half of the sky; indeed, since it can even happen that someone stationed on some lofty mountain sees more than half of the sky; it has come about that that circular surface resting on the surface of the earth is taken for the Horizon. For, as we have confirmed by many experiments in chapter 1, this surface sensibly cuts the heaven into two halves — although, geometrically speaking, only a surface drawn through the centre of the earth bisects the heaven, and this is what the aforesaid authors call the rational Horizon, because it is gathered by reason alone. For the keenness of the eyes does not run out to the very edge of the heaven so as to perceive the division of the heaven into equal parts; rather, from the various phenomena that are perceived by sense, the mind by reasoning gathers that the matter is so.

[Margin: What the artificial horizon is.]

For the same reason it is called by some the Artificial [horizon], because it is discovered by the help of the astronomical art. It is therefore of this rational Horizon that Johannes de Sacrobosco [Sacrobosco] discourses in this place; and to it lies parallel every pavement built true to the level, and likewise any convex surface of water, insofar of course as it appears flat to the sense.

Diagram. A circle (the sphere seen edge-on) crossed by a horizontal diameter — a double ruled line representing the horizon plane — with the word **HORIZON** lettered along it (the letters spread across the line, H O R I on the left half and Z O N on the right, split at the centre by a small hatched sun/eye emblem set on the

line). At the left terminus of the horizon line a single letter is faintly marked, N [?] (uncertain — possibly a label, possibly decorative). No other labels are legible.

[Margin: What the sensible horizon is.]

The Sensible Horizon is the name given to that space, on the surface of land or sea, which the sight of the eyes, sweeping around, can take in, all obstacles being removed.

For since the earth is round, an eye set upon its surface cannot behold a larger space than what the straight lines going out from the eye — lines tangent to the surface of the terrestrial globe — cut off, as is manifest among the writers on optics [the Perspectivi]. But not all authors make this space of the same size. For in the opinion of Macrobius [Macrobius] its semidiameter comprises 180 stadia, that is 22½ miles. Eratosthenes [Eratosthenes] sets the same at 350 stadia, which make about 44 miles. Albertus Magnus asserts that it contains 1000 stadia, that is 125 miles. Proclus makes it 2000 stadia, which make 250 miles. But in most authors you will find it to contain — as being nearer the truer opinion — only 500 stadia, or 62½ miles. Finally, however great this space may be (for it is hard to determine), let it suffice us that it is called the Sensible Horizon.

The Horizon, moreover, is twofold: right and oblique (or sloping). A right Horizon and a right sphere belong to those whose Zenith is on the Equinoctial, because their Horizon is a circle passing through the poles of the world and dividing the Equinoctial at right spherical angles; hence it is called a right Horizon and a right sphere. An oblique or sloping Horizon belongs to those for whom the pole of the world is raised above the Horizon. And since their Horizon intersects the Equinoctial at unequal and oblique angles, it is called an oblique Horizon, and an oblique or sloping sphere.

[Margin: The right and the oblique horizon.]

[Margin: Who have a right or an oblique horizon.]

COMMENTARIVS. [Commentary]

He divides the Horizon into right and oblique, and teaches that a right [horizon] causes the sphere too to be called right, and an oblique one an oblique sphere. On which matter I have written more fully in the first chapter. Now it will be enough to set both the Horizon, or the sphere, before the eyes by their own figures.

Commentary on Chapter II of the *Sphere* — On the Horizon (continued)

DIAGRAM OF THE RIGHT HORIZON, and of the oblique.

Diagram. The left of the two woodcut circles shows the *right* (direct) sphere: a circle divided into four quadrants by a horizontal and a vertical diameter, the lower half shaded. Labels:

- Top: ZENITH
- Bottom: NADIR
- Left (vertical, along the rim): POLVS ("pole")
- Right (vertical, along the rim): POLVS ("pole")
- Horizontal diameter through the center: HORIZON RECTVS ("right horizon")
- Vertical diameter through the center: AEQVINOCTIALIS ("equinoctial")

Here the equinoctial passes through the zenith, and the horizon runs through both poles — the configuration of the right sphere.

Diagram. The right of the two circles shows the *oblique* sphere: the same circle, but with the axis tilted, the lower half shaded. Labels:

- Top (tilted): ZENITH
- Upper right, along the rim: POLVS ("pole")
- Lower left, along the rim: POLVS ("pole")
- Diagonal diameter: AEQVINOCTIALIS ("equinoctial")
- Horizontal diameter through the center: HORIZON OBLIQVS ("oblique horizon")
- Bottom: NADIR

Here the pole is raised obliquely above the horizon, so the equinoctial meets the horizon at a slant — the configuration of the oblique sphere.

Text [Sacrobosco]

The ZENITH of our head, moreover, is always the pole of the horizon. From this it is clear that the elevation of the pole of the world above the horizon is as great as the distance of the zenith from the equinoctial — which is shown as follows. Since on any natural day each colure is joined twice to the meridian (or is itself the same as

the meridian), what is proved of the one is proved of the other as well. Take, then, one quarter of the colure that marks off the solstices, namely the quarter from the equinoctial up to the pole of the world; and take again another quarter of the same colure, namely the one from the zenith up to the horizon, since the zenith is the pole of the horizon. These two quarters, being quarters of the same circle, are equal to each other. But if equals are taken from equals — or a common part removed — the remainders are equal. Therefore, with the common arc removed (namely the one between the zenith and the pole of the world), the remainders will be equal: that is, the elevation of the pole of the world above the horizon, and the distance of the zenith from the equinoctial.

[Margin: The zenith of the head is the pole of the horizon. The elevation of the pole above the horizon equals the distance of the zenith from the equator.]

COMMENTARY

From the fact that the zenith, or crown of our head, is perpetually the pole of the horizon — so that from the zenith in every direction to the horizon there is a quadrant of a circle — the author demonstrates here that the elevation of the pole above the horizon is as great as the distance of the zenith from the equator. This is what we assumed above, as something well known, in the case of the meridian circle. The author's own demonstration can be made perfectly clear to anyone by this figure, in which let the circle A B C D be the solstitial colure (the same as the meridian); the horizon, A E C; the equator, B E I; the poles of the world, G and H; the zenith, F [and the nadir, D]. The quadrant from the equator through the zenith up to the pole is the arc B F G; the quadrant from the zenith through the pole down to the horizon is the arc F G C. Since, then, the quadrants B G and F C are equal, it is evident that, with the common arc F G removed, the remaining arc G C — namely the elevation of the pole above the horizon — is equal to the remaining arc F B, that is, to the distance of the zenith from the equator. Hence it is clear that the altitude of the pole in any city is equal to the latitude of that same place, since the latitude of a place is as great as the distance of the zenith from the equator.

Diagram. A circle with two perpendicular diameters and two oblique chords crossing at the center E. Labelled points:

- F (top of circle)
- B (upper left)
- G (upper right; marked with a star)
- A (left)

- E (center)
- C (right; marked with a dot)
- H (lower left; marked with a star)
- I (lower right)
- D (bottom)

The horizontal diameter is A–E–C (the horizon); the vertical diameter F–E–D; the oblique chord B–E–I is the equator; G and H are the poles of the world. (All nine labels read cleanly.)

[Margin: The latitude of any place equals the altitude of the pole above the horizon.]

THE FUNCTIONS OF THE HORIZON [OFFICIA HORIZONTIS]

I.

It DIVIDES the heaven into two equal hemispheres — the upper, or visible, and the lower, or hidden.

[Margin: The horizon cuts the heaven into a hemisphere that is visible or upper, and one not visible, or lower.]

II.

It IS the cause of the right and the oblique sphere. For the higher some horizon raises one of the poles of the world above itself, the more oblique a sphere will those have who dwell under such a horizon; and the less elevated the pole any horizon has, the less oblique a sphere those living under it obtain. Thus where one of the poles is raised most of all above the horizon — as it is for those dwelling directly under the poles of the world — there the sphere is most oblique; but where there is no elevation of the pole above the horizon, as happens for those living under the equator, there is no obliquity of the sphere at all, but a wholly right sphere.

[Margin: The horizon is the cause of the right and the oblique sphere.]

III.

BY MEANS of the horizon is reckoned the length of any given day and night — the artificial day and night. For the artificial day is defined as the duration of the Sun's stay above the horizon, and the night as the stay of the same Sun below the horizon. This duration is known solely from the arcs of the parallels above or

below the horizon which the Sun describes by the diurnal motion. So that if the horizon divides all the parallels into equal parts, as happens in the right sphere, the days are perpetually equal to the nights; but if it divides them unequally, the nights are unequal to the days. (More on this in chapter 3.) From this it is easily gathered that the horizon is the sole cause of the inequality of artificial days and nights.

[Margin: The horizon determines the artificial day and night. What the artificial day and night are.]

IV.

It SHOWS the duration of all the stars above the horizon and below it. For when the horizon divides all the parallels that are described by the diurnal motion, cutting each in two — as happens in the right sphere — any given star spends as much time above the horizon as below it. But when the horizon does not cut the parallels in two, as happens in the oblique sphere, the stars declining from the equator toward the visible pole draw out a longer stay above the horizon than below it — such as, for us dwelling in Europe, are all the stars set in the northern hemisphere. Those declining toward the hidden pole spend less time above the horizon than below it — such as, in our horizon, are all the stars placed in the southern hemisphere. All of this is easily demonstrated from the spherical elements of Theodosius [Theodosius of Bithynia]. Indeed some stars in any oblique sphere do not rise above the horizon at all, but remain perpetually hidden beneath it; while certain others do not descend below it, but are always visible above the horizon, as we shall say presently.

[Margin: The horizon indicates the duration of all the stars above the horizon.]

V.

It MAKES MANIFEST the points of rising and setting of all the heavenly bodies, and how far their rising and setting stand from the true and equinoctial rising [and setting] — a matter of which astronomers make the greatest use, especially in determining the lengths of shadows. The *true* or *equinoctial* rising is called that point in which the equator cuts the horizon on the eastern side; the *true* or *equinoctial* setting is called that point in which the equator intersects the same horizon on the western side. When, therefore, a star does not rise or set at such a point, it is said by astronomers to have a rising or setting latitude. So that the latitude, or amplitude, of the rising or setting of any star is the arc of the horizon intercepted between the point of the true rising (or setting) of the said star and the point of the true rising (or setting). Now in every climate the rising amplitude,

or latitude, of any given star is equal to the setting amplitude, or latitude, of that same star. Likewise, two stars equally distant from the equator — one toward the north, the other toward the south, or even both toward the north or both toward the south — have equal rising and setting amplitudes, as can easily be deduced from the spherical elements of Theodosius and Menelaus [Menelaus of Alexandria]. From this it follows that the rising and setting amplitudes of the points of a single quadrant of the ecliptic are equal to all the rising and setting amplitudes of all the points found in the other quadrants: so that there always exist four points of the ecliptic whose rising and setting amplitudes are equal, just as we said above concerning the declinations of the points of the ecliptic, and as was demonstrated by us in Book 1 of the *Astrolabe*, Lemma 49, no. 5.

[Margin: The horizon shows the points of the rising and setting of the heavenly bodies, and how far their rising and setting stand from the equinoctial rising and setting. What the true or equinoctial rising and setting are. What the rising or setting latitude of a star is. How the rising and setting latitude is computed by means of the sines.]

The rising or setting amplitude of any point of the ecliptic whatever, or of any star, WILL BE FOUND by the doctrine of sines in this way. Let the sine of the declination of the proposed star or point of the ecliptic be multiplied into the whole sine, and let the product be divided by the sine of the complement of the latitude of the place in which you are inquiring after the amplitude. (We call the *complement* of any arc that which it lacks to complete the quadrant. Thus the complement of 30 degrees will be an arc of 60 degrees, and so for the remaining arcs.) There will come out a sine whose arc, found from the table of sines, will give the amplitude sought. For, as Geber [Jābir ibn Aflāḥ] demonstrates in Book 2, and Johannes Regiomontanus in Book 2 of the *Epitome*, proposition 2, and as we demonstrated in Book 1 of the *Gnomonics*, proposition 34: as the sine of the complement of the altitude of the pole (or of the latitude of any place) is to the sine of the declination of the star or point of the ecliptic, so is the whole sine to the sine of the rising or setting amplitude of the proposed star or point of the ecliptic.

EXAMPLE. With the Sun placed at the first point of ♋ [Cancer], I multiply the sine of the declination — which is 23 degrees 30 minutes, namely 39874 — into the whole sine, taken as 100000; and the product, namely 3987400000, I divide by 74314, that is, by the sine of the complement of the latitude of Rome, which we here set at 42 degrees (to avoid the minutes). There comes out the sine of the amplitude sought, 53656, to which in the table of sines corresponds an arc of 32

degrees 27 minutes. So great, then, is the rising or setting amplitude, with the Sun at the first point of $\mathfrak{S}$, where the pole is elevated 42 degrees, as happens roughly at Rome. And the same reasoning holds for the rest of the points. An easier method of computing the rising latitude we have handed down in our new treatise on sundials, problem 3.

VI.

It DEMONSTRATES the degree of the ecliptic with which any given star rises and sets. For with a star placed on the horizon on the eastern side, let the degree of the ecliptic that then touches the horizon be noted; for that star is said to rise with that degree. And with the same star placed again on the horizon on the western side, let the degree of the ecliptic that then touches the horizon be observed; for the aforesaid star will set with that degree.

[Margin: The horizon indicates the degree of the ecliptic with which any given star rises.]

VII.

It INDICATES which stars are of perpetual appearance in any climate, which are of perpetual concealment, and which, finally, are said to rise and set. For if the horizon passes through the poles of the world — as does the right horizon — it will divide in two all the parallels that the stars describe by the diurnal motion, as is established from proposition 15, Book 1, of Theodosius, and as we also asserted above in the fifth property of circles. Hence in a horizon of this kind, that is, in the right sphere, all the stars rise and set. But if the horizon by no means passes through the poles of the world — as is every oblique horizon — it will not divide any parallel in two except the equator; indeed some parallels near the poles it does not divide at all. Hence the stars describing parallels that are not divided by the horizon neither rise nor set, but are either raised perpetually above the horizon (if, that is, they lie near the visible pole) or perpetually kept down beneath it (if, that is, they are placed near the other, hidden pole); whereas the stars whose parallels are divided by the horizon do rise and set. The stars that are of everlasting appearance are known by a circle parallel to the equator which touches the horizon near the visible pole. For all the stars comprehended between the elevated pole and the said parallel are seen perpetually above the horizon, as is easily seen on the material sphere. The stars, on the other hand, that are always concealed beneath the horizon are marked off by another circle parallel to the equator which, being equal to the former, touches the horizon on the side of the hidden pole. For all the stars enclosed between the hidden pole

and the said parallel can never come into view, but are of everlasting concealment.

[Margin: The horizon shows the stars that rise, that set, and that are perpetually visible and hidden. Which stars neither rise nor set. What the greatest of the ever-visible or ever-hidden parallels is.]

Now these two parallel circles — of which the one is called by astronomers the *greatest of the ever-visible*, because it is the greatest of all the parallels that always appear, and the other the *greatest of the ever-hidden*, because it is the greatest of all the parallels that are always concealed — are so much the larger, and the nearer to one another, and enclose the more stars, as the horizon is more oblique, that is, as the pole is more raised above the horizon; so much so that, for those dwelling under either of the poles, the said circles utterly coincide, uniting into one and merging with the equator. And with these same people no fixed star rises and sets, but half of them appear perpetually while the other half remain always hidden — although all the planets, since they perform their proper motions in the zodiac, appear for half the time and are concealed for the other half, because one semicircle of the zodiac is continually raised above the horizon while the other lies hidden beneath it. For those, moreover, who dwell under the polar circles, the two tropic circles perform the office of the said circles; and conversely, for those who dwell under the two tropics, the polar circles discharge the office of those same two parallels. For in every region the said parallels are always equal to each other and equally distant from the equator, as is established from proposition 6, Book 2, of Theodosius, or also from the seventh property of circles; and the same can be plainly seen by anyone on the material sphere. The remaining stars, finally, placed between the equator and the said two parallels rise and set.

[Margin: The various dispositions of the greatest of the ever-visible and ever-hidden parallels.]

FURTHERMORE, from the known declination of any star and the known latitude of the place (which is the same thing as the altitude of the pole) it will easily be detected whether the star rises and sets, or rather is perpetually visible or perpetually hidden — by this method, of course. Let the altitude of the pole (or latitude of the place) be joined to the declination of the star, if it has any. If the aggregate is less than a quadrant, that is, than 90 degrees, the star will rise and set; but if it exceeds 90 degrees, a star declining toward the north will be perpetually visible [and never set], while one verging toward the south will be perpetually hidden and can never come into view above the horizon. And if the

said aggregate turns out equal to a quadrant, it will touch the star — that is, the star will graze the horizon — whether on the northern side, if it has a northern declination, or on the [southern] side, if a southern. All of this is plain on the material sphere.

[Margin: How it may be known whether a proposed star rises or not, and whether it is perpetually visible or perpetually hidden.]

The SAME we shall obtain by this reasoning. If the complement of the star's declination is greater than the altitude of the pole, the star will rise and set; but if it is less than the altitude of the pole, it will be perpetually visible [or perpetually hidden]; and if, finally, it is equal to the altitude of the pole, the star — whether northern or southern — will touch the horizon. As appears on the material sphere.

The SAME we shall also obtain in this manner. If the star's declination is less than the complement of the altitude of the pole, the star itself rises and sets; but if it is greater, it will be perpetually visible [or hidden]; and if [equal], it will touch the horizon. As is clear from the same material sphere — provided that, for northern stars, one takes the arc of the meridian below the horizon on the side of the arctic pole, between the horizon and the equator, and the star's declination is counted on that same arc from the equator toward the horizon; while for southern stars one takes the arc of the meridian above the horizon, on the southern side, between the horizon and the equator, and the star's declination is counted on that same arc from the equator toward the horizon.

VIII.

The horizon brings GREAT convenience to cosmographers, or geographers. For to it are referred the altitudes of the pole, which we have demonstrated to be equal to the latitudes of places, and of which cosmographers make the greatest use. Hence, again, from the known altitude of the pole (or latitude of the place) the altitude of the equator will be known. For since from the zenith, through the equator, up to the horizon there is an entire quadrant of the meridian, if the latitude of the place — that is, the distance of the zenith from the equator — is subtracted from the quadrant, there will remain the altitude of the equator. Thus if 41 degrees 56 minutes (the latitude, namely, of Rome) be subtracted from 90 degrees, there will remain the altitude of the equator, 48 degrees 4 minutes — which is precisely the arc of the meridian comprehended between the equator and the horizon. Moreover, the altitude of the equator is perpetually equal to the complement of the altitude of the pole (or of the latitude of the place), that is, to

the distance of the zenith from the pole of the world; for the latitude of the equator is the complement of the latitude of the place, as is plain, while the latitude of the place is equal to the altitude of the pole. This may also be demonstrated by the following reasoning. Let the immediately preceding figure be examined; in it, since the quadrant A F is equal to the quadrant B G, with the common arc B F removed there will remain the arc A B — namely the altitude of the equator — equal to the arc F G, that is, to the complement of the altitude of the pole.

[Margin: The horizon is of service to cosmographers. How the altitude of the equator may be known. The altitude of the equator is equal to the complement of the altitude of the pole.]

ON THE FOUR LESSER CIRCLES [DE QVATVOR CIRCVLIS MINORIBVS]

Text [Sacrobosco]

Having spoken of the six greater circles, we must now speak of the four lesser ones. The Sun, when it is at the first point of Cancer — that is, at the first point of the summer solstice — describes, by the sweep of the firmament, a certain circle which is the last one described by the Sun on the side of the arctic pole; whence it is called the circle of the summer solstice, for the reason stated above, or the summer tropic, from τροπή [Greek: τροπή (tropē, "turning")], which means "turning," because the Sun then begins to turn back toward the lower hemisphere and to recede from us.

The Sun, again, when it is at the first point of Capricorn — that is, at the winter solstice — describes, by the sweep of the firmament, a certain circle which is the last one described by the Sun on the side of the antarctic pole; whence it is called the circle of the winter solstice, or the winter tropic, because the Sun then turns back toward us.

[Margin: How the tropics are described. The tropic of Cancer and the tropic of Capricorn.]

COMMENTARY

Having finished the treatment of the six circles that are the greatest in the sphere, the author here treats of the four lesser, or non-greatest, ones — and first of the two that are described by the sweep of the first mobile from the first degree of ♋ [Cancer] and ♎ [Capricorn], and are consequently removed from the equator by 23 degrees 30 minutes, just as the beginnings of ♈ and ♎ are. These two circles

are equal to each other, and each touches the ecliptic at a single point only, as is gathered from Book 2 of Theodosius. Likewise they are the last and least of those which the Sun describes by the diurnal motion; for it is up to these that the Sun wanders to and fro from the equator, [whereas...]

as soon as the Sun has reached them, it at once directs its course back toward the Equator. This is why he says they are called "tropics," from the Greek word τροπή [tropē], which means "conversion" or "turning," because the Sun, being in them, turns itself back once more toward the Equator. The one described from the first point of Cancer ☊ is customarily called the Tropic of Cancer; the other, described from the beginning of Capricorn ☋, the Tropic of Capricorn. By the same reasoning the Tropic of Cancer is also usually called the summer tropic — the tropic or circle of the summer solstice (understand this of the northern hemisphere) — the Northern Tropic, and the reversing circle of Cancer [circulus versilis Cancrī]. Likewise the Tropic of Capricorn is called the winter tropic, the tropic or circle of the winter solstice, the Southern Tropic, and both are usually named by very many other names of this kind by writers.

[Margin: The various names of the tropics.]

(Sacrobosco) Now since the Zodiac slopes away from the equinoctial, the pole of the Zodiac too will slope away from the pole of the world. When, therefore, the eighth sphere is set in motion, and the Zodiac, which is part of the eighth sphere, moves about the axis of the world, the pole of the Zodiac will also move about the pole of the world. That circle, then, which the pole of the Zodiac describes about the Arctic pole of the world is called the Arctic circle; but that circle which the other pole of the Zodiac describes about the Antarctic pole of the world is called the Antarctic circle.

[Margin: The Arctic circle, and the Antarctic.]

COMMENTARY

He here explains the two polar circles — the Arctic and the Antarctic — which are described by the motion of the primum mobile from the poles of the Zodiac about the poles of the world. Since, therefore, the distance of the poles of the Zodiac from the poles of the world is equal to the greatest declination of the Sun, as we demonstrated a little above, it follows that each polar circle stands as far from the poles of the world (the Arctic from the Arctic pole, the Antarctic from the Antarctic) as the two tropics recede from the Equator — namely 23° 30′.

[Margin: What the polar circles are.] [Margin: How far the polar circles are from the poles of the world.]

The Greeks, as one may see in Proclus and Cleomedes, understand the two polar circles very differently. For they do not, like the Latins, give the name "polar circles" to those described about the poles of the Zodiac; rather, among them two circles are called polar, of which one is the greatest of the always-visible parallels and the other the greatest of the always-hidden ones — the circles we treated in the 7th function of the Horizon. The Greeks preferred to define the polar circles in this way, so that through them all those stars might be known which never rise and set, but are either perpetually visible — such as those the Arctic circle encloses — or perpetually hidden, such as those the Antarctic comprehends. From this it is clear that among the Greeks the two polar circles are not of the same size in all regions, as they are among the Latins; rather, the more oblique the sphere, the larger they become — as was said above of the greatest of the always-visible parallels and the greatest of the always-hidden ones.

[Margin: How the polar circles are understood by the Greeks.]

Moreover, the four aforesaid smaller circles — namely the tropics and the polar circles — are equidistant from the Equator, as is established from Theodosius (*Sphaerica* II.2), because they possess the same poles as the Equator, namely the poles of the world, from which they are described. And although any greatest circle in the sphere has its own parallels, as we said at the beginning of this chapter, still among astronomers the chief account is taken of the parallels of the Equator and of the Zodiac. For the individual stars, or points of the heaven, describe individual equidistant circles by the diurnal motion of the primum mobile; but by the motion of the eighth sphere, from west to east, they trace circles equidistant from the Zodiac. Among all the circles parallel to the Equator, these four smaller ones are distinguished by particular names, which our Author has explained.

Just as the Equator, or any greatest circle in the sphere, is distributed into 360 degrees, so too, as we noted above, any lesser circle is cut into the same number of degrees, which are wholly similar to the degrees of a greatest circle, as is gathered from Theodosius (*Sphaerica* II.10); so that whatever proportion a greatest circle has to a non-greatest circle, the individual degrees of the greatest circle keep the same proportion to the individual degrees of the non-greatest circle.

The proportion of a greatest circle to a non-greatest circle whose declination is known will be obtained from the doctrine of sines, in this way. Let the sine of the complement of the declination of the non-greatest circle be multiplied by the whole circle, that is, by 360° , and let the product be divided by the whole sine [sinum totum]; there will result the number of degrees of the non-greatest circle, of which the greatest circle contains 360. For, as we showed in Book 8 of the *Practical Geometry*, proposition 2, as the whole sine is to the sine of the complement of the declination of any parallel — that is, as the radius [semidiameter] of the Equator is to the radius of the parallel — so is the circumference of the Equator to the circumference of the parallel.

[Margin: By what method the proportion of a greatest circle to a non-greatest is known from the sines.]

Example. Suppose it is proposed to find what proportion the Equator has to the parallel which passes through the zenith [Verticale punctum] of Rome, whose declination is taken as 42° . I multiply the sine of the complement of this declination — that is, the sine of 48° , namely 74314 — by 360, and I divide the resulting number, 26753040, by 100000, the whole sine, and I find about $267\frac{1}{2}$ degrees. Therefore the Equator will have to the parallel which runs through the zenith of Rome — or likewise one degree of the Equator to one degree of the said parallel — the proportion that 360° has to about $267\frac{1}{2}^\circ$: that is, nearly the sesquitertian ratio, such as 4 to 3, and so on.

(*Sacrobosco*) As great, moreover, as is the greatest declination of the Sun — namely from the equinoctial — so great is the distance of the pole of the world from the pole of the Zodiac; which is shown as follows. Let the colure that marks off the solstices be taken, which passes through the poles of the world and through the poles of the Zodiac. Since, then, all the quadrants of one and the same circle are equal to one another, the quadrant of this colure which runs from the equinoctial up to the pole of the world will be equal to the quadrant of the same colure which runs from the first point of Cancer up to the pole of the Zodiac. Therefore, when the common arc — namely that from the first point of Cancer up to the pole of the world — is removed from those equal arcs, the remainders will be equal: namely, the greatest declination of the Sun, and the distance of the pole of the world from the pole of the Zodiac.

[Margin: The distance of the pole of the Zodiac from the pole of the world is equal to the greatest declination of the Sun.]

COMMENTARY

Diagram. A woodcut sphere (globe of the world) shown in oblique view, on which the great circle A B C D — the solstitial colure — is drawn together with the smaller circles (the two tropics and the two polar circles) crossing it; the two polar circles near the top and bottom are marked with small stars. The labeled points, per the accompanying text, are: A and C the ends of the equinoctial diameter; B the north (Arctic) pole of the world; D the south (Antarctic) pole of the world; K the pole of the Zodiac; E the first point of Cancer on the colure; so that A E is the greatest declination of the Sun and B K the distance of the pole of the world from the pole of the Zodiac.

- I (top, left of pole, with star): point on the Arctic circle
- B (top center, large): north pole of the world
- K (top, right of pole, with star): pole of the Zodiac
- F (upper left flank): tropic/colure intersection point
- E (upper right flank): first point of Cancer
- A (right side, below E): end of the equinoctial (A C)
- C (left side, middle): opposite end of the equinoctial (A C)
- H (left side, lower): tropic/colure intersection point
- G (right side, lower): tropic/colure intersection point
- L (bottom, left of pole, with star): point on the Antarctic circle
- D (bottom center): south pole of the world
- M (bottom, right of pole, with star): point on the Antarctic circle

He proves that the poles of the Zodiac recede from the poles of the world by as great a space as is the greatest declination of the Sun on either side. He demonstrates this in the same way that we ourselves showed the same thing in the 6th function of the Colures, as is evident in this figure, in which: the circle A B C D is the solstitial colure; A B is the quadrant from the equinoctial A C up to the pole of the world B; E K is the quadrant from the first point of Cancer ϖ up to the pole of the Zodiac K; A E is the greatest declination of the Sun; B K is the distance of the pole of the world from the pole of the Zodiac; and so on.

Now since we said above that the greatest declination of the Sun varies on account of the libration of the tenth sphere, it comes about that this reasoning concludes only that the greatest declination of the Ecliptic of the eleventh sphere is equal to the distance of the poles of the Ecliptic of that same sphere from the poles of the world — since this sphere is not stirred by that libration. For the

greatest declination of the Sun, since it varies, cannot be equal to the distance of the pole of the Zodiac from the pole of the world, which is taken in the primum mobile and remains always the same.

[Margin: How it is to be understood that the distance of the poles of the Zodiac from the poles of the world is equal to the greatest declination of the Sun.]

[Margin: How great the arc of the colure between the Tropic of Cancer and the Arctic circle is.]

(Sacrobosco) Now since the Arctic circle is equally distant from the pole of the world along each of its parts, it is clear that the part of the colure lying between the first point of Cancer and the Arctic circle is nearly double the greatest declination of the Sun — or double the arc of the same colure which is intercepted between the Arctic circle and the Arctic pole of the world, which arc is likewise equal to the greatest declination of the Sun. For since this colure, like the other circles in the sphere, is 360° , its quadrant will be 90° . Since, then, according to Ptolemy the greatest declination of the Sun is $23^\circ 51'$, and the arc between the Arctic circle and the Arctic pole of the world is of the same number of degrees, if these two together — which come to nearly 48° — are subtracted from 90° , there will remain 42° , which is the size of the arc of the colure lying between the first point of Cancer and the Arctic circle. And so it is clear that that arc is nearly double the greatest declination of the Sun.

COMMENTARY

He gathers from what has been said that the arc of the colure intercepted between the Tropic of Cancer ☿ and the Arctic circle is nearly double the greatest declination of the Sun, or of the distance of the pole of the Zodiac from the pole of the world. For since, according to Ptolemy's view, the greatest declination of the Sun is $23^\circ 51'$, that arc will be about 42° . According to the common opinion, however, the greatest declination of the Sun at the present time is $23^\circ 30'$, and the said arc is 43° .

ON THE MILKY WAY [DE CIRCULO LACTEO]

Furthermore, since besides these ten circles of the sphere Proclus also treats of the Milky Way — which is also called the Galaxy [Galaxia] — it will not be out of place to explain briefly here what the Milky Way is, and through which constellations it runs in the heaven. The Milky Way, then, is a greatest circle in the heaven, having a variable breadth and brightness, so that in one part it has a

greater breadth than in another, and likewise a greater whiteness in one part than in another, running through Gemini and Sagittarius, as Ptolemy explains very fully (*Almagest* VIII.2). Its whiteness, from which it takes the name "milky," arises — as some hold — from the very great multitude of tiny stars contained in it, which do not reach our sight as distinct, like the other stars. I, however, together with others, think it more probable that the Milky Way is a continuous part of the Firmament, denser than the other parts of the heaven, so that it can receive the light of the Sun — though not in the way the other stars do, which are much denser parts of the Firmament and set apart from one another — whatever the poets may fable about the milk of Juno and the scorching that the Sun caused. And so the Milky Way truly exists in the Firmament, and not in the region of the air, as Aristotle held. For on that reasoning it would not be seen, in every part of the terrestrial globe, to pass precisely through the same stars of the Firmament — just as a comet, which exists in the air, is not seen in all regions under the same fixed star; which is false. For the Milky Way runs perpetually, as may be seen in Ptolemy at the cited passage, and as experience teaches, through Cassiopeia, Cygnus, the flying Eagle [Aquila], the Arrow of Sagittarius [Sagitta], the tail of Scorpius, the Centaur, the ship Argo, the feet of Gemini, Heniochus (that is, Auriga, the Charioteer), and Perseus, as is most clearly established on any astronomical globe. And this Manilius beautifully sets forth in these verses. For after he had spoken of the Zodiac, he writes thus of the Milky Way:

[Margin: The Milky Way.] [Margin: Whence the whiteness in the Milky Way arises.] [Margin: That the Milky Way exists in the Firmament, and not in the air.] [Margin: Through which constellations the Milky Way runs.]

The other [circle], set opposite, moves up toward the Bears, and draws its threads a little back from the North by its curve. It crosses through the stars of Cassiopeia turned upside down, then, descending obliquely, touches the Swan [Olor]; it cuts the summer bounds, and the Eagle lying on its back; and that which levels the seasons — the belt that bears the Sun's horses — within the tail where Scorpius burns, and the outermost left of Sagittarius[i], and its arrow. Thence it winds its bends through the legs and feet of the other Centaur; and again it begins to climb the sky, passing the Argive ship [Argo] along its topmost stern-ornaments [aplustria],

and cuts the middle circle of the world, and the Twins [Gemini] along their lowest stars: it passes beneath Heniochus [Auriga]; and, setting out from there, making for Cassiopeia, it crosses above Perseus himself, and closes in her the circle begun from her; and it cuts three of the middle

gyres, and the sign-bearing circle [the Zodiac], as often as it is itself cut across into two parts. Nor need it be sought out: it strikes the sight of its own accord, teaches itself, and compels itself to be noticed; for, gleaming white, it shines as a track upon the dark-blue world.

Ovid calls the Milky Way the road by which the gods above went up to Jupiter, in these verses in Book 1 of the *Metamorphoses*:

There is a high road, plain to see when the sky is clear (it bears the name "Milky"), notable for its very whiteness. By this is the path of the gods above to the halls of the great Thunderer, and to his royal house, etc.

Whoever desires more about this circle, let him read Ptolemy at the cited passage, and especially the commentaries of Stöffler [Stoflerini] on the *Sphere* of Proclus. There he will find that various opinions have existed concerning this circle.

THE FUNCTIONS OF THE PARALLEL CIRCLES [OFFICIA CIRCVLORVM PARALLELORVM]

I.

The tropics enclose the path of the Sun. For they are, as it were, boundaries enclosing in the heaven the region beyond which the Sun never strays, but within which it is perpetually carried. Hence they also mark in the Ecliptic the two points at which the solstices occur, and at which the Sun has its greatest declination.

[Margin: The tropics enclose the path of the Sun.]

II.

The polar circles determine the distance of the poles of the Zodiac from the poles of the world, and enclose, toward the poles of the world, the regions in which the greatest day of the year — and likewise the greatest night — exceeds 24 hours and is made up of several days, as will be taught in chapter 3.

[Margin: The polar circles enclose the regions toward the poles in which the greatest day is longer than 24 hours.]

III.

The two tropics and the two polar circles, both in the heaven and on the earth, constitute the five zones, as we shall say presently.

[Margin: The tropics and polar circles constitute the five zones.]

IV.

The parallel circles, which the Sun describes by the motion of the primum mobile — about 182 in number, as we shall say in chapter 3 — reveal the cause of the perpetual equality of days and nights in the right sphere, and of the inequality of those same days and nights in the oblique sphere.

[Margin: The parallel circles indicate the equality of days and nights in the right sphere, but the inequality in the oblique.]

V.

The parallels running through the vertical points [zeniths] of all places set before the eyes, throughout the whole circuit of the heaven, the limits of the latitude of cities; and along these same parallels the longitudes of places are counted from west to east, as was said above.

[Margin: The parallel circles determine the latitudes of places, and along them the longitudes are counted.]

VI.

The parallels which the planets, or the fixed stars, describe by the diurnal motion from east to west fix the limits of the declinations of all the heavenly bodies from the Equator; but those they trace from west to east with respect to the Ecliptic mark out the bounds of the latitudes from the Ecliptic.

[Margin: The parallels indicate the declinations of the stars and their latitudes.]

VII.

The parallel circles have great use among cosmographers. For by means of them they separate on the earth spaces at such an interval that the greatest artificial days differ from one another by a quarter of one hour; and by the same parallels the various climes are constituted, as will be clear from chapter 3.

[Margin: The parallel circles are in use among cosmographers.] [Margin: In what sphere the five parallels exist.] [Margin: The four smaller parallels distinguish, in heaven and on earth, five zones.]

ON THE FIVE ZONES [DE QVINQVE ZONIS]

(*Sacrobosco*) The equinoctial, together with the four smaller circles, are called the five parallels, as being (as it were) equidistant — not because, by however much the first is distant from the second, by so much the second is distant from the third (for that is false, as has already appeared), but because any two circles, taken by themselves, are equidistant from each other along each of their parts. And they are called: the parallel of the Equinoctial, the parallel of the summer solstice, the parallel of the winter solstice, the Arctic parallel, and the Antarctic parallel. Note also that the four smaller parallels — namely the two tropics, the Arctic parallel, and the Antarctic parallel — mark off in the heaven five zones, or regions. Hence Virgil, in the first [Georgic]:

DE QVINQVE ZONIS (continued)

Text (*Sacrobosco*)

Five zones hold the heaven, one of which, ever glowing red with the flashing Sun, is always scorched with fire; around it, on the right hand and the left, are drawn two more, stiff with dark-blue ice and with black rains. Between these and the middle zone lie two, granted by the gift of the gods to wretched mortals; and a path is cut aslant through both, along which the oblique order of the signs may wheel round.

Quinq; tenent coelum Zonaë, quarum vna corusco Semper Sole rubens, & torrida semper ab igne: Quam circum extremæ dextra, leuaq; trahuntur Caerulea glacie concretæ, atq; imbribus atris. Has inter, mediamq; duæ mortalibus ægris Munere concessæ Diuum, & via secta per ambas, Obliquus qua se signorum verteret ordo. — [Virgil], Georgics I [233–239]

Just as many regions [*plagae*] are likewise distinguished upon the earth, placed directly beneath the aforesaid Zones. On which Ovid writes: [Margin: Ovid, *Metamorphoses* I.]

And just as two zones cut off the heaven on the right and as many on the left, while the fifth is hotter than these, so the care of God marked off the enclosed mass by the same number, and just as many regions are stamped upon the earth. Of these the middle one is not habitable, for its heat; deep snow covers two; and between each pair He set as many more, and gave them a temperateness, flame mingled with cold.

*Vtque duae dextra coelum, totidemque sinistra Parte secant Zonae, quinta est ardentior illis: Sic onus inclusum numero distinxit eodem Cura Dei, totidemque plagae tellure premuntur. Quarum quae media est, non est habitabilis aestu: Nix tegit alta duas: totidem inter vtramque locauit Temperiemque dedit, mista cum frigore flamma. — [Ovid], *Metamorphoses* I [45–51]*

That Zone, therefore, which lies between the two Tropics is called uninhabitable, because of the heat of the Sun that runs perpetually between the Tropics; and likewise the region of the earth placed directly beneath it is called uninhabitable, on account of the heat of the Sun running above it. But those two Zones which are bounded by the Arctic circle and the Antarctic circle about the poles of the world are uninhabitable because of their excessive cold, since the Sun is most removed from them; and the same is to be understood of the regions of the earth placed directly beneath them. The remaining two Zones, however — one lying between the summer Tropic and the Arctic circle, and the other between the winter Tropic and the Antarctic circle — are habitable, being tempered by the heat of the torrid Zone that lies between the Tropics and by the cold of the outermost Zones that lie about the poles of the world. Understand the same of the regions of the earth placed directly beneath them.

[Margin: Which Zones are said to be uninhabitable, and which habitable.]

COMMENTARY

In this third part of the chapter he treats of the five Zones, which he says are marked off in the heaven by four smaller circles, in such a way that the middle Zone, called torrid, is comprised between the two Tropics; the two called temperate lie between each Tropic and its polar circle; and finally the remaining two, called frigid, lie between the two polar circles and the poles of the world — as you see in the figure set forth. He then teaches that there are just as many Zones on the earth, placed directly beneath those celestial ones. As testimony for the celestial Zones he adduces certain verses of [Virgil] from *Georgics* I; in confirmation of the terrestrial ones he cites verses of [Ovid] from *Metamorphoses* I; and he assigns the reason why the middle Zone of all is called torrid, the outermost frigid, and the remaining two, lying between the torrid and the frigid, temperate. All of which is clear in the Author.

Diagram. A circle representing the sphere, divided by a vertical axis (the poles) and a horizontal diameter, and crossed by five parallel chords which are labelled, from top to bottom, with the four lesser circles and the equator. A small circle at

the center marks the Earth. The horizontal bands between the chords carry the zone-names, and the word ZONA runs repeatedly around the rim.

- Chord 1 (upper): CIRC. ARCT. — *circulus Arcticus* (Arctic circle)
- Chord 2: TROP. CANC. — *Tropicus Cancrī* (Tropic of Cancer)
- Chord 3 (center): AEQVA·TOR — *Aequator* (Equator), split about the central Earth-disc
- Chord 4: TROP. CAPRIC. — *Tropicus Capricorni* (Tropic of Capricorn)
- Chord 5 (lower): CIRC. ANTA[R]. — *circulus Antarcticus* (Antarctic circle)
- Rim / band labels: ZONA (repeated around the circumference); the curved outer labels along the right side read, top to bottom, [TOR]RIDA, TEMPERATA, FRIGIDA [?]; the top arc reads ZONA FRIGID[A] / TEMPERAT[A] [?] (the outermost caps are the frigid zones, the intermediate bands temperate, and the central band about the equator the torrid zone)

[Margin: Zona torrida. Zona temperata. Zona frigida. — Torrid zone. Temperate zone. Frigid zone.]

Only this must be noted here in passing: since each of the two Poets adduced by the Author made mention of a right and a left part in the heaven, "right" and "left" are not taken in the same way by everyone with respect to the celestial bodies. For Plato, [Aristotle], and the rest of the Philosophers, as well as the Geographers, call the Eastern parts "right" and the Western "left." Aristotle indeed and the Philosophers do so because the motion of the heavens begins from the East, just as in animals the beginning of motion arises from the right side. The Geographers (I speak of geographers on the near [northern] side of the Equator) do so because, wishing to determine the elevation of the pole so as to depict the situation of the earth more correctly, they turn their face toward the Arctic pole; whence the East is necessarily set on their right and the West on their left. Hence it comes about that all maps of the world and charts of regions are so drawn by the cosmographers (as may be seen in [Ptolemy] and others) that, to one looking at the maps or charts, the East is placed on the right side and the West on the left.

[Margin: What the right and left part of the heaven is among the Philosophers and Cosmographers.]

The Astronomers, on the contrary, call the Western parts of the heaven "right" and the Eastern "left," because, dwelling on the near [northern] side of the Equator, they turn their face toward the equinoctial circle, where the motion is swiftest, in order to observe the courses of the stars more accurately; and so they have the West on their right and the East on their left. The Poets, finally, call the

Northern parts of the heaven "right" and the Southern "left"; for, observing the settings of the stars, they turn their face [westward], so that the North is set on their right and the South on their left. This opinion — namely that the Northern part in the heaven is called "right" and the Southern "left" — holds because in every clime the rising Sun has the North on its right and the South on its left, and because there are more stars near the Boreal pole than near the Austral, as was said above. From all this, then, it is clear that Virgil and Ovid understood by the name "right part" and "left part" the North and the South. Lucan too understood the right and the left in this way, in book 3, when he says:

[Margin: What the right and left part of the heaven is among the Astronomers.]

[Margin: What the right and left part of the heaven is among the Poets.]

Ignotum vobis Arabes venistis in orbem, Vmbras mirati nemorum non ire sinistras. — [Lucan, *Pharsalia* III.247–248]

(You Arabs have come into a world unknown to you, marveling that the shadows of the groves do not go to the left.)

For he [Lucan] meant to signify that the Arabs had come to the near [northern] side of the Tropic of Cancer (☿), where at midday the shadows of bodies are perpetually cast toward the North — that is, toward the right part of the world — and not toward the South, that is, toward the left part, as we shall explain in chapter 3.

[Margin: The various names of the Zones.]

The Zones are sometimes called by the Authors *Fasciae* (bands), *Cinguli* (girdles), *Plagae* (regions), and by [Cicero] in the *Dream of Scipio* [*Somnium Scipionis*] *Maculae* (spots). Now, since there are two kinds of zones — the one celestial, the other terrestrial — the celestial are the primary ones and the causes of the terrestrial; not that those celestial zones are hot, or cold, or temperate — for such qualities are far removed from the celestial bodies — but because the Sun, through the varied reflection of its rays, direct namely or oblique, either renders the terrestrial zones wholly cold, on account of the excessive obliquity of the rays (as happens in the two outermost zones next to the poles of the world), or wholly sets them ablaze, on account of the directness of the rays (as occurs in the zone that is the middle of all, between the two Tropics), or finally induces in them a tempered heat and cold, when the Sun's rays are neither too direct nor too oblique but hold a middle manner (as befalls in the temperate zones, which are placed between the Tropics and the polar circles).

[Margin: That the torrid zone and the frigid zones are habitable.]

But what the Poets fable — that the frigid zones are uninhabitable from excessive cold, and the torrid from excessive heat — is not true. For by experience, and by the navigation of the Portuguese and the Spanish, it is sufficiently established that beneath the Equator, that is, beneath the middle of the torrid zone, very many peoples dwell; likewise beneath the poles, at least beneath the Arctic pole, that is, beneath the middle of the frigid zones, as [Olaus Magnus] the Great, the Goth, reports. Indeed, all who have sailed thither affirm that the habitation beneath the Equator is the best — the causes of which it would take long to recount here. For whatever be the case concerning cold and heat, we must believe that Nature, which distinguished the regions by heat and cold, also brought forth human beings and the other animals with a capacity to endure their places; especially since we see that both the Portuguese and the Spanish have at length grown accustomed to bear the intemperateness of the torrid zone, now that many at this time dwell beneath the Equator.

[Margin: In what way the terrestrial Zones are placed beneath the celestial.]

Diagram. A large circle representing the sphere shown obliquely, with a small circle at its center (the Earth). From the center, straight lines are drawn outward to the circumference; at the top and bottom are two lens-shaped (elliptical) figures representing the parallel circles seen edge-on, and meridian-like lines run from top to bottom. This illustrates the straight lines drawn from the four lesser celestial circles down to the center of the earth. (No lettered labels appear on the figure.)

In what way the terrestrial zones are placed directly beneath the celestial, the figure below clearly explains: in it, straight lines are drawn from all four of the lesser circles of the heaven down to the center of the earth. For where these lines cut the surface of the earth, there the same circles are described upon the earth, so that all the circles on the earth are set perpendicularly beneath the celestial circles. For thus it will come about — as may easily be gathered from the last proposition of book 6 of [Euclid] — that, since the heaven and the earth have the same center, the segments of the earth enclosed by the said circles are similar to the segments of the heaven comprised between the same celestial circles.

[Margin: Any Zone is of the same width [latitude], but not of the same length [longitude] with respect to all its parts.]

Hence, if from the said celestial parallels perpendiculars were dropped to the surface of the earth — which would necessarily converge toward the center of

the world — there would be described by them, on the earth's surface, the very same circles, directly corresponding to those celestial ones.

Every Zone is always of the same width [*latitudo*] from North to South, wherever you begin, because it is contained between two equidistant circles; but it is not of the same length [*longitudo*] from East to West. For the parts of any Zone, the nearer they are to the Equator, the greater length they will have; the nearer to the poles, the less — since the parallels toward the poles always grow smaller, as was said above.

[Margin: How great the widths of the Zones are. — By what method the lengths of the Zones may be found, both at the beginning and at the middle and end.]

The width of any Zone will readily be had from what has been said. For since each Tropic is distant from the Equator $23^{\circ} 30'$, the width of the whole torrid Zone will be 47° , which make $2937\frac{1}{2}$ miles [*milliaria*]. Again, since each polar circle recedes from its neighboring pole of the world by $23^{\circ} 30'$, just so great will be the width of either frigid Zone from the pole to the polar circle — that is, it will contain $1468\frac{3}{4}$ miles; but the whole width, taken along the diameter [across the pole], will comprise 47° , that is, $2937\frac{1}{2}$ miles. Finally, if from 90° you subtract the distance of the polar circle from the pole and of the Tropic from the Equator — namely 47° [their sum] — there will remain the width of either temperate Zone: 33° [recte: 43° ; the $2687\frac{1}{2}$ miles that follow require 43° at $62\frac{1}{2}$ miles per degree], to which correspond $2687\frac{1}{2}$ miles.

The length of each Zone we shall also obtain — at its beginning, its middle, and its end — if first, by the methods we taught above, we investigate the ratio of the Equator to any given parallel: that is, how many degrees or parts each parallel comprises of those of which the Equator contains 360. Thus, since the parallel passing through Rome contains about $267\frac{1}{2}$ such parts, the length of the temperate Zone along the parallel that runs through Rome will be $267^{\circ} 30'$ — that is, nearly 16719 miles. And so on.

Moreover, given any city whatever, we shall know with the greatest ease in which Zone it is situated, if we carefully inspect some cosmographical globe, or else a universal map of the whole world. For since, whether on the globe or on the map, there are depicted the parallel circles that divide the whole earth into the five aforesaid Zones, all cities that are found within the two Tropics will lie in the torrid Zone; those that lie between either Tropic and the neighboring polar circle, in a temperate Zone; and those, finally, between any polar circle and the neighboring pole of the world, will be set in a frigid Zone.

[Margin: In what Zone a given city lies, and how it may be known.]

But if there is no supply of a cosmographical globe or of a map, the Zone of any city must be inferred thus. Every city having a latitude less than $23^{\circ} 30'$ will lie in the torrid Zone, since each Tropic declines from the Equator by $23^{\circ} 30'$. But if the latitude of the city offered be precisely $23^{\circ} 30'$, and it lie toward the North, it will be placed exactly beneath the Tropic of Cancer (♋), which is the end of the torrid zone and the beginning of the northern temperate; but if it lie toward the South, it will be beneath the Tropic of Capricorn (♎), which is likewise the end of the torrid zone and the beginning of the southern temperate. Every city, however, having a latitude greater than $23^{\circ} 30'$ but less than $66^{\circ} 30'$ will have the northern temperate Zone, if it incline toward the North; for if it decline toward the South, it will be in the southern temperate Zone. But if the latitude of the city be precisely $66^{\circ} 30'$, it will be placed directly beneath the Arctic circle, or the Antarctic, according as it inclines toward the North or the South. Every city, finally, whose latitude exceeds $66^{\circ} 30'$ will have a frigid Zone, either the northern or the southern. And if the elevation be precisely 90° , that city will be set directly beneath one of the poles of the world. From all this it is plain that, if the latitude of any place be known, one can say in which Zone it is contained.

[Margin: Who the Periscii, Heteroscii, and Amphiscii are.]

This too seems by no means to be passed over: that among various writers, especially the Astronomers and Cosmographers, those peoples who inhabit either of the frigid zones are called *Periscii* [whose shadows go round about them], because their shadows, as though in a circle, in the manner of millstones, are wheeled around in the plane of the Horizon at certain times of the year. For the Sun sends its rays to those places in a manner somehow parallel to the plane of the Horizon (as is clear from the material sphere), and they are always borne round in a ring. Those, however, who occupy either of the temperate zones are called *Heteroscii* [whose shadows fall one way], because they cast their noon shadows toward only one pole of the world — the Northerners toward the Arctic pole, the Southerners toward the Antarctic; for the Sun never crosses their zeniths [vertices]. Those, finally, who inhabit the torrid zone are called *Amphiscii* [whose shadows fall both ways], because their noon shadows, at different times of the year, are cast now toward the Arctic pole, now toward the Antarctic — since the Sun sometimes passes beyond their zeniths, as is evident on the material sphere.

CHAPTER THREE

ON THE RISING AND SETTING OF THE SIGNS.

On the diversity of days and nights, and on the division of the climes.

[*Lemma — Sacrobosco*]

The rising and setting of the signs is understood in two ways, since it may be taken either as the poets take it or as the astronomers do. As the poets understand it, therefore, the rising and setting of the signs is threefold: namely the Cosmic, the Chronic, and the Heliac.

[Margin: The rising and setting of the stars according to the poets is threefold. What the Cosmic rising is.]

The **Cosmic** rising (or "mundane") occurs when a sign or star ascends above the horizon on the eastern side by day. And although on any artificial day six signs rise in this way, nevertheless it is the sign with which and in which the Sun rises in the morning that is said, par excellence [antonomastice], to rise cosmically. And in this sense it is called the proper, principal, and daily rising. An example of this rising is found in *Georgics* 1, where the sowing of beans and millet in spring is taught, with the Sun standing in Taurus, thus:

The white Bull opens the year with his gilded horns, etc.

[Margin: What the Cosmic setting is.]

The **Cosmic** setting, by contrast, is defined by opposition: namely, when the Sun rises together with some sign, the sign opposite to that one sets cosmically. This setting is spoken of in the *Georgics*, where the sowing of grain at the end of autumn is taught, with the Sun standing in Scorpio; for since Scorpio rises with the Sun, Taurus, the sign opposite to it — where the Pleiades are — sets, thus:

Before the Eastern Atlantides [the Pleiades] vanish from your sight,
before you commit the due seed to the furrows, and before you hasten to
entrust the year's hope to the reluctant earth.

[Margin: What the Chronic rising is.]

The **Chronic** rising (or "temporal") occurs when a sign or star emerges above the horizon on the eastern side chronically after the setting of the Sun — that is, by night. It is called "temporal" because the day of the mathematicians begins with

the setting of the Sun. We have an example of this rising in Ovid, *ex Ponto* Book 1, where, complaining of the length of his exile, he says fittingly:

The risen Pleiades has made four autumns.

For by "four autumns" he means that four years have passed since he was sent into exile. But Virgil meant that the Pleiades set in autumn; so the two seem to contradict each other. The explanation, however, is this: according to Virgil they set cosmically, whereas according to Ovid they rise chronically — which can well happen on the same day, though differently: for the cosmic setting is defined with respect to the morning, while the chronic rising is defined with respect to the evening.

[Margin: What the Chronic setting is.]

The **Chronic** setting is defined by opposition. Hence Lucan says in Book 4:

Then the short night was pressing upon the Thessalian arrows
[Sagittarius].

[Margin: What the Heliac rising is.]

The **Heliac** rising (or "solar") occurs when a sign or star can be seen through its separation from the Sun, which previously could not be seen because of the Sun's nearness. Ovid gives an example of this in *Fasti* Book 2, thus:

Now the light Water-bearer has sunk down with his slanting urn.

And Virgil in *Georgics* Book 1:

and let the Cnossian star of the blazing Crown withdraw.

This star, being next to Scorpio, was not visible while the Sun was in Scorpio.

[Margin: What the Heliac setting is.]

The **Heliac** setting occurs when the Sun approaches a sign and, by its presence and brightness, does not allow it to be seen. An example of this is in Virgil, *Georgics* Book 1:

... and the Dog sets, giving way to the star that faces it.

IOANNES DE SACRO BOSCO. [191]

COMMENTARY.

Having in Chapter 2 explained all ten circles out of which the material sphere is composed — and by which the celestial sphere is understood to be composed — the Author now, in this third chapter, treats of the various phenomena that arise from the motion of the *primum mobile* and of the Sun in the zodiac. This chapter can be divided into four parts. In the first he treats of the rising and setting of the stars; in the second, of the natural and artificial days; in the third he assigns certain properties that belong to human beings by reason of their different places of habitation on the earth; and in the fourth, finally, he discusses the climes of the world.

[Margin: The argument of the third chapter, and its division.]

Now the rising of any star is its elevation, or ascent, above the horizon — or else its appearance, when previously it was not seen because of the Sun's nearness. The setting, by contrast, is the star's sinking, or descent, below the horizon — or else the fact that it cannot be discerned because of the Sun's nearness. Thus every rising and setting of the stars is reckoned either by comparison with the horizon or by comparison with the Sun. From this it follows, as the Author says, that among the poets the rising and setting of the stars is threefold: namely the Cosmic and the Chronic, both of which are reckoned with respect to the horizon, and the Heliac, which is referred to the Sun.

[Margin: What the rising of a star is. What the setting of a star is. By what the rising and setting of the stars is reckoned.]

A sign or star is said, properly, to rise cosmically when it ascends above the horizon together with the Sun in the morning; but improperly, any star is said to rise cosmically that is raised above the horizon by day — in which sense the six signs of the zodiac are said to rise cosmically each day, even though, because of the Sun's brightness, they cannot be seen at all. It was the cosmic rising in the proper sense that Virgil understood in that verse of *Georgics* 1 which the Author quoted, namely:

The white Bull opens the year with his gilded horns, etc.

For he meant to signify the month of April, in which Taurus emerges above the horizon in the morning together with the Sun, since at that time the Sun stands in Taurus.

By the same reasoning, a sign or star is said, properly, to set cosmically when it descends below the horizon in the morning at sunrise; but improperly, any star is said to set cosmically that slips below the horizon by day. Thus when any sign or star rises cosmically, the sign or star diametrically opposite to it must necessarily set cosmically — indeed, so must all the stars that at that moment touch the horizon on the western side. Virgil speaks of this cosmic setting in *Georgics* 1 in these verses:

Before the Eastern Atlantides [the Pleiades] vanish from your sight,
before you commit the due seed to the furrows, and before you hasten to
entrust the year's hope to the reluctant earth.

He means the time of autumn, in which, with the Sun standing in Scorpio, the Pleiades — set in Taurus, the opposite sign — set in the morning; that is, cosmically.

[Margin — reading uncertain: the printed word for "autumn" here is hard to resolve, but the parallel Chronic paragraph ("in autumn, with the Sun standing in Scorpio") and the Sun-in-Scorpio context make "autumn" the reading. [?]]

A sign or star is said, properly, to rise **chronically** — or rather, as some prefer, *acronychally* — when it emerges above the horizon on the eastern side in the evening, as the Sun descends below the horizon; but improperly, whatever ascends above the horizon at night. In this sense, on any given night six signs can be said to rise chronically. Ovid writes of the chronic rising in *ex Ponto* Book 1, Elegy 9:

Since I have been deprived of you, thrust out to the Scythian shores, the
risen Pleiades has made four autumns.

For in the autumn season, namely with the Sun standing in Scorpio, the Pleiades rise in the evening about sunset; that is, chronically.

A star or sign is said, properly, to set **chronically** when it descends below the horizon together with the Sun; but improperly, any sign that is pressed below the horizon at night — in which sense the six signs of the zodiac are said to set chronically each night. And so, when any star or sign rises chronically, the opposite sign or star necessarily sets chronically. This must be understood of all the stars, too, that at that moment touch the horizon on the western side and therefore set with the Sun. Lucan, according to the Author, spoke of the chronic setting in Book 4:

... For the Sun held the Ledaean stars [Gemini], when the highest daylight is near to Cancer: then the short night was pressing upon the Thessalian arrows [Sagittarius].

For he meant to indicate the time near dawn, with the Sun standing near the end of Gemini; whence, shortly before sunrise, Sagittarius — which is opposite Gemini — must set, improperly, chronically. But perhaps Lucan understood no particular kind of setting in that passage, and only meant to signify that time before sunrise at which Sagittarius goes down. But Ovid writes of this setting in *Fasti* Book 2:

The Dolphin, engraved with stars, that you saw just now, will flee your sight on the following night.

For he speaks of the third of February, before which the Dolphin appeared above the horizon after sunset, but on the third day set chronically together with the Sun, since it stands in Aquarius, in which the Sun was then lingering. From this it is clear that one and the same sign in which the Sun stands rises cosmically in the morning and sets chronically in the evening; and likewise that the sign opposite the Sun rises chronically in the evening and sets cosmically in the morning. So it is no wonder that Virgil said the Pleiades set in autumn — namely, cosmically — while Ovid taught that they rise at the same time — namely, chronically — which is perfectly true. Hence there exist two little verses:

[Margin: A sign rising chronically sets cosmically, and the reverse.]

A sign sets cosmically that rises chronically. A sign sets chronically that rises cosmically.

COMMENTARY ON CHAPTER 3 OF THE SPHERE [192]

This, however, is not true — in an oblique sphere — of stars set outside the ecliptic. For no such star that rises together with the Sun can set with the same Sun, nor can one that sets with it rise with the same Sun. Rather, a star that is more northerly than the point of the ecliptic with which it rises together sets later than that point of the ecliptic; while the point of the ecliptic with which it sets together it rises before. The contrary is understood of a star more southerly than a given point of the ecliptic. From this it follows that a star more northerly or more southerly than a given point of the ecliptic, if it rises cosmically with that

point, cannot set chronically with the same point; and if it sets chronically with it, cannot rise cosmically with the same, or the reverse. Stars situated on the ecliptic, however, in any oblique horizon, and all stars in the right sphere, rise and set with the same points of the ecliptic. Therefore those that rise cosmically set chronically, and those that rise chronically set cosmically, and conversely — as is evident on the material sphere or the astronomical globe.

A star is said to rise **heliacally** when it brings itself into view, after having previously lain hidden, covered by the rays of the nearby Sun. Virgil speaks of this rising in *Georgics* 1:

Now the light Water-bearer has sunk down with his slanting urn: next,
the Fish receives the ethereal horses.

For in February, when the Sun was standing in Aquarius, it hid the Water-bearer by its excessive brightness; but toward the end of February, as the Sun entered Pisces, the Water-bearer appeared in the morning before sunrise, and thus rose heliacally. Virgil understood this same heliacal rising when he wrote in *Georgics* 1 about the Cnossian star — namely, the star of the Northern Crown:

Before the Eastern Atlantides [the Pleiades] vanish from your sight, and
before the Cnossian star of the blazing Crown withdraws, before you
commit the due seed to the furrows, etc.

For when the Pleiades set cosmically — namely, in autumn — the Northern Crown rises, which formerly stood near the end of Libra, rising heliacally in the morning before sunrise while the Sun was in Scorpio.

A star is said to set **heliacally** when it is dimmed by the excessive brightness of the Sun, so that, having previously been visible, it can no longer be discerned. Virgil speaks of this setting in the last of these two verses:

The white Bull opens the year with his gilded horns, and the Dog sets,
giving way to the star that faces it.

For since Canis Maior formerly stood in Gemini, it set heliacally when the Pleiades set cosmically, with the Sun standing right in Taurus, near the Pleiades. But how far any star must precede the Sun, or follow it, in order to rise or set heliacally cannot be determined with certainty, since the stars are neither all of the same magnitude nor all at the same latitude from the ecliptic. It is certain, however, that smaller stars, and those closer to the ecliptic, rise heliacally later and set heliacally sooner than larger stars more distant from the ecliptic.

[Margin: In what part of the sky a planet or star rises and sets heliacally.]

Now since the motion of the Sun from setting to rising is faster than the motion of the fixed stars, the result is that the fixed stars, when they emerge from the Sun's rays, are left free of the Sun toward the western regions of the sky, and rise heliacally in the morning near the horizon on the eastern side, before sunrise. For it is then that they first begin to appear, whereas before they had lain hidden because of the nearness of the Sun, which has now withdrawn from them toward the east. For the same reason those same stars must set heliacally in the evening near the horizon on the western side, after the Sun has descended below the horizon. For whereas before they had always appeared after sunset, they now first begin to hide themselves because of the nearness of the Sun, which is approaching them. Exactly the same must be said of Saturn, Jupiter, and Mars, because their proper motions are slower than the Sun's. But the contrary must be understood of the Moon. For since it advances by its proper motion faster than the Sun, the result is that it does not withdraw from the Sun (as the fixed stars do), but rather is itself carried away from the Sun toward the east. Hence the Moon will rise heliacally in the evening on the western side after sunset, as we see happen after the new moons, because after any new moon the Moon at once withdraws from the Sun toward the east. And it sets heliacally on the eastern side in the morning before sunrise, as we observe before the new moons, because it is always approaching the Sun toward the east. This is the reason why we see the Moon gradually wax after the new moons and wane before them. Finally, Venus and Mercury, since they sometimes go ahead of the Sun and sometimes follow it, will sometimes rise heliacally toward the east and set toward the west; but sometimes rise heliacally toward the west and set toward the east. But more must be said of all this in the *Theories of the Planets*. Hence it comes about that Venus is now called Lucifer, namely when it rises in the morning before the Sun, and now Hesperus, namely when it is seen after sunset toward the west.

[Margin: When Venus is called Lucifer, and when Hesperus.]

At what time of year any star, in this present age, rises cosmically, chronically, or heliacally — or likewise sets — is beautifully shown by the celestial globe or by any astrolabe. For, the globe being set at its proper elevation, let any star be placed on the horizon on the eastern side, and let the degree of the ecliptic touching the horizon in the east be noted: for when the Sun reaches that degree of the ecliptic, the said star will rise cosmically; and when the Sun occupies the opposite degree of the ecliptic, the same star will rise chronically. Likewise, the star being placed on the horizon on the western side, let the degree of the ecliptic

touching the horizon in the west be noted. For when the Sun possesses that degree of the ecliptic, the same star will set chronically; and when the Sun stands at the opposite degree of the ecliptic, the same star will set cosmically. The heliacal rising and setting, however, will be more or less recognized once it is known at what degree of the ecliptic any given star is situated.

[Margin: How to know when any star rises cosmically, chronically, or heliacally.]

Astronomers divide the rising and setting of the stars into the **True** and the **Apparent**. The true rising and setting is when a star truly ascends above the horizon or descends below it. And this is twofold: namely the *Morning* rising, when, at sunrise, some star rises or sets — which the poets call the cosmic rising and setting — and the *Evening* rising, when, at sunset, some star rises or sets, which the poets call the chronic rising and setting. The apparent rising and setting, by contrast, is what the poets call the heliac; and this too they distinguish into morning and evening, according as the star, freed from the Sun's rays, begins to appear in the morning or in the evening, as has been said.

[Margin: The true and apparent rising and setting; likewise, what the Morning and Evening kinds are.]

Ptolemy [Ptolemy] (in the *Almagest* [Dict.] VIII.4) calls the risings of the stars, and their configurations relative to the Sun, "appearances," and he lists nine kinds of Difference. Since each of these is in turn manifold, the total number of appearances comes to twenty-four. On this subject, however, consult Ptolemy at the passage cited, and Johannes Regiomontanus [Regiomontanus] in his *Epitome*, Book VIII, chapter 5. It would take too long to review every one of these appearances here.

Moreover, the knowledge of the poetic rising and setting is of the greatest help for understanding the works of the ancient poets and historians. Very often, in fact, they try to fix some definite time by the rising of a particular star — as is clear from the examples already cited.

[Margin: In what sense Ptolemy calls the risings and settings of the stars.]

[Margin: What use the poetic rising and setting serves.]

ON THE RISING AND SETTING OF THE SIGNS ACCORDING TO the astrologers, that is, on the ascensions and descensions of the signs, both right and oblique.

There follows the treatment of the rising and setting of the signs as the astronomers understand them, and first in the right sphere [sphaera recta].

COMMENTARY

Now that the author has explained the rising and setting of the heavenly bodies as the poets understand them, he takes up the rising and setting of the signs according to the astronomers. This astronomical rising and setting the astronomers are accustomed to call the ascensions and descensions of the signs, and the present treatment concerns those ascensions and descensions. It carries very many important applications, for the greatest part of the doctrine of the primum mobile seems to depend on it.

The author explains three things in this part. First, what rising and setting are according to the astronomers, and how many kinds there are. Second, how the signs rise and set in the right sphere. Third, how the signs behave with respect to their astronomical rising and setting in any oblique sphere whatever. But before all else we must briefly explain the difference between rising and setting as the poets understand it and as the astronomers do; and it is this. In the rising and setting of the signs the poets observe the *quality* of the time — namely whether some sign rises in spring, or in summer, or in autumn, or in winter; likewise whether it does so in the morning or in the evening. The astronomers, by contrast, consider the *quantity* of time: how long, that is, this or that sign takes to rise or set at this or that obliquity of the sphere, whether this happens in spring or in summer and so forth, and whether by day or by night. Hence among the astronomers the rising and setting is not divided into cosmic (or morning) and chronic (or temporal), as the poets divide it, but into right and oblique, as will shortly be explained.

[Margin: What the difference between rising and setting is with respect to the poets and with respect to the astronomers.]

It must be understood that in the right sphere as much as in the oblique the equinoctial circle [Aequinoctialis circulus] always ascends uniformly — that is, in

equal times equal arcs ascend. For the motion of the heavens is uniform, and the angle which the equinoctial circle makes with the horizon does not vary at different hours.

[Margin: The equator ascends uniformly above every horizon.]

COMMENTARY

Before he explains what rising or setting is according to the astronomers, he first demonstrates two conclusions, the first of which is this. The equinoctial circle (that is, the equator [Æquator]) is raised uniformly above the horizon, whether right or oblique, in respect of all its parts, so that in equal times equal arcs of the equator ascend above the horizon. He proves this conclusion in two ways.

First, because the diurnal motion of the heavens is uniform and regular in every horizon. It is never carried now more swiftly, now more slowly. Since, then, the equator is the measure and rule of the primary motion, and revolves about the same poles about which the whole heaven turns — namely the poles of the world — it must in any sphere emerge above the horizon uniformly in respect of all its parts.

Next, because the equator perpetually makes the same angles with the horizon — right angles with the right horizon, oblique angles with the oblique. From this it follows that it is raised above any horizon uniformly in respect of all its parts. The clearest observed phenomena of the astronomers testify to the same thing. For it has been established that in any sphere whatever fifteen degrees of the equator ascend above the horizon in each hour, and as many descend below it, while in the space of four minutes of one hour one degree of the equator is raised and one lowered [deprimi], and so on. This would by no means happen if the equator did not ascend above the horizon regularly and uniformly.

The parts of the zodiac, however, do not necessarily have equal ascensions in either sphere; for the more nearly upright some part of the zodiac rises, the more time is spent in its rising. The proof of this is that six signs rise on a long, or on a short, artificial day, and likewise at night.

COMMENTARY

This is the second conclusion: the zodiac, in the right sphere as much as in the oblique, does not ascend above the horizon uniformly in respect of all its parts. He seems to confirm this by the following reasoning. Since the zodiac is carried by the diurnal motion about poles not its own, from which it is at one place

farther off and at another nearer, it comes about that some of its parts make more oblique angles with any given horizon and others less oblique. Therefore that part which makes more nearly right angles with the horizon — and which for that reason rises more nearly upright — will be raised above the horizon with a slower motion, and will require more time in its rising than the part which makes less nearly right angles with the horizon, as experience teaches in any material sphere; for the more upright some arc rises, the more its parts ascend in succession. He confirms the same conclusion by plain experiment: namely that on any day or night, artificial, be it the longest or the shortest, exactly six signs of the zodiac ascend above the horizon and [descend] below it. below it — so that on any given day one half of the zodiac rises. For since the zodiac and any horizon whatever cut each other into two equal parts (because they are great circles of the sphere), it comes about that the half of the zodiac contained between the Sun placed in the east and the point opposite to it rises during the day, passing through the middle of the night. This is plainly seen on the instruments. For this reason the zodiac will not rise above the horizon uniformly in respect of all its parts, since it is in unequal times — namely in unequal days and nights — that equal arcs always ascend, that is, the halves of the zodiac. And if any half of the zodiac ascended uniformly in respect of all its parts, all days and nights would be equal to one another, which is contrary to experience. The same can be proved of the remaining parts smaller than a semicircle from the doctrine of spherical triangles.

[Margin: What rising and setting are according to the astronomers.]

It must therefore be noted that the rising or setting of any sign is nothing other than the rising of that part of the equinoctial which rises together with that sign as it rises — that is, as it ascends above the horizon; or the setting of that part of the equinoctial which sets together with that sign as it sets — that is, as it moves toward its setting below the horizon.

COMMENTARY

He now sets out what the rising and setting of any sign, or arc of the zodiac, is according to the astronomers. He says that for some sign to rise is nothing other than for that arc of the equator which ascends above the horizon together with that sign to rise; and that for some sign to set is nothing other than for that arc of the equator which descends below the horizon together with that sign to set. Hence the rising of a sign, or of any arc of the zodiac, is defined as the arc of the equator which rises together with it; and the setting of a sign, or of any arc of the

zodiac, is said to be the arc of the equator which sinks below the horizon together with the sign or arc.

For instance, at Rome $17^{\circ} 21'$ of the equator rise together with the whole arc of Aries; therefore the arc of the equator containing $17^{\circ} 21'$ is called the rising of Aries at Rome. By the same reasoning, since at Rome $38^{\circ} 27'$ descend below the horizon together with the sign of Aries, the arc of the equator comprising $38^{\circ} 27'$ will be called the setting of the sign of Aries — and so of the rest. Hence it has come about that the rising of a sign, or of an arc of the zodiac, is called by the astronomers Ascension, and the setting Descension: because in the rising or setting of any arc they consider precisely the proportion of the equator which ascends or descends together with that arc.

[Margin: Why the astronomers define rising and setting by means of the equator.]

The astronomers, moreover, define the rising and setting of any arc or sign whatever by the arc of the equator that ascends with it or descends with it; for when they had observed that the zodiac is raised unequally above the horizon, and descends below it, by the motion of the primum mobile — since it does not possess the same poles as the primum mobile — whereas the equator rises and sets uniformly in respect of all its parts, because it holds the same poles as the primum mobile (as was shown in the two preceding conclusions), it was necessary for them to learn, by means of something uniform and regular, the time which each arc of the zodiac takes up in its rising and setting. This was most conveniently done by the aid of the equinoctial circle. For since in each hour 15° of the equator are raised in any horizon, if 45° of the equator, for example, are raised above some horizon together with some arc of the zodiac, it is most certainly inferred that such an arc rises entirely in three whole hours, and so forth.

[Margin: What the ascension and descension of any star, or of any point of the ecliptic, is.]

Not only are the ascensions and descensions of the arcs of the zodiac defined by the arcs of the equator ascending and descending with them at the same time; the ascension and descension of any point of the ecliptic, and of any star as well, are also defined. For the ascension of any star, or of any point of the ecliptic, is the arc of the equator reckoned from the vernal section — that is, from the beginning of Aries [Υ , Aries] — following the order of the signs as far as the horizon, while the star or point of the ecliptic is rising. For example, since at Rome, with the third degree of Leo [♌ , Leo] placed in the east, the said arc of the equator

comprises $106^{\circ} 40'$, this arc of the equator is called the ascension of the third degree of Leo, because it ascends together with that degree. The descension, on the other hand, of any star or point of the ecliptic is the arc of the equator numbered from the vernal section — that is, from the beginning of Aries — following the order of the signs as far as the horizon, while the star or point of the ecliptic is setting. For example, since at Rome, with the third degree of Leo placed in the west, the said arc of the equator contains $143^{\circ} 57'$, this arc is called the descension of the third degree of Leo, because it descends together with it — and so of the rest. Thus the ascension or descension of any point of the ecliptic, or of any star, is the same as the ascension or descension of the arc of the ecliptic which is reckoned from the beginning of Aries, following the succession of the signs, as far as the horizon, with the star or degree of the ecliptic placed exactly on the horizon — on the side of the east, if it is a question of ascension, and on the side of the west, if the descension is in view.

A sign, moreover, is said to rise upright [recte] when the greater part of the equinoctial rises with it, and obliquely [oblique] when the lesser part does. The same is to be understood likewise of setting.

[Margin: What it is for a sign to rise or set upright, or obliquely.]

COMMENTARY

Since it has been stated that the equator is raised uniformly above the horizon in respect of all its parts, but not the zodiac, it comes about that sometimes a greater arc of the equator ascends with one arc of the ecliptic (or zodiac), and sometimes a lesser. He now teaches that a sign, or arc of the ecliptic, with which a greater arc of the equator rises is said to rise upright, whereas the one with which a lesser arc of the equator ascends is said to rise obliquely. In the same way a sign, or arc of the ecliptic, with which a greater arc of the equator moves below the horizon is said to set upright; and the one with which a lesser arc does so, obliquely.

Example. At Rome, with the arc of Libra, which comprises 30° , there rises an arc of the equator containing $38^{\circ} 27'$; therefore the sign of Libra [♎ , Libra] will be said to rise upright. But with the arc of Aries there ascend $17^{\circ} 21'$ of the equator, so the sign of Aries will be said to rise obliquely. Likewise, since with the sign of Aries there descend $38^{\circ} 27'$, Aries will be said to set upright; but Libra will be said to set obliquely, because only $17^{\circ} 21'$ of the equator descend below the horizon together with it — and so forth.

[Margin: Why rising and setting are called upright or oblique.]

The former rising and setting is called upright when, that is, more degrees of the equator rise or set together, because then the arc of the zodiac that rises or descends makes more nearly right angles with the horizon. The latter rising and setting, when fewer degrees of the equator ascend or descend at the same time, is called oblique, because that arc of the zodiac, as it emerges or sinks, makes more oblique angles with the horizon.

All of which is clearly seen in the material sphere. Hence the arc of the zodiac with which an equal arc of the equator rises or sets can be said to rise and set in an intermediate manner — of which kind are the four quadrants of the zodiac in the right sphere. For they rise, each one, together with each of the quadrants of the equator, as we shall say presently.

Ptolemy, however, whom all the astronomers follow, calls "right ascensions" all those that occur in the right sphere, and "oblique" those that are had in the oblique sphere, whether a greater arc of the equator, or a lesser, or an equal one rises with the sign. So too the astronomers name them in the tables of ascensions. Hence the right ascension of any arc, or degree of the ecliptic, is taken by them to be the ascension it has in the right sphere, whether a greater arc rises with it or a lesser; while the oblique ascension of any arc is understood to be that which it has in the oblique sphere, with however great an arc of the equator it rises. The same is to be said of right and oblique descensions.

[Margin: What right and oblique ascensions are according to Ptolemy and the astronomers.]

ON THE RISING AND SETTING OF THE SIGNS in the right sphere.

And it must be known that in the right sphere the quadrant of the zodiac beginning from the four points — the two solstitial, that is, and the two equinoctial — is made equal to its ascensions; that is, the amount of time a quadrant of the zodiac takes in its rising is the same amount in which the quadrant of the equinoctial bordering upon it rises. Nevertheless the parts of those quadrants vary, and do not have equal ascensions, as will now become clear.

[Margin: The rising of the arcs of the zodiac in the right sphere.]

COMMENTARY

Here he lays down two rules for knowing the rising and setting of the signs in the right sphere. The first is this: the four quadrants of the zodiac, which take their beginning from the four cardinal points, are in the right sphere made equal to their ascensions — that is, they rise precisely together with the corresponding quadrants of the equator, so that each of them takes 6 whole hours in its rising above the horizon, just as each quadrant of the equator too emerges above the horizon in 6 hours. The *parts* of the said quadrants, however, are not equal to their ascensions; that is, together with their parts there rise now greater arcs of the equator, now lesser, so that 15° , for example, sometimes require more time than an hour to rise above the horizon, and sometimes less. For the first 15° of Aries ascend with $13^\circ 48'$ of the equator — that is, they require 55 minutes and 12 seconds of one hour to emerge above the horizon; but the last 15° of Gemini ascend with $16^\circ 17'$ of the equator — that is, they demand 1 hour, 5 minutes, and 8 seconds to ascend above the horizon.

The first part of this rule can easily be proved. Since each colure [Colurus], as it passes through the poles of the world, is joined with the right horizon twice a day, the said quadrants cannot touch the horizon with their outermost points without the other colure — passing through the same points by its extremities — touching it at the very same moment of time and being joined with the horizon. Therefore, after the whole quadrant of the zodiac has emerged above the horizon, the corresponding quadrant of the equator must likewise have wholly ascended above the horizon.

The latter part of the same rule can be shown from Proposition 16 of Book I of Menelaus's [Menelaus] *Spherics*, or from Proposition 11 of our own *Spherical Triangles*; for any part of the ecliptic, apart from the said quadrants, makes with the right horizon now an obtuse angle, now an acute one — as is established from Theodosius [Theodosius] — since the horizon does not pass through its poles. Therefore, since by the aforesaid propositions the greater side is opposite the greater angle in a spherical triangle, and the lesser side the lesser angle, it is clear that the parts of the quadrants having their beginning at the equinoctial points are not made equal to their ascensions.

That the parts of the other quadrants too — those which have their beginning at the solstitial points — are not made equal to their ascensions can be demonstrated as follows. Since, as will be proved in the same way, the parts of the zodiac beginning at the equinoctial points which are greater than a quadrant are unequal to their ascensions, then if equal quadrants are subtracted — one of

the zodiac from an arc of the zodiac, and the other of the equator from the arc of the equator that rises with the arc of the zodiac — the remaining arcs will still be unequal, namely the arc of the zodiac and its ascension. But all this can easily be observed by anyone in the material sphere, and will be made plain from the table of right ascensions.

For there is this rule: any two equal arcs of the zodiac, equally distant from any one of the four points already mentioned, have equal ascensions.

COMMENTARY

The second rule is this: any two equal arcs of the zodiac, equally distant from any one of the four cardinal points, have in the right sphere equal ascensions in relation to each other. For example, the sign of Gemini [♊, Gemini] and the sign of Cancer [♋, Cancer], because they are equal arcs and equally removed from the summer solstitial point, have one and the same ascension; for with either sign there ascend 32° 12' of the equator. The same reasoning holds for the sign of Taurus [♉, Taurus] and Leo; likewise for the sign of Aries and Virgo [♍, Virgo], and so of the other equal arcs, provided that they are equally removed from any one of the said four points, as will be evident from the table of right ascensions.

This rule can be confirmed from spherical triangles: because arcs of the ecliptic of this kind, since they decline equally from the equator at their outermost points (as was said above), make equal angles with the horizon, whence equal arcs of the equator must necessarily correspond to them, and therefore they will have equal ascensions in relation to each other. But this we have demonstrated in Book I of our *Astrolabe*, Lemma 49, Number 6.

And from this it follows that opposite signs have equal ascensions. And this is what Lucan [Lucan] says in Book 9, speaking of Cato's [Cato] march into Libya toward the equinoctial line.

[Margin: Which arcs of the zodiac have equal ascensions in the right sphere.]

(Continuing the lemma from the previous folio: the closing verses of Lucan's description, with the zodiac names set in capitals.)

It has been detected that this is the place where the circle of the high Solstice strikes the mid-belt of the signs. The signs do not move aslant here, nor does SCORPIO rise more steeply than TAURUS; nor does ARIES grant its own times to LIBRA; nor does ASTRAEA [Virgo] bid the slow PISCES to descend; CHIRON [Sagittarius] is matched with GEMINI, and the same as

burning CANCER is watery CAPRICORN [Aegoceros]; nor is LEO raised higher than the URN [Aquarius].

Here Lucan [Lucan, *Pharsalia* IX] says that, for those living beneath the Equator, opposite signs have equal risings and settings. The opposition of the signs is contained in this verse:

Est Lib. Ari. Scor. Taur. Sa. Gemi. Capri. Cancr. A. Le. Pis. Vir.

(A mnemonic pairing the opposite signs: Libra–Aries, Scorpio–Taurus, Sagittarius–Gemini, Capricorn–Cancer, Aquarius–Leo, Pisces–Virgo.)

COMMENTARY

Clavius here gathers, from the second rule, that opposite signs in the right sphere have equal ascensions among themselves. He confirms this on the authority of Lucan, Book 9, where Lucan describes Cato's arrival beneath the equinoctial circle — which Lucan calls "the circle of the high Solstice" — saying that all opposite signs have equal ascensions and descensions, so that no sign rises or sets more directly or more obliquely than its opposite, as happens in the oblique sphere (as will soon be made clear). For Lucan did not mean, in that passage, that all the signs in the right sphere rise directly and none obliquely — as Sulpitius and Omnibonus, the interpreters of Lucan, wrongly explain. That is false. He meant only that none rises more directly, or more obliquely, than its own opposite, although some there rise directly and some obliquely, as is evident from the table of right ascensions, and as we showed in the first book of the *Astrolabe*, Lemma 49, Number 6.

[Margin: The passage of Lucan corrected.]

But this passage of Lucan is not free of error. For Lucan does not mean that Cato reached the Equator — as the verses cited seem to indicate — but rather the temple of Jupiter Ammon, which Lucan supposed to be situated near the Tropic of Cancer. To make this plainer, some verses of Lucan must be brought forward, as they are found in the common copies, but in a disordered arrangement; then the same verses are to be restored to their proper order. So, then, as it now reads, Lucan describes the nature of that place:

*Hic quoque nil obstat Phœbo, cum cardine summo Stat librata dies:
truncum vix protegit arbor: Tam brevis in medium radijs compellitur
vmbra. Deprehensum est, hunc esse locum, qua circulus alti Solstitij
medium signorum percutit orbem. Non obliqua meant, nec Tauro Scorpius*

*exit Rectior: aut Aries donat sua tempora Libræ: Aut Astræa iubet lentos
descendere Pisces: Par Geminis Chiron: & idem quod Carcinus ardens,
Humidus Aegoceros; nec plus Leo tollitur Vrna. At tibi, quæcunque es
Lybico gens igne dirempta, In Noton vmbra cadit, quæ nobis exit in Arcton.
Te segnis Cynosura subit, tu sicca profundo Mergi Plaustra putas,
nullumque in vertice summo Sidus habes immune maris, procul axis
vterque est, Et fuga signorum medio rapit omnia cœlo.*

(In English:) Here too nothing stands in Phoebus's way when the day rests balanced at the topmost point of the sky: the tree scarcely shades its own trunk, so short is the shadow driven inward by the rays. It has been found that this is the place where the circle of the high Solstice strikes the mid-belt of the signs. The signs do not move aslant, nor does Scorpio rise more steeply than Taurus; nor does Aries grant its own times to Libra; nor does Astraea [Virgo] bid the slow Pisces to descend; Chiron [Sagittarius] is matched with Gemini, and watery Capricorn [Aegoceros] is the same as burning Cancer; nor is Leo raised higher than the Urn [Aquarius]. But as for you, whatever people you are, sundered by the Libyan zone of fire, the shadow falls toward the South Wind [Notus], which for us goes out toward the Bear [Arctos]. The sluggish Cynosura [Little Bear] sinks beneath you; you think the Wain [Ursa Major], dry with us, is plunged in the deep; you have no star at the very zenith exempt from the sea; both poles lie far off, and the flight of the signs sweeps everything away through the middle of heaven.

Now if these verses had been composed by Lucan in this order, then without doubt he would have understood "the circle of the high Solstice" to mean the Equator, since what follows — about the rising and setting of the signs — can suit no other region than the one lying directly beneath the Equator. But why he should afterward have added,

At tibi quæcunque es Lybico gens igne dirempta, &c.

I do not understand, since these lines too suit the right sphere. It is plain, then, that by "the circle of the high Solstice" he understood the Tropic of Cancer — which strikes the mid-belt of the signs, that is, the Ecliptic, that is, merely touches it. Then, when he says *At tibi quæcunque es, &c.*, he signifies the right sphere, which lies beneath the Equator, where all the stars rise and set, and where opposite signs likewise have the same ascension and descension. Hence the verses are to be arranged thus, as Petrus Iaconus Hispanus — a man most skilled in the subtlety of all the arts — observed. So it reads from that passage: *At tibi*

quæcunque es, &c. describes the right sphere, since he had earlier described the oblique sphere beneath the Tropic of Cancer, as is evident.

(The verses restored to their proper order:)

*Hic quoque nil obstat Phœbo, cum cardine summo Stat librata dies:
truncum vix protegit arbor: Tam brevis in medium radijs compellitur
vmbra. Depresum est, hunc esse locum, qua circulus alti Solstitij medium
signorum percutit orbem. At tibi, quæcunque es Lybico gens igne dirempta,
In Noton vmbra cadit, quæ nobis exit in Arcton. Te segnis Cynosura subit,
tu sicca profundo Mergi Plaustra putas, nullumque in vertice summo Sidus
habes immune maris, procul axis vterque est, Et fuga signorum medio rapit
omnia cœlo. Non obliqua meant, nec Tauro Scorpius exit Rectior: aut Aries
donat sua tempora Libræ:*

*Aut Astræa iubet lentos descendere Pisces: Par Geminis Chiron: & idem
quod Carcinus ardens Humidus Aegoceros; nec plus Leo tollitur Vrna.*

*(...nor does Astraea [Virgo] bid the slow Pisces to descend; Chiron [Sagittarius] is
matched with Gemini, and watery Capricorn [Aegoceros] is the same as burning
Cancer; nor is Leo raised higher than the Urn [Aquarius].)*

Now that a further rule follows from the second: that opposite signs in the right sphere have equal ascensions and descensions — this too can be proved by the following argument.

Any two opposite signs have a certain agreement with some third sign, such that this third sign and each of the two opposites are equally distant either from one of the two solstitial points, or from one of the two equinoctial points. Therefore each of the two will have the same ascension as that third sign, by the second rule; and consequently the opposite signs themselves will have equal ascensions among themselves. For example, ♈ [Aries] and ♎ [Libra] are opposite signs; and because ♈ [Aries] has the same ascension as ♍ [Virgo] — since these signs are equally distant from the summer solstice — and likewise ♎ [Libra] also has the same ascension as ♍ [Virgo], because these signs recede equally from the autumnal equinox — therefore ♈ [Aries] and ♎ [Libra] will obtain the same ascension. In the same way ♉ [Taurus] and ♏ [Scorpio], opposite signs, agree with ♌ [Leo] in ascension; ♊ [Gemini] and ♐ [Sagittarius] with ♋ [Cancer]; ♋ [Cancer] and ♑ [Capricorn] with ♊ [Gemini]; ♌ [Leo] and ♒ [Aquarius] with ♉ [Taurus]; ♍ [Virgo] and ♒ [Pisces] with ♈ [Aries] — as is evident from the material sphere. Therefore all opposite signs obtain equal ascensions in the right sphere.

The same can also be demonstrated from the fact that opposite signs make equal angles with the Horizon — one toward the region of the Arctic pole, the other toward the region of the Antarctic pole. For from this, by the doctrine of spherical triangles, it follows that the arcs of the Equator corresponding to them are equal. This the table of right ascensions itself will make plain.

And it is to be noted that such an argument does not hold: These two arcs are equal, and they begin to rise together, and the greater part of the one always rises before the greater part of the other; therefore that arc will finish rising sooner whose greater part was always rising. An instance of this argument is manifest in the parts of the aforesaid quadrants. For if one takes the quarter of the Zodiac that runs from the beginning of ♈ [Aries] up to the end of ♊ [Gemini], the greater part always rises from the quarter of the Zodiac than from the quarter of the Equator adjoining it, and yet those two quarters finish rising together. Understand the same of the quarter of the Zodiac that runs from the beginning of ♎ [Libra] up to the end of ♐ [Sagittarius]. LIKEWISE, if one takes the quarter of the Zodiac that runs from the beginning of ♋ [Cancer] up to the end of ♍ [Virgo], the greater part rises from the quarter of the Equator than from the quarter of the Zodiac adjoining it, and yet those two quarters finish rising together. Understand the same of the quarter of the Zodiac that runs from the first point of ♑ [Capricorn] up to the end of ♒ [Pisces].

COMMENTARY

[Margin: The solution of a certain doubt.]

Here the Author resolves, from what he has said, a certain doubt that might cause someone trouble: namely, that the following argument does not hold — There are two arcs in the sphere altogether equal to each other, which begin to rise above the Horizon together at the same instant of time, and the greater part of the one has always risen than of the other; therefore that whole arc will ascend above the Horizon sooner, of which the greater part has always finished rising, than the arc of which the smaller portion had risen. For this argument is resolved by what was said in the first rule. For any Quadrant of the Zodiac, taking its beginning from one of the four cardinal points (as we said), rises whole together with the corresponding quadrant of the Equator, and yet, before both Quadrants finish rising, the greater part of one of them has always risen than of the other. For the greater part of any quadrant of the Zodiac beginning from either equinox always ascends above the Horizon than of the quadrant of the Equator, the start being made in every case from the arcs rising from the equinoctial point, because such

an arc of the Zodiac always makes a smaller angle with the Horizon toward the region of the Equator than the Equator does. Hence, by Proposition 10 of Book 1 of Menelaus, or by Proposition 11 of our own [book] on spherical triangles, the smaller arc of the Equator will correspond, until at the end of the Quadrant both angles become right, and consequently the arcs become equal, by Proposition 4 of the same Book 1 of Menelaus, or by Proposition 5 of our own [book] on spherical triangles. In like manner, the greater part of any Quadrant of the Equator taking its beginning from the Colure of the Solstices always emerges above the Horizon than of the corresponding Quadrant of the Zodiac, as is most clearly deduced from spherical triangles, and will plainly appear from the table of right ascensions; namely because such an arc of the Equator always makes a smaller angle with the Horizon than the Zodiac does, and so on — as we have demonstrated in Book 1 of the *Astrolabe*, Lemma 49, Number 7.

But that the whole Quadrants finish rising together, even though the greater part of the one is always risen than of the other, arises from the fact that the greater part of the one does not always rise in the same proportion as the other, but that proportion gradually decreases, as is manifest from the table of right ascensions, so that at the end the whole inequality of the ascensions is already compensated. That this can indeed happen — apart from the example of the Quadrants of the Zodiac and the Equator adduced — can be grasped from this one example.

Let there be two moving bodies A and B, which move through one and the same space, beginning at the same instant of time, yet on this condition: that A always moves regularly and uniformly, while B, up to the middle of the space, is carried faster or slower, and from the middle to the end slower or faster in exactly the same proportion by which it earlier outstripped moving body A, or was outstripped by it. This being granted, it is certain that both bodies will reach the end of the space at the same time, since by the said proportion the whole inequality is compensated; nevertheless, before the end of the whole space, A will always be ahead of, or behind, B. Otherwise they would not both complete the whole space together, as is evident. Thus, then, one must understand the Quadrants of the Zodiac and Equator to move: they rise wholly indeed at the same time, but their parts in unequal times. For the quadrants of the Zodiac beginning from the Colure of the Equinoxes rise faster near the beginning, slower near the end; but the Quadrants begun from the Colure of the Solstices rise slower at the beginning than at the end.

[Margin: The ascension of any arc of the Zodiac in the right sphere is equal to the descension of the same in the same right sphere, and to the culmination [mediation of the heaven] both in the right sphere and in the oblique.]

Furthermore, in the right sphere the ascension of any sign, or arc of the Zodiac, is equal to its descension; since the descension in one right Horizon is the ascension in another right Horizon (which the Antipodes of those living in the former Horizon obviously have) — and conversely. Moreover it is certain that the ascension of one and the same arc of the Zodiac is the same in every right Horizon, on account of the equal inclination of the Zodiac. In the same manner the ascen-

—sion of any sign is equal to the culmination [mediation of the heaven] of the same, that is: however long some sign takes to rise above the right Horizon, in exactly that much time it also crosses the Meridian of any place whatever — because any Meridian can be called a right Horizon, since it passes through the poles of the world. Therefore everything that has been said about the ascensions of the signs, or of the arcs of the Zodiac, in the right sphere is to be understood also of their descensions in the same right sphere, and likewise of the culminations of the heaven both in the right sphere and in the oblique.

HOW THE RIGHT ASCENSION OF ANY ARC OF THE ZODIAC BEGUN FROM THE VERNAL POINT IS TO BE COMPUTED

[Margin: By what method the right ascension of any arc of the Ecliptic is to be investigated by means of sines.]

Johannes Regiomontanus [Regiomontanus] demonstrated it in the last proposition of Book 1 of the *Epitome*, and Geber [Jābir ibn Aflāḥ] in his astronomical work, and we too demonstrated it in the scholium to Proposition 9 of Book 2 of the *Gnomonics*: that the proportion of the sine of the complement of the declination of the point terminating an arc of the Ecliptic begun from either equinox, to the sine of the complement of the given arc of the Ecliptic, is such as the sine of the whole [radius] is to the sine of the complement of the right ascension. Therefore, if — according to the rule of proportions — the whole sine is multiplied into the sine of the complement of the proposed arc, and the resulting number is divided by the sine of the complement of the declination of the last point of the arc, the sine of the complement of the right ascension will be found, and thus the ascension will be known. This being so, the right ascensions of all arcs of the Ecliptic beginning from the Vernal point will be found by this method.

[Margin: When the arc of the Ecliptic is smaller than a quadrant.]

If the proposed arc is smaller than a quadrant, the rule just set out will yield its right ascension. EXAMPLE. Let the right ascension of the 20th degree of ♊ [Gemini] be sought — that is, of the arc containing 80 degrees. Let the whole sine, namely 100000, be multiplied by 17364, the sine of the complement of the said arc, and let the resulting number, 1736400000, be divided by 91970, the sine of the complement of the declination. For there results 18880, the sine of the complement of the right ascension, to which corresponds in the table of sines the arc of 10 degrees 53 minutes; and this being taken from 90 degrees, there remains the right ascension of 79 degrees 7 minutes. But if the arc of the Zodiac is precisely a quadrant, namely 90 degrees, its right ascension will be a quadrant too, namely 90 degrees.

[Margin: When the arc of the Ecliptic is larger than a quadrant, yet smaller than a semicircle.]

If the arc turns out to be larger than a quadrant but smaller than a semicircle, it must be subtracted from the semicircle — that is, from 180 degrees — and the right ascension of the remaining [arc], beginning from the autumnal point, must be found. For if this is again subtracted from the semicircle, the right ascension of the proposed arc will remain — because the whole semicircle of the Zodiac ascends together with the whole semicircle of the Equator. EXAMPLE. Let the right ascension of the 10th degree of ♋ [Cancer] be sought — that is, of the arc containing 100 degrees. Subtracting this arc from the semicircle, there remains the arc of 80 degrees, whose right ascension is 79 degrees 7 minutes; and this, taken from the semicircle, gives the ascension of the proposed arc as 100 degrees 53 minutes. But if the arc of the Zodiac is precisely a semicircle, its ascension too will be a semicircle, namely 180 degrees.

[Margin: When the arc of the Ecliptic is larger than a semicircle, but smaller than 270 degrees.]

When the arc is indeed larger than a semicircle, but smaller than 270 degrees, the semicircle — that is, 180 degrees — must be subtracted from it, and the right ascension of the remaining arc must be added again to the semicircle, so that the sought ascension may be obtained. EXAMPLE. Let the right ascension of the 20th degree of ♐ [Sagittarius] be sought — that is, of the arc of 260 degrees. Let the semicircle be subtracted, and there remains the arc of 80 degrees, whose right ascension, namely 79 degrees 7 minutes, added to the semicircle, gives the desired ascension of 259 degrees 7 minutes. But if the arc of the Zodiac

constitutes precisely three quadrants, namely 270 degrees, the ascension owed to it will be of just as many degrees.

[Margin: When the arc of the Ecliptic is larger than 270 degrees.]

Finally, when the arc exceeds three quadrants, yet remains smaller than the whole circle, it must be taken away from the whole circle — as from 360 degrees — and the right ascension of the remaining arc must again be subtracted from the whole circle; for the sought ascension will remain. EXAMPLE. Let the ascension of the 10th degree of ♑ [Capricorn] be explored — that is, of the arc of 280 degrees. Subtracting this arc from 360, there remains the arc of 80 degrees, whose right ascension is 79 degrees 7 minutes; and this, taken from 360, will make plain the sought right ascension of 280 degrees 53 minutes. But if the arc of the Zodiac is a whole circle, it certainly rises together with a whole circle of the Equator too.

[Margin: By what art the table of right ascensions is to be constructed.]

From these things it is manifest by what art the table of right ascensions is to be constructed — the ascensions, namely, that occur in the right sphere. For if we compute the right ascensions of all [arcs] taking their start from ♈ [Aries], we shall have the ascensions of all the arcs of the first Quadrant of the Ecliptic, that is, the right ascensions of all the points of the first Quadrant of the Ecliptic. And if we subtract each of them from the semicircle, the start being made from the larger, or later, ones, the remainders will be the right ascensions of all the points of the second Quadrant of the Ecliptic, the start being made from the beginning of ♈ [Aries] up to the beginning of ♎ [Libra]. Again, if we add the ascensions of the same first Quadrant to the semicircle, the start being made from the smaller or earlier ones, we shall produce the right ascensions of all the points of the third Quadrant of the Ecliptic, the start being made from the beginning of ♈ [Aries] up to the end of ♐ [Sagittarius]. If, finally, we take away these same ascensions of the first Quadrant from the whole circle, the start being again made from the larger, or later, ones, there will remain the right ascensions of all the points of the last Quadrant of the Ecliptic, beginning from the start of ♈ [Aries] up to the end of ♓ [Pisces], as is evident. And so the whole labor consists in this: that the ascensions of the individual arcs of the first Quadrant of the Ecliptic be sought out. By this art Johannes Regiomontanus [Regiomontanus] computed the right ascensions of all the arcs of the Ecliptic, proceeding degree by degree, which it has pleased [us] to set down in this place, so that all the ascensions of the arcs of the Zodiac, and the descensions of the right sphere, and likewise the culminations of the heaven in any sphere, may be set before the eyes. For the knowledge of them is useful for

many purposes, as can in part be made plain from what we handed down in our *Gnomonics* concerning the rising signs.

Another method of computing the right ascension — and indeed an easier one — you will find demonstrated by us in Book 1 of the *Astrolabe*, Lemma 49, Number 16.

CAPUT TERTIUM (continued)

Tabula Ascensionum rectorum (Table of Right Ascensions)

**** The table gives, for each degree of the zodiac (argument column **G**, 0–30 down the left of each block), the right ascension of the ecliptic point reckoned from the start of Aries, expressed in equatorial **degrees (G) and minutes (M)**. The six spring–summer signs (♈ Aries – ♍ Virgo) occupy the upper block; the six autumn–winter signs (♎ Libra – ♋ Pisces) occupy the lower block. Each cell below is written as degrees minutes.

Upper block — right ascensions of ♈ Aries through ♍ Virgo:

D eg	♈ Aries	♉ Taurus	♊ Gemini	♋ Cancer	♌ Leo	♍ Virgo
0	0 0	27 54	57 48	90 0	122 12	152 6
1	0 55	28 51	58 51	91 6	123 14	153 3

USUS TABULÆ ASCENSIONUM RECTARUM (Use of the Table of Right Ascensions)

[Margin: How the right ascensions are drawn from the table of right ascensions.]

At the head of the table you take the sign, and down the left-hand side the degree of the sign; for at the common meeting of the given sign and degree you find the degrees and minutes of the Equator that rise together with the given degree of the ecliptic. Thus you see that with 19° Leo — that is, with the arc of the ecliptic beginning at the start of Aries and ending at 19° Leo, which comprises 139 degrees — there rise in the right horizon 141°26' of the equinoctial circle. And if minutes are attached to the given arc, you must extract the proportional part corresponding to the minutes offered, as was explained in the use of the table of declinations, and add it to the ascension of the arc of whole degrees next smaller.

EXAMPLE. Let the right ascension be sought of an arc of the ecliptic containing 125°40' — that is, 5°40' Leo. I subtract the ascension of 5° Leo, namely 127°22' [printed "127°12'"; the difference stated next (1°2') and the value in the table both require 22' — see Numerical impossibles], from the ascension of 6° Leo, namely 128°24'; and there remains 1°2', the difference between the two ascensions, which answers to 60 minutes. Therefore, by the rule of proportion, to the 40 minutes there are due 41⅓ minutes; and if these are added to the ascension of 5° Leo, the ascension of the proposed arc will be about 128°3'.

But if the ascension is to be sought of an arc of the ecliptic that does not begin at the start of Aries — for instance, an arc of the zodiac beginning at 10° Taurus and ending at 18° Gemini, which spans 38 degrees — then the ascension of 10° Taurus, namely 37°35', must be subtracted from the ascension of 18° Gemini, namely 76°57', so that there remains the ascension of the proposed arc, 39°22'.

By this method you will easily gather the right ascension of any sign of the zodiac taken by itself, as appears in the following table.

Ascensiones Signorum in Sphæra recta (Right Ascensions of the Signs in the Right Sphere)

Sign	Sign	Sign	Sign	G	M
♈ Aries	♍ Virgo	♎ Libra	♐ Pisces	2	5
				7	4
♉ Taurus	♌ Leo	♏ Scorpio	♑ Aquarius	2	5

Sign	Sign	Sign	Sign	G	M
				9	4
♊ Gemini	♋ Cancer	♐ Sagittarius	♑ Capricorn	3	1
				2	2

From this it clearly follows that, in the right sphere, the four signs surrounding the two solstitial points rise directly, while the remaining eight rise obliquely; likewise, that those arcs rise more obliquely which are nearer the equinoctial points, and more directly those that lie closer to the solstitial points. The same you will say of the settings and of the culminations. In the right sphere, therefore, four signs always have equal ascensions, equal descensions, and equal culminations — all of which can be demonstrated from spherical triangles, and have been shown by us in Book 1 of the *Astrolabe*, Lemma 49, No. 6.

DE ORTU, ET OCCASU SIGNORUM in sphæra obliqua (On the Rising and Setting of the Signs in the Oblique Sphere)

[Margin: The rising and setting of the signs in the oblique sphere.]

In the oblique or inclined sphere, however, the two halves of the zodiac are matched to their ascensions. I mean the halves taken from the two equinoctial points; for the half of the zodiac running from the start of Aries to the end of Virgo rises together with the half of the equinoctial bordering upon it. Likewise the other half of the zodiac rises with the remaining half of the equinoctial. But the parts of those halves vary according to their ascensions, since in that half of the zodiac from the start of Aries to the end of Virgo a greater part always rises of the zodiac than of the equinoctial — and yet those halves finish rising together. The reverse occurs in the other half of the zodiac, from the start of Libra to the end of Pisces: for there a greater part always rises of the equinoctial than of the zodiac — and yet those halves finish rising together. Hence the objection raised here is made more evident against the argument stated above.

COMMENTARIUS (Commentary)

He now sets out three rules by which the rising and setting of the signs, or of arcs of the ecliptic, may be known in any oblique sphere. The first is: *The halves of the zodiac beginning at the equinoctial points are, in any oblique horizon, matched to their ascensions* — that is, together with them there rise the halves of the Equator as well, namely 180 degrees, so that in the space of 12 hours they emerge whole above the horizon. The parts of these halves, however, are not equal to their

ascensions — that is, no part of them rises together with an equal part of the Equator, but with either a greater or a smaller, as was said of the parts of the quadrants in the right sphere. For with the sign of Aries there rise at Rome $17^{\circ}21'$, but with the sign of Virgo there rise $38^{\circ}27'$, and so on. The first part of the rule is clear: since the ecliptic and the Equator bisect each other mutually at the equinoctial points, the beginning of each half must reach any given horizon at the same time; and you will say the same of their end-points, since the same point is the beginning of the one and the end of the other. Hence they rise together. The latter part of the rule can easily be shown from Proposition 10, Book 1

of Menelaus, or from Proposition 11 of our [treatise] on spherical triangles: for the half of the zodiac from Aries to Libra always makes a smaller angle with the horizon than the Equator does. Therefore a greater part of the zodiac will always rise than of the Equator. But the remaining half of the zodiac, from Libra to Aries, always makes a greater angle with the horizon than the Equator; hence a greater part of the Equator will finish rising than of the zodiac. Yet the whole halves finish rising together, as has been said. All this is evident in the material sphere, and will be plain from the tables of oblique ascensions; and it has been demonstrated by us in Book 1 of the *Astrolabe*, Lemma 49, No. 11.

From these considerations he gathers, once again, an objection against the argument brought forward above; namely, that this inference does not hold: "There are two equal arcs in the sphere, and a greater part of the one has always risen than of the other; therefore the whole of the one will rise sooner than the whole of the other." For this argument is very easily resolved from what was said in this first rule, as is evident.

But the arcs that follow Aries up to the end of Virgo diminish, in the oblique sphere, their ascensions below the ascensions of the same arcs in the right sphere, because less of the equinoctial rises. And the arcs that follow Libra up to the end of Pisces increase, in the oblique sphere, their ascensions above the ascensions of the same arcs in the right sphere, because more of the equinoctial rises. They increase them, I say, by just as much as the arcs following Aries diminish theirs.

[Margin: Comparison of the ascensions in the oblique sphere with the ascensions in the right sphere.]

COMMENTARIUS (Commentary)

In this second rule he compares any oblique sphere with the right sphere, saying that the individual arcs of the zodiac, beginning from Aries up to the end of Virgo, have smaller individual ascensions in the oblique sphere than in the right sphere; but the individual arcs of the zodiac, beginning from Libra up to the end of Pisces, have greater individual ascensions in the oblique sphere than in the right — and greater by as much as the ascensions of the earlier arcs are smaller, provided equal arcs are taken on both sides. For example, at Rome, with the end of Taurus there rise $38^{\circ}27'$, but in the right sphere $57^{\circ}48'$. You see, then, that this [oblique] ascension is exceeded by that [right one] by $19^{\circ}21'$. But at Rome the end of Scorpio rises with $257^{\circ}9'$ [leading digit reconstructed — see Numerical impossibles], while in the right sphere with $237^{\circ}48'$, where you see that this [oblique] exceeds that [right one] likewise by $19^{\circ}21'$. And so with the rest. This too is evident from the doctrine of spherical triangles, and is found by experience in the material sphere and from the tables of oblique ascensions, as we demonstrated in Book 1 of the *Astrolabe*, Lemma 49, No. 12.

From this it appears that two equal and opposite arcs in the inclined sphere have their ascensions, taken jointly, equal to the ascensions of the same arcs in the right sphere taken together; because as much as is subtracted on the one side, so much is added on the other. For although the arcs of the ascensions are unequal among themselves, yet by as much as the one is smaller, by so much the other recovers, and thus the equality is plain.

COMMENTARIUS (Commentary)

From the second rule it is manifest that in any oblique sphere the opposite signs or arcs do not have equal ascensions, provided the arcs take their beginning from the equinoctial points. For since opposite equal arcs have equal ascensions in the right sphere, while in any oblique sphere the ascension of an arc beginning at the start of Aries is smaller than in the right sphere, and the ascension of an arc beginning at the start of Libra is greater in that same oblique sphere than in the right, it is clear that opposite arcs have unequal ascensions in the oblique sphere. Therefore the author infers from this second rule that opposite arcs of this kind, in any oblique sphere, have their ascensions taken together equal to the ascensions of the same arcs in the right sphere taken together, although among themselves they are quite unequal — because, namely, by as much as the ascension of the one is greater in the oblique sphere than in the right, by so much the ascension of the other is smaller in that same obliquity than in the right sphere. The reason for this depends on Proposition 3, Book 1 of the *Arithmetic* of

Jordanus [Jordanus de Nemore], where it is demonstrated: If two unequal numbers be set about two equal numbers, in such a way that the greater of the unequal exceeds one of the equal by the same amount by which the smaller is exceeded by the other, then the two unequal together are equal to the two equal together — as is clear in these numbers, 4, 9, 9, 14; likewise in these, 20, 70, 70, 120. So it happens with the ascensions. For the two ascensions of two opposite arcs in the right sphere are equal, and about them are set the unequal ascensions of the same arcs in the oblique sphere, in such a way that the greater exceeds the one equal by the same excess by which the smaller is exceeded by the other equal. As appears in these four ascensions: $17^{\circ}21'$, $27^{\circ}54'$, $27^{\circ}54'$, $38^{\circ}27'$. Of these the first is the ascension of Aries at Rome; the second, the ascension of the same Aries in the right sphere; the third, the ascension of Libra, the opposite sign, in the right sphere; and the fourth, finally, the ascension of the same Libra at Rome. And since the first is exceeded by the second by just as much as the fourth exceeds the third — for in both cases the excess is $10^{\circ}33'$ — therefore the first and fourth together make just as many degrees and minutes as are made up from the two middle ones, namely $55^{\circ}48'$. And the same reckoning is to be had for the rest.

Again, equal arcs equally distant from either of the solstitial points have their ascensions taken together equal to the ascensions of the same arcs in the right sphere taken together — namely ♈ Taurus and ♌ Leo; ♊ Pisces and ♎ Libra, and so on — as Geber [Jābir ibn Aflāḥ] and Regiomontanus [Iohannes de Regiomonte] demonstrate (*Epitome*, Book 2, Prop. 20), and as we too have shown (*Astrolabe*, Book 1, Lemma 49, No. 10).

[Margin: Equal arcs, equally removed from either of the solstitial points, have in the oblique sphere their ascensions taken together equal to the ascensions of the same taken together in the right sphere.]

COMMENTARIUS (Commentary)

In the same way, the ascensions of any two equal and opposite arcs — even if they do not take their beginning from the equinoctial points — taken together will be equal to the ascensions of the same arcs in the right sphere taken together, although among themselves they are unequal. It is true, however, that then the oblique ascension of an arc contained in the northern half of the zodiac is not always smaller than the right ascension of the same arc, nor is the oblique ascension of an arc contained in the southern half of the zodiac always greater than the right ascension of the same; but sometimes the former is greater and the latter smaller, and sometimes the former smaller and the latter greater. All of which can be shown geometrically from the doctrine of spherical triangles, and

are most clearly perceived ...are found in the tables of oblique ascensions. Nevertheless, this same point can also be confirmed by the following reasoning. Let there be two opposite signs, ♈ and ♏. I say that their ascensions taken together are equal to the ascensions of the same signs taken together which they have in the right sphere. For the ascension of ♈ and the ascension of ♏ in the oblique sphere, taken together, are equal to the ascensions they have taken together in the right sphere, as has been said, because these signs recede equally from the solstitial point — that is, they are equal to the right ascensions of ♈ and ♏, since ♏ and ♈ have equal ascensions in the right sphere (inasmuch as they are equally distant from the beginning of ♈). And the ascension of ♏ in the oblique sphere is equal to the ascension of ♏, as will be established from the third rule, because these signs are removed equally from the equinoctial point. Therefore the ascension of ♈ and the ascension of ♏ together will be equal to the ascensions of the same signs in the right sphere.

This can also be confirmed another way. The ascension of the arc from the beginning of ♈ to the end of ♈, together with the ascension of the arc from the beginning of ♏ to the end of ♏, are in the oblique sphere together equal to the ascensions of the same arcs taken together in the right sphere, as is clear from the preceding corollary. Likewise, the ascension of the arc from the beginning of ♈ to the beginning of ♈, together with the ascension of the arc from the beginning of ♏ to the beginning of ♏, are in the oblique sphere together equal to the ascensions of the same arcs together in the right sphere, as is evident from the same corollary. It follows that if these latter ascensions are subtracted from those former ones, the remaining ascensions of the arcs ♈ and ♏ together in the oblique sphere will be equal to the remaining ascensions of the same arcs together in the right sphere. You will say the same of any opposite and equal arcs whatever, because the ascension of the one is always equal to the ascension of some equal arc that is equally distant with the other from the solstitial point, as is clear.

[Margin: Equal arcs, and ones equally distant from either of the equinoctial points, have equal ascensions in the oblique sphere.]

From this the truth of the second rule proposed is evident. For the reasoning about equal and opposite arcs is the same, whether they take their beginning from the equinoctial points or not, as is established.

In the given example, however, the ascension of ♈ in the oblique sphere at Rome, containing $38^{\circ}42'$, is greater than the ascension of the same ♈ in the right sphere, which comprises $29^{\circ}54'$. The ascension of ♏, on the other hand, in the same

oblique sphere, containing $21^{\circ}6'$, is less than the ascension of the same ϖ in the right sphere, since in the latter it comprises $29^{\circ}54'$ — even though ϱ lies in the northern half of the Ecliptic and ϖ in the southern half. This is indeed no contradiction of the second rule, because these signs do not begin at the equinoctial points, as the second rule required.

[Margin: Solution of a certain difficulty.]

[Margin: The ascension of any arc in the oblique sphere is equal to the descension of the opposite arc; and, in the same sphere, the ascension and descension of any sign taken together are equal to the ascension and descension of the opposite sign taken together, in any sphere.]

Rule [III]. In the oblique sphere, indeed, the rule is that any two arcs of the Zodiac which are equal and equally distant from either of the equinoctial points have equal ascensions.

COMMENTARY

The third rule is this: any two arcs of the Zodiac that are equal and equally removed from either of the equinoctial points — whether they begin at the equinoctial point itself or not — have equal ascensions between themselves in any inclined sphere. For example, Aries and Pisces; Taurus and Aquarius; and so on. This is established from the doctrine of spherical triangles, and it is demonstrated both by Geber [Jābir ibn Aflāḥ] and by Ioannes Regiomontanus [Regiomontanus] in *Epitome* Book 2, proposition 19.

This rule may perhaps seem to someone contrary to the preceding one. For it was said in the second rule that the arcs of the half of the Ecliptic from γ to α have smaller ascensions in the oblique sphere than the arcs of the other half. Since, then, Aries is contained in the former half and Pisces in the latter, how can it come about that these arcs have equal ascensions? It must nevertheless be answered that this rule is entirely true and does not conflict with the preceding one. For the preceding rule was understood of arcs beginning at the start of γ or of α ; but arcs of this kind are not Aries and Pisces. For although the arc of Aries has its beginning at the first point of γ , yet the arc of Pisces does not begin at the first degree of α .

[Margin: The ascension of any sign in the oblique sphere is unequal to the descension of the same sign.]

Moreover, in every sphere, whether right or inclined, the ascension of any arc, or of any sign, is equal to the descension of the opposite arc or sign. For since the Horizon and the Zodiac cut one another in two, being great circles, half of the Zodiac will always be above the Horizon. Hence, at whatever point of the Zodiac is rising above the Horizon, it is necessary that the opposite point be descending below the Horizon — otherwise a greater arc than a semicircle, or a smaller one, would stand above the Horizon. And so, when the beginning of some sign is precisely in the East, the beginning of the opposite sign is precisely in the West; and when the extreme point of the earlier sign is in the East, the extreme point of the later one will be in the West. Therefore, as one rises, the other necessarily descends.

From this it follows that the ascension and the descension of any sign taken together are equal to the ascension and descension of the opposite sign taken together, in any sphere; because, of course, the ascension of one sign is the descension of the opposite sign, and the descension of the same sign is the ascension of the opposite sign. Hence, if equals are added to equals, the wholes become equal. For instance, the ascension of ♈ is equal to the descension of ♎, and the descension of ♈ is equal to the ascension of ♎, and so on.

[Margin: The ascension and descension of the same sign in the oblique sphere taken together are equal to the ascension and descension of the same sign taken together in the right sphere.]

Likewise, it is evident that the ascension of any sign in the oblique sphere is unequal to the descension of the same sign — so that, if it rises directly, it sets obliquely, and conversely. For since the ascension of each sign is equal to the descension of the opposite sign, if the ascension of this later sign were equal to the descension of the same, the opposite signs would have equal ascensions, which is contrary to what was said in the second rule. Yet the ascension of any sign together with the descension of the same in the oblique sphere are equal to the ascension and descension of the same sign taken together in the right sphere; because the more obliquely, or the more directly, some sign rises in the oblique sphere than in the right, by so much the more directly, or the more obliquely, does it set, as is established from spherical triangles, and will be manifest from the tables of oblique ascensions.

All these matters concerning both right and oblique ascensions have been clearly demonstrated by us in Book 1 of the *Astrolabe*, Lemma 49.

By what method the oblique ascension of any arc of the Zodiac, reckoned from the vernal section, may be found

Since it was said in the second rule that the oblique ascensions of the arcs of the Ecliptic contained in the northern half — the beginning always being made from the first point of ♈ — are smaller than the right ascensions of the same arcs by as much as the oblique ascensions of the arcs of the Ecliptic comprised in the southern half — the beginning likewise always made from the beginning of ♎ — are greater than the right ascensions of the same arcs; it is manifest that if from the right ascensions of the arcs of the earlier half of the Ecliptic the ascensional differences are subtracted (those, namely, by which the right ascensions differ from the oblique), the oblique ascensions of the same arcs are left; but if the same ascensional differences are added to the right ascensions of the arcs of the later half of the Ecliptic, the oblique ascensions of the same arcs are produced, the beginning always being made from the beginnings of ♈ and ♎.

[Margin: How the oblique ascensions may be found from the ascensional differences. By what method the ascensional differences may be found by means of sines.]

This ascensional difference you will find, by this art, from the doctrine of Sines. As Geber demonstrates, and as we too have demonstrated in the scholium to proposition 9 of Book 2 of the *Gnomonics*: the sine of the complement of the declination of the proposed point of the Ecliptic is to the sine of the complement of the ortive (or occidental) latitude of the same point of the Ecliptic as the whole sine is to the sine of the complement of the ascensional difference. Therefore, if the sine of the complement of the ortive latitude is multiplied into the whole sine, and the resulting number is divided by the sine of the complement of the declination of the proposed point, as the rule of proportions prescribes, the sine of the complement of the ascensional difference will be obtained. And so it will be known from the table of sines.

Example. Let the difference at Rome be sought by which the oblique ascension of an arc of the Ecliptic from ♈ to the end of ♐ differs from its right ascension. Since, then, the declination of the extreme point of ♐ is $23^{\circ}30'$, and the ortive latitude is $32^{\circ}27'$: I multiply the sine of the complement of the ortive latitude, namely 84386, into the whole sine, that is into 100000; the resulting number, 8438600000, I then divide by 91706, the sine of the complement of the declination

of the extreme point of Π , and there will come out the sine of the complement of the ascensional difference, about 92018, to which corresponds in the table of sines $66^{\circ}57'$. Therefore the ascensional difference will be $23^{\circ}3'$. When this is subtracted from the right ascension of the proposed arc — namely from 90° , since it is in the earlier half of the Ecliptic — there will be left the oblique ascension of the said arc at Rome, $66^{\circ}57'$.

Now since we taught above that the declinations and ortive latitudes of all the points of a single Quadrant are equal to the declinations and latitudes which all the points of the remaining Quadrants have, it is plain that it is enough if the ascensional differences of a single Quadrant of the Ecliptic are investigated; for the four points of the Ecliptic have the same ascensional difference, as we demonstrated in Book 1 of the *Astrolabe*, Lemma 49, Number 15.

[Margin: It is enough if the ascensional differences of the points of a single quadrant of the Ecliptic are investigated. How, by another method, they may be found by means of sines.]

By another method the ascensional difference of any arc, or point, of the Ecliptic will be found, without knowledge of the ortive or occidental latitude, by this art. Let the sine of the elevation of the pole be multiplied into the whole sine, and the resulting number be divided by the sine of the complement of the elevation of the pole. For there will come out a sine which in one and the same region never varies, whence not without reason it may be called the *sine of the region*; at Rome it is about 90041. Now this sine of the region is nothing other than the tangent of the elevation of the pole. And so it is not necessary that it be found by multiplication and division, but it is enough to take from the table of tangents the tangent of the arc of the elevation of the pole. Then, since — as Ioannes Regiomontanus demonstrates in *Epitome* Book 2, proposition 22 — such is the proportion of the sine of the complement of the declination of the proposed point (which of course terminates the given arc) to the sine of the declination, as the proportion of the sine which we called the sine of the region is to the sine of the ascensional difference of the proposed point of the Ecliptic: if, according to the precept of the rule of proportions, the sine of the declination of the proposed point is multiplied into the sine of the region so found, and the resulting number is then divided into the sine of the complement of the declination, the sine of the ascensional difference will be obtained.

Example. At Rome I seek the ascensional difference of the last point of the first Quadrant of the Ecliptic, namely of the last point of Π . I multiply 39874, the sine of the declination, into the sine of the region of Rome, 90041; the resulting

number, 3590294834, I divide by 91706, the sine of the complement of the declination, and there will come out the sine of the ascensional difference sought, 39150, to which corresponds an arc of $23^{\circ}3'$, just as before.

By this art Ioannes Regiomontanus computed the ascensional differences of all the points that decline from the Equator, beginning from 1° of declination up to 32° . For no Planet — for whose sake he wrote the tables — ever had a greater declination. If, therefore, you desire the ascensional difference of any arc of the Ecliptic, seek at the head of the table of ascensional differences the elevation of the pole, and on the left side the declination of the extreme point of the proposed arc; for in the angle of common concurrence you will find the difference sought. Thus at Rome, where the pole is elevated 42° , a point of the Ecliptic that declines 18° from the Equator has an ascensional difference of $17^{\circ}1'$, and so on.

[Margin: How the ascensional differences may be found from the table of ascensional differences.]

But if the declination of the point is not found on the left side, the excess between the ascensional difference of the next-greater declination and the ascensional difference of the next-lesser declination must be sought. Then the proportional part corresponding to the minutes of the proposed declination must be extracted. For this, added to the ascensional difference of the next-lesser declination, will give the ascensional difference sought.

Example. At Rome let there be found the ascensional difference of the last point of Π , or of the first degree of $\mathfrak{S}$ — that is, of the first Quadrant of the Ecliptic. Since, then, the declination of the first degree of $\mathfrak{S}$ is $23^{\circ}30'$: I take the ascensional difference belonging to a declination of 23° , namely $22^{\circ}28'$; likewise the ascensional difference belonging to a declination of 24° , namely $23^{\circ}38'$; the difference between these is $1^{\circ}10'$, which is then owed to a whole degree of declination. Therefore, by the rule of proportions, to 30 minutes are owed 35 minutes; and these, added to the ascensional difference belonging to a declination of 23° (namely $22^{\circ}28'$), give an ascensional difference of $23^{\circ}3'$, just as before — belonging to a declination of $23^{\circ}30'$, namely to the beginning of $\mathfrak{S}$. And so for the rest.

It is therefore established from these things by what art the table of ascensional differences is to be constructed for any elevation of the pole, and consequently, from the table of ascensional differences, the table of oblique ascensions. Yet, in order to relieve the reader of this burden, I have appended from Ioannes Regiomontanus the tables of ascensional differences—

—for all elevations of the pole, beginning from 1° up to 60° ; and likewise the tables of oblique ascensions for the individual altitudes of the pole, beginning from 36° up to 60° — because they have notable uses in astronomical matters, as is established in part from what we wrote in the *Gnomonics* concerning the ascending signs.

[Margin: How, from the tables of oblique ascensions, the oblique ascensions and descensions may be found.]

You will find, from these tables of oblique ascensions, the oblique ascension of any arc no differently than was set forth in the use of the table of right ascensions — taking, however, the table of oblique ascensions of that elevation of the pole for which you are inquiring the oblique ascensions in any oblique sphere. But the descension of each arc you will explore thus. In the right sphere the ascension and descension of the same arc are equal. It has been shown that the ascension of any arc is equal to the descension of the opposite arc, and the descension of any arc equal to the ascension of the opposite arc; therefore, if the descension of some arc is sought, the ascension of the opposite arc must be investigated, for this will be the descension of the proposed arc.

Example. Let the descension be desired of the arc from Υ to $8^\circ \text{ } \mathbb{M}$, at Rome, where the pole is elevated 42° . The opposite arc is from $\text{ } \mathbb{A}$ to $8^\circ \text{ } \mathbb{X}$; and since $8^\circ \text{ } \mathbb{X}$ rises with $347^\circ 29'$ of the Equator, counting from Υ , if 180° — namely the semicircle from Υ to $\text{ } \mathbb{A}$ — are subtracted, there will remain the ascension of the arc from $\text{ } \mathbb{A}$ to $8^\circ \text{ } \mathbb{X}$, that is, the descension of the arc from Υ to $8^\circ \text{ } \mathbb{M}$: $167^\circ 29'$.

Similarly, the descension is sought of the arc from the beginning of $\text{ } \mathbb{M}$ to $20^\circ \text{ } \mathbb{A}$. The opposite arc is from $\text{ } \mathbb{X}$ to $20^\circ \text{ } \mathbb{Q}$; and since $20^\circ \text{ } \mathbb{Q}$, counting from the beginning of $\text{ } \mathbb{X}$, rises with $110^\circ 15'$ [?] of the Equator, we shall say that this is the descension of the arc comprised between the beginning of $\text{ } \mathbb{M}$ and $20^\circ \text{ } \mathbb{A}$.

By the same reasoning, the descension of the last degree of $\text{ } \mathbb{X}$ [?] must be investigated — that is, of the arc comprised between the beginning of Υ and the last degree of $\text{ } \mathbb{X}$. Opposite to this arc is the arc contained between the beginning of $\text{ } \mathbb{A}$ and the end of $\text{ } \mathbb{I}$; for the first points of the said arcs, and likewise their extreme points, are opposite through the diameter in the sphere. Now the arc from the beginning of Υ to the end of $\text{ } \mathbb{I}$ rises with $66^\circ 57'$ of the Equator; and if 180° are added to these, the ascension will be obtained of the arc from the beginning of $\text{ } \mathbb{A}$ to the end of $\text{ } \mathbb{X}$: $246^\circ 57'$. And so for the rest.

[Margin: How, by another method, the oblique descensions may be sought from the tables of oblique ascensions.]

It is also customary to investigate the descension in a way other than we have said — the descension, that is, of any arc beginning from the beginning of $\mathcal{V}$ — by this method. From the ascension of the point which is opposite, through the diameter, to the extreme point of the proposed arc, let the whole semicircle, that is 180° , be subtracted. But if the subtraction cannot be made, let a whole circle, that is 360° , be added first to the ascension of the opposite point. For what remains will be the descension sought.

Example. At Rome the descension of $8^{\circ} \varrho$ is sought. From the ascension of $8^{\circ} \approx$ — that is, from $327^{\circ}45'$ — I subtract 180° , and there remains the descension of the arc from γ to $8^{\circ} \varrho$: $147^{\circ}45'$. Again, the descension of $20^{\circ} \mathfrak{M}$ is to be found. I add to the ascension of $20^{\circ} \vartheta$ — namely to $30^{\circ}46'$ — a whole circle, that is, [I make it] $390^{\circ}46'$; from this composite I subtract a semicircle, and there is left the descension of the arc from γ to $20^{\circ} \mathfrak{M}$: $210^{\circ}46'$, and so on.

Other methods of computing the ascensional differences — and consequently the oblique ascensions as well — and indeed easier ones, you will find in Book 1 of the *Astrolabe*, Lemma 49.

Table of Ascensional Differences [Tabula Differentiarum Ascensionalium]

The table gives the **ascensional difference** [differentia ascensionalis] in degrees (G = *gradus*) and minutes (M = *minuta*) for each combination of a **degree of declination** [Gradus Declinationum, the row-argument, 1°–32°] and an **elevation of the pole** [Elevatio Poli, the column-parameter]. On this page the elevations run 1°–14°, presented as two stacked blocks (elevations 1°–7°, then 8°–14°); each block re-uses the same declination argument 1–32. Each cell below is rendered as degrees°minutes’.

Elevation of the pole 1° – 7° (declination 1° – 32°)

Continuation of the Table of Ascensional Differences [Residuum Tabulæ Differentiarum Ascensionalium]

Same argument (declination 1°–32°); the elevation of the pole here runs 31°–44° in two stacked blocks.

Elevation of the pole 31°–37° (declination 1°–32°)

Christoph Clavius, *Commentary on the Sphere of Sacrobosco* — Chapter III (continued)

Table of Ascensional Differences [Tabula Differentiarum Ascensionalium] — conclusion

(Continuation and conclusion of the table begun in the preceding pages. Row argument = degrees of declination [Gradus Declinationum], 1–32; column parameter = elevation of the pole [Elevatio Poli]. Each entry is in degrees° and minutes'. This page carries two stacked blocks: elevations 45°–52° above, 53°–60° below.)

Table of Oblique Ascensions for latitude 36° [Tabula Ascensionum obliquarum ad latitudinem graduum 36]

(Row argument = degree within the zodiacal sign [G], 0–30; each entry is the oblique ascension in degrees° and minutes'. The full circle of twelve signs is split into an upper block, Aries–Virgo, and a lower block, Libra–Pisces.)

Signs ♈ Aries – ♍ Virgo

These three pages continue the **Tables of Oblique Ascensions** [Tabula Ascensionum obliquarum], giving for each degree of the ecliptic (argument 0–30 within each sign) the oblique ascension in degrees and minutes at three successive elevations of the pole: latitude 38°, 39°, and 40°. Each table is laid out in two blocks — the first six signs (♈ Aries through ♍ Virgo) above, the last six (♎ Libra through ♓ Pisces) below. Within every column, **G** = degrees, **M** = minutes; the leftmost column is the ecliptic argument in degrees. The printed opening runs latitude 39° on the verso (p. 212) facing latitude 40° on the recto (p. 213), with latitude 38° on the preceding recto (p. 211); the tables are presented here in ascending order 38° → 39° → 40°, each reproduced from its own page.

Table of Oblique Ascensions at latitude 38°

Tabula Ascensionum obliquarum ad latitudinem graduum 38.

Commentary on the *Sphere* of Sacrobosco — Chapter III

(continued: Tables of Oblique Ascensions, at successive elevations of the pole)

These pages give the tables of oblique ascensions [ascensiones obliquae] for the elevations of the pole (geographical latitude) 41°, 42°, and 43°. In each table the argument (leftmost column, headed **G**) is the degree of the ecliptic within a sign, 0–30. For each of the twelve zodiacal signs two columns are given: **G** = degrees and

M = minutes of the oblique ascension. The upper block of each page covers the six signs Aries–Virgo (♈–♍, ascensions 0°–180°); the lower block covers Libra–Pisces (♎–♊, ascensions 180°–360°). The obliquity of the ecliptic assumed throughout is 23°30′.

Tabula Ascensionum obliquarum ad latitudinem Graduum
41.

CHAPTER THREE (continued) — Tables of Oblique Ascensions

These three pages continue the series of tables of oblique ascension, one table per successive elevation of the pole (latitude), for latitudes 44°, 45°, and 46°. In each table the argument (leftmost column, headed **G** = *gradus*, degrees) runs 0–30 and gives the degree within a sign; the twelve sign-columns give the oblique ascension reached by the end-point of that degree. Values are stated as **degrees ° minutes ’** (column heads **G** and **M**). The six spring/summer signs (♈ Aries through ♍ Virgo) form the upper block; the six autumn/winter signs (♎ Libra through ♏ Pisces) form the lower block, printed beneath the upper on the same page. Block closures hold throughout: Virgo 30° = 180°0’ and Pisces 30° = 360°0’.

Table of Oblique Ascensions for latitude 44 degrees

Commentary on the *Sphere* of Johannes de Sacrobosco — Chapter III

Tables of Oblique Ascensions (continued)

Batch covers (printed pp. 220–222): the tables of oblique ascensions for latitudes (elevations of the pole) 47°, 48°, and 49°.

Each table gives the oblique ascension for every degree of the ecliptic (argument **G** = 0–30) under each of the twelve zodiacal signs. Every cell holds two numbers, **degrees minutes** (e.g. 15 18 = 15°18'), as printed under the paired column heads **G** (*gradus*) and **M** (*minuta*). Each latitude is printed as an upper block (♈ Aries – ♍ Virgo, closing at 180°0') and a lower block (♎ Libra – ♊ Pisces, closing at 360°0'). Sign-boundary closures (30° of one sign = 0° of the next) were checked throughout; the few cells that break a column's smooth progression are transcribed as printed and flagged.

Tabula Ascensionum obliquarum ad latitudinem Graduum 47.

Commentary on the Third Chapter of the *Sphere* of Johannes de Sacrobosco

CAPVT TERTIVM (continued) — Tables of Oblique Ascensions

These three pages continue the series of tables of oblique ascension, one table per elevation of the pole. Each table gives, against the argument (the ecliptic degree, 0–30, at the left), the oblique ascension in degrees (G, *gradus*) and minutes (M, *minuta*) for each of the twelve signs. The upper block of each table runs ♈ Aries → ♍ Virgo (oblique ascensions 0°→180°); the lower block runs ♎ Libra → ♈ Pisces (180°→360°). Latitudes 50°, 51°, and 52° are covered here; the series continues at higher latitudes on the following pages.

Table of Oblique Ascensions for the latitude of 50 degrees [*Tabula Ascensionum obliquarum ad latitudinem graduum 50.*]

Upper block — ♈ Aries to ♍ Virgo

COMMENT. IN III. CAP. SPHÆRÆ

CAPVT TERTIVM — Tables of Oblique Ascensions (continued)

Table of oblique ascensions for the latitude of 53 degrees [Tabula Ascensionum obliquarum ad latitudinem Graduum 53.]

The argument column (G) is the ecliptic degree, 0–30, within each sign. For each of the twelve signs the oblique ascension is given as degrees (G) and minutes (M). The six signs Aries (♈) through Virgo (♍) form the upper block; Libra (♎) through Pisces (♓) form the lower block.

Latitude 53° — signs ♈ Aries to ♍ Virgo

CAPVT TERTIVM — Tables of Oblique Ascensions (continued)

This opening carries three further tables of oblique ascensions, one per successive elevation of the pole (56°, 57°, 58°). Each table is arranged with the ecliptic degree (0–30) as its argument in the leftmost G column, and gives, for each of the twelve signs, the oblique ascension in degrees (G) and minutes (M). The six northern signs (Aries–Virgo) occupy the upper block; the six southern signs (Libra–Pisces) the lower block. No running prose appears on these pages.

Tabula Ascensionum obliquarum ad latitudinem graduum 56.

[Table of oblique ascensions for the latitude of 56 degrees.]

Northern signs (upper block):

signs per block, each in a G/M degree-minute pair). Every sign-column boundary was cross-checked against the next sign's argument-0 value, and every block closes correctly (each northern column's arg-30 = the next sign's arg-0; Virgo 30 = 180°0'; Pisces 30 = 360°0'; Aries 0 = 0°0'). Cells carrying an inline [recte: ...] are printed hundreds-digit compositor errors corrected from the monotone context and confirmed by the adjacent block boundary. Cells marked [?] have an

ambiguous tens-digit glyph that also breaks the smooth progression of its column (see Numerical impossibles).

Commentary on Chapter III of the Sphere (continued)

Table of Oblique Ascensions for the latitude of 59 degrees

**

Argument = degree of the ecliptic (0–30). Each sign column gives the oblique ascension as degrees (G) and minutes (M).

From the tables of oblique ascensions you can also easily gather the ascension of any single sign of the zodiac taken by itself, or indeed of any arc whatever not begun from the beginning of Aries, as you see in the following table.

Oblique ascensions of the signs at Rome

**

Sign	Equal-ascension sign	Deg	Min
♈ Aries	♓ Pisces (<i>Pices</i>)	17	21
♉ Taurus	♒ Aquarius (<i>Æquarius</i>)	21	6
♊ Gemini	♑ Capricorn (<i>Capricor.</i>)	28	30

Sign	Equal-ascension sign	Deg	Min
♋ Cancer	♐ Sagittarius	35	54
♌ Leo	♏ Scorpio (<i>Scorpius</i>)	38	42
♍ Virgo	♎ Libra	38	27

[The six entries sum to 180°: the oblique ascension of each individual sign, symmetric about the equinoctial points.]

It follows from these that the segments of the signs rise the more directly [*rectius*] the closer they are to the point of the autumnal equinox, but the more obliquely the nearer they lie to the point of the vernal equinox — because at the former they make more upright angles with the horizon, at the latter more oblique ones, as is evident from the material sphere and from the preceding table.

[Margin: Which signs rise more directly in an oblique sphere, and which more obliquely.]

Moreover, from the tables of oblique ascensions it is clear that the more oblique a sphere is, the more the ascensions of the arcs of the ecliptic differ from the right ascensions — those, that is, which occur in the right sphere; and understand the same of the descensions. This very point is demonstrated most clearly from spherical triangles.

[Margin: The more oblique the sphere, the more the ascensions and descensions of the signs differ from the ascensions and descensions in the right sphere.]

Finally, in the preceding table you see that, in an oblique sphere, six signs contained in the descending semicircle of the zodiac — namely Cancer, Leo, Virgo, Libra, Scorpio, and Sagittarius — rise directly and consequently set obliquely; while the six signs comprised in the ascending semicircle of the zodiac — namely Capricorn, Aquarius, Pisces, Aries, Taurus, and Gemini — rise obliquely and set directly. Understand this of the greater part of the oblique sphere toward the north. For those whose zenith [*vertex capitis*] lies between the Arctic circle and the pole always have some part of the zodiac standing above the horizon, and some part — greater or smaller — below it, according as their zenith approaches the pole more or less. Hence certain signs will there rise or set neither directly nor obliquely. Furthermore, for those who have a latitude — that is, a distance from the equator — of less than 10 degrees, Virgo and Libra rise obliquely and yet are contained in the descending semicircle of the zodiac; while, on the contrary, Gemini and Capricorn rise directly and yet are comprised in the ascending semicircle. For since the former two signs rise obliquely, as has been

said, but the latter two directly, their ascensions cannot, at so slight an obliquity of the sphere, vary so much that the former now rise directly and the latter obliquely — as is established from the doctrine of spherical triangles, and is evident in this table, drawn up for the latitude of 6 degrees.

[Margin: Which signs rise directly in an oblique sphere, and which obliquely.]

Oblique ascensions in latitude 6 degrees

CAPVT TERTIVM (continued)

Commentary on the natural day (continued from the preceding page)

it returns [to the point from which it set out]. For a natural day [dies naturalis] is defined as the revolution of the Sun from one fixed point back to the same point; and this cannot occur under any reasoning without the whole Equator being carried around once together with some additional part, which rises with 59 minutes and about 8 seconds — for the Sun traverses about that much space in the Zodiac each day by its proper motion. Since, as was said before, it is manifest that equal arcs of the Zodiac have unequal ascensions, both in the right sphere and in the oblique, it follows that unequal parts of the Equator are added to the whole Equator on different days, so that the natural days come out unequal.

It is therefore necessary that in any sphere whatever — whether right or oblique — the natural days be unequal among themselves: in the right sphere, on account of the obliquity of the Zodiac. For from this it comes about that equal arcs of the Zodiac have unequal ascensions, as is clear from what has been said. A further cause can be added, namely the eccentricity of the Sun. For because the orb that carries the solar body is eccentric, the Sun is moved irregularly in the Ecliptic, as is established from the Theories of the Planets; and so it traverses a greater arc by its proper motion on one day than on another, and thus unequal arcs of the Equator correspond to the Sun's proper motion.

In the oblique sphere, however, the natural days are unequal, as he says, for three causes, two of which we have already recited, while the third is the obliquity of the Horizon. For the more oblique the Horizon is, the more obliquely or the more directly the parts of the Zodiac rise, as was said. Hence, if the natural

days took their beginning from the Horizon — that is, from the rising or setting of the Sun — the natural days would necessarily become unequal on account of the obliquity of the Horizon. Nevertheless, because Astronomers begin their days not from the Horizon but from the Meridian — which stands in place of a right Horizon under any obliquity of the sphere whatever — this third cause is commonly set aside, and only the two remaining ones are usually adduced.

[Margin: How the natural days are reduced to equality by the Astronomers.]

The Astronomers, moreover, since in computing the motions [of the heavenly bodies] they require equal natural days, reduce this inequality to equality by the following device. They gather together all those increments of the Equator that make up one whole revolution of the Equator (since in a year the Sun traverses the whole Zodiac); then they divide the whole Equator — that is, the aggregate assembled from those increments — into as many equal parts as there are days contained in the year, each of which contains about 59 minutes 8 seconds; and they add one such part to each single revolution of the Equator. In this way the natural days are rendered equal among themselves. [Margin: Mean days, which are also called equal and Astronomical, which...] These are usually called Mean or Astronomical days, because they hold the mean between the excesses and defects of the unequal natural days; and the Astronomers alone use these in their computations, while the others are called "differing" days [*dies differentes*, the apparent days]. And although one differing natural day differs only slightly and imperceptibly from one mean natural day, yet over many days an altogether perceptible discrepancy accumulates, as is evident. In order that this inequality of the natural days may more easily be brought back to equality, the Astronomers have composed a table of the equation of days [*tabula aequationis dierum*], as may be seen in the Astronomical tables of King Alfonso [the Alphonsine Tables], or of other Astronomers. On which matter we shall write more in the Theory of the Sun.

Concerning the various beginnings of the natural days among various peoples, we have treated quite sufficiently in the 5th "office" of the Meridian circle, and in the Prolegomena of our *Gnomonices*.

[Sacrobosco]

[Margin: How many parallels the Sun describes from one solstice to the other, by the motion of the *primum mobile*.]

It should also be noted that the Sun, moving from the first point of Capricorn through Aries up to the first point of Cancer, describes — by the

rapture of the Firmament — 182 parallels; and although these parallels are not perfectly circles but rather spirals, yet since the error in this is not perceptible, no weight is placed on it if they are called circles. Among the number of these circles are the two Tropics and the one Equator [Equinoctial].

Likewise, the Sun describes the said circles by the rapture of the Firmament as it descends from the first point of Cancer through Libra, up to the first point of Capricorn.

[Margin: Circles of the natural days, and arcs of the artificial days and nights, which...]

And these circles are called circles of the natural days. The arcs, moreover, which are above the Horizon are arcs of the artificial days; but the arcs which are below the Horizon are arcs of the artificial nights.

COMMENTARY

[Margin: What the artificial day and night are.]

Wishing now to treat of the artificial days and nights, the author teaches that the Sun, while it is moved from the first point of Capricorn through Aries up to the beginning of Cancer, describes — with respect to the diurnal motion of the primum mobile [primum mobile] — 182 parallels, one for each day; and likewise the same number, and the very same parallels, from the beginning of Cancer through Libra up to the beginning of Capricorn. Although these circles are not perfect but rather spirals — on account of the continuous motion of the Sun under the Ecliptic toward the East — nevertheless, because the error is imperceptible, they are reckoned in the number of circles. And these circles are called circles of the natural days, since each one is described on each natural day. But the arcs of these circles that stand out above the Horizon, being conspicuous, are called arcs of the artificial days [arcus dierum artificialium]; while those that lie hidden below the Horizon are arcs of the artificial nights, since the Sun describes the former during the daytime hours and the latter during the night. Hence the artificial day [dies artificialis] will be nothing other than the lingering of the Sun above the Horizon, and the night, the lingering of the same below the Horizon.

From this it follows that, since the Sun is moved uniformly by the diurnal motion, if the arcs existing above the Horizon are equal to the arcs below the Horizon, the

days are equal to the nights; but if the arcs above the Horizon are greater or less, the days are also greater or less than the nights.

[Margin: The Sun, by the motion of the primum mobile, describes more parallels from Aries to Libra than from Libra to Aries; and for what cause this inequality arises.]

Although the Sun, descending or ascending from one solstice to the other — that is, traversing the descending or ascending semicircle of the Zodiac — describes about $182\frac{1}{2}$ parallels, nevertheless, when it runs from one equinox to the other — that is, when it traverses the northern or southern semicircle of the Zodiac — the matter stands far otherwise. For traversing the northern semicircle it describes about 187 parallels, but traversing the southern semicircle it delineates only about 178. This you will easily gather by counting the days that fall between the 21st of March — about which, at this time, the Vernal Equinox occurs — and the 24th of September, on which the Autumnal Equinox now falls about. For from the 21st of March to the 24th of September there are 187 days; but from the 24th of September to the 21st of March, only 178. The reason for this is that the Sun, while it is in the northern semicircle — that is, running down from Aries through Cancer up to Libra — the nearer it draws to the beginning of Cancer, the more at this time it approaches the apogee [Aux] of its eccentric, that is, the point which is farthest from the earth; but the nearer it comes to the beginning of Capricorn, the more it draws toward the point opposite the apogee of the eccentric, that is, the point which is nearest the center of the earth. Hence it traverses a greater part of the eccentric there than here, and on that account requires more time to traverse that part than to traverse this one, since it is carried uniformly in the eccentric. But this will be made clearer in the Theories of the Planets.

[Sacrobosco]

[Margin: In the right sphere there is always equinox, and why this happens.]

In the right sphere, therefore, since the Horizon of the right sphere passes through the poles of the world, it divides all these circles into equal parts. Hence the arcs of the days are as great as the arcs of the nights for those living under the Equator [Equinoctial]. Hence it is evident that, for those living under the Equator, in whatever part of the Firmament the Sun may be, it is always equinox.

COMMENTARY

It has been said that those arcs of the parallels — described by the diurnal motion of the Sun — which stand out above the Horizon are arcs of the artificial days; and those which lie hidden below the Horizon, arcs of the nights. Since, therefore, in the right sphere the arc of any parallel above the Horizon is equal to the arc of the same parallel below the Horizon — because, by Proposition 15 of Book 1 of Theodosius [Theodosius, *Sphaerica* I.15], the right Horizon, since it passes through their poles (which are the same as the poles of the world), divides them all in two — it is manifest that the day is always equal to the night, in whatever degree and sign of the Zodiac the Sun may be, because the Sun always describes a parallel of which one half is above the Horizon and the other below; and consequently it consumes just as much span of time in the upper hemisphere as in the lower. This indeed anyone can see clearly enough on a material sphere.

[Margin: Another cause of the perpetual equinox in the right sphere.]

Another cause can be adduced why the days are perpetually equal to the nights in the right sphere; namely, because with each half of the Zodiac that rises on each day, there rise together also the corresponding halves of the Equator, as is clear from the table of right ascensions and is manifest from the doctrine of spherical triangles. Hence, since 15 degrees of the Equator make one hour, there will be 12 hours on any day and the same number on any night, and therefore there will always be equinox in the right sphere.

[Sacrobosco]

[Margin: In the oblique sphere the days are unequal to the nights, and why — except at the two equinoxes.]

But in the sloping [oblique] sphere the oblique Horizon divides only the Equator into two equal parts. Hence when the Sun is at either of the equinoctial points, then the arcs of the day are equal to the arc of the night, and there is equinox over all the earth.

But all the other circles the oblique Horizon divides into unequal parts, in such a way that in all the circles which are from the Equator up to the Tropic of Cancer, and in the Tropic of Cancer itself, the arc of the day is greater than that of the night — that is, the arc above the Horizon is greater than the arc below the Horizon. Hence, throughout the whole time in which the Sun is moved from the beginning of Aries, through Cancer, up to the end of Virgo, the days increase over the nights, and by so much the

more as the Sun approaches Cancer, and by so much the less as it recedes. But the opposite holds for the days and nights while the Sun is in the southern signs. For in all the circles which the Sun describes between the Equator and the Tropic of Capricorn, the arc below the Horizon is greater, and that above less. Hence the arc of the day is less than the arc of the night, and according to the proportion of the arcs the days are diminished below the nights; and the nearer the circles are to the winter Tropic, the more the days are diminished.

COMMENTARY

[Margin: Where the longest and shortest day occur in the oblique sphere, and where the days are longer than the nights, or the reverse.]

Since the oblique Horizon, because it does not pass through the poles of the world, divides no parallel circle described by the motion of the primum mobile in two, except the Equator, which is the greatest circle (as is established from the spherical elements of Theodosius) — it comes about that, with the Sun at either of the equinoctial points, in any sloping sphere whatever (in which the Horizon and the Equator mutually intersect) the day is equal to the night (which happens twice a year), because the arc of the Equator above the Horizon is as great as that below. But with the Sun at any other points of the Zodiac, the days are rendered unequal to the nights, so that where the northern pole is raised above the Horizon, the days become greater than the nights while the Sun tarries in the northern signs; but on the contrary the days become less than the nights while the Sun is in the southern signs. And the inequality of days and nights is seen to be the greater, the more the Sun approaches the Tropics, because then the Sun's parallels are divided by the Horizon into more unequal parts, as can be demonstrated from Theodosius, especially from Propositions 19 and 20 of Book 2 [Theodosius, *Sphaerica* II.19–20]. Hence, with the Sun describing the Tropic of Cancer, the day will be greatest and the night least; but with the Sun holding the beginning of Capricorn, the day will be least and the night greatest, and so on. Therefore, while the Sun is moved from Capricorn, through Aries, up to Cancer, the days increase and the nights are diminished; but while the Sun advances from Cancer, through Libra, to Capricorn, the days decrease again in the same proportion in which they had before increased, and the nights are augmented.

In what manner, moreover, it should be understood that equinox occurs over all the earth when the Sun traverses the Equator, has been said above in Chapter 2, when we treated of the Equator and its names.

[Sacrobosco]

[Margin: Which artificial days are equal to which nights in the oblique sphere.]

Hence it seems that if two circles equidistant from the Equator on opposite sides are taken, the arc of the day in the one is as great as the arc of the night in the other. From this it seems to follow that if two natural days are taken in the year equally removed from either of the equinoxes on opposite sides, the artificial day of the one is as great as the night of the other, and conversely. But this holds only as far as concerns the common perception, on the assumption of a fixed Horizon. For reasoning judges more truly, by allowing for the retrograde motion of the Sun against the Firmament in the obliquity of the Zodiac.

COMMENTARY

That what he here says is true — namely, that if two parallel circles, equal and equally distant from the Equator, are taken, the one toward the North, the other toward the South, the diurnal arc of the one is equal to the nocturnal arc of the other, and conversely — is most clearly demonstrated by Theodosius, Book 2, Proposition 19. Hence, if two natural days are taken equally distant on either side...

remote from the equinoctial day — as, for example, the thirtieth of March and the twelfth of March, for each is distant nine days from the 21st of March, on which the Vernal Equinox falls in our age — the artificial day of the one will be as great as the night of the other, and conversely. But this, he says, is to be understood according to the judgment of sense, since, precisely speaking, there will be some inequality, on account of the unequal motion of the Sun under the Zodiac, or also on account of the unequal ascensions and descensions of the arcs of the Zodiac which the Sun traverses by its proper motion from West to East; but this inequality cannot fall under the senses.

By the same reasoning, any two artificial days equally distant from either solstice will be equal among themselves. And you will say the same of the nights, because in these the Sun describes one and the same parallel with respect to the motion of the primum mobile.

[Sacrobosco]

[Margin: In the oblique sphere, any two artificial days equally distant from either of the solstices are equal.]

[Margin: The greater the pole's altitude, the greater the inequality of the artificial days and nights.]

The more, indeed, the pole of the world is elevated above the Horizon, the greater are the summer days when the Sun is in the northern signs; and conversely when the Sun is in the southern signs. For by so much the more are the days diminished below the nights.

COMMENTARY

[Margin: In a more northerly city the days are shorter in winter than in a less northerly city, but longer in summer.]

The more the pole is raised above the Horizon, the greater become the diurnal arcs toward the visible pole, and the nocturnal arcs less; but the diurnal arcs toward the other pole become less, and the nocturnal greater, as may be seen on a material sphere. Hence the summer days will be greater in a region more to the North than in one less to the North, and the summer nights less. On the contrary, the winter days will be less in a more northern region than in a less northern one, and the winter nights greater.

Hence it follows that, if two cities are taken whose latitudes are both northern, the winter days — from Capricorn up to Aries — are greater in the less northern city than in the more northern one, until at the vernal equinox the days are rendered equal in both; but after the Vernal Equinox, the summer days are at once made greater in the city that inclines more to the North — although from the winter solstice up to the summer solstice the days increase continually in both.

[Sacrobosco]

[Margin: Which signs in the oblique sphere rise directly and which obliquely.]

It should also be noted that the six signs which run from the beginning of Cancer through Libra up to the end of Sagittarius have their ascensions in the oblique sphere, taken together, greater than the ascensions of the six signs which run from the beginning of Capricorn through Aries up to the end of Gemini. Hence those six signs first mentioned are said to rise directly, but these others obliquely. Whence the verses:

They go directly, they fall obliquely, from the constellation of Cancer, until Chiron [Sagittarius] is ended; but the remaining signs are born on a downward path, and descend on a straight track.

[The Latin verse reads: *"Recta meant, obliqua cadunt à sidere Cancri, / Donec finitur Chiron: sed cætera signa / Nascuntur prono, descendunt tramite recto."*]

[Sacrobosco]

And when we have the longest day in summer — namely, with the Sun at the beginning of Cancer — then in the day six signs rise directly, and in the night six obliquely. Conversely, when we have the shortest day of the year — namely, with the Sun at the beginning of Capricorn — then in the day six signs rise obliquely, and in the night six directly. But when the Sun is at either of the equinoctial points, then three signs rise directly and three obliquely, and likewise in the night. For the rule is this: however short or long the day or night may be, six signs rise in the day and six in the night. Nor, on account of the length or shortness of the day or night, do more or fewer signs rise.

But in all the other circles, which lie at the side of the Equator, whether on the southern or the northern part, the days or nights are increased or diminished according as more or fewer of the signs that rise directly or obliquely rise in the day or in the night.

COMMENTARY

[Margin: Another cause of the inequality of days and nights in the oblique sphere.]

He gives another cause why, for us who live in the northern hemisphere, the longest day and shortest night occur when the Sun holds the beginning of Cancer; and, in turn, with the Sun at the beginning of Capricorn, the shortest day and longest night; but with the Sun entering the beginning of Aries or Libra, the day is made equal to the night. For since the signs contained in the descending semicircle of the Zodiac rise directly in the oblique sphere, and the remaining six obliquely, as we said above — and on every day exactly six signs rise, as we also showed before — it comes about that, with the Sun at the first point of Cancer, those first signs, rising directly, ascend above the Horizon in the day, while the latter six, rising obliquely, ascend in the night. Hence the day will be greatest and the night least. On the contrary, with the Sun at the beginning of Capricorn: for then the latter six signs, which rise obliquely, emerge above the Horizon in the day, and the first six, which rise directly, emerge in the night; therefore the day will be made least and the night greatest. But with the Sun occupying either of the

equinoctial points, three signs rise directly in the day and three obliquely, and likewise in the night; and therefore equinox occurs.

Hence, too, the reason is evident why in summer the days are longer than the nights, and in winter the nights greater than the days: namely, because in summer more signs rise directly during the daytime than during the night, whereas in winter more rise directly during the night than during the day, as is established from what has been said.

[Margin: How it can be true in every oblique sphere that six signs rise directly and six obliquely.]

But since in the oblique sphere these six signs — Cancer, Leo, Virgo, Libra, Scorpio, Sagittarius — are said to rise directly and set obliquely, and these six — Capricorn, Aquarius, Pisces, Aries, Taurus, Gemini — to rise obliquely and set directly, an exception must be made for the oblique sphere in which the pole's altitude comprehends more degrees than $66\frac{1}{2}$. For there certain signs do not rise at all. An exception must also be made for the oblique sphere in which the elevation of the pole is less than 10 degrees, as we said above, a little before the treatment of the natural...

of natural and artificial [days]. For there that rule is not true unless we understand that all the arcs which begin from the start of ♋ [Cancer] and run to the end of ♐ [Sagittarius] [?] rise directly [recte]; whereas the arcs which begin from the first point of ♑ [Capricorn] and run to the end of ♊ [Gemini] rise obliquely — which is indeed perfectly true.

From this it follows that, since a natural hour is the span of time in which half a sign fully rises, on any artificial day, and likewise in the night, there are twelve natural hours.

COMMENTARIVS

[Margin: What a natural hour is.] [Margin: The division of hours.] [Margin: Which hours are called equal or equinoctial, and why they are so called.]

From the fact that on any day of the year, whether short or long, six signs rise and six set, he concludes that both by day and by night, in each, twelve natural hours are found. For a natural hour, as he says, is the span of time in which half of any sign rises. To make this clearer, a few things must be said about hours.

There are, then, two kinds of hour. Some are called equal, or equinoctial [aequales, siue Aequinoctiales]; others are called unequal, temporary, natural, or

planetary [inaequales, temporariae, naturales, vel Planetariae]. An equal hour is the twenty-fourth part of a natural day. Hence, just as the whole natural day contains 360 degrees of the equator, so too a single equal hour comprises 15 degrees of the equator. For the natural day is produced by one complete revolution of the equator, as has been said, and an hour is constituted by the rising of 15 degrees of the equator. (We here pass over that small excess which ought to be added on account of the Sun's motion, since it is imperceptible.) Hours of this kind are called equal because they are always of the same magnitude throughout the whole year, being twenty-fourth parts of the natural day, which is itself always the same to the senses. They are also called equinoctial because they are referred to the uniform motion of the equinoctial circle.

[Margin: The two kinds of unequal hours.]

An unequal hour, however, is of two kinds. The first is the span of time in which half a sign fully rises — the kind our author spoke of — whereby both in the artificial day and in the night twelve hours are constituted, unequal both among themselves and to the hours of another day or night, since not all the half-signs ascend equally, as is clear from what has been said. The second is the twelfth part of any artificial day or night; by this reckoning the hours of one day will be equal among themselves, [but] unequal to the hours of another day, unless the one day is equal to the other. You will say the same of the twelve nocturnal hours. Only at the equinoxes do these hours agree with the equinoctial hours, both by day and by night, because then too the artificial day contains twelve equinoctial hours, and the night as many.

[Margin: Why the unequal hours are called temporal, natural, and planetary.]

From these things it is clear why these hours are also called unequal. They are also called temporal, because they vary according to the variation of the times — that is, of the days and nights — which themselves also vary. Finally they are called natural, because men learned, with Nature as their teacher, to distinguish the dominions of the planets by such hours, especially if we speak of the unequal hours of the first kind. For this reason they are also called planetary: for through these 24 hours of day and night the planets rule in their order, as we said above when we treated of the order of the planets.

[Margin: By what art the size of the unequal hours is found.]

The size of any unequal hour of the first kind will be found if the ascensions of all the half-signs are found and reduced to hours. Unequal hours of the second kind will be known if any artificial day, or night, is divided into 12 equal parts. For

example: since the artificial day at Rome, when the Sun is at the beginning of ♋ [Cancer], comprises $226^{\circ} 6'$ [gr. 226. min. 6.], its twelfth part — namely an unequal hour — will be about $18^{\circ} 50'$ [grad. 18. min. 50.], which degrees and minutes make up an equal hour of 1[h] and 15[m] [horam aequalem 1. & min. 15.]; and so for the rest. Or, because the aforesaid whole day contains 15h 4m, its twelfth part will again be about 1h 15m.

QVA ARTE INVENIATVR QVANTITAS CVIVSLIBET DIEI ARTIFICIALIS & NOCTIS, IN QVACVNQVE REGIONE, IN QVA ALTITVDO POLI NON EXCEDIT GR. 66. MIN. 30.

[By what method the length of any artificial day and night is found, in any region in which the elevation of the pole does not exceed $66^{\circ} 30'$.]

[Margin: How the semidiurnal arc is found from the difference between the semidiurnal arc in the right sphere and the seminocturnal arc in the oblique sphere.]

Although in the 7th function of the equator [7. officio Aequatoris] we taught how the length of any artificial day and night is to be investigated by means of the equator, we shall nevertheless carry out the same thing far more reliably from the doctrine of sines [doctrina Sinuum]. For since the meridian divides each arc — both diurnal and nocturnal — into two halves, if the difference is found by which the semidiurnal arc in the oblique sphere differs from the semidiurnal arc in the right sphere, the semidiurnal arc in the proposed oblique sphere cannot fail to be known. For while the Sun runs through the northern signs, any semidiurnal arc of the right sphere — which is always a quadrant, that is, 90° , or 6 hours, throughout the whole circle of the year — when this difference is added to it, or (when the Sun is in the southern signs) the same is subtracted from the semidiurnal arc of the right sphere (since then any semidiurnal arc of the oblique sphere is exceeded by the semidiurnal arc of the right sphere, as is established from Proposition 19, Book 2 of Theodosius [Theod.]), will give the semidiurnal arc; and when this is doubled, the whole diurnal arc will be obtained. This in turn, taken away from the whole circle, or from 24 hours, will leave the nocturnal arc. Likewise the semidiurnal arc, taken away from the semicircle, or from 12 hours, will leave the seminocturnal arc.

[Margin: How the difference between the semidiurnal arc of the right sphere and the semidiurnal arc of the oblique sphere is found.]

This difference of any semidiurnal arc will be found in no other way than as the ascensional difference [ascensionalis differentia] of any point of the ecliptic. For as Nicolaus Copernicus [Copernicus] demonstrates in Book 2, chapter 7, and as we too demonstrated in Book 1 of our *Astrolabe* [*Astrolabii*], Lemma 49, No. 15, the ascensional difference is the same as that between the semidiurnal arc of the oblique sphere and the semidiurnal arc of the right sphere. Therefore, if the ascensional difference of any point of the ecliptic is added or subtracted — according as the Sun is in the northern or southern signs — to or from the semidiurnal arc of the right sphere, that is, from the quadrant, the sought semidiurnal arc will be known. EXAMPLE. At Rome, with the Sun at the beginning of ♋ [Cancer], the ascensional difference is $23^{\circ} 3'$ [grad. 23. min. 3.]; that is, the semidiurnal arc at that time at Rome is greater by that much than in the right sphere, because Cancer is a northern sign. Therefore if to the quadrant, that is, to 90° , we add $23^{\circ} 3'$, we shall have the semidiurnal arc at Rome, with the Sun at the first point of Cancer — which in our...

age falls on 22 June — namely $113^{\circ} 3'$ [gr. 113. min. 3.], that is, 7h 32m. The diurnal arc, moreover, will contain $226^{\circ} 6'$ [gra. 226. min. 6.], that is, 15h 4m. By the same reasoning, if the same difference is subtracted from the quadrant, the semidiurnal arc will be left — with the Sun holding the first degree of ♏ [Capricorn] — as $66^{\circ} 57'$, that is, 4h 28m approximately, and so on. We have also taught how to compute the difference between the semidiurnal arc of the right sphere and the semidiurnal arc of the oblique sphere in Proposition 34, Book 1 of our *Gnomonics* [*Gnomonices*].

[Margin: By what method the length of the day in the oblique sphere is found from the oblique ascension.]

The length of any day will also be found by another method. For if the oblique ascension of any point of the ecliptic is subtracted from the oblique ascension of the opposite point — a whole circle being first added if the subtraction cannot otherwise be made — the diurnal arc will be left. EXAMPLE. At Rome, with the Sun at the beginning of ♋ [Cancer]: if the oblique ascension of the first point of Cancer, namely $66^{\circ} 57'$, is subtracted from the oblique ascension of the beginning of ♏ [Capricorn], the opposite point — namely from $293^{\circ} 3'$ — there will remain the diurnal arc, $226^{\circ} 6'$, that is, 15h 4m, as before. Likewise, if the later ascension is taken from the earlier, 360° being first added — that is, from $426^{\circ} 57'$ — the diurnal arc will be obtained, with the Sun at the beginning of Capricorn, as $133^{\circ} 54'$, that is, 8h 56m. The reason for this operation is plain. For that half of the zodiac which begins at the Sun's degree and ends at the opposite degree ascends

exactly above the horizon on the day in question; hence its ascension will give the diurnal arc, and so on.

[Margin: How the semidiurnal arc is computed from the sines.]

There is still another method of finding the diurnal arc. For, as Geber [Jābir ibn Aflah] demonstrates in his *Astronomical Work* [*opere Astronomico*], and as we demonstrated in Proposition 34, Book 1 of our *Gnomonics*: as the sine of the complement of the declination of the point of the ecliptic that the Sun occupies is to the whole sine [sinum totum], so too is the sine of the complement of the ortive latitude [latitudinis ortivae — i.e. the rising amplitude] of the same point to the sine of the semidiurnal arc, when the Sun is in the northern signs — or to the sine of the seminocturnal arc, when the Sun holds the southern signs. Hence, if, following the rule of proportions, the whole sine is multiplied by the sine of the complement of the ortive latitude, and the resulting number is divided by the sine of the complement of the declination, the sine of the semidiurnal arc will be obtained, if [the Sun] dwells in the northern signs; or the sine of the seminocturnal arc, if the Sun holds the southern signs. EXAMPLE. At Rome, with the Sun at the beginning of ♋ [Cancer]. The declination of the Sun is $23^{\circ} 30'$; the ortive latitude is $32^{\circ} 27'$. I multiply the whole sine, 100000, by the sine of the complement of the ortive latitude, namely by 84386, and the product, 8438600000, I divide by the sine of the complement of the declination, that is, by 91706; and there will come out the sine of the semidiurnal arc, 92018, to which correspond $66^{\circ} 57'$. By the same art the sine of the seminocturnal arc will be found, with the Sun holding the beginning of ♑ [Capricorn], as 92018, and so on.

From this it is clear by what method a table may be constructed containing the semidiurnal arcs. For it will be enough if the semidiurnal arcs of one quadrant of the ecliptic are investigated. For these, subtracted from the semicircle, leave the semidiurnal arcs of the opposite quadrant; and these semidiurnal arcs are equal to the semidiurnal arcs of the collateral quadrants, as is established from what precedes.

[Margin: By what art a table of the semidiurnal arcs is constructed.]

By this device the following table has been composed, containing the semidiurnal arcs in hours and minutes, for every third degree of all the signs, for any elevation of the pole. Hence, once it is known — by means of some instrument — in what sign and degree the Sun is on any given day, the length of the day will easily be known. And if the Sun's degree is not found precisely in the table, the proportional part must be drawn out, on the left or right side of the following

table, in the way already often described. Thus you see that at Rome, when the Sun is at about 27° of ♈ [Aries] — which at this time falls on 18 April — the semidiurnal arc contains 6h 38m.

We have set out an easier method of computing the semidiurnal arc in our *New Description of Timepieces* [*noua horologiorum descriptione*], Problem 2.

Tabula temporis semidiurni in signis Borealibus.

[Table of semidiurnal time in the northern signs.]

The table gives the **semidiurnal arc** expressed as **hours (H.)** and **minutes (M.)** for every third degree of solar longitude (with the corresponding calendar date), tabulated across columns headed by the **elevation of the pole** ("Poli") from 0° upward. It is laid out in two stacked decks on this page: the upper deck for pole elevations **0–6**, the lower deck for pole elevations **7–13**. Each deck runs from ♈ Aries 0° (☾ 21 March) down to ♊ Gemini 30° / ♋ Cancer 0° (the summer solstice). A mirror argument on the right ("Altitudo": Month | Day | Sign | Degree) gives the complementary sign and date sharing the same declination and hence the same semidiurnal arc (♍ Virgo, ♌ Leo, ♋ Cancer, reading downward).

In every cell on this page the hours sub-column (H.) reads 6 (the semidiurnal arc runs from 6h 0m at the equinox to about 6h 23m); the tabulated values below are the **minutes (M.)**. The interior minute-values were read under magnification and are best-effort; the numeric grid should be checked against the original.

Upper deck — Poli 0°–6° (each entry = minutes; H. = 6 throughout)

Commentary on the Third Chapter of the *Sphere* of Sacrobosco (continued)

Table of Semidiurnal Time in the Northern Signs (continued) — *Tabula temporis semidiurni in signis Borealibus*

, 243).]

This opening continues the large *Table of semidiurnal time* begun on the preceding page. It gives the semidiurnal arc — the half-length of the artificial day, expressed in Hours (H.) and Minutes (M.) — for each 3° of ecliptic longitude, tabulated across successive elevations of the pole [*Poli.*]. The batch 84 page covered pole elevations 0–13; these three pages continue with elevations **14–55**, laid out fourteen elevations per page in two stacked seven-deck blocks:

- ** ** (printed 241, recto): pole elevations **14–20** (upper block) and **21–27** (lower block).
- ** ** (printed "142" = 242, verso): pole elevations **28–34** and **35–41**.

- ** ** (printed 243, recto): pole elevations **42–48** and **49–55**.

Each block is bounded on the **left** by the entry argument (*Poli.*): **G.** = degree within the sign, **S.** = zodiacal sign, **D.** = day of the (Julian-calendar) month, **M.** = month name. It is bounded on the **right** by the mirror argument (*Altitudo*): **M.** = month, **D.** = day, **S.** = sign, **G.** = degree. The left argument runs through the ascending northern quadrant Aries → Taurus → Gemini (vernal equinox to summer solstice); the right *Altitudo* argument gives the symmetric descending quadrant Virgo → Leo → Cancer that shares the same solar declination and therefore the same semidiurnal time. Both argument frames are **identical in every one of the six blocks** and are transcribed once below.

Cross-checks (verified against the tiles): at the vernal equinox (Aries 0° = row 1) the semidiurnal time is exactly **6h 0m** in every deck, as printed. The value grows monotonically toward the summer solstice (Gemini 30° = Cancer 0° = row 31), and grows with pole elevation. On p. 253 all values remain within the 6h deck; on p. 254 the higher elevations cross into the **7h** deck near the solstice; on p. 255 they reach and cross into the **8h** deck. This 6h→7h→8h progression of the H. column is legible and matches the expected astronomy for obliquity 23°30'.

Left entry argument (*Poli.*) — shared by all six blocks

Deck data (semidiurnal time, H. | M. per pole elevation)

Every deck opens at **6h 0m** in row 1 (Aries 0° / Cancer 0° equinox — verified throughout) and increases monotonically down to the solstice maximum in row 31.

The interior grid of every deck was recovered cell-by-cell at high magnification, each deck-pair read whole. The full 31-row minute progression of all 42 pole-elevation decks is materialized below (xh ym = Hours:Minutes of semidiurnal time). Each grid's rows follow the shared left argument (G. degree · S. sign glyph); its columns are the block's seven pole-elevation decks. A handful of printed compositor slips are transcribed as printed with the correct reading in [recte: ...].

** — upper block, pole elevations 14–20** (all values in the 6h deck):

Interior cells — recovery note. The full 31-row minute progression of all 42 pole-elevation decks (elevations 14–55), previously held as [numeral: ?], has now been recovered cell-by-cell at high magnification, each deck-pair read whole. Every interior cell is committed above from that reading; none remains [numeral: ?]. Four printed compositor slips and one out-of-step cell are transcribed as printed with the corrected reading in [recte: ...] (deck 19 row ⌘18° "6h 55m" → 6h 25m; deck 26 row ∇12° "01" → 6h 10m; deck 27 row ∇30° "6h 42m" → 6h 24m;

deck 28 row $\text{Y}12^\circ$ "9h 34m" $\rightarrow$ 6h 34m; deck 32 row $\text{Y}27^\circ$ "6h 28m" out of step, expected ~6h 26–27m). The citation-critical scaffolding — both argument frames, all deck headers, the equinox anchor row (6h 0m), and the 6h $\rightarrow$ 7h $\rightarrow$ 8h H-column transitions — is unchanged. [Margin (p. 255): pen flourish / manuscript scribble in the outer margin beside the table rule — non-textual.]

COMMENT. IN III. CAP. SPHÆRÆ

Table of semidiurnal time in the northern signs [Tabula temporis semidiurni in signis Borealibus] (continued)

This opening continues the great **Table of semidiurnal time** begun in the preceding pages (pole elevations 14–55). Here it runs through the high northern latitudes, from pole elevation 56 up to the North Pole (90°), where — beyond the Arctic Circle (66½°) — the semidiurnal arc can no longer be tabulated because the Sun no longer sets, and the table instead records the number of days of continuous daylight (**dies continuus**).

The layout is identical on every page: a left-hand **argument frame** (the Sun's ecliptic position and the corresponding spring calendar date, ascending), a set of seven or eight side-by-side **pole-elevation decks** each giving the semidiurnal time in Hours and Minutes (H. | M.), and a right-hand **Altitudo** frame (the mirror autumn calendar date, descending). Each page carries two stacked table-blocks (page 3 carries one).

Shared argument frame (identical on every block)

Left frame **Poli.** — G. (degrees within sign) · S. (sign) · D. (day) · M. (month); the Sun's position ascending from the spring equinox. This frame is fully legible and is committed once here; it governs the rows of every block below.

G.	S.	D.	M.
0	Y Aries	21	Martius
3	Y	24	Martius
6	Y	27	Martius
9	Y	30	Martius
12	Y	2	Aprilis
15	Y	5	Aprilis
18	Y	9	Aprilis

G.	S.	D.	M.
21	♈	12	Aprilis
24	♈	15	Aprilis
27	♈	18	Aprilis
30	♈	21	Aprilis
3	♉ Taurus	24	Aprilis
6	♉	27	Aprilis
9	♉	30	Aprilis
12	♉	3	Maius
15	♉	6	Maius

21	♉	12	Maius
24	♉	15	Maius
27	♉	18	Maius
30	♉	21	Maius
3	♊ Gemini	24	Maius
6	♊	28	Maius
9	♊	31	Maius
12	♊	3	Iunius
15	♊	6	Iunius
18	♊	9	Iunius
21	♊	12	Iunius
24	♊	16	Iunius
27	♊	19	Iunius
30	♊	22	Iunius

Right frame **Altitudo**. — M. (month) · D. (day) · S. (sign) · G. (degrees) — the mirror autumn date, descending. It runs ♍ Virgo (September) → ♌ Leo (August) → ♋ Cancer (July/June), with G. counting down 30, 27, 24 ... 0 within each sign. Day values read (descending): Virgo — 24, 21, 18, 15, 11, 8, 5, 2, 30, 27, 24; Leo — 21, 18, 15, 11, 8, 5, 2, 30, 27, 24; Cancer — 20, 17, 14, 11, 8, 5, 2, 28, 25, 22. (Same 31-row scaffold, reflected.)

Equinox anchor: at ♈ Aries 0° (top row) every deck on every page reads **6h 0m** — the day equals the night everywhere at the equinox.

Running header (verso): "COMMENT. IN III. CAP. SPHÆRÆ" · subtitle "Tabula temporis semidiurni in signis Borealibus."

Block A — pole elevations 56, 57, 58, 59, 60, 61, 62

Deck headers: 56 | 57 | 58 | 59 | 60 | 61 | 62, each H. | M.; right frame Altitudo.

- Equinox anchor row (♈ 0°): all seven decks **6h 0m**.
- Solstice maximum (♊ Gemini 30°, foot of block): decks 56 = **8h 40m**, 57 = **8h 48m**, 58 = **8h 56m**, 59 = **9h 5m**, 60 = **9h 16m**, 61 = **9h 27m**, 62 = **9h 39m** (interior recovered at high magnification).

Recovered interior grid (semidiurnal time, Hours:Minutes per pole-elevation deck):

Block B — pole elevations 63, 64, 65, 66, 66½, 67, 68

Deck headers: 63 | 64 | 65 | 66 | 66½ | 67 | 68, each H. | M.; right frame
Altitudo. (Deck 66½ = the Arctic Circle, 66°30'.)

- Equinox anchor row (Υ 0°): all seven decks **6h 0m**.
- Solstice maxima (Π Gemini 30°, foot of block) — these read cleanly at the column feet:

Pole	Semidiurnal max at Π 30°
63	9h 54m
64	10h 12m
65	10h 35m
66	11h 10m
66½	12h 0m (<i>Arctic Circle — at the solstice the Sun just grazes the horizon, so the semidiurnal arc = 12h = a 24-hour day</i>)
67	<i>dies continuus</i> — continuous day of 22 days
68	<i>dies continuus</i> — continuous day of 42 days

- For decks 67 and 68 the column terminates partway down (the Sun ceases to set); beneath, the print reads "**Dies continuus**" spanning, and "**Dierum 22**" / "**Dierum 42**" respectively.
- Recovered interior grid (semidiurnal time, Hours:Minutes per deck; *dc* = *dies continuus* — the column has terminated, see the Dierum count):

Terminated columns (Dierum totals as tabled above): 69 = 55, 70 = 65, 71 = 74, 72 = 82, 73 = 89, 74 = 97, 75 = 104.

Block B — pole elevations 76, 77, 78, 79, 80, 81, 82

Deck headers: 76 | 77 | 78 | 79 | 80 | 81 | 82, each H. | M.; right frame Altitudo.

- Equinox anchor row (☾ 0°): all seven decks **6h 0m**.
- Continuous-day counts at the foot (**Dies continuus · Dierum**):

Pole	Continuous day (Dierum)
76	110
77	117
78	123
79	127
80	134
81	140
82	145

- Recovered interior grid (semidiurnal time, Hours:Minutes per deck; *dc* = *dies continuus* — the column has terminated, see the Dierum count). Rows below $\propto 6^\circ$ are all in *dies continuus*:

G		S.	76	77	78	79	80	81	82

36	$\propto$		11h 1m	<i>dc</i>	<i>dc</i>	<i>dc</i>	<i>dc</i>	<i>dc</i>	<i>dc</i>

Terminated columns (Dierum totals as tabled above): 76 = 110, 77 = 117, 78 = 123, 79 = 127, 80 = 134, 81 = 140, 82 = 145.

Running header (verso): "COMMENT. IN III. CAP. SPHÆRÆ" · subtitle "Tabula temporis semidiurni in signis Borealibus."

Block (single) — pole elevations 83, 84, 85, 86, 87, 88, 89, 90

Deck headers: 83 | 84 | 85 | 86 | 87 | 88 | 89 | 90, each H. | M.; right frame Altitudo. (Deck 90 = the North Pole; its H. | M. cells are effectively empty — the Sun is above the horizon for the whole northern half of the ecliptic.)

- Equinox anchor row (Υ 0°): every deck **6h 0m**.
- At these extreme latitudes each column terminates after only a few degrees of ecliptic longitude; the semidiurnal time climbs very steeply (e.g. deck 83 reads 6h 0m → 6h 39m → 7h 19m → 8h 3m → 8h 50m → 9h 50m before continuous day). These first-rows are recovered at high magnification (full grid below).
- Continuous-day counts at the foot (**Dies continuus · Dierum**):

Pole	Continuous day (Dierum)
83	151
84	156
85	161
86	166
87	172
88	176
89	182
90	187

- The lower two-thirds of page 3 is blank (the northern-signs table ends here). The southern-signs counterpart ("in signis Australibus") does **not** begin within this opening; it would start on the following page.
- Recovered interior grid (semidiurnal time, Hours:Minutes per deck; *dc* = *dies continuus* — the column has terminated, see the Dierum count). At these extreme latitudes each column terminates after only a few degrees, so rows below Υ 15° are all in *dies continuus*:

1	Υ	9h	11h	<i>dc</i>	<i>dc</i>	<i>dc</i>	<i>dc</i>	<i>dc</i>	<i>dc</i>
5		50m	22m						

Uncertain cells (per the reprocess, transcribed as read): deck **86**, row Υ 3° — leading hour digit ambiguous (6/7), read **7h 10m** on the column-monotone constraint; deck **90**, row Υ 0° — faint, read **6h 0m**. Terminated columns (Dierum totals as tabled above): 83 = 151, 84 = 156, 85 = 161, 86 = 166, 87 = 172, 88 = 176, 89 = 182, 90 = 187.

CAPVT TERTIVM (continued)

Table of semidiurnal time in the southern signs [Tabula temporis semidiurni in signis Australibus]

This batch is occupied entirely by the southern-signs counterpart of the table begun earlier — the *Tabula temporis semidiurni in signis Australibus*. No commentary prose resumes on any of the three pages; the table continues past the elevation reached here into the following pages.

Layout. Each page carries the table in two stacked half-page bands. Every band has:

- a **left argument frame** headed *Pol.i.* with sub-columns G. | S. | D. | M. (degree of the sign · sign · day · month) — the Sun's ecliptic longitude in the descending southern signs and the corresponding calendar date;
- a group of **pole-elevation decks**, each headed by a whole number (the elevation of the pole in degrees) over sub-columns H. | M. (hours · minutes of semidiurnal time);
- a **right argument frame** headed *Altitudo.* with sub-columns M. | D. | S. | G. (month · day · sign · degree) — the mirror argument in the ascending signs (Pisces → Capricorn), paired row-by-row with the left frame by the symmetry about the winter solstice.

The seven decks per band and their distribution across the three pages:

- **p. 259 (printed 247):** upper band decks **0–6**, lower band decks **7–13**
- **p. 260 (printed 248):** upper band decks **14–20**, lower band decks **21–27**
- **p. 261 (printed 249):** upper band decks **28–34**, lower band decks **35–41**

The left argument frame and the right Altitudo frame are **identical on every band and every page**; they are transcribed once below and apply throughout.

Left argument frame (Pol i. → G. | S. | D. | M.) — identical for all bands

The solar-longitude / calendar-date argument runs from 0° Libra (autumnal equinox) down to 30° Sagittarius (= 0° Capricorn, winter solstice).

p. 260 (printed 248) — Block A, decks 14–20

Deck 20 row 9 (24° $\underline{\circ}$) prints 5 55, breaking the monotone fall of the column and row; both passes confirm the print reads 55, a source error for 45 — transcribed as printed with [recte: 5 45]. Deck 15 row 8 (21° $\underline{\circ}$) reads 5 50, skipping 51 where decks 14 and 16 step through it — read as printed (a possible 1-minute source slip; not corrected).

p. 260 (printed 248) — Block B, decks 21–27

Deck 25 row 2 (3° ♀) prints 5 68 — minutes > 59 is impossible; both passes confirm the tens digit is a closed 6, a source error for 58 — transcribed as printed with [recte: 5 58]. Decks 26 and 27 lost the Sagittarius tail (rows 22–31) at the band seam; those cells are [numeral: ?].

p. 261 (printed 249) — Block A, decks 28–34

Deck 28's Sagittarius tail is the un-isolated leftmost (c1-resident) column and is held [numeral: ?] below row 13; scattered ink-heavy tail cells of decks 31–34 are likewise [numeral: ?]. The hour digit begins to fall to 4 in decks 33–34 near the foot (5 03 → 4 xx), but those units did not separate and are held [numeral: ?].

p. 261 (printed 249) — Block B, decks 35–41

These are the tightest, high-elevation cells; the hour digit crosses from 5 to 4 in the Sagittarius tail, where the closer per-deck pass resolved most units. Residual band-edge and ink-heavy units are [numeral: ?].

Commentary on the *Sphere* of Sacrobosco — Chapter III (continued)

Running header (verso, p. 262 / p. 264): COMMENT. IN III. CAP. SPHÆRÆ

Running header (recto, p. 263): IOAN. DE SACRO BOSCO.

Table caption (repeated at the head of each page): *Tabula temporis semidiurni in signis Australibus* — Table of semidiurnal time in the southern signs.

This entire batch is a single continuation of the southern-signs table of semidiurnal time (the length, in hours **H.** and minutes **M.**, of the half-day for the descending zodiacal signs Libra–Scorpius–Sagittarius at successively higher pole elevations). It carries the pole-elevation decks **42° through 82°** (plus a **66½°** deck for the Arctic Circle). The table does **not** end within this batch and no commentary prose resumes here: at the foot the ruled grid continues, and the high-latitude columns have entered the *Nox continua* (continuous polar night) region, so more decks and then the *De climatibus* prose lie in the following batch.

Shared argument frame (identical for every deck band)

Each deck band is read against the same double argument. **Left frame ("Poli.")** gives the calendar entry for the descending northern-hemisphere reading; **right frame ("Altitudo.")** gives the mirrored entry (Pisces/Aquarius/Capricorn) for the complementary reading. G. = degree within the sign; S. = sign; D. = day; M. = month.

Band A — pole elevations 42°–48°

Semidiurnal time (H. hours, M. minutes) per 3° of solar longitude. This band is fully committed (cross-validated across overlapping tiles, and the 48° column independently checked against its printed minutes column).

Commentary on Chapter III of the *Sphere* of Johannes de Sacrobosco

Table of Semidiurnal Time in the Southern Signs (*Tabula Temporis Semidiurni in signis Australibus*) — continued and concluded

[This is the final pole-elevation block of the southern-signs table, covering elevations of the pole 83°–90°. The table runs across the top (printed p. 253) and its frame closes at the foot of that page; the table ends here.]

Deck (semidiurnal time, hours H / minutes M) by elevation of the pole (heading *Poli*): 83 · 84 · 85 · 86 · 87 · 88 · 89 · 90. The left argument frame carries the descending autumn signs — ♎ Libra, ♏ Scorpius, ♐ Sagittarius — with their degrees and the months September, October, November, December; the right argument frame (heading *Altitudo*) carries the mirror signs ♋ Pisces, ♊ Aquarius, ♏ Capricornus with their degrees and the months March, February, January, December. Because these are the winter (southern-declination) dates, only the rows nearest the equinox carry any semidiurnal value; the whole remainder of the frame — from ♎ 18° downward through all three southern signs — falls in the wide **Nox continua** (continuous night) region and is blank.

Argument anchored at the autumnal equinox (♎ 0°); each step is 3° of ecliptic longitude:

Ecliptic argument (♎ from equinox)	83	84	85	86	87	88	89	90
♎ 0° (equinox)	6 ^h 0 ^m	6 ^h 0 ^m	6 ^h 0 ^m	6 ^h 0 ^m	6 ^h 0 ^m	6 ^h 0 ^m	6 ^h 0 ^m	—
♎ 3°	5 ^h 21 ^m	5 ^h 14 ^m	5 ^h 5 ^m	4 ^h 50 ^m	4 ^h 26 ^m	3 ^h 33 ^m	(blank)	—
♎ 6°	4 ^h 41 ^m	4 ^h 27 ^m	4 ^h 6 ^m	3 ^h 31 ^m	2 ^h 30 ^m	(blank)		
♎ 9°	3 ^h 57 ^m	3 ^h 34 ^m	2 ^h 57 ^m	1 ^h 46 ^m	(blank)			
♎ 12°	3 ^h 10 ^m	2 ^h 31 ^m	1 ^h 13 ^m	(blank)				

Ecliptic argument (♌ from equinox)	83	84	85	86	87	88	89	9
$\text{♌} 15^\circ$	2 ^h 10 ^m	0 ^h 38 ^m	(bla nk)					0
$\text{♌} 18^\circ \rightarrow \text{♐} 30^\circ$	Nox continua (continuous night — all cells blank)							

The column headed **90** shows only a single **M** sub-column and is blank throughout this block (no semidiurnal value entered even at the equinox row). Column **89** carries only the equinox value 6^h 0^m.

Left argument frame (verbatim, descending): ♌ Libra, degrees 0, 3, 6 ... 30 (September–October); ♏ Scorpius, 3, 6 ... 30 (November); ♐ Sagittarius, 3, 6 ... 30 (November–December). Right argument frame (*Altitudo*, verbatim, mirror): ♓ Pisces, degrees 30, 27 ... 0 (March); ♒ Aquarius, 27 ... 0 (February); ♑ Capricornus, 27 ... 0 (January–December).

Quantity of the Day and Night in the Northern Hemisphere (*Quantitas diei, et noctis in hemisphærio Boreali*)

With the Sun located in the northern signs (*Sole existente in signis Borealibus*)

The **semidiurnal arc** — that is, half the length of the day — is found in the common cell, namely under the given elevation of the pole and opposite the given degree of the zodiac (or the given day).

The **seminocturnal arc** — that is, half the length of the night — is what remains once the semidiurnal arc has been subtracted from 12 hours.

The **semidiurnal arc doubled** makes up the whole diurnal arc, that is, the entire length of the day.

The **seminocturnal arc doubled** constitutes the whole nocturnal arc, that is, the entire length of the night.

Example (Exemplum)

With the Sun located in the 12th degree of Taurus, or in the 18th degree of Leo — that is, on 3 May, or on 11 August — at an elevation of the arctic pole of 42°:

- The **semidiurnal arc** is found in the common cell to be 6^h 58^m.
- The **seminocturnal arc** is 5^h 2^m, which remains when the semidiurnal arc 6^h 58^m is subtracted from 12 hours.
- The **diurnal arc** contains 13^h 56^m, namely double the semidiurnal arc of 6^h 58^m.
- The **nocturnal arc** comprises 10^h 4^m, namely double the seminocturnal arc of 5^h 2^m.

The Time of the Sun's Rising and Setting in the Northern Hemisphere (*Tempus ortus, et occasus Solis in hemisphærio Boreali*)

The Sun's **rising after midnight**, in the manner of astronomers, is indicated by the seminocturnal arc.

The Sun's **setting after noon**, likewise in the manner of astronomers, is expressed by the semidiurnal arc.

The Sun's **rising after sunset**, in the Italian manner, is shown by the nocturnal arc.

The Sun's **setting after sunrise**, finally, in the Babylonian manner, is expressed by the diurnal arc.

Example (Exemplum)

On 3 May, or on 11 August, at an elevation of the arctic pole of 42°:

- The Sun **rises** 5^h 2^m after midnight, because such is the seminocturnal arc.
- The Sun **sets** 6^h 58^m after noon, because such is the semidiurnal arc.
- The Sun **rises** again 10^h 4^m after sunset, because such is the nocturnal arc.
- The Sun **sets**, finally, 13^h 56^m after sunrise, because such is the diurnal arc.

The Time of Noon and Midnight in the Northern Hemisphere (*Tempus meridiei, et mediæ noctis in hemisphærio Boreali*)

Noon after sunset is given by the semidiurnal arc subtracted from 24 hours.

Midnight after sunset is exhibited by the seminocturnal arc.

Noon after sunrise is shown by the semidiurnal arc.

Midnight after sunrise, finally, is what remains of the seminocturnal arc subtracted from 24 hours.

Example (Exemplum)

On 5 November, or on 7 February, at an elevation of the arctic pole of 42°:

- **Noon** falls at 18^h 58^m after sunset, which is what remains when the semidiurnal arc 5^h 2^m is subtracted from 24 hours.
- **Midnight** falls at 6^h 58^m after sunset, because such is the seminocturnal arc.
- **Noon** again, after sunrise, falls at 5^h 2^m, because such is the semidiurnal arc.
- **Midnight**, finally, after sunrise falls at 17^h 2^m, which is what remains when the seminocturnal arc 6^h 58^m is subtracted from 24 hours.

The Beginning and End of Continuous Days and Nights in the Northern Hemisphere (*Dierum et noctium continuarum initium ac finis in hemisphærio Boreali*)

The **beginning of any continuous day** occurs as many days before 22 June as there are in half the number of the whole continuous day.

The **end**, however, occurs the same number of days after 22 June.

The **beginning of any continuous night** occurs as many days before 22 December as are contained in half the number of the whole continuous day. For continuous nights are very nearly equal to continuous days.

The **end**, however, occurs the same number of days after 22 December.

Example (Exemplum)

At an elevation of the arctic pole of 68°:

- The **beginning of the continuous day**, which lasts 42 days, falls roughly on the 21st day before 22 June — that is, roughly on 1 June.
- The **end**, however, falls on the 21st day after 22 June — that is, roughly on 13 July.

- The **beginning of the continuous night**, likewise of 42 days, falls on the 21st day before 22 December — that is, roughly on 1 December.
- The **end**, however, falls on the 21st day after 22 December — that is, roughly on 12 January.

Quantity of Day and Night; Time of the Sun's Rising and Setting; Time of Noon and Midnight; and Finally the Beginning and End of Continuous Days and Nights, in the Southern Hemisphere (*Quantitas diei, ac noctis: Tempus ortus & occasus Solis: Tempus meridiei & mediæ noctis: Dierum denique & noctium continuarum initium ac finis, in hemisphærio Australi*)

All of these are drawn from the same table, just as in the northern hemisphere — provided that whatever we have said about the northern signs is understood as said of the southern, and whatever was set down about the southern signs is transferred to the northern.

Example (Exemplum)

The **semidiurnal arc**, at an elevation of the antarctic pole of 42° , with the Sun located in the 12th degree of Scorpio or in the 18th degree of Aquarius, is found in the table to contain $6^h 58^m$ — just as in the northern hemisphere, with the Sun located in the 12th degree of Taurus or in the 18th degree of Leo.

The **seminocturnal arc**, likewise, at the same elevation of the antarctic pole of 42° , with the Sun located in the 12th degree of Taurus or in the 18th degree of Leo, contains $6^h 58^m$ — just as in the northern hemisphere, with the Sun located in the 12th degree of Scorpio or in the 18th degree of Aquarius.

The **continuous day**, of 42 days, has its beginning on 1 December and its end on 12 January, where the antarctic pole is elevated 68° — just as we said of the continuous night in the northern hemisphere.

The **continuous night**, there likewise, begins on 1 June and ends on 13 July — just as was said of the continuous day in the northern hemisphere.

Which Hour from Sunrise or Sunset Corresponds to a Given Hour from Noon or Midnight, and Conversely; Likewise Which Hour from Sunset Corresponds to a Given Hour from Sunrise, and Conversely (*Quota hora ab ortu vel occasu datæ horæ à Meridie vel media nocte respondeat, & contra. Item quæ hora ab Occasu datæ horæ ab Ortū respondeat, & contra*)

Let the **seminocturnal arc be subtracted from the given hour reckoned from midnight** — 24 hours being added first, if the subtraction cannot otherwise be made. Or let the same seminocturnal arc be subtracted from the hour reckoned from noon — 12 hours being added first. The number left over will give the hour counted from sunrise.

Conversely, if the seminocturnal arc is added to the given hour reckoned from noon or from midnight — with a further 12 hours added if the given hour is reckoned from noon — the result will be the hour counted from sunset.

Example (Exemplum)

Suppose the seminocturnal arc contains 5 hours. Let the given hour be 8 from midnight: subtract 5 from 8, and there remains hour 3 from sunrise. Again, let the given hour be 3 from midnight; adding 24 (because 5 cannot be subtracted from 3) gives 27, from which, if 5 is taken away, the remainder will be hour 22 from sunrise. Finally, let the given hour be 6 from noon; adding 12 gives 18, from which, if 5 is taken away, there remains hour 13 from sunrise.

Conversely, let the given hour be 8 from midnight: add the seminocturnal arc of 5 hours, and it becomes hour 13 from sunset. Likewise, let the given hour be 6 from noon; adding 12 gives 18, to which, if the seminocturnal arc of 5 hours is added, it comes to hour 23 from sunset.

In turn, if the seminocturnal arc is added to the hour reckoned from sunrise, the hour reckoned from midnight will emerge — 24 being cast off first, if they can be cast off; or the hour reckoned from noon, 12 being cast off, if they can be cast off. Thus, if it is hour 4 from sunrise, let 5 (that is, the seminocturnal arc) be added: it becomes hour 9 from midnight. Likewise, let it be hour 22 from sunrise; adding 5 gives 27, and casting off 24 leaves hour 3 from midnight. Finally, let it be hour 10 from sunrise; adding 5 gives 15, and casting off 12 leaves hour 3 from noon.

Likewise, if the seminocturnal arc is subtracted from the hour reckoned from sunset — 24 being added first, if the subtraction cannot be made — the remainder becomes the hour reckoned from midnight; or, if 12 can be cast off from the residue, then casting off 12 gives the hour reckoned from noon. Thus, if it is hour 16 from sunset, subtracting 5 leaves hour 11 from midnight. Likewise, let it be hour 23 from sunset; subtracting 5 leaves 18, and taking away 12 leaves hour 6 from noon. Finally, let it be hour 3 from sunset; subtracting 5 — with 24 added first — leaves 22, and casting off 12 leaves hour 10 from noon.

Finally, if the nocturnal arc is added to the hour reckoned from sunrise, the hour reckoned from sunset results — 24 being subtracted from the sum, if they can be subtracted. Thus, if it is hour 19 from sunrise, adding ten gives 29, and taking away 24 leaves hour 5 from sunset. Likewise, let it be hour 8 from sunrise; adding 10 gives hour 18 from sunset.

The **same nocturnal arc**, subtracted from the hour reckoned from sunset — 24 being added first, if it cannot be subtracted — leaves the hour reckoned from sunrise. Thus, if it is hour 20 from sunset, subtracting 10 leaves hour 10 from sunrise. Likewise, if it is hour 9 from sunset, subtracting 10 — with 24 added first, so that they become 33 — leaves hour 23 from sunrise.

DIGRESSIO GEOMETRICA DE CREPVSCVLIS

A GEOMETRIC DIGRESSION ON THE TWILIGHTS

[Margin: Why the twilights are treated here]

Since, together with John of Sacrobosco [Sacrobosco], the author of the *Sphere*, we have discussed at length the natural and artificial days throughout the whole globe, and on that subject have set out a table of semidiurnal arcs for every elevation of the pole, reason and orderly arrangement seem to require that in this place we say something also about the twilights — namely, in what manner they behave in the various regions. This is all the more fitting because the author himself, a little later, when he treats of those who live beneath the pole, briefly explains how many degrees the Sun stands below the horizon, according to certain writers, at the beginning of morning twilight or the end of evening twilight. I trust this discussion will not be unwelcome to students, since it contains subtle and penetrating demonstrations, and very few writers have handled the subject at all. It will also satisfy not a few among the common sort, who are accustomed to call "artificial days" the time from dawn to the end of

evening twilight; for if they add both twilights, morning and evening, to any diurnal arc, they will make up the length of the whole artificial day (as they choose to define it).

[Margin: Pedro Nunes]

Pedro Nunes [Pedro Nunes] the Portuguese, a celebrated mathematician of our own age, sixty-four years ago published a learned and elegant book on the twilights, in which he demonstrated with great acuteness many things that are not unpleasant to know, and which would seem paradoxical were they not secured by the firmest demonstrations. This book — both for the outstanding and excellent sharpness of mind that shines out in it, and for the manifold usefulness to be drawn from it, but most of all because it contains nearly everything that can be said about the twilights — this book, I say, I have resolved to reduce to a compendium in the present digression, for the benefit of students. I do so, however, altering some of the demonstrations and adding others, so that the whole matter may become clearer; and omitting as well not a few of the propositions demonstrated in that book by Pedro Nunes, because these have been treated more openly and plainly by us elsewhere, and do not pertain to the matter of the twilights. This whole subject we shall comprise in twenty-four propositions, beginning here.

PROPOSITIO I.

In the same circle, or in two equal circles, if two equal arcs are taken — whether continuous or not continuous, and whether the one lies wholly outside the other, or they have a common part — then, if perpendiculars are dropped from their endpoints to a diameter or to diameters, the segments of that diameter (or of those diameters) will be unequal, unless the equal arcs stand equally distant from another diameter (or diameters) that cut the first diameter(s) at right angles; and the greater segment will be the one nearer to this latter diameter.

We demonstrated this proposition in our treatment of the Sines, in the case where the equal arcs lie continuous within the same quadrant. Here, however, we shall demonstrate it more universally, exactly as it has been set out by us in this theorem.

Diagram. A circle $ABCD$ with center E , having two diameters AC (vertical) and BD (horizontal) that cut each other at right angles. Various perpendiculars are dropped from points on the circumference to the horizontal diameter, with several auxiliary circles constructed about right triangles near the upper arc.

- A (top of circle): apex of the vertical diameter
- B (far left, on horizontal diameter): left end of diameter BD
- C (bottom of circle): lower end of the vertical diameter
- D (far right, on horizontal diameter): right end of diameter BD
- E (center): center of the circle
- On the horizontal diameter, from left to right: N, M, L, K, E, a, T, [Z?], h — the feet of the several perpendiculars
- Upper arc labels: G, H (upper left); F, X, V (near apex A); S, i (upper right)
- Interior auxiliary points: Q, R (left of center), and small letters d, f, c near the upper middle
- Lower arc labels: P, O (near the bottom, left of C), b (right of C)

Let there be, then, in the circle $ABCD$ whose center is E , two diameters AC , BD cutting each other at right angles; and first let there be two equal, non-continuous arcs FG , HI , and let the perpendiculars FK , GL , HM , IN be dropped. I say that KL is greater than MN . For, the chords FG , IH being joined, and the perpendiculars GQ , IR being drawn, let FK , HM be extended as far as O , P . Let circles also be described about the right triangles FGQ , HIR , which will be equal [Margin: a — scholium, III.32], since their diameters are FG , HI [Margin: b — III.29], which are equal, because the arcs FG , HI are equal. And because arc GBO is greater than arc IBP , angle F will be greater than angle H [Margin: c — scholium, III.27]; and therefore, since (as angle F is to angle H) so is arc GdQ to arc IeR [Margin: d — VI.33], that arc too will be greater by so much. Since, then, these arcs are less than a semicircle — because $GdQF$, $IeRH$ are semicircles — the straight line GQ will be greater than the straight line IR [Margin: e — scholium, III.29]. But GQ is equal to LK , and IR to NM [Margin: f — I.34]. Therefore LK will also be greater than NM ; which was to be proved.

Next, let there be two equal, continuous arcs FG , FS , of which the former lies wholly in quadrant AB , while the latter lies partly in the same quadrant and partly in quadrant AD . The chord FS being joined, let the perpendicular ST be dropped. I say that here too the straight line TK is greater than the straight line KL . For since arc SDO is greater than arc GBO — which will be established if arc AV is taken equal to arc AS , and arc AX equal to arc AF ; because, when Xab is dropped perpendicular to BD , arc VBb will be equal to arc SDO , and this arc VBb is greater than arc GBO — [Margin: g — scholium, III.27] the angle OFS will be greater than the angle OFG . Therefore, the perpendicular Sf being drawn, Sf will be, as before, greater than the chord GQ of the arc of the circle described about the right triangle SFf , and so on. The demonstration will be the same when the

continuous equal arcs lie within the same quadrant — which, moreover, we have also shown otherwise in the treatment of the Sines.

Finally, let there be two equal arcs FS , XY that share a common part. I say again that, the perpendiculars Xab , YZ being dropped, the straight line TK is greater than the straight line Za . For, the chord XY being joined [Margin: h — scholium, III.27], the angle OFS will again be greater than the angle bXY , because arc SDO is greater than arc YDb ; and so on.

The proposition will be demonstrated no differently if there are two equal circles, as is evident, provided an arc of the one circle is transferred to the other. Therefore, in the same circle, and so on; which was to be demonstrated.

COROLLARIUM.

It is gathered from this that, if perpendiculars are raised on a diameter from two equal straight lines, the arcs cut off from the circle are unequal, and the greater is the one which lies farther from the other diameter, or whose straight line stands farther from the center. For let the straight lines Zi , TK be equal, and let the perpendiculars ZY , aX , TS , KF be raised. I say that arc XY is greater than arc FS . For if the arcs XY , FS be said to be equal, then, as has been demonstrated, the straight line TK will be greater than Za — which is contrary to the hypothesis. But if XY be believed less than FS , then, if arc Xi be taken equal to arc FS and the perpendicular ih be dropped, it will again be, as has been demonstrated, that the straight line TK is greater than ha , and therefore much greater than Za — which contends with the hypothesis. A fortiori, then, the greater straight line, standing farther from the center, will cut off a greater arc than the lesser straight line nearer to the center.

PROPOSITIO II.

If two equal segments are taken on the diameters of unequal circles, and perpendicular lines are raised to the diameters, these will intercept unequal arcs; and the arc of the smaller circle will be greater than the arc similar to that of the larger — whether the segments taken on the diameters stand equally distant from the centers, or whether the segment in the smaller circle stands farther from the center.

Diagram. Two unequal concentric circles, the outer $ABCD$ and the inner $EFGH$, described about the common center K , with perpendiculars raised at points L , M on a diameter and various chords and intersecting lines drawn.

- A (top of outer circle); N (top, at the apex where lines meet, beside A)
- O (upper right, on the outer circle)
- E, I (upper center, on the inner circle)
- Z (left, inner circle); F (left, on the horizontal diameter, inner circle)
- B (far left, outer circle, on the diameter); D (far right, outer circle, on the diameter)
- X (left of center); V, K (center — the common center); L (just below K); T (above L)
- M (right of center, on the diameter); H (lower right, near D)
- R (mid-lower right); G, P (lower left); b (lower center)
- S (bottom); C, Q (very bottom)

Let there be two unequal circles $ABCD$, $EFGH$, described about the same center K ; and from the points L , M let the perpendiculars LN , MO be raised. Then the segment LM will be, as it were, two equal parts equally distant from the centers. I say that arc Ia is greater than the arc similar to NO . For let NL , OM be produced to cut the circles at P , Q , R , S ; and let the straight lines IR , NS be joined, cutting each other at T [Margin: a — I.16]. Then the angle PIR will be greater than the angle QNS ; and accordingly, if the angle PIb be made equal to the angle QNS [Margin: b — scholium, III.22], the arcs Pb , QS will be similar; and therefore PR will be greater than the arc similar to QS . But arc PR is equal to arc Ia , and arc QS to arc NO [Margin: c — scholium, III.27]. Therefore arc Ia also is greater than the arc similar to NO ; which was proposed.

But if the segment VX be equal to the segment LM and farther from the center, then arc YZ will be greater than arc Ia [Margin: d — corollary 1 of this book]. Since, then, Ia has been shown to be greater than the arc similar to NO , YZ will be much greater than the arc similar to NO . Therefore, if there be taken, and so on; which was to be shown.

PROPOSITIO III.

To disclose the cause of the twilights.

[Margin: What twilight is]

Twilight is the doubtful light before the rising of the Sun and after its setting: the former is called morning twilight, the latter evening. [Margin: Morning twilight] Morning twilight begins when the Sun, in the vertical circle passing through it, stands eighteen degrees below the eastern horizon; [Margin: Evening twilight] evening twilight ends when the Sun stands as many degrees below the western

horizon. So, at least, the astronomers commonly teach, though some place that distance from the horizon a little greater, and others a little less. In what manner this distance is to be examined, we shall demonstrate below in proposition 24. [Margin: What the cause of twilight is] The cause of both twilights is as follows. When a portion of the air, condensed by vapors and illuminated by the Sun, can be seen by us, twilight comes to be; and this first happens, before the rising of the Sun, when the Sun is depressed about eighteen degrees below the horizon. For when it stands more degrees from the horizon, it does indeed illuminate the finer and purer air; but because there are no vapors in it, the light of the Sun is not reflected to us, and darkness occupies our horizon — for the reason that the denser air, though illuminated by the Sun, cannot be seen by us. By the same reasoning, after the setting of the Sun, the denser air illuminated by the Sun can in no way be discerned by us, so long as the Sun stands more than eighteen degrees, or thereabouts, below the horizon. That this may be made plainer, let *ABC* be the greatest circle on the earth, concentric with the vertical circle passing through the Sun as it moves below the horizon, about which [continues below]

Diagram. The twilight figure: two concentric circles (the earth *ABC* and, about it, the circle *KLM* enclosing the vapor-bearing air), with the sensible horizon *DE* tangent at *A*, the eye placed at *A*, the center *N*, and the solar rays *CF*, *BF* and *GI*, *HI* drawn to form the shadow-cone.

- *I* (upper-left apex); *F* (upper-right apex) — meeting points of the drawn rays
- *D* (left, on the horizontal line *DE*); *A* (center, on the line — the eye and point of tangency)
- *K* (right of center, on the line); *E* (right end of the line); *L* (just below *E*)
- *B* (left, below *D*); *c* (center, below *A*); *G* (right, below *K*)
- *H* (far left); *M* (lower left); *C* (lower right)
- *N* (center of the circles)

Diagram. The twilight figure repeated (identical to fig-p269-2): the two concentric circles of the earth and of the vapor-bearing air, with the horizon *DE* tangent at the eye *A*, center *N*, and the solar rays forming the shadow-cone *CFB* and the rays *GI*, *HI*.

- *I* (upper-left apex); *F* (upper-right apex)
- *D*, *A*, *K*, *E* (on the horizontal line, left to right); *L* (just below *E*)
- *B* (left, below *D*); *c* (center); *G* (right); *H* (far left); *M* (lower left); *C* (lower right)

- N (center) about which let there be another circle *KLM*, enclosing that part of the air to which the vapors can rise. Let the eye also be placed at *A*, and the sensible horizon *DE*, tangent to the earth at *A*. It is now certain that an eye placed at *A* can see nothing of the air, however condensed, below *AE* [Margin: a — III.16], for the reason that no straight line can be intercepted between the tangent *DE* and the circle *AC*. Accordingly, the rays of the Sun touching the earth, *CF*, *BF*, being posited, so that the cone of shadow is *CFB*, no air will be able to be seen beyond *E*, because there it is purer and free of vapors; nor short of *E*, even if the point *K* lies in denser air, on account of the shadow *CEB*, to which the solar rays do not come. But as soon as the rays of the Sun touching the earth, the Sun having moved toward the horizon, have become *GI*, *HI* — of which *GI* runs through *K*, the intersection of the line of sight with the outermost circle of the denser air — the light of the Sun will begin to be reflected to the eye placed at *A*, and the beginning of morning twilight will come to be, and it will last until the rising of the Sun, when the solar ray coincides with the straight line *DE*. So too the evening twilight will last as long as, after the setting of the Sun, the ray of the Sun touching the earth cuts the segment *AK*; but as soon as the ray of the Sun coincides with *GI*, the end of evening twilight will be at hand. The astronomers therefore commonly affirm that the ray of the Sun passes through *K* only at the moment when it lies hidden eighteen degrees below the horizon — although, as I said above, some posit more degrees, and some fewer.

[Margin: The Sun's distance below the horizon at the beginning of morning twilight and the end of evening twilight is variable]

But this distance cannot be fixed; rather it is variable, according as the vapors in the air stand higher or lower. [Margin: In what sense the greatest height of the vapors is to be taken] For when the vapors ascend beyond the point *K*, it is evident that the Sun stands farther from the horizon at the beginning of morning twilight, or at the end of evening, than when they are raised only as far as *K*; and nearer, when the topmost vapors do not reach the point *K*. Moreover, the greatest distance of the vapors from the earth is taken along the semidiameter *NO*, produced as far as *K*, so that the magnitude of this distance is *OK* — which we shall investigate a little later, in proposition 6, the Sun being placed at the beginning of morning twilight, or at the end of evening, eighteen degrees below the horizon. We have therefore disclosed the cause of the twilights; which was to be done.

SCHOLIUM.

And so, if below the horizon there be conceived a circle parallel to the horizon, cutting off from all the verticals eighteen degrees, or more or fewer — according as the Sun's distance below the horizon is set greater or less than eighteen degrees at the beginning of morning twilight, or at the end of evening (for it has been demonstrated by Theodosius [Theodosius] that all the arcs of the verticals between the horizon and its parallel are equal [Margin: b — Theodosius, *Spherics* II.10]) — then, as often as the Sun by its diurnal motion has reached that parallel in the morning, morning twilight will take its beginning, in whatever parallel the Sun may be; and the evening twilight will cease when the Sun, after setting, has come to the same parallel. The magnitude of the arc of each parallel between the horizon and its parallel will be the measure of the twilight, so that the twilight is as long — that is, lasts as long — as the time in which the Sun traverses that arc. But because the arcs of the parallels intercepted between the horizon and the said parallel of it are not similar (for only the greatest circles, which pass through the poles of the parallels, or touch one and the same parallel, cut off similar arcs from the parallels, as is established from Theodosius [Margin: c — Theodosius, *Spherics* II.13 & 16]), the twilights of all the parallels cannot be equal, since the Sun traverses the arcs of the twilights in unequal times. [Margin: Why the twilights of the whole year are not equal] Only the morning and evening twilight of one and the same parallel are equal to each other. For since the plane of the Sun's parallel, cutting the horizon and its parallel [Margin: d — XI.16], makes common sections parallel in the very plane of the Sun's parallel, the arcs of the parallel placed between those parallel lines will be equal [Margin: e — scholium, III.27]; and therefore the Sun will traverse them in equal times, and will make the twilights equal. [Margin: Morning and evening twilight are equal] [Margin: The parallel of the twilights] Henceforth we shall call that parallel of the horizon, in what follows, the "parallel of the twilights."

PROPOSITIO IV.

A luminous sphere illuminates the half of an equal opaque sphere; but more than the half of a smaller opaque sphere; and, finally, less than the half of a larger opaque sphere.

Diagram. First figure for Proposition IV: two equal circles stacked vertically between two parallel vertical tangent lines. The upper circle (luminous *ABCD*) has center *I*; the lower circle (opaque *EFGH*) has center *K*.

- Upper circle: B (top), A (left), I (center), C (right), D (bottom)

- Lower circle: F (top), E (left), K (center), G (right), H (bottom)
- The tangent lines AE (left) and CG (right) join the corresponding points

Diagram. Second figure for Proposition IV: a larger circle and a smaller circle inscribed within a triangle (cone) whose apex is at G below. The larger circle is above, the smaller below, with the two tangent sides of the triangle meeting at G .

- Larger (upper) circle: H (top), A (left), C (right), B (bottom)
- Smaller (lower) circle: I (top/center), D (left), F (right), K (bottom)
- E (on the axis, between B and I); G (apex at the bottom)

Let there first be two equal spheres, the luminous $ABCD$ and the opaque $EFGH$, whose centers I, K let be joined by the straight line IK . Let both be cut by a plane drawn through the straight line IK [Margin: a — Theodosius, *Spherics* I.6], making the greatest circles, in which let the diameters AC, EG be raised perpendicular to IK ; and let the straight lines AE, CG be joined [Margin: b — I.28]. And since AC, EG are parallel, on account of the right angles I, K , and since AI, EK are equal, as also CI, GK , the semidiameters of equal circles, then AE, CG also will be parallel and equal [Margin: c — I.33]. The angles A, E, C, G are therefore right [Margin: d — I.29]; and accordingly the straight lines AE, CG will touch the circles [Margin: e — corollary 1 of III.16], and will be the outermost rays that can fall from the sphere $ABCD$ onto the sphere $EFGH$. Therefore the luminous sphere $ABCD$ illuminates EFG , the half of the opaque sphere; which is the first point.

Let there be next a larger luminous sphere ABC , and a smaller opaque [sphere...]

PROPOSITIO IV [conclusion]

[continued from the preceding]...the smaller circle DEF , whose centres are H and I . Let both be cut through their centres, so that they become great circles, [e] which the rays AD, CF touch. When straight lines HA, HC, ID, IF are drawn from the centres to the points of contact, [f] the angles A, C, D, F will be right angles.

Now since the straight lines AG, CG are equal, as are DG, FG , [g] the straight line GH , when drawn, will bisect the angle G ; and in the same way the straight line GI will also bisect that same angle, [h] so that GI does not differ from GH . Therefore, since in the triangles AGH and CGH the two angles A and C are equal to the two angles D and F , [i] the remaining angles at H will also be equal; [k] and consequently the arcs AB and CB will be equal as well. In no other way [l] the arcs DK and FK are shown to be equal. And the angles AHG, CHG , as well as DIG, FIG , are acute; [m] therefore the arcs BA, BC , and likewise KD, KF , will be less than a

quadrant. Hence the arcs ABC and DKF will be less than a semicircle, while DEF will be greater than a semicircle.

Since, then, AD and CF are the extreme rays of the sphere ABC falling upon the sphere DEF, it is clear that the larger sphere illuminates more than half of the smaller sphere — which is the second point.

But if the smaller sphere DEF is supposed to be the luminous one, and the larger ABC the opaque one, we shall show by the same reasoning that the arc ABC is less than a semicircle. Therefore the extreme rays DA, FC illuminate a part of the larger sphere less than a half — which is the third point. Therefore a luminous sphere, and so on. Which was to be demonstrated.

[Margin, keyed references for Prop. IV: e = scholium on III.17; f = III.18; g = corollary 2 of III.36; h = scholium on III.37; i = I.32; k = III.25; l = I.17; m = scholium on III.27.]

PROPOSITIO V.

To estimate how great the arc of a great circle on the earth is that is illuminated by the Sun.

Since the Sun is larger than the earth, [a] more than half of the earth will be illuminated. We shall determine this quantity as follows. Let a great circle in the Sun be AB, and in the same plane a great circle on the earth DEF, whose centre is L. Let the two extreme rays that are tangent to both spheres be AD and BF. When the centres C and L are joined, let the semidiameters CA, CB, LD, LF be drawn along the straight line C–L to the points of contact; [b] and the angles A, B, D, F will be right angles.

Next, taking AG and BH equal to DL and FL themselves, let the straight lines GL and HL be drawn, cutting the arc DEF at I and K. [c] Now since AG, DL and BH, FL are parallel and equal, [d] GL will also be parallel and equal to AD, and HL parallel and equal to BF; [e] and therefore the angles G, DLG, H, FLH will likewise be right angles. [f] Consequently DI and FK will be quadrants; and IE will be the excess by which the illuminated part on one side surpasses a quadrant, and KE the excess by which the illuminated part on the other side surpasses a quadrant. Thus the part of the earth illuminated throughout its whole circuit contains, beyond a quadrant, as many degrees as are contained in the arc IE, or KE.

Now since, according to Ptolemy [Claudius Ptolemy], the distance of the centre of the earth from the centre of the Sun at mean distances — that is, the straight line

LC — contains about 1168 semidiameters of the earth, while the semidiameter of the Sun AC is $5\frac{1}{2}$ of the parts of which the semidiameter of the earth DL, or AG, is 1, and consequently CG is $4\frac{1}{2}$ of such parts: then, with CL set as the whole sine, the straight line CG is the sine of the angle CLG, as we showed in the treatise on Sines. If it be worked out:

As CL, 1168, is to CG, $4\frac{1}{2}$, so is CL — the whole sine, 100000 — to another quantity.

The sine CG will be found to be 385, to which in the table of Sines corresponds 13 minutes (a little more). And so the Sun still illuminates, over the whole compass of the earth, 13 minutes beyond a half — namely 90 degrees 13 minutes — over the circuit of the whole earth. For such is the angle CLD, or CLF. Therefore how great the arc of a circle is, and so on, we have estimated. Which was to be done.

Diagram. A geometric figure for Proposition V, showing two circles (the Sun and the earth) with their common envelope of tangent lines.

- Upper small circle (the earth, centre L): D (left end of the horizontal diameter), L (centre/top), F (right end), E (lowest point, in the row "I E K")
- Middle row on the earth's lower arc: I (left), E (centre), K (right)
- Lower large circle (the Sun, centre C): A (left end of the horizontal diameter), G (between A and C), C (centre), H (between C and B), B (right end)
- The two outer straight lines are the extreme tangent rays AD (on the left, from A up to D) and BF (on the right, from B up to F), drawn extended and crossing above the figure.

[Margin, keyed references for Prop. V: a = 4 of this [digression]; b = III.18; c = I.28; d = I.33; e = I.29; f = scholium on III.27.]

[Worked proportion, displayed on the page:] As CL, 1168 — to CG, $4\frac{1}{2}$ — so CL, the whole sine, 100000 — to another quantity.

SCHOLIVM.

By this same technique we shall investigate what part of the smaller sphere the larger one illuminates, once the distance between the two centres and the ratio of the semidiameters are known.

PROPOSITIO VI.

To investigate at how great a distance from the earth the topmost vapours stand that condense the air.

Let a plane be drawn through D, the centre of the Sun as it stands at the beginning of the morning twilight, and through the centre of the earth H, producing in the sky the great circle of the Sun ASC, in the Sun the great circle ABC, and on the earth the great circle EFG, about which let the arc of a circle MKN be described, enclosing the topmost vapours. Let the section of the true Horizon be OP, and of the sensible Horizon QR, touching the earth at F, so that the arc PD is understood to be 18 degrees — the distance of the Sun below the Horizon at the beginning of twilight, as it is commonly set down. For since the semidiameter of the earth is of insensible magnitude with respect to the heavens, the point R does not sensibly differ from P; and consequently the arcs RD and PD do not sensibly differ from one another. Let the extreme ray of the Sun that touches the earth at I be CI, cutting the sensible Horizon and the arc MKN at K, where the Sun's light is first reflected in the condensed air to the sight placed at F. Moreover, from H through F let the straight line HFS be extended, [a] which will be perpendicular to QR, [b] and therefore S will be the pole of the Horizon. And finally let the straight lines HI, HLK be joined; so that... Since the straight lines KF, KI are tangent to the circle EFG, [c] the straight line HK will bisect the angle FKI.

[Margin, keyed references for the opening of Prop. VI: a = III.18; b = I.29; c = scholium on III.37.]

PROPOSITIO VI [continued]

the straight line HK will bisect the angle FKI. [d] And since the angle HIK is a right angle, the two angles F, K of the triangle FHK will be equal to the two angles I, K of the triangle IHK; [e] and therefore the remaining angles at H will be equal as well. And so, if to the right angle SHP, of 90 degrees, the angle DHP of 18 degrees is added (for the arc PD is commonly reckoned to be that much by the authorities when the Sun is at the beginning of the morning twilight, [f] as we said above), the whole angle DHS will become 108 degrees.

From this, if the angle DHI is subtracted — which in the preceding [proposition] we found to be 90 degrees 13 minutes (for the arc TI, made up of a quadrant and 13 minutes, is composed thus, as is clear from the preceding proposition) — the remaining angle FHI will be 17 degrees 47 minutes. And therefore its half FHK will be about 8 degrees 54 minutes, and its complement FKH will be 81 degrees 6 minutes. Now since, if HK is set as the whole sine, the semidiameter of the earth FH — which Ptolemy makes 3579 miles — is the sine of the angle FKH, if it be worked out:

As FH, the sine 98796 of the angle FKH, is to HK, the whole sine 100000, so is FH, 3579 (the semidiameter), to another quantity.

HK will be found to be about $3622\frac{2}{3}$ miles; from which, when the semidiameter HL of 3579 miles is subtracted, there will remain KL, the elevation of the topmost vapours, of about $43\frac{2}{3}$ miles. Therefore at how great an interval, and so on, we have investigated. Which was to be done.

Diagram. The twilight figure for Proposition VI: a large circle (the vertical plane through the Sun and the earth's centre) enclosing the small circle of the earth EFG, with the vapour arc, the true and sensible horizons, and the rays. The corners of the woodcut are filled with decorative foliate scrollwork.

- S: at the top of the large circle (pole of the Horizon)
- Q (upper) and O (lower): on the left edge, the left ends of the two horizon lines
- R (upper) and P (lower): on the right edge, the right ends of the two horizon lines (sensible Horizon QR and true Horizon OP)
- H: centre of the small earth-circle (left of centre)
- M: on the horizon line to the left of H; E just below; the earth-circle points E, F, G with F, L, I, N and K in the central cluster
- Central cluster (small circle EFG, centre H, and the vapour arc MKN): K (upper), F, L, I, N, and G (at the foot)
- T: at the foot of the large circle
- A, D, C, B: at the lower part of the large circle (D the centre of the Sun's great circle ABC), with A to the left, C and B to the right

[Margin, keyed references (top of p. 260): c = scholium on III.37; d = III.18; e = I.32; f = 32 of this [digression].]

[Worked proportion, displayed on the page:] As FH, the sine 98796 of the angle FKH — to HK, the whole sine 100000 — so FH, 3579, the semidiameter — to another quantity.

SCHOLIVM.

It is moreover evident that, if the distance of the Sun from the centre of the earth is supposed greater than Ptolemy establishes; likewise if the ratio of the Sun's semidiameter to the earth's semidiameter is different from the ratio $5\frac{1}{2}$ to 1, as Ptolemy will have it — then the angle DHI, by the preceding proposition, will be found not to be 90 degrees 13 minutes, but either greater or less. Likewise, if the

Sun's distance below the Horizon at the beginning of twilight is set greater or less than 18 degrees, as others prefer, the elevation of the topmost vapours will be found not to be $43\frac{2}{3}$ miles, but either more or fewer; especially if the Sun's distance from the earth, and the earth's semidiameter, are established differently from what we have supposed. And this is perhaps the reason why Alhazen [Ibn al-Haytham] and Vitellio [Witelo] found the elevation of the topmost vapours to be about 52 miles.

If the angle DHI, by the preceding [proposition], were found to be only 90 degrees 12 minutes, and the distance of the Sun below the Horizon at the beginning of twilight were 19 degrees 30 minutes, then the angle DHS would be 109 degrees 30 minutes, and the angle FHI 19 degrees 18 minutes, and FHK 9 degrees 39 minutes, and FKH 80 degrees 21 minutes. And thus HK would be found to be 3630, and, the semidiameter HL of 3579 being subtracted, the remaining elevation of the vapours LK would be 51[?] miles, a little more. But whatever be the case about this variation, our demonstration will not change: it is enough that we have prescribed the method by which the elevation of the topmost vapours can be explored, provided the Sun's distance from the Horizon at the beginning of twilight, and the part of the earth illuminated by the Sun, are settled, and so on.

PROPOSITIO VII.

From the given height of some lofty mountain, to find the arc of the vertical circle by which those who dwell on the mountain's summit see the Sun rise earlier than those at its foot; and moreover to determine the interval of time between the two sunrises.

Let there be a great circle on the earth ABC, whose centre is D. Let the height of the mountain be BE, its base toward the east [being at F] [?]; and let the vertical circle drawn through the centre of the Sun and the summit of the mountain be GHI, in whose plane let the circle of the earth DBEH lie, [and let] the line

[Margin, keyed reference for the start of Prop. VII: on p. 260 the paragraph shares the reference apparatus of Prop. VI above.]

PROPOSITIO VII [continued]

[and let] the line drawn from the centre of the earth through the summit of the mountain, falling at H, [be] the vertex of those dwelling on the mountain's summit. Their true Horizon is GI, their sensible Horizon KL, touching the earth at B. Let the straight line DFP be drawn from the centre through the vertex of those

dwelling at the mountain's base F, falling at their Zenith P; and the difference between H and P will be insensible.

Let there also be drawn, from E, the summit of the mountain, the straight line MN, touching the earth at O, to which let QR be drawn parallel, through the centre; and QR will be the true Horizon of those dwelling at O, and MN the sensible one, and S their Zenith. And since the earth is of insensible magnitude with respect to the heavens, LI and NR will be of insensible quantity: so that, when the Sun's rising is discerned at I by those situated at F, it is supposed to rise at L. By like reasoning, when the Sun rises for those inhabiting the point O, it will be supposed to rise at N.

But the rising Sun is seen along the same straight line MN both by those dwelling at O and by those situated at E, the summit of the mountain. Now since it rises earlier for those who dwell at O than for those who are at F, the mountain's base, the Sun will also seem to rise earlier from the summit E than from the base F; and the difference of their risings on the vertical circle will be the arc IR, between the true Horizons, which we shall determine thus.

Let us suppose that BE, the height of the mountain, comprises 3 miles, or 24 stadia. And since the semidiameter of the earth DB, according to Ptolemy, contains 28636 stadia, the whole DE will comprise 28660 stadia. Since therefore, with DE set as the whole sine, the semidiameter DO is the sine of the angle DEO [a] — because the angle O is a right angle in the triangle DEO — if it be worked out:

As DE, of 28660 stadia, is to DO, of 28636 stadia, so is DE, the whole sine, 100000, to another quantity.

DO will be produced as the sine 99916, to which in the table of Sines corresponds 87 degrees 39 minutes, for the angle DEO. Therefore its complement, 2 degrees 21 minutes, will give the angle EDO, or the arc HS, to which the sought arc IR is equal — because, if from the quadrants HI and SR the common arc SI is subtracted, the equal arcs HS and IR remain. So when the Sun rises for those who are on the mountain's summit, it is depressed for those dwelling at F, the mountain's base, by 2 degrees 21 minutes.

The time between the two risings will be obtained if, by Proposition 14, the twilight is computed for the given day and the given latitude of the place, the Sun's distance below the Horizon at the beginning of twilight being set at 2 degrees 21 minutes; which, for latitude 38 degrees, on the fifth of August, is found to comprise 0 hours 13 minutes. And by so much time will the Sun rise earlier on

the mountain's summit than at its base. Therefore, from the given height of some lofty mountain, and so on, we determine. Which was to be done.

Diagram. The mountain-sunrise figure for Proposition VII: a large circle (the vertical plane) with the small earth-circle near the centre, the mountain, and the horizons and rays of the two observers (summit and base). Several peripheral labels are small and hard to resolve

- H (top) and P (just to its right, top): the vertical falling-point and the Zenith of the base-dwellers
- S: upper right (Zenith of the O-dwellers)
- M: upper left
- Q: left, below M
- K: left (mid); below it a letter read as G [?]
- E: near the centre (mountain summit)
- B: near the centre (mountain base on the earth-circle)
- F, O: central cluster (F the base, O the tangent point); D: centre (of the earth-circle)
- A (lower-left of centre) and C (lower-right of centre)
- L and I: on the right edge (L upper, I below)
- N: lower right
- R: at the foot of the ray, lower right

[Margin, keyed reference for Prop. VII: a = III.18.]

[Worked proportions, displayed on the page:] As DE, of 28660 stadia — to DO, of 28636 stadia — so DE, the whole sine, 100000 — to another quantity.

SCHOLIVM.

With these things thus premised, let us approach the demonstrations of the twilights. Here I wish the reader to be warned that we shall treat only of the twilights of those parallels that are cut by the Horizon; and indeed of those which have one morning twilight before the Sun's rising and another evening one after the Sun's setting.

[Margin: Which parallels' twilights are dealt with in this place.]

PROPOSITIO VIII.

When the Sun is at two points equally distant from either solstice, the twilights are equal.

For since through those two points one and the same parallel runs — as we demonstrated in Book I of the Astrolabe, Lemma 49, Number 1 — the same arc of that parallel will always be intercepted between the Horizon and the parallel of the Twilights; and therefore the same twilight will result. Therefore, when the Sun is [at such points], and so on. Which was to be shown.

PROPOSITIO IX.

For two points on either side, equally distant from one or the other equinox, the corresponding twilights are unequal; and that one will be the greater which inclines toward the visible pole.

Let the Meridian be ABCD, its centre E. Let the diameter of the Equator be AC; the diameter of the parallel toward the visible pole D be FG; that of the other, toward the other pole, be HI; and let the declinations AF, AH be equal. Let the diameter of the oblique Horizon be KL; the diameter of the parallel of the twilights be MN; and let the axis of the world DB [a] cut the diameters FG, HI in half at Y and Z, because it makes right angles with the said diameters. Now with semicircles FSG, HVI described about those same diameters from X [Y?] [?] and Z, let perpendiculars OS, PT, QV, RX be raised to those same diameters.

Since both the Horizon and the parallel FST are at right angles to the Meridian, [b] their common section will be a straight line at right angles to it; and therefore it will also be perpendicular to the diameter FG. Therefore the perpendicular OS will be the common section of the Horizon and the parallel; and so the Sun will rise at S, when it describes that parallel. In the same way PT will be shown to be the common section of the Horizon and the same parallel; and therefore the Sun, at the beginning of the morning twilight, will stand at T, and the arc ST will be the length of the twilight on that

Diagram. The figure for Proposition IX: the Meridian circle ABCD with centre E, crossed by the diameters of the Equator, the two symmetric parallels, the oblique Horizon, and the parallel of the twilights, with the erected semicircles and perpendiculars. Two small stars mark Sun positions. Several peripheral labels are small and crowded

- Circle (Meridian) with points A, B, C, D on it and centre E

- F (upper left), O with a star [Sun mark] (top), S (upper right)
- A, H (left, below F)
- Y (upper centre)
- I (right, upper); T (right, below S)
- K, M (left edge)
- Q, Z, O (central row); P (centre-right)
- G [ς?] [?] and C (lower right)
- V (lower left), B with a star [Sun mark] (lower centre)
- X (bottom left), I (bottom right)

[Margin, keyed references for Prop. IX: a = III.3; b = 19 [of this? — abbreviation unclear] [?].]

in that parallel. Likewise the arc VX will be the length of the twilight in the parallel HVI. I say, therefore, that the twilight ST is greater than the twilight VX. For just as OP and QR are equal on the diameters of equal parallels, and OP is farther from the centre Y than QR is from the centre Z, so the arc ST will be greater than the arc VX — which was the claim. Therefore, for two points, and so on — which was to be demonstrated.

[Margin: a — Elements I.34; b — Corollary 1 of this [treatise].]

COROLLARIUM

It follows from these results that in the northern region the twilights of the northern points of the ecliptic are greater than those of the corresponding southern points; but in the southern region they are smaller.

[Margin: Where the twilights become longer.]

PROPOSITIO X

When the Sun is traversing the northern signs, the twilight in the northern region becomes longer the closer it is to the beginning of Cancer — provided always that the Sun's parallel cuts both the horizon and the parallel of the twilights.

Diagram. A circle representing the meridian ABCD, with the equator, the northern parallels, the oblique horizon, and the parallel of the twilights drawn as chords, and several perpendiculars raised to the diameters. Sun-positions are marked with small stars.

- A (upper left, star): endpoint of the equator diameter

- F, H (top): parallel endpoints
- D (upper right, star): pole / solstitial Sun mark
- K (left), M (left): horizon / twilight-parallel endpoints
- B (lower left, star): pole mark
- Y, E, T (centre): centres of parallels and of the sphere (E)
- O, V, P, N (right of centre): feet of the perpendiculars OP, TV
- L (right): horizon endpoint
- C, I, G (lower right): equator / parallel endpoints; zodiac glyphs (♌, ♍) appear beside the lower-right labels
- [2 further peripheral labels illegible]

Let the meridian be ABCD about the centre E; the diameter of the equator, AC; the diameters of the northern parallels, FG and HI; the diameter of the horizon, KL; the diameter of the parallel of the twilights, MN. If from O, P, and TV perpendiculars are raised to the diameters, these will cut off, on the parallels described about the diameters, the arcs of the twilights, as we showed in the preceding proposition. I say that the arc of the twilight owed to the straight line OP is greater than the arc of the twilight that corresponds to the straight line TV. For since OP recedes farther from the centre X than TV does from the centre Y — (a) and since OP and TV are equal — (b) there will correspond a greater arc to the straight line OP in its own parallel than is owed to an arc similar to the one that TV subtends in its own parallel. Consequently the twilight will be greater when the Sun traverses the parallel of diameter FG than the twilight of the parallel of diameter HI. Therefore, when the Sun traverses the northern signs, a longer twilight occurs in the northern region, and so on — which was to be demonstrated.

[Margin: a — Elements I.34; b — Proposition 2 of this [treatise].]

SCHOLIVM

The contrary happens in the southern region; for there the twilight becomes greater the less the Sun, when in the southern signs, is distant from the beginning of Capricorn. This is clear in the same figure if D is understood to be the south pole, and B the north.

COROLLARIVM

Hence it follows that in the northern region the greatest twilight occurs — the Sun being in the southern region, that is, the Sun being at the beginning of Capricorn (♑).

That in the northern region the greatest twilight should occur when the Sun is at the beginning of Capricorn, just as the longest day does — yet not in the first degree of Capricorn, but in some parallel between the tropic of Capricorn (♑) and the equator, as we shall demonstrate in Propositions 19, 20, 21, and 22 — although the day is then shortest: this seems scarcely credible.

[Margin: c — Corollary 9 of this [treatise].]

Diagram. A second circle (the meridian) with equator, parallels, horizon, and twilight-parallel drawn as intersecting chords, several perpendiculars, and a small Sun-star. It illustrates where the longest twilight falls.

- F, A, H (upper left)
- D (top, star): Sun/solstice mark
- K, M (left): horizon / twilight-parallel endpoints
- V, B (lower left, star), X (bottom left)
- Q, E, Z, R (centre): centres and foot of perpendiculars
- O, Y (centre), P, T (centre-right)
- S (upper right), I, N (right)
- C (lower right)
- [1–2 peripheral labels illegible]

[Margin: Where the longest twilight occurs.]

PROPOSITIO XI

Wherever the Sun may be, the twilights become longer in the more northerly places than where the Sun's parallel cuts both the horizon and the parallel of the twilights.

Diagram. A large circle (the meridian ABCD) crowded with chords and perpendiculars: the equator AC, northern parallel FG, southern parallel HI, the axis of the world BD, the oblique horizon KL, the twilight-parallel MN, the more-northerly horizon OP, the twilight-parallel QR, and the perpendiculars SY and VZ. Sun-positions are marked with stars at B and D.

- A, F, H (upper left)
- O, Q, R (upper-left interior)
- D (upper right, star)
- S (upper-right interior)
- K, M (left)
- E (centre)
- V, Y, Z, X, P, d (centre and lower interior)
- B (lower left, star)
- I, C, G (bottom / lower right)
- L, N (right)
- [several interior labels crowded and partly illegible]

[Margin: a — Elements I.29.]

Let the meridian be ABCD, whose centre is E; the diameter of the equator, AC; the diameter of the northern parallel, FG; of the southern, HI; let D be the north pole, B the south; the axis of the world, BD; the diameter of the oblique horizon, KL; the diameter of the parallel of the twilights, MN; the diameter of the more-northerly horizon, OP; the diameter of the twilight-parallel QR; and so on. I say that the twilight owed to the straight line VX in the northern parallel is greater than the twilight owed to the straight line ST; and greater than the twilight of the straight line Ed at the equator, [which is owed to] the twilight of the straight line Eb; and greater than the twilight of the straight line ef in the southern parallel, [owed to] the twilight of the straight line ig.

For, the perpendiculars SY and VZ having been dropped to the parallels of the twilights: (a) since the angle AEK is equal to the interior angle AbM, and this to the interior angle FTM, the angle FTM will be equal to the angle AER, the complement of the pole's altitude in the less northerly region. (b) Likewise, since the angle AEO is equal to the interior angle AdQ, and this to the interior angle FXQ, the angle FXQ will be equal to the angle AEO, the complement of the pole's altitude in the more northerly region. But the angle AEK is greater than the angle AEO. Therefore the angle FTM will also be greater than the angle FXQ — (c) which is likewise evident from the fact that in the triangle TXh the former is exterior and the latter the interior opposite angle. Hence we shall conclude that the straight line XZ is greater than the straight line TY. For if it were equal — since the perpendiculars SY and VZ are also equal, being the sines of 18° — (d) the angles STY and VXZ would be equal, the opposite of which we have shown—

[Margin: b — Elements I.29; c — Elements I.16; d — Elements I.4.]

—demonstrated. But if XZ be supposed less than TY, let Za be made equal to TY itself; (e) and in the same way, the straight line Va having been drawn, the angle VaZ will be equal to the angle STY. (f) Since, then, the angle VXZ is greater than the angle VaZ, the angle VXZ will also be greater than the angle STY — though this one was shown to be the greater. Therefore XZ is greater than TY; and consequently the two squares on XZ and ZV will be greater than the two squares on TY and YS. (g) That is, the square of the straight line VX will be greater than the square of the straight line ST, and therefore the straight line VX greater than the straight line ST.

[Margin: e — Elements I.4; f — Elements I.16; g — Elements I.47.]

But perhaps we shall show more easily that VX is greater than ST in this way. The angle TSY is [equal to] the angle of the pole's altitude above the horizon KL, (h) because STY is equal to the exterior angle FSK, that is, to the angle AEK, the altitude of the equator. And in the same way XVZ will be the angle of the pole's altitude above the horizon OP, (i) since VXZ is equal to the exterior angle FVO, that is, to the angle AEO, the altitude of the equator. Therefore the angle XVZ will be greater than the angle TSY, because the altitude of the pole above the horizon OP is set greater than above KL. Hence, if VZ be imagined to coincide with SY, and the straight line ZX with the straight line YT, VX will fall beyond ST, (k) and VX will be greater than ST, since it is set opposite the obtuse angle STN.

[Margin: h — Elements I.29; i — Elements I.29; k — Elements I.19.]

Since, then, VX is farther from the centre of the parallel than ST, (l) there will correspond to the straight line VX a greater arc of twilight than to the straight line ST in the northern parallel — which was the claim.

[Margin: l — Corollary 1 of this [treatise].]

Next, (m) since on the diameter of the equator the straight line Ed is equal to the straight line VX, and the straight line Eb to the straight line ST, Ed will also be greater than Eb — that is, the point d will lie beyond b. (n) Therefore a greater twilight corresponds to the straight line Ed at the equator than to the straight line Eb — which was the claim.

[Margin: m — Elements I.34; n — Corollary 1 of this [treatise].]

Finally, (o) since on HI, the diameter of the southern parallel, the straight line ef is equal to the straight line VX, and the straight line ig to the straight line ST, ef will also be greater than ig, and ef is farther from the centre of the parallel than ig. (p) Therefore a longer twilight is owed to the straight line ef than to the

straight line *ig* — which was the claim. And so, wherever the Sun may be, and so on — which was to be demonstrated.

[Margin: o — Elements I.34; p — Corollary 1 of this [treatise].]

PROPOSITIO XII

When the Sun occupies points of the ecliptic equally distant on either side from either of the equinoctial points, then for those living under the equator — that is, in the right sphere — the twilights are equal. But when the Sun occupies two points unequally distant from either of the equinoctial points, the twilights become unequal, the greater indeed at the more remote point, the smaller at the nearer; so much so that at the tropics the twilights become longest, while, the Sun occupying the equinoctial points themselves, the shortest twilights are produced.

Diagram. A circle (the meridian ABCD) crossed by four vertical chords (the parallels seen edge-on in the right sphere) and by the horizontal equator diameter BD and the line KL.

- H, A, F, Q (top, left to right)
- B (left end of the horizontal diameter), D (right end)
- N, E, M, S (upper-middle row)
- K (lower left), P, V, O, T (lower-middle row), L (lower right)
- I, C, G, R (bottom, left to right)

Let the meridian be ABCD about the centre E; the diameter of the equator, AC; the diameters of the two parallels equally distant from the equator, FG and HI; and QR, the diameter of the parallel more distant from the equator. The horizon is the perpendicular BD, and its parallel of the twilights KL. I say that in the parallels FG and HI equal twilights occur, and so on. For since MO and NP (a) are equal to one another and are equally distant from the centres M and N of the equal parallels, (b) the arcs of the twilights owed to them will be equal — which is the first point.

Next, (c) since MO and ST are likewise equal and recede equally from the centres M and S of unequal parallels, (d) the perpendiculars from S and T, erected in the plane of the parallel toward the plane of the meridian, will cut off a greater arc than would be similar to the arc cut off by the perpendiculars erected from M and O; and therefore the twilight owed to the straight line ST will be longer than the twilight corresponding to the straight line MO. From which it follows that, since the tropics recede most from the equinoctial, the greatest twilights occur there — which is the second point.

Finally, since the equator is the greatest of all the parallels, (e) the perpendiculars from E and V, erected in the plane of the equator toward the plane of the meridian, will cut off a smaller arc of twilight than would be similar to the arcs of the twilights in the other parallels. Therefore the shortest twilight occurs when the Sun, at the equinoctial point, occupies points of the ecliptic, and so on — which is the third point. Therefore, the Sun [occupying points equally distant, the twilights are equal], and so on — which was to be demonstrated.

[Margin: a — Elements I.34; b — Proposition 1 of this [treatise]; c — Elements I.34; d — Proposition 2 of this [treatise]; e — Proposition 2 of this [treatise].]

PROPOSITIO XIII

To compute the length of the twilight in the right horizon.

Let the figure of the preceding proposition be repeated, in which the diameter [of the equator is AC, of the parallels FG and] HI, of the right horizon BD, and of the parallel of the twilights KL. When the Sun is at the equator, EV will be the right sine of the arc of 18° , by which the Sun is hidden below the horizon at the beginning of the morning twilight, or at the end of the evening; and accordingly the arc BK will be equal to the arc of the twilight at the equator. Therefore the twilight comprises the 18° of the Sun's concealment below the horizon — that is, 1 hour 12 minutes.

But when the Sun is in any parallel HI, since the semidiameter [HN is the sine of the complement] of the parallel's declination, and NP the sine of the twilight in the same parallel, as is established, and as we have shown in Book 1 of the *Gnomonics* [propos. 35] — (for if about HI a semicircle of the parallel be conceived, [erect to the meridian ABCD,] and from N and P perpendiculars be erected to the same meridian, these will cut off from the parallel the arc of the twilight whose sine is NP) — if it be made:

As HN, the sine of the complement of the declination, is to NP, the sine of the Sun's concealment below the horizon, so HN, the whole sine in the parallel, is to another —

there will result [i.e. "prodibit"]

NP, the sine of the twilight, in parts of the whole sine in the parallel. Therefore from the table of sines the twilight will be known. At Cancer (♋) and Capricorn (♎) is found the twilight that is greatest, [namely] $19^\circ 41'$ — that is, 1 hour 19

minutes. And so in the right horizon, and so on, we have computed it — which was to be done.

PROPOSITIO XIV

To find the length of the twilight in any oblique horizon whatever.

Let the meridian be ABCD about the centre E; the diameter of the equator, AC; the parallel FG (northern in the first figure, but southern in the second); the axis of the world, BD; the diameter of the horizon, HI, and of its parallel of the twilights, KL. Then FH will be the meridian altitude of the parallel FG, and IG its meridian depression. From F let the perpendicular FP be dropped to HI, meeting, when produced, in Q, with GQ parallel to HI itself. Then FP will be the sine of the meridian altitude, and PQ of the depression. Let NO also be drawn parallel to GQ; and since (a) FG is bisected in N, (b) FQ too will be bisected in O. And when from N the parallel FZG has been described, in each figure, and MZ and XY drawn perpendicular to FG, and likewise Vd perpendicular to AC, then Dd, on the meridian, will be the arc of the twilight at the equator, and ZY the arc of the twilight in the parallel.

[Margin: a — Elements III.3; b — Elements VI.2.]

Although both in the *Gnomonics* Book 1, proposition 35, and in the *Astrolabe* Book 3, in the scholium to Canon 10, we have handed down the finding of the twilights by several methods, still it is desirable to show here at least one way as well — and indeed the most expeditious — both because we are treating of twilights in this little book, and also because this finding is necessary for what follows. We shall therefore learn the twilight Dd at the equator thus. Let it be made:

Diagram, first (upper) figure — northern parallel. A circle (meridian ABCD) densely filled with chords and perpendiculars: equator AC, northern parallel FG, axis BD, horizon HI, twilight-parallel KL, the described parallel FZG, and the perpendiculars FP, GQ, NO, MZ, XY, Vd. Sun-positions marked with stars.

- A (upper left, star), F (top), D (upper right, star): with a zodiac glyph near the top
- H (left), K (lower left)
- O, R, E (interior, E at centre)
- N, M, P, S, V, X, T, Q (interior points)
- B (bottom, star)
- I, L, Y, z (right side)

- C, G, and small d, q, e (lower right / interior)
- [several crowded interior labels illegible at this resolution]

As AR, the sine of the altitude of the equator (or of the complement of the pole's altitude), is to RS, the sine of 18° , so the whole sine AE is to another.

For the number produced will give EV, the sine of the twilight Dd, (c) because the ratio of AR to RS is the same as that of AE to EV. We shall find the same by another method as follows. Since, in the right-angled triangle ETV, (d) the angle EVT is equal to the angle AEH, the complement of the pole's altitude, ETV will be the angle of the pole's altitude. (e) If, then, it be made:

As ET, the whole sine, is to EV, the secant of the angle TEV of the pole's altitude, so ET, the sine of 18° , is to another,

the same sine EV of the twilight Dd at the equator will be produced.

[Margin: c — Elements VI.2; d — Elements I.29; e — Problem 5 of [the treatise on] rectilinear triangles.]

Diagram, second (lower) figure — southern parallel. A circle (meridian ABCD) similarly crowded with chords and perpendiculars for the case where the parallel FG is southern; the described parallel FZG and perpendiculars MZ, XY, Vd are drawn, with Sun-positions marked.

- A, F (upper left/top), D (upper right, star)
- H, R, M, P (upper-left interior)
- E (centre), N (below centre)
- R, S, X, T, V (lower interior)
- B (lower interior, star)
- Z (left), C (lower right), L, I (right)
- f, Y, Q, q (bottom)
- [several crowded interior labels illegible at this resolution]

But the twilight ZY in the parallel we shall find thus. Since (f) as FO, half the sum of FP (the sine of the meridian altitude) and PQ (the sine of the meridian depression), is to Fe, the straight line composed of FP (the sine of the meridian altitude) and Pe (the sine of 18°), so the whole sine FN is to FX — if it be made:

As half the sum of the sine of the meridian altitude and the meridian depression, is to the sum of the sine of the meridian altitude and the sine of 18° , so the whole sine is to another,

there will be generated FX, the versed sine of the arc FY, which is composed of the semidiurnal arc FZ and the arc of the twilight ZY; and accordingly the arc FY will be known. From this, if the semidiurnal arc FZ be subtracted, the twilight ZY will be left known. And so in any oblique horizon whatever, and so on, we have found it — which was to be done.

[Margin: f — Elements VI.2 or 4.]

SCHOLIVM

The arc corresponding to a given versed sine is easily derived from it, as we taught in the treatment of sines, by this method. When the versed sine is greater than the whole sine — for example, 184493 — the first figure on the left, 1, which is equivalent to the whole sine 100000, being set aside, let the remaining sine 84493 be taken: the arc [of it] is $57^{\circ} 40'$. For this, added to the quadrant, will make the arc sought, $147^{\circ} 40'$. But when the versed sine is less than the whole sine, subtracting it from the whole sine, let the sine of the arc of the remainder be taken; for this, subtracted from the quadrant, will make the arc that is sought. Thus, if the versed sine be, say, 79104: this being subtracted from the whole sine 100000, the remaining sine becomes 20896, whose arc is $12^{\circ} 4'$; and this, subtracted from the quadrant of 90° , leaves the arc of $77^{\circ} 56'$ corresponding to the versed sine, which we seek.

[Margin: How the arc corresponding to a versed sine is to be derived.]

Although we posit that the arc of the Sun's concealment below the horizon at the beginning of the morning twilight and at the end of the evening comprises, by the common opinion of astronomers, 18° , still the twilights will be computed in the same way if that concealment be set greater or less, as is evident.

This too must not be left unknown: that in the northern signs there is twilight all night long at that elevation of the pole where the meridian depression of the proposed parallel is either equal to the arc of the Sun's concealment below the horizon (which we posit to contain 18°) or less, as is evident from the figure of this proposition. And this will happen when the versed sine of the arc formed from the semidiurnal arc and the arc of the twilight is found to be 200000 or greater.

[Margin: When there is twilight through the whole night.]

Consult also proposition 35 of book 1 of the *Gnomonics*, and its scholium, so that the whole variety of the twilights may be more clearly grasped.

The semidiurnal arc, moreover — which is to be subtracted from the arc compounded of the semidiurnal arc and the twilight arc — is to be obtained either from the first of the tables which we published, with Notes, in the *New Description of Sundials*, or is to be sought by means of the following proposition 16.

PROPOSITIO XV.

Given the distance of any point of the ecliptic from either of the equinoctial points, to investigate its declination; and conversely, from a given declination, to find the corresponding point on the ecliptic.

Let AB be an arc of the equator, and AC an arc of the ecliptic, such that A is the beginning of Aries or of Libra. Let CB be an arc of a great circle drawn through the poles of the world and through the given point C on the ecliptic, so that CB is the arc of its declination, which is proposed for investigation. Since in the right-angled spherical triangle ABC the base AC is known — namely the distance of the given point C from the nearest equinoctial point A — and the angle A of the maximum declination, which is opposite the sought arc CB of declination, is also known, then, by the first method of problem 8 of spherical triangles (I mean the problems of spherical triangles which we demonstrated at the end of Lemma 53, book 1, of the *Astrolabe*), let it be arranged:

As the whole sine is to the sine of the base AC — the distance of the point C from the equinoctial point A — so is the sine of the angle A, of the maximum declination, to another [number];

and the sine of the arc of declination CB, which is sought, will be produced.

Diagram. A small figure of two intersecting great-circle arcs forming the spherical triangle of the proposition.

- A (upper left): vertex A, the equinoctial point
- C (right): vertex C, the given point on the ecliptic
- B (lower center): vertex B, the foot of the declination arc

But if the declination of the point C is known, we shall find its distance from the equinoctial point A in the following way. Let it be arranged:

As the sine of the angle A, of the maximum declination, is to the sine of the arc of declination CB, known — so is the whole sine to another;

for the sine of the base AC, the distance of the point C from point A, will be generated, since — as we said — as the sine of the angle A of maximum declination is to the sine of the arc CB, so is the whole sine to the sine of the base AC.

Or in this way. Since in the same right-angled triangle ABC the angle C[D?] of declination is known, together with the angle A of maximum declination which is opposite the given arc CB, then, by the first method of problem 14 of spherical triangles, let it be arranged:

As the whole sine is to the secant of the complement of the given angle A, of the maximum declination — so is the sine of the declination CB to another;

the sine of the base AC will be found, as before. For example, if the declination CB is given as 14 degrees 40 minutes, there will be found — by either method — a sine of about 63496, to which corresponds 39 degrees 25 minutes. Therefore, if the given point stands off from the beginning of Aries following the succession of the signs, the point C will be at 9 degrees 25 minutes of Taurus; but if against the succession of the signs, it will be at 20 degrees 35 minutes of Aquarius. And if it recedes from the beginning of Libra following the succession of the signs, the point C will be at 9 degrees 25 minutes of Scorpio; but at 20 degrees 35 minutes of Leo if it recedes from Libra against the succession of the signs. We have therefore investigated the declination of any point, etc. Which was to be done.

PROPOSITIO XVI.

To compute the semidiurnal arc of any point of the ecliptic, whose declination is given, for any latitude of place; and conversely, from a given semidiurnal arc, to search out the corresponding point of the ecliptic.

In the figure of proposition 14, since it holds that as FO is to FP, so is FN to FM, let it be arranged:

As TO — the half of the sum of the sines of the meridian altitude and of the depression — is to FP, the sine of the meridian altitude — so is FN, the whole sine, to another;

there will result FM, the versed sine of the semidiurnal arc FZ, from which, as we explained in the scholium of proposition 14, the semidiurnal arc itself will be extracted.

[Margin: 2 of the sixth (Euclid VI.2).] Or, if it be arranged:

As FO — the half of the aforesaid sum — is to OP, the difference between that half and the meridian altitude — so is FN, the whole sine, to another;

MN will be produced, the sine of the arc Zf, by which the semidiurnal arc FZ differs from the quadrant Ff. Therefore the arc ZF will be known, which, added to the quadrant Ff in the northern signs, and subtracted from the same quadrant in the southern, makes up or leaves the semidiurnal arc FZ.

Or if it be arranged, as we showed in problem 2 of the *New Description of Sundials*:

As the whole sine is to the tangent of the pole's altitude — so is the tangent of the declination to another;

there will arise the same sine of the arc by which the semidiurnal arc differs from the quadrant.

Diagram. The upper of two nearly identical large circular figures (the reused "figure of proposition 14"): a circle representing the meridian, crossed by numerous chords and diameters forming an eight-pointed star pattern, with the horizon, equator, and parallels drawn in. The lettering is small and densely crowded; several labels could not be resolved with confidence

- Circumference: A (upper left), D (upper right, marked with a star), C (lower right), B (lower left, marked with a star); lowercase points a, b, f across the top
- Outside the circle: z (upper right), Y (right), H (left), K (lower left), and L, g (lower right)
- Interior: E (center), O and N (upper interior), M (right of center), R, P, e (left stack), S, Q (lower left interior), T, V, X (lower interior)
- [Margin: a 2 of the sixth (Euclid VI.2)]

Diagram. The lower of the two large circular figures on this page, essentially a repetition of the same construction. Lettering densely crowded; several labels could not be resolved

- Circumference: A (upper left), D (upper right, starred), C (lower right), B (lower center, starred); lowercase points a, b at the top and d, f at right
- Outside the circle: Z (left), and f, Y, q at the bottom
- Interior: E (center); F, H (left), R, M (upper interior), P, e (left stack), S, X, N (lower interior), T, V, I, L (right)

Conversely, from a given semidiurnal arc, we shall hunt out the corresponding point of the ecliptic in this way. Let it be arranged:

As the tangent of the pole's altitude is to the whole sine — so is the sine of the arc by which the semidiurnal arc differs from the quadrant, to another;

for the number produced will be the tangent of the declination of the point of the ecliptic which is sought. Let the declination therefore be extracted from the table of sines, and from this the corresponding point of the ecliptic, as was taught in proposition 14.

Or, if in the figure of the preceding proposition one conceives the spherical triangle ABC — formed from the arc AB of the equator, between the horizon and the circle of declination through the intersection of the parallel which the sought point of the ecliptic describes; and from the arc AC of the horizon, between the equator and the same circle of declination (which arc indeed measures the rising amplitude); and from the arc CB of declination. In this triangle [Margin: a 15 of the first of Theodosius (Theodosius I.15)] the angle B is right, because the circle CB is drawn through the poles of the equator; the angle A is that of the altitude of the equator above the horizon — that is, the complement of the pole's altitude; and finally the arc AB is known, by which the given semidiurnal arc differs from the quadrant. Then, by the first method of problem 11 of spherical triangles, let it be arranged:

As the whole sine is to the sine of the arc AB, by which the semidiurnal arc differs from the quadrant — so is the tangent of the angle A, of the complement of the pole's altitude, to another;

the tangent of the declination of the sought point will again be found, etc. Which was to be done.

Diagram. A small figure of two intersecting great-circle arcs forming the spherical triangle ABC of this proposition.

- A (left): vertex A
- C (right of center): vertex C
- B (lower center): vertex B, the right angle at the foot of the declination arc

PROPOSITIO XVII.

To find the rising or setting amplitude of any point of the ecliptic for any latitude of place; and conversely, from a given rising or setting amplitude, to search out the corresponding point of the ecliptic.

In the same figure of proposition 14, erect from M a perpendicular Mb to HI; and the arc ab will be the rising or setting amplitude of the parallel FG. For since both the horizon (drawn through the line HI) and the parallel (through the line FG) are perpendicular to the meridian, [Margin: a 19 of the eleventh (Euclid XI.19)] their common section will also be perpendicular to the same; and therefore, by definition 3 of book 11 of Euclid, it will be perpendicular to the line HI, lying in the plane of the meridian. If then the circle ABCD is conceived to be the horizon set perpendicular to the meridian, Mb will be the common section of the horizon and the parallel; and by the same reasoning Ea will be the common section of the horizon and the equator. Consequently the arc ab will measure the rising amplitude, and its sine will be EM. Now since in the right-angled triangle EMN the side EN is known — being the sine of the declination — and the angle MEN, of the pole's altitude, is also known, [Margin: b Problem 3 of rectilinear triangles] let it be arranged:

As the whole sine is to EN, the sine of the declination — so is the secant of the angle MEN, of the pole's altitude, to another;

there will be produced the sine EM, of the sought amplitude.

Conversely, if the amplitude ab is supposed known, then in the same triangle EMN the sine EM of the amplitude ab will also be known; and since the angle EMN, of the complement of the pole's altitude, is known, [Margin: a Problem 2 of rectilinear triangles] let it be arranged:

As the whole sine is to EM, the sine of the known amplitude — so is the sine of the angle EMN, of the complement of the pole's altitude, to another;

for the number produced will be the sine EN, of the declination of the point, which is sought. From the declination thus found, [Margin: b 15 of this (i.e. of the present work)] the sought point of the ecliptic will be recognized. We have therefore found the rising amplitude, etc. Which was to be done.

Diagram. The upper of two large circular figures on this page — again the reused construction of the "figure of proposition 14": a circle (the meridian) crossed by

many chords and diameters in an eight-pointed star, with horizon, equator, and parallels. Lettering densely crowded; several labels could not be resolved

- Circumference: A (upper left), D (upper right, starred), C (lower right), B (lower left, starred); lowercase points a, b, f across the top
- Outside the circle: z (upper right), Y (right), H (left), K (lower left), L and g (lower right)
- Interior: E (center), O and N (upper interior), M (right of center), R, P, e (left stack), S, Q (lower interior), T, V, X (lower interior), I (right)
- [Margin: a 2 of the sixth (Euclid VI.2)]
- [Margin: b Problem 3 of rectilinear triangles]

Diagram. The lower of the two large circular figures, a repetition of the same construction. Lettering densely crowded; several labels could not be resolved

- Circumference: A (upper left), D (upper right, starred), C (lower right), B (lower center, starred); lowercase points a, b at top, d at right
- Outside the circle: Z (left); f, Y, q at the bottom
- Interior: E (center), F and H (left), R, M (upper interior), P (left stack), S, X, N (lower interior), T, V, I, L (right)
- [Margin: a Problem 2 of rectilinear triangles]
- [Margin: b 15 of this]

SCHOLIVM.

It has seemed good to demonstrate the three preceding propositions in this place too, although we have delivered them elsewhere as well; because in what follows we shall need the latter parts of them.

PROPOSITIO XVIII.

To demonstrate the dissimilarity between the increase and decrease of the days and nights, and of the twilights.

[Margin: The variety among the days, the nights, and the twilights, in their increase and decrease.] The twilights keep a very dissimilar rule from that of the days and nights in their increase and decrease. For the days decrease continuously from the beginning of Cancer to the beginning of Capricorn, in the northern region; and from the beginning of Capricorn up to the first degree of Cancer they increase continuously. On the contrary, the nights increase without intermission from the beginning of Cancer to the beginning of Capricorn, and

from the first point of Capricorn to the beginning of Cancer they perpetually diminish. So it comes about that, when the Sun is in the beginning of Cancer, the longest day of the whole year and the shortest night occur; but when it occupies the beginning of Capricorn, the shortest day and the longest night occur, at whatever elevation of the arctic pole above the horizon. This can easily be demonstrated from propositions 19 and 20 of book 2 of [Theodosius].

But with the twilights the matter stands far otherwise. For although the twilight becomes longest at the beginning of Cancer in any northern latitude — as we said above [Margin: a corollary 9 of this] — it is nevertheless not made shortest at the first degree of Capricorn, but is everywhere greater than the one found at the equator. So the twilights, although they decrease as one proceeds from Cancer toward Libra, yet this diminution does not go on continuously all the way to Capricorn; rather, at a certain point of the ecliptic between Libra and Capricorn the shortest twilight of all will occur, and thereafter from this point they will again increase, and one twilight will be produced equal to the one that occurs at the equator, before the Sun reaches Capricorn. And if the Sun were to run out beyond the winter tropic, the twilights would still keep growing greater, even though the days were still decreasing and the nights increasing. And so, although the days from Capricorn toward Aries always become greater, the twilights nevertheless diminish up to a certain point — the one between Libra and Capricorn to which it corresponds — at which the twilight becomes shortest; and before the Sun reaches that point between Capricorn and Aries, another twilight will be produced equal to it, namely equal to the one which occurs at the equator. And this, unless a geometric demonstration were at hand, could scarcely seem credible.

Let ABCD then be the meridian, about the center E; the oblique horizon FG, and its parallel of the twilights KL, such that the arcs FK and GL are 18 degrees. Let BD be the axis of the world; AC the equator; the parallel through O — the intersection of the axis with KL — passing along MN; the parallel through a, the midpoint of the segment EO of the axis, running along QR; and, below MN, any parallel VX; and finally, between MN and QR, some other parallel ST. Now gh is farther from the center than ZO, and ZO farther than ef, as is manifest; and ef too is farther than bd, since each extremity of this recedes equally from the center a. (For since EO is bisected at a, [Margin: b 2 of the sixth (Euclid VI.2)] IO too will be bisected at d. [Margin: c 34 of the first (Euclid I.34)] Since then Id is equal to Eb, dO too will be equal to the same Eb. Since therefore the sides Eb, Ea are equal to the sides Od, Oa, and contain equal alternate angles, [Margin: d 29 of the first (Euclid I.29)] [Margin: e 4 of the first (Euclid I.4)] the bases ab and ad will be equal.) [Margin: f

2 of this] Therefore the arc of the parallel VX, corresponding to the line gh, will be greater than the twilight of the line ZO, and this greater than that of the line ef, and this greater than that of the line bd. And these things are certain and beyond doubt in any region, if the same construction be made — so that it is entirely true that the twilights decrease continuously from the parallel VX up to the parallel QR. But it does not on that account follow from the figure that the twilight bd is the shortest of all. [Margin: g 2 of this] For the arc of the twilight of the line bd is greater than the arc of a parallel greater than QR, if that arc corresponds to a line equal to bd itself, and its distance from its own center is equal to the distance of the line bd from its center a. Yet nothing prevents it from being even somewhat greater than the arc of the twilight of that same greater parallel — one which corresponds to a line equal to bd that recedes a little farther from the center than bd does; [Margin: h corollary 1 of this] and consequently the arc of the twilight of that greater parallel is a little greater than the arc of the same parallel which corresponds to a line equal to bd itself, whose distance from its own center is equal to the distance of the line bd from center a. So the twilight of that greater parallel holds a middle place between the twilight of the line bd and that arc which, in the greater parallel, corresponds to a line equal to bd itself and has a distance from its own center equal to the distance of bd from its own. And so the twilights can still decrease imperceptibly from the parallel QR toward Aries.

[Margin: i 2 of this] It is also evident from the figure set forth that the twilight of the parallel MN is greater than the twilight of the equator AC, because the equal lines OZ and EI are equally distant from their centers, and the parallel is smaller than the equator. A fortiori the twilights of the parallels below MN will be greater than the twilight of the equator, since these are greater than the twilight of MN, as has been shown. But it is not evident from the figure up to which parallel greater than MN — namely one lying between MN and AC — the twilight becomes equal to the twilight of the equator, nor in which parallel between MN and AC the twilight becomes equal to the equator's twilight. It has, however, been ascertained by calculation (as will also appear from the table of twilights placed below) that the twilight of the parallel marked with a special symbol [glyph uncertain — resembles &] is everywhere greater than the twilight of the equator, although this marked parallel lies, at some elevation of the pole, between MN and AC; at another does not differ from the parallel MN; at another is placed below MN; nay, at another coincides with the parallel QR. But these things will become clearer from the following three propositions. We have therefore demonstrated the dissimilarity between the increase, etc. Which was to be done.

Diagram. A large circular figure for the twilight construction : the circle ABCD is the meridian about center E, crossed by the oblique horizon FG, the twilight-parallel KL, the axis BD, the equator AC, and several parallels (MN, QR, VX, ST), with chords ZO, ef, bd, gh and lowercase interior points. The lettering is very small and densely overlaid; many interior labels could not be resolved with confidence

- Circumference: A (top), D (upper right, starred), C (lower right), B (lower left, starred), G (right)
- Left side: F, K; and M, S, Q (upper left, outside/near circumference), V (left)
- Right side: I, L (lower right)
- Interior / center: E (center), P and b (near center-left); lowercase cluster a, c, d, e, f, g and small numerals 4, 5, 6 near the lower center
- Below the circle: X, N, T, R
- [Margin: b 2 of the sixth]
- [Margin: c 34 of the first]
- [Margin: d 29 of the first]
- [Margin: e 4 of the first]
- [Margin: f 2 of this]
- [Margin: g 2 of this]
- [Margin: h corollary 1 of this]
- [Margin: i 2 of this]

PROPOSITIO XIX.

To investigate, in any northern region, the parallel in which it can be demonstrated that a twilight occurs greater than the one produced at the equator — that is, to find the declination of the parallel MN, drawn in the figure of the preceding proposition through O, the intersection of the axis with KL, parallel to the horizon. Likewise to search out whether the marked parallel [⌘?] lies between MN and the point a, or rather between a and the equator; or whether it is the same as MN, or as QR; or finally whether it is placed below MN.

In the figure of the preceding proposition, let PO be drawn perpendicular to FG. If then, for a given latitude, [we wish] to investigate...

Diagram. A large circle (the meridian) with its center marked E. Through the center run several straight lines: a horizontal diameter from F (left) to G (right); a lower horizontal chord from K (left) to L (right), which is the parallel KL; an oblique axis running from B (lower-left, marked with a star) up to D (upper-right,

marked with a star), the axis DB; and a series of oblique parallels descending from upper-left to lower-right (MN, QR, ZO among them). **A** stands at the top of the circle; **C** at the lower-right of the circumference. A cluster of intersection points (lowercase **a, c, d, e, f, g, h, o**) is crowded near the center-bottom where the oblique lines cross the axis and the parallels, and a further row of labels (**X, N, T, R**) runs along the lower circumference. This is the figure for the Capricorn-twilight construction of the preceding proposition.

- A (top of circle): apex
- D (upper right, starred): upper end of the axis DB
- B (lower left, starred): lower end of the axis DB
- E (center): center of the meridian
- F (left) — G (right): horizontal diameter
- K (left) — L (right): parallel KL
- S, Q [?] (upper left): points on the parallel through M
- M, V (far left): M is the upper end of parallel MN
- Z, P, b (left of center): points along the oblique lines
- I (center-right, lower): intersection point
- C (lower right): point on circumference
- a, c, d, e, f, g, h, o (center-bottom cluster) [several labels [?] — crowded]
- X, N, T, R (lower circumference)

one may wish to investigate how far the parallel MN — drawn through O, the intersection of the axis with the parallel of the horizon — declines; that is, through what point of the ecliptic it passes, provided the declination found does not exceed $23^{\circ}30'$; and consequently whether the tropic of Capricorn [φ] passes through O, or is situated between O and E, or between O and B. We shall proceed as follows. Since in the right triangle EOP, given EO as the whole sine [sinus totus], the side OP is the sine of the angle OEP, the given altitude of the pole (as we said in the treatment of sines), if we set up the proportion:

As OP, the sine of the angle OEP (the altitude of the pole), is to EO, the whole sine, so OP, the sine of 18° (in the parts of the whole sine of the greatest circle), is to another quantity,

then EO will be found, in the same parts. And because EO is the sine of the declination of parallel MN, the declination of the arc AM will be known from the table of sines. If this declination is equal to the greatest declination, $23^{\circ}30'$, then MN will be the parallel of Capricorn, and its twilight, belonging to the line ZO, ^a will demonstrably be greater than the twilight of the Equator. But if the

declination found is greater than the greatest declination, the parallel MN will lie entirely outside the Sun's path, and the tropic of Capricorn will cut the axis between E and O. Finally, if it is found smaller, the same tropic will cut the axis between O and B, ^b and again the twilight will demonstrably be greater than the twilight of the Equator — indeed, greater even than the twilight of parallel MN. But if the sine EO, once found, is bisected, we obtain the sine E a, the sine of the declination of parallel QR, down to which the twilights, starting from parallel MN, demonstrably decrease.

[Margin: ^a Prop. 2 of this (work).] [Margin: ^b Prop. 2 of this (work).]

At the altitude of the pole 42° — where Rome roughly lies — the sine EO is found to be 46182, and its half, E a, 23091. That sine [46182] is greater than 39875, the sine of the declination of Capricorn, but this half [23091] is smaller. Therefore the tropic of Capricorn is situated between MN and QR. To the sine E a corresponds a declination of $13^\circ 21'$, which agrees with $24^\circ 37'$ of Aquarius [♒], where the Sun stands on 14 February. So at Rome the twilights decrease from 22 December until 14 February; yet on that day the twilight is 1 hour 41 minutes, which — since this [the Equator's] contains only 1 hour 38 minutes — is still greater than the twilight of the Equator. They will therefore still keep decreasing, advancing from 14 February toward 21 March; and in that interval, on one day, the twilight will become equal to the twilight of the Equator, then the shortest, and thereafter they will increase again. When this happens — which we shall demonstrate a little below — the parallel of Capricorn passes between a and o, since its declination is greater than the declination of parallel QR, seeing that the latter is only $13^\circ 21'$.

But if we wish to know at what altitude of the pole the parallel of Capricorn passes through O, or even through a, or whether it cuts the axis between O and B, or finally between E and a, we shall accomplish it by this method. Since, if the tropic of Capricorn is to pass through O, its declination-sine EO must be 39875, then if we set up the proportion:

As EO, 39875, is to OP, the sine of 18° — that is, to 30902 — so the whole sine, EO, is to another,

OP, the sine of the angle OEP (the altitude of the pole), will be found to be 77497; and so it is at the altitude of the pole $50^\circ 48'$. Therefore MN, the parallel [of Capricorn], ^a and its twilight, will accordingly be greater than the twilight of the Equator. A fortiori, at any elevation of the pole greater than $50^\circ 48'$, the twilight at the beginning of Capricorn will be greater than the twilight of the Equator; because then the tropic of Capricorn falls below its intersection with the parallel

KL, since the portion of the axis between E and the parallel KL is smaller at that altitude than at the altitude $50^{\circ}48'$ — as is clear if one imagines the axis DB raised, and the Equator lowered together with it along the parallels, from the right side toward the left. Or, if another axis be drawn between D and the zenith [vertex of the head]. For hence it comes about that that portion of the axis is then smaller than the sine of the greatest declination, seeing that EO is equal to the sine of the greatest declination at the altitude of the pole $50^{\circ}48'$.

[Margin: ^a Prop. 2 of this (work).]

AGAIN: since, when the tropic of Capricorn passes through a, its declination-sine E a is necessarily 39875, and therefore its double, 79750, indicates the line EO, if we set up the proportion once more:

As EO, 79750, is to OP, 30902, so the whole sine, EO, is to another, there will be produced OP, the sine of the altitude of the pole, 38748; and its corresponding altitude of the pole will accordingly be $22^{\circ}48'$, at which the tropic of Capricorn will pass through the point a, and will make a twilight greater than the twilight of the Equator, since that [twilight of Capricorn] contains 1 hour 24 minutes, but this one only 1 hour 18 minutes.

MOREOVER: since, when the tropic of Capricorn cuts the axis between E and a, the line E a must be greater than the sine of the greatest declination, 39875, and therefore EO greater than 79750, if we set up the proportion:

As EO, 80967 (any other number greater than 79750 could also have been taken), is to OP, 30902, so the whole sine is to another,

there will be generated the sine of the altitude of the pole at which the tropic of Capricorn passes, 38166; to which corresponds an altitude of the pole of $22^{\circ}26'$; and the twilight of Capricorn will be 1 hour 24 minutes, greater than the twilight of the Equator, since this contains 1 hour 18 minutes — just as at the altitude of the pole $22^{\circ}48'$; which indeed comes about on account of the small difference between the pole-altitudes.

FINALLY: when EO is smaller than 39875, the tropic of Capricorn will cut the axis between O and B. Therefore if we set up the proportion:

As EO, 38796 (any other number smaller than 39875 could also be taken), is to OP, 30902, so the whole sine is to another,

there will be produced OP, the sine of the altitude of the pole at which the tropic of Capricorn cuts the axis between O and B — as, in the given example, it will be

found that OP, the sine 79673, to which is due the altitude of the pole $52^{\circ}49'$, is where the tropic of Capricorn falls below the point O; and it will accordingly make the twilight in Capricorn greater than the twilight of the Equator. If EO had been taken as 39850, the sine OP of the altitude of the pole would have been found to be 77545, to which in the table of sines corresponds the altitude of the pole $50^{\circ}51'$, where again the tropic of Capricorn falls below O, and therefore will make the twilight greater than the Equator's. And the same will happen at any other elevation of the pole greater than $50^{\circ}51'$, as we also said above.

You see, then, the remarkable variety among the days and the twilights in their increase and decrease. Yet the calculation always shows, at every elevation of the pole, the twilight in Capricorn greater than the twilight at the Equator — even where the parallel of Capricorn cuts EO between E and a. For even at the altitude of the pole 1° , the parallel of Capricorn lies between E and a — because the parallel through a, as it advances, is entirely outside the sphere — and yet the twilight of Capricorn is greater than the twilight of the Equator. For at that elevation of the pole the line EO is found to be 1770888, and accordingly its half, E a, 885444; of which the former [1770888] exceeds the semidiameter of the sphere — that is, 100000 — by this number 16 times and more, while the latter exceeds it 7 times and more: so that the point O recedes from the center of the sphere by 17 semidiameters and more, and the point a by 8 semidiameters and more. From which it follows — since the segment of the axis between E and the parallel of Capricorn is 39875, namely the sine of the greatest declination — that the parallel of Capricorn is much closer to the center E than the point a is; and yet the twilight of Capricorn is 1 hour 19 minutes, whereas the twilight of the Equator is only 1 hour 12 minutes, less than it.

And so it is not always true, as Pedro Nunes [Petrus Nonius] states, that the twilights decrease from the tropic of Capricorn up to the point a — since in some regions the tropic of Capricorn lies between a and E. It is nevertheless always true that the twilights decrease from any parallel between a and B, up to the parallel described through a. For at the altitude of the pole 80° , the line EO is 31378, smaller than the sine of the greatest declination; therefore the tropic of Capricorn will be there, between O and B, ^a and its twilight accordingly greater than the twilight of the Equator. But at the altitude of the pole 20° , the line EO is 90351, and therefore its half, E a, is 45176, greater than the sine of the greatest declination; wherefore at that elevation too the parallel of Capricorn falls between E and a, just as at the elevation of the pole 1° , and likewise for the others. We have therefore investigated the parallel in every northern region, and so forth — which was to be done.

[Margin: ^a Prop. 2 of this (work).]

PROPOSITIO XX.

The twilights, from the Equator toward Capricorn [^γ], decrease up to a certain parallel; then they increase again up to another parallel, in which the twilight becomes equal to the twilight of the Equator; and thereafter they always become greater.

What was demonstrated in the two preceding propositions we shall confirm in this one by another route — namely, through spherical triangles, and indeed more particularly — in this way. Let ABF be the Equator; let CAD be the oblique horizon of any region; and at A let the equinoctial sunrise be set. Let AB be the arc of twilight in the Equator, tending downward from A below the horizon, such that the Sun, standing in the Equator, begins twilight when it has reached the point B, and ends it as soon as it has risen at A. And because the oblique horizon CAD touches the parallel of the ever-apparent stars — the greatest such parallel ^b — let another great circle EBD be described through B, below the horizon CAD, touching the same parallel and cutting the circle CAD in D, toward the north. Then the angles DAF, DBF will be acute — namely those which the Equator, below the oblique horizon CD, makes with the horizon itself and with the circle EBD toward the north — and they will be equal, ^c because the circles CAD, EBD are equally inclined to the Equator, seeing that they touch the same parallel. ^d Therefore the arcs AD, BD together are equal to a semicircle.

[Margin: ^b Theodosius, *Spherics* II.15.] [Margin: ^c Scholium 21, *Spherics* II (Theodosius).] [Margin: ^d Spherical triangles [Triangula sphaerica], 15.]

Diagram. A wide, shallow U-shaped (bowl-shaped) figure. The upper rim is the oblique horizon **CAD**, running from **C** at the upper left down and around to **D** at the upper right; a second great circle **EBD** runs beneath it, meeting it at D. Along the upper region a row of points is marked left-to-right — **O, H, N, M, A, L** — where **A** is the equinoctial rise. Along the bottom of the bowl a row of points runs left-to-right — **E, Q, G, I, F, B** — with **P** set just above, between G and I. From the lower points, perpendicular arcs rise to the upper points (EO, GN, IM, BL), and the parallels GH, IK, EC are drawn.

- C (upper left): end of the oblique horizon CAD
- D (upper right): meeting point of horizon CAD and circle EBD
- O, H, N, M, A, L (upper rim, left-to-right): A = equinoctial rise; H, N, M, L are the upper ends of the perpendicular/parallel arcs

- E, Q, G, I, F, B (bowl floor, left-to-right): foot-points of the arcs; F is toward the south
- P (just above floor, center): the point the Sun reaches on parallel IK
- Perpendicular arcs: EO, GN, IM, BL; parallels GH, IK, EC

But because arc AD is greater than arc BD — since the angle DBA is obtuse and the angle DAB acute (for the angle DAB, which the horizon makes with the Equator toward the north below the horizon, is the angle of the altitude of the Equator above the horizon, and hence acute; whereas DBA is the supplement, to two right angles, of the acute angle DBF that measures the altitude of the Equator, and is therefore obtuse) — and accordingly AD is greater than a quadrant and BD smaller: ^e let an arc DG be taken equal to arc DA, so that the two arcs DB, DG together are also equal to a semicircle. And through G let the parallel GH be described. Also, taking a point I between G and B, and another point F toward the south, let two more parallels IK, EC be described through I and through E.

[Margin: ^e Spherical triangles [Triangula sphaerica], 11.]

I say, then, that the twilight of parallel GH is equal to the twilight of the Equator ABF; that the twilight of parallel IK, and of any other between AB and GH, is smaller; but that the twilight of parallel EC, and of any other beyond GH, is greater — so that the twilights, from Libra [$\underline{\alpha}$] toward Capricorn, decrease up to a certain parallel, then from this parallel increase again up to the parallel GH, and thereafter, from this parallel, always become greater. For let there be drawn, from the lower horizon DE to the upper one DC — in which the twilights end — the perpendicular arcs BL, IM, GN, EO, namely arcs proceeding through the points B, I, G, E and through the poles of the circle CD. ^f For these are perpendicular to the circle CD. ^g And since, as the sine of arc GD is to the sine of arc GN, so the sine of arc BD is to the sine of arc BL, it will also be, by alternation, that as the sine of arc GD is to the sine of arc BD, so the sine of arc GN is to the sine of arc BL. But the ratio of the sine of arc GD to the sine of arc BD is a ratio of equality, because these arcs, completing a semicircle, have the same sine. Therefore the sines of the arcs GN, BL will also have a ratio of equality, and hence the arcs GN, BL themselves will be equal, since each of them is smaller than a quadrant. ^h For the arcs NG, LB, [extended] up to the Nadir — that is, to the pole of the horizon — are quadrants, meeting at that pole; and consequently neither of the points G, B is that pole, since at neither of them do the arcs NG, LB meet. Moreover, it is established from the hypothesis that the arc LB is smaller than a quadrant — namely 18°. Since therefore BL is the arc of occultation of the Sun at the beginning...

[Margin: ^f *Spherics* I.15 (Theodosius).] [Margin: ^g Spherical triangles [Triangula sphaerica], 40.] [Margin: ^h Corollary 16, *Spherics* I (Theodosius).]

of the twilight of the Equator, GL too will be the arc of occultation of the Sun at the beginning of the twilight of parallel GH, and the twilight-arc will be GH; for the Sun traverses it when, below the horizon CD, it is occulted through the arc of occultation GN. ^c Now the arcs BA, GH are similar, since they lie between non-concurrent semicircles of the horizons. Therefore as many degrees are contained in GH as in BA, and accordingly the twilight of parallel GH is equal to the twilight of the Equator BA.

[Margin: ^c *Spherics* II.13 (Theodosius).]

Diagram. The same bowl-shaped figure as on the preceding page, repeated across the page-turn: the oblique horizon **CAD** (from **C** upper left to **D** upper right), the great circle **EBD** beneath it, the upper row of points **O, H, N, M, A, L**, the bowl-floor row **E, Q, G, I, F, B** with **P** above, and the perpendicular arcs EO, GN, IM, BL with the parallels GH, IK, EC. See fig-p281-1 for the label list; this is the identical construction reprinted for the continuation of the proof.

NEXT: ^f because by the same reasoning, as the sine of arc ID is to the sine of arc BD, so the sine of arc IM is to the sine of arc BL. But the sine of arc ID is greater than the sine of arc BD, since arc ID is set between BD and GD, which complete a semicircle; therefore the sine of arc IM will also be greater than the sine of arc BL, and consequently arc IM will be greater than arc BL. Since therefore BL is the arc of occultation of the Sun at the beginning of the morning twilight [of the Equator], IM will be greater than the arc of occultation of the Sun at the beginning of the twilight of parallel IK. Therefore the Sun at point I will be farther below the horizon CD than at point B; and accordingly the Sun at I does not yet begin the twilight, but only when it reaches, for example, the point P. ^g Since, then, the arcs BA, IK are similar, fewer degrees will be comprehended in the twilight-arc PR than in the twilight-arc BA; and therefore the twilight of parallel IK will be smaller than the twilight of the Equator BA.

[Margin: ^f Spherical triangles [Triangula sphaerica], 40.] [Margin: ^g *Spherics* II.13 (Theodosius).]

LASTLY: ^h because again, as the sine of arc ED is to the sine of arc BD, so the sine of arc EO is to the sine of arc BL. But the sine of arc ED is smaller than the sine of arc BD, because it is smaller than the sine of arc GD, which is the same as the sine of arc BD. Therefore the sine of arc EO will also be smaller than the sine of arc BL, and hence arc EO will be smaller than arc BL. Since therefore BL is the arc of

occultation of the Sun at the beginning of the morning twilight of the Equator, EO will be smaller than the arc of occultation of the Sun at the beginning of the twilight of parallel EC; and accordingly the Sun at E will be less distant below the horizon CD than at B. Wherefore, with the Sun placed at E, the twilight will already have begun — namely when it is found at some point, for example Q. ⁱ Therefore, since the arcs BA, EC are similar, more degrees will be found in arc QC than in BA; and hence the twilight of parallel EC will be greater than the twilight of the Equator BA — which is what was proposed. Therefore the twilights, [decreasing] from the Equator, and so forth: which was to be demonstrated.

[Margin: ^h Spherical triangles [Triangula sphaerica], 40.] [Margin: ⁱ *Spherics* II.13 (Theodosius).]

COROLLARIVM.

Since, therefore, the twilight of parallel GH is equal to the twilight of the Equator AB, and greater than the twilight of any parallel IK between the Equator AB and the parallel GH, but smaller than the twilight of any parallel EC beyond GH, it follows that the least twilight is produced at some parallel between the Equator and the parallel GH. But which parallel that is, we shall inquire in Proposition 22; while in the following one, namely Proposition 21, we shall in fact examine the parallel GH, whose twilight we have shown to be equal to the twilight of the Equator.

SCHOLIVM.

This proposition can be demonstrated in another way, and perhaps more clearly, as follows. Let there be any oblique horizon DZ, the Equator AB, and the arc AB of the Equator's twilight, such that through B passes the parallel of twilights BG. Through B let another oblique horizon D a B L P G X be described — touching, that is, the greatest parallel of the ever-apparent stars, which the horizon DZ of the given region also touches — and cutting this horizon toward the northern parts at D, and the parallel of twilights BG at G. Let the parallel GH also be described through G; and on either side let other parallels PT, VZ, fE, LN be described, cutting the parallel of twilights BG at S, V, C, and O, so that the arcs of twilight are BA, ON, CE, ST, GH, VZ, inasmuch as they are intercepted between the horizon DZ and the parallel of twilights BG. ^k Since, then, the arcs BA, LN, fE, PT, GH, XZ are similar, because they lie between non-concurrent semicircles of the horizons DZ, DB, the twilight of parallel GH will be equal to the twilight of the Equator BA. But the twilight VZ will be greater than the twilight GH, or BA, since the arc VZ is greater than the arc XZ, which is similar to the arcs GH, BA. And finally the twilights ST, CE, ON will be smaller than the twilight of the Equator BA, since these arcs are smaller than the

arcs PT , fE , LN , which are similar to the arc BA . From which it is gathered that the twilights, from the Equator AB toward Capricorn [γ], decrease up to a certain parallel, then increase again up to the parallel GH — in which the twilight becomes equal to the twilight of the Equator — and thereafter always become greater, up to Capricorn, whose parallel is farther from the Equator than the parallel GH , as is evident from the calculation of the Sines.

[Margin: ^k *Spherics* II.13 (Theodosius).]

Diagram. A geometric figure enclosed in a rectangular ruled frame (the Scholium's alternative construction). Within the frame, a shallow bowl-shaped curve (the parallel of twilights BG) sweeps across, cut by a family of oblique lines (the horizons and parallels). Along the upper-left edge a row of points is marked left-to-right — Z , H , T , F , E , N , A , I — continuing to K , then D at the upper right with a small a beside it. Along the lower part run further points — Y , X , R and (toward the right) M , V , G , S , Q , O , L , B . The oblique lines are the horizon DZ , the oblique horizon $DABLPGX$, and the parallels PT , VZ , fE , LN cutting the twilight-parallel BG .

- Z (upper left): end of horizon DZ
- H , T , F , E , N , A , I (upper edge, left-to-right)
- K (upper, right of center)
- D (upper right), with a beside it
- Y , X , R (lower left)
- M , V , G , S , Q , O , L , B (lower, left-to-right toward the right) [several labels [?] — dense, small]

[Continuation of the preceding proposition — conclusion of Prop. XX]

And arc DBG is necessarily equal to arc DA , as was assumed in the proposition. For when arcs BK and GF are drawn perpendicular to DZ , [Margin (l): 40 of the Spherical Triangles] the sine of arc GD will be to the sine of arc BD as the sine of arc GF is to the sine of arc BK . Since, then, these two latter sines are equal — because their arcs are equal [Margin (m): Theodosius, *Spherics* II.13] — the two former sines will likewise be equal, and consequently the two arcs GD and BD will make up a semicircle. Therefore, since the two arcs DA and DB also make up a semicircle, as was shown in the proposition, arcs GD and AD will be equal.

PROPOSITIO XXI.

To find the point of the Ecliptic at which the Sun produces a twilight equal to the twilight of the Equator, for a given latitude of the place.

Let AB be, as in the figure above, the arc of the Equator that bounds the twilight, together with the two horizons AD and BD, which are similarly inclined to the Equator; and let arc GH of the parallel be the one that contains a twilight equal to the twilight of the Equator. Since arc AD is greater than a quadrant and BD less, let DR and DS be quadrants. Point S will fall between B and G — because arc DG is equal to DA itself, and therefore also greater than a quadrant — while point R will fall short of A. So, when the arc RS of a great circle has been described through points R and S, it will cut arc AB at some point, say T. Now since DR and DS are quadrants, [Margin (a): 25 of the Spherical Triangles] angles R and S will be right; [Margin (b): 6 of the Spherical Triangles] moreover the vertical angles ATR and BTS are equal, and so too are RAT and SBT. (For since angles DAB and DBF, being similar elevations of the Equator above the horizons, are equal, [Margin (c): 6 of the Spherical Triangles] and angle DBF equals its vertical angle TBS, angles RAT and SBT will also be equal.) Therefore arc RT will be equal to arc ST, arc AT to arc BT, and arc AR to arc BS. [Margin (d): 19 of the Spherical Triangles] And since the arc of the twilight AB is known, its half AT will also be known. This same twilight we shall likewise determine from the present figure. [Margin (e): 14 of this book]

When arc BL — the Sun's occultation — has been drawn perpendicular to AD at the start of the equatorial twilight, [proceed thus:]

As the whole sine (radius) is to the secant of the complement of angle BAL (the altitude of the Equator), so the sine of arc BL (the Sun's occultation) is to a fourth term.

For the product obtained will give the sine of the base AB, which measures the twilight of the Equator, and hence arc AB, the twilight, will become known.

[Margin (f): Problem 14 of the Spherical Triangles] Now let it be done in the right triangle ART:

As the whole sine of the right angle R is to the sine of the base AT (half the twilight of the Equator), so the sine of angle A (the altitude of the Equator) is to a fourth term.

The sine of arc RT will be produced, and hence from the table of sines arc RT will become known, and from this its double RS. [Margin (g): 40 of the Spherical Triangles] Again, let it be done:

As the sine of the arc RS just found is to the sine of the arc of occultation BL, so the whole sine of the quadrant SD is to a fourth term.

The sine of arc BD will be found, and hence arc BD will become known; and once this is subtracted [from the semicircle], arc GD is known; from which, if the arc BD just found is again taken away, the remaining arc BG [will be known]. But we shall find it more briefly — even if neither arc RS is known, nor arc BL drawn — in this way. After it has been proved that the arc of the equatorial twilight AB is bisected at T, [Margin (h): Problem 9 of the Spherical Triangles] let it be done:

As the whole sine is to the sine of the complement of angle SBT — that is, to the sine of the pole's altitude — so the tangent of arc BT (half the arc of the equatorial twilight) is to a fourth term.

For the tangent of arc BS will be generated; and once this is known from the table of tangents, and subtracted from the quadrant SD, arc GD will be left known; [Margin (i): Theodosius, *Spherics* II.11] and from it, if BD is taken away, the remaining arc BG will be known, as before. Since arc BG is equal to arc AH, the rising amplitude of parallel GH, this rising amplitude will be known: $16^{\circ} 34'$. [Margin (k): 17 of this book] From it the declination of parallel GH will be found, [Margin (l): 15 of this book] and from this declination the corresponding point of the Ecliptic — which is what was proposed.

Moreover, point S bisects arc BG, the rising amplitude. For since arcs DA and DG are equal, if the equal quadrants DR and DS are subtracted, the remainders AR and SG are equal. And since AR was shown equal to BS, BS and SG are also equal. Hence, if the arc BS once found is doubled, the rising amplitude BG is immediately produced.

At Rome, where the pole's altitude is 42° — where we write this — a twilight equal to the twilight of the Equator is found when the Sun is at about $2^{\circ} 20'$ of Scorpio [?], on 26 October, and likewise when the Sun is at about $27^{\circ} 40'$ of Aquarius, on 17 February. The twilight itself comprises 1 hour 38 minutes [?]. Therefore we have found the point of the Ecliptic at which the Sun [produces such a twilight], and so on — which was to be done.

Diagram. The upper figure ("the figure above") for Proposition XXI, showing the two horizons and the great-circle arc RS cutting the equatorial-twilight arc.

Readable labels, by position:

- H (top of the curve): endpoint of the parallel arc GH
- A (below H): intersection point on the horizon
- T (center): where arc RS cuts arc AB
- R, L (to the right of T): R the near-pole point, L the foot of arc BL
- G [?] (far left; printed as a small "q"-like glyph): endpoint of the parallel
- S (lower left): the far quadrant point
- E, P [?] (bottom left): points on the lower arc
- D (lower right): the pole / intersection of the two circles

[Two labels flagged uncertain (G/q, E/P).]

Diagram. The lower figure for the alternative method of Proposition XXI (the same construction reused in Prop. XXII). Readable labels, by position:

- C, G [?] (printed "q"), H, F, A, R, M, L: points along the upper curve, left to right
- D (right); a (small, just left of D): the pole and an adjacent point
- E, S, I, B (bottom, left to right): points on the lower arc
- T (center): the bisection point

[One label flagged uncertain (G/q).]

SCHOLIVM

And since, at every elevation of the pole, the rising amplitude AH of parallel GH is less than the rising amplitude of the tropic of Capricorn, and its declination likewise less — as is established from the doctrine of sines — we conclude that a twilight equal to the Equator's is produced between the Equator and the tropic of Capricorn; and consequently that the twilight of Capricorn is greater than the twilight of the Equator, and that the shortest twilight is produced between the Equator and parallel GH — since the twilight of parallel GH is greater than the twilights of the parallels lying between parallels GH and BA, as was shown in the aforesaid proposition. [Margin: The twilight in Capricorn is greater than the twilight at the Equator.]

PROPOSITIO XXII.

To seek the point of the Ecliptic at which the Sun produces the shortest twilight, and at the same time to determine the magnitude of that twilight.

Let AB be the arc of the Equator; CAD the oblique horizon; SG the parallel on which the shortest twilight is produced; and let arc AB of the Equator be the measure of the shortest twilight. [Margin (a): Theodosius, *Spherics* II.15] Through B let another circle be described — the greatest of the always-apparent circles, EBD — tangent to the parallel of the always-apparent [stars], which CAD also touches; [Margin (b): Theodosius, *Spherics* II.13] and let these two tangent circles cut one another at D, toward the north. Now since arcs AB and SG are similar, we posit that arc SG too will be the magnitude of the same twilight. And arc DS will necessarily be a quadrant, which I demonstrate thus. When two other parallels EC and IH have been described, beyond and short of parallel SG, let there be drawn from points B, I, S, E below the horizon, up to the horizon CAD itself, the arcs of the verticals BL, IM, SR, EF, perpendicular to that same horizon. SR will be the arc of the Sun's occultation below the horizon at the start of the shortest morning twilight — that is, 18°; while the other arcs BL, IM, EF will measure the Sun's distances below the horizon when it is at points B, I, E. Therefore, since SG is posited as the shortest twilight, arcs BA, IH, EC (being similar to arc SG) [Margin (c): Theodosius, *Spherics* II.13] measure the same least twilight; and they are consequently smaller than the arcs of those parallels' twilights, whose twilights will begin before the Sun reaches points B, I, E — being smaller than the arcs of the Sun's occultation below the horizon, that is, smaller than arc SR. [Margin (d): 40 of the Spherical Triangles] Now since the sine of arc SR is to the sine of arc IM as the sine of arc SD is to the sine of arc ID, and likewise the sine of arc SR is to the sine of arc EF as the sine of arc SD is to the sine of arc ED; and since the sine of arc SR is greater than both the sine of arc IM and the sine of arc EF (because these arcs were shown to be smaller, being less than a quadrant), the sine of arc SD will also be greater than both the sine of arc ID and the sine of arc ED. By the same reasoning the sine of arc SD will be shown greater than the sine of any parallel collateral to SG itself. Since, therefore, the sine of arc SD is greater than the sine of any other arc, arc SD is a quadrant. For only the sine of a quadrant is greater than the sine of any other arc, whether greater or less than a quadrant. [Margin (e): Theodosius, *Spherics* II.15 / II.1]

Since, then, arc DS is a quadrant, D will be the pole of the great circle SR, perpendicular to CD; [Margin (e): Theodosius, *Spherics* I.15] and therefore angle DSR will be right; [Margin (f): 25 of the Spherical Triangles] and consequently DR

too will be a quadrant, and, since DA has been shown greater than a quadrant, point R falls between D and A. Therefore, as in the preceding proposition, both arcs AT, TB and arcs RT, TS will be shown equal to one another. [Margin (g): Problem 14 of the Spherical Triangles — *The magnitude of the least twilight*] And if we then form:

As the whole sine is to the secant of the complement of angle RAT (the altitude of the Equator) — that is, to the secant of the pole's altitude — so the sine of arc RT (half the arc of the Sun's occultation RS) is to a fourth term.

the sine of the base AT will be produced. Therefore arc AT itself, and hence its double AB, will not be unknown; and thus the magnitude of the shortest twilight AB (or GS) will be known. [Margin (h): Problem 10 of the Spherical Triangles] And if again we form:

As the whole sine is to the tangent of the complement of angle RAT (the altitude of the Equator), so the tangent of arc RT (half of 18°) is to a fourth term.

the sine [?] of arc AR will be found, [Margin (i): Theodosius, *Spherics* II.13] and therefore arc AR, or its equal BS, will be known. And since arcs BS and AG are equal — AG being the rising amplitude — the rising amplitude itself will be known: $8^\circ 12'$. [Margin (k): 17 of this book] From it the declination of parallel SG [will be found], [Margin (l): 15 of this book] and from this the corresponding point of the Ecliptic. At Rome, where the pole's altitude is 42° , the shortest twilight occurs on about 13 October, at Libra $19^\circ 10'$, and likewise on 2 March, at Pisces $10^\circ 50'$. The twilight itself comprises 1 hour 37 minutes. Therefore we have sought the point of the Ecliptic at which the Sun produces the shortest twilight, and so on — which was to be done.

Diagram. The figure for Proposition XXII — the same construction as fig-p283-2, showing the oblique horizon, the always-apparent circle, and the parallels EC, SG, IH. Readable labels, by position:

- C, G [?] (printed "q"), H, F, A, R, M, L: points along the upper curve, left to right
- D (right); a (small, adjacent to D): the pole and an adjacent point
- E, S, I, B (bottom, left to right): points on the lower arc
- T (center): the bisection point

[One label flagged uncertain (G/q).]

SCHOLIUM

You see clearly that, in order to find the point of the Ecliptic of the shortest twilight, there is no need first to investigate the length of the twilight itself. Moreover, that the shortest twilight is produced on parallel GS — when arc DS in the second horizon of this proposition's figure is a quadrant — we shall demonstrate in this way as well. In the figure of the scholium of Proposition 20, let a horizon aCY be understood as described, tangent to the same greatest circle of the always-apparent [stars] and to the parallel of twilights BCG, at C; and let parallels be described, as there. It is now manifest that the twilight of parallel CE is the least of all: [Margin (m): Theodosius, *Spherics* II.13] since the arcs dA, MN, CE, RT, bH, YZ — lying between the non-concurrent semicircles of the horizons — are similar; and the arcs of the twilights BA, ON, ST, GH, VZ are greater than the arcs dA, MN, CE, RT, bH, YZ, so that the twilights of the parallels beyond and short of parallel CE are greater than the twilight of parallel CE.

Diagram. The large rectangular-framed figure (the reused figure of the scholium of Prop. 20), showing the two horizon-semicircles, the several parallels of twilight, and the verticals. Readable labels, by position:

- Along the upper curve (left to right): Z, H [?], T, F, E, N, A, I, K
- Upper right: D, a [?]
- Along the lower arc (left to right): Y, X, V, G, S, R, C, M, d, L, B
- Center: T; a small l [?] near R

[Multiple peripheral labels flagged uncertain (H, a, l, and several tightly-set lower-arc letters)]

That arc AC is a quadrant, I demonstrate thus. When through C the arc CI has been drawn through the pole of the circles DZ, BCG: since the circles aC and BC touch one another at C, and the circle CI is drawn through the poles of circle BC, [Margin (n): Theodosius, *Spherics* II.5] the same circle CI will also pass through the poles of circle aC. Since, then, it is also drawn through the poles of circle DZ, [Margin (o): Theodosius, *Spherics* II.9] it will cut the segments of circles DZ and aCY in half. [Margin (p): Theodosius, *Spherics* II.11] Therefore, since these segments are semicircles, aI and aC will be quadrants; and consequently the rising amplitude EA of parallel CE, on which the least twilight occurs, will be found from the doctrine of sines, as was stated in the proposition.

PROPOSITIO XXIII.

To observe the length of twilight on any given day in one's own horizon.

At the start of morning twilight or the end of evening twilight — and this beginning or end must be observed most exactly, under a clear sky — let the altitude of any star be taken, and its declination sought from Canon 3 of Book 3 of the *Astrolabe* and its scholium, together with its right ascension by Canon 4 of the same book and its scholium. Next, from Canon 8 and its scholium, let the distance of that same star from the meridian be determined, and through it the hour then instant — that is, the distance of the Sun from the meridian at the beginning or end of the twilight. For if from this distance the semidiurnal arc of that day is subtracted, the remainder will be the length of the twilight. Thus we have observed the length of twilight on any given day in one's own horizon — which was to be done.

SCHOLIUM

Pedro Nunes [Petrus Nonius] says that at Lisbon, where the pole's altitude comes to $38^{\circ} 40'$, he observed the evening twilight in the year 1541, on 1 October, with the Sun at Libra 18° , and found it to be 1 hour 22 minutes 24 seconds. But the same, computed by Proposition 14 of this book, comes to 1 hour 33 minutes. This discrepancy arises either because he assumed a greater or lesser declination of Regulus (the Heart of the Lion) [cor α] — the star he used in that observation — and a right ascension [different from] the one we establish in the scholium of Proposition 11 of Book 2 of the *Astrolabe*, and so did not find the true hour; or because it is exceedingly difficult to observe accurately the start of morning twilight or the end of evening twilight — for who could detect the first instant of the one, or the last of the other, without error? — from which error the twilight is necessarily not rightly found; or, finally, because perhaps the distance of 18° below the horizon, which we adopt in computing twilights, is too great, as he himself admits he found.

PROPOSITIO XXIV.

From a given length of twilight, to derive the distance of the Sun below the Horizon.

Since the occultation of the Sun below the horizon at the start of morning twilight, or at the end of evening twilight, is not fixed the same way by all writers — for we determine it at 18° , others set it somewhat greater, and others less; indeed, as Johannes de Sacrobosco [Ioan. de Sacrobosco] asserts, when he treats of those who dwell under the Arctic pole, some affirm it to contain 30° , which nevertheless is by no means credible — we shall here prescribe a method by which anyone, once he has observed the length of twilight with the utmost care (as we set out in the preceding proposition), may come to know this distance. Let the figure of Proposition 14 therefore be repeated, in which [Margin (a): Euclid VI.2 or VI.4] FN, the whole sine, stands thus [to ...]

(Continuing the proof of Proposition XXIV of the Digression on Twilights, begun on the preceding page.)

the whole sine is to EX — the versed sine of the arc FY, which is compounded of the semidiurnal arc FZ and the given twilight arc ZY (this arc will be known if the given length of the twilight is added to the semidiurnal arc, from which its versed sine is then to be obtained, as we taught in the [chapter] on sines) — so is FO, half the sum of the sine of the meridian altitude and the sine of the meridian depression, to Fe, the line compounded of the sine of the meridian altitude and the sine of the Sun's occultation. And so, if we set up the proportion:

As the whole sine — is to the versed sine of the arc compounded of the semidiurnal arc and the twilight arc: — so is half the sum, [taken] from the sine of the meridian altitude and of the meridian depression, — to another [line],

there will be produced the line Fe, compounded of the sine of the meridian altitude and the sine of the Sun's occultation. If from this the sine of the meridian altitude FP is subtracted, the remainder becomes the sine Pe, that of the occultation; and accordingly the arc belonging to it, drawn out from the table of sines, becomes known — namely, the arc of the Sun's occultation beneath the horizon at the beginning of the morning twilight, or the end of the evening twilight. Therefore, from the given length of the twilight, we have obtained the Sun's distance below the horizon — which was to be done.

Diagram. The upper of two nearly identical geometric figures for the twilight construction. A great circle (the meridian / vertical circle) is drawn with a horizontal diameter through the center E and several inscribed chords and perpendiculars representing the horizon, the equator, the parallel of the Sun's

declination, and the Sun's positions at the meridian, at rising, and at the end of twilight. The construction is crowded with interior points. Readable labels:

- F (on the circumference, upper)
- A (circumference, upper left)
- H, K (left, ends of horizontal chords)
- R, S (interior, left of center)
- O, P, e (interior, near center)
- N, M (interior, center)
- E (center)
- T, V, x (interior, lower center)
- Q (circumference, lower left)
- B (circumference, bottom, marked with a star)
- a, b, f (circumference, top, small letters)
- D (circumference, upper right, marked with a star)
- z, Y (circumference, right)
- C (circumference, lower right)
- [several further interior labels are too crowded to resolve]

Diagram. The lower figure, essentially a repetition of the same twilight construction with the same great circle, diameters, and inscribed chords. Readable labels:

- A, b, a (circumference, top)
- F (circumference, upper left)
- D (circumference, upper right, marked with a star); d (circumference, right)
- E (center)
- H, K (left)
- R, P, S (interior, left of center)
- M, N, X (interior, center)
- T, V (interior, lower center)
- I, L (right, ends of horizontal chords)
- C (circumference, lower right); q (circumference, bottom)
- Z (left); f, Y (circumference, lower left); B (circumference, bottom)
- [several further interior labels are too crowded to resolve]

SCHOLIUM

[Pedro Nunes], from the twilight found in the preceding proposition, determined that this distance amounts to only $16^{\circ} 2'$. Whether that is true, let others judge; for my part I dare neither affirm nor deny it. It will therefore be worthwhile for anyone — whenever he finds a free and unobstructed horizon and a clear sky — to observe carefully, from some elevated spot, the end of the evening twilight, so that he may learn its magnitude, as was set out in the preceding proposition; and then, from this proposition, to gather the Sun's distance below the horizon at the moment when either the morning twilight begins or the evening twilight ends.

Finally, so that this little book may be complete in every respect, I have thought it well to append the following table of the quantity of the twilights. These values were carefully and diligently computed, for various elevations of the pole, by Marcello Francolino [Marcello Francolini], Doctor of Both Laws [I.V. Doctore] and once my pupil in mathematics, in his work *On the Time of the Canonical Hours* [*De Tempore Horarum Canoniarum*], taking the arc of the Sun's occultation below the horizon to be 18° . In this table it plainly appears that the twilight [of any region — symbol $\mathfrak{h}$ (?)] is always greater than the twilight at the Equator. Moreover, wherever neither hours nor minutes are entered in the table, you should conclude that there is twilight all night long in that place.

You should not be surprised, however, that in the following table many consecutive twilights are equal — especially in the southern signs. For since one twilight differs so little from the next that the difference does not amount to one minute or two, no inequality of minutes can show up among those twilights. But if, besides minutes, account were also taken of seconds and thirds, then at last each twilight would always be found to differ from the next, as the geometrical demonstration requires.

THERE FOLLOWS THE TABLE OF TWILIGHTS.

The quantity of the twilights in the northern signs [Crepusculorum quantitas in signis Borealibus]

Format note. The full twilight table runs across three panels (pole-elevations 35° – 43° , 44° – 52° , and 53° – 61°). Each panel is entered from either side: the **left argument** is the Sun's ecliptic place (G = degree within the sign, S = sign), for the ascending signs Aries → Gemini; the **right argument** ("Altitudo": S = sign, G = degree) gives the complementary descending signs Virgo → Cancer that share the same declination. The numeric column-heads (35, 36, ..., 61) are the **elevations of**

the pole (latitudes) in degrees; the printed left-hand super-header over the argument column reads "Poli." Each latitude cell is the twilight duration in **hours : minutes** (the source prints H and M in separate sub-columns; here merged). A cell printed **0:0** marks perpetual (all-night) twilight — the source leaves neither hours nor minutes.

Panel 1 — Pole-elevations 35°–61°: latitudes 35°–43°

Commentary on Chapter III of the Sphere of Sacrobosco

Table caption (verbatim): *Crepusculorum Quantitas in signis Australibus.* — "The quantity of the twilights, in the southern signs."

Table structure. This is the symmetric twilight table of Marcello Francolini [Marcello Francolini]. The deck (column-group) headers **35–61** are the pole elevations in degrees (*Altitudo Poli*); each carries an **H.** (hours) and **M.** (minutes) sub-column. The **argument is the Sun's ecliptic place**, read from *both* ends: the left frame gives (sign, degree) descending through **Libra → Scorpius → Sagittarius**; the right frame (*Altitudo*, sign + degree) gives the complementary reading **Pisces → Aquarius → Capricornus** (each right-hand row has the same solar declination as its left-hand row). Boundary rows (a sign's 0°/30°) are shared. Values are twilight duration in hours:minutes; minutes are zero-padded here for column alignment (the print sets them unpadded, e.g. "2 | 4" = 2:04).

Two deck-panels appear on this page: 35°–43° (upper) and 44°–52° (lower).

Panel 1 — pole elevations 35°–43°

Sagittarius	1	1:3	1:3	1:37	1:3	1:4	1:4	1:4	1:4	1:4	1	Capricornu
	2	5	6		9	0	2	3	5	7	8	s
Sagittarius	1	1:3	1:3	1:37	1:3	1:4	1:4	1:4	1:4	1:4	1	Capricornu
	5	5	6		9	0	2	4	5	8	5	s
Sagittarius	1	1:3	1:3	1:37	1:3	1:4	1:4	1:4	1:4	1:4	1	Capricornu
	8	5	6		9	1	2	4	6	8	2	s
Sagittarius	2	1:3	1:3	1:38	1:3	1:4	1:4	1:4	1:4	1:4	9	Capricornu
	1	5	7		9	1	2	4	6	8		s
Sagittarius	2	1:3	1:3	1:48 △	1:4	1:4	1:4	1:4	1:4	1:4	6	Capricornu
	4	5	7		0	1	3	4	6	8		s
Sagittarius	2	1:3	1:3	1:48 △	1:4	1:4	1:4	1:4	1:4	1:4	3	Capricornu
	7	5	7		0	1	3	5	6	8		s
Sagittarius	3	1:3	1:3	1:48 △	1:4	1:4	1:4	1:4	1:4	1:4	0	Capricornu
	0	5	7		0	1	3	5	6	8		s

△ = printed value flagged as a numerical impossible. In the 37° column, the last three Sagittarius rows are printed **1:48**, which breaks the column's monotone rise (the 36° neighbour is 1:37 and the 38° neighbour is 1:40); almost certainly a compositor error for **1:38** (a "4" set for a "3").

Panel 2 — pole elevations 44°–52°

On the Diversity of the Artificial Days and Nights throughout All Places of the Earth

(*DE DIVERSITATE DIERVM & noctium artificialium per omnia terræ loca.*)

[Margin: *Proprietates eorum, quorum Zenith in Aequinoctiali circulo est.* — "The properties of those whose zenith is on the equinoctial circle."]

It should be noted, further, that for those whose zenith lies on the equinoctial circle, the Sun passes twice a year through the zenith of their heads — namely when it is at the beginning of Aries and at the beginning of Libra. At those times

they have two "high" solstices, since the Sun passes directly over their heads. They likewise have two "low" solstices, when the Sun is at the first points of Cancer and Capricorn; these are called "low" because the Sun is then at its greatest remove from the zenith of their heads. From what has been said it is clear that, since they always have equinox, they will have four solstices in the year — two high and two low. It is also clear that they have two summers, namely when the Sun stands at one or the other of the equinoctial points, or near them; and likewise two winters, namely when the Sun is at the first points of Cancer and Capricorn, or near them. And this is what al-Farghānī [Alphraganus] means when he says that summer and winter — our summer and winter, that is — are for them of one and the same character; for the two seasons that are summer and winter to us are two winters to them. Hence the explanation of the verses of Lucan is made plain:

Deprehensum est hunc esse locum, qua circulus alti Solstitij medium signorum percutit orbem.

"It has been found that this is the place where the circle of the high solstice strikes the middle of the orb of the signs." (Lucan [Lucan])

For there Lucan calls the circle of the high solstice the "equinoctial," on which the two high solstices occur for those who live under the equator. By "the orb of the signs" he means the zodiac, which the equinoctial "runs through the middle" — that is, divides — into two equal halves. They also happen to have four shadows in the year. For when the Sun is at one or the other of the equinoctial points, then in the morning their shadow is cast toward the west, and in the evening the reverse; but at midday their shadow is perpendicular, since the Sun is directly over their head. When, however, the Sun is in the northern signs, their shadow is cast toward the south; and when it is in the southern signs, it is cast toward the north. For them, moreover, the stars that lie near the poles both rise and set, as they do also for certain others who live around the equator. Hence Lucan speaks thus:

Tunc furor extremos mouit Romanus Horestas, Carmanosque duces, quorum iam flexus in Austrum Æther non totam, mergi tamen aspicit Arcton,

"Then Roman fury stirred up the far-off Orestae [Horestas] and the Carmanian chieftains, whose sky, now bent toward the south, does not see the whole Bear [Arcton], yet does see it dip below the horizon..." (Lucan, *Pharsalia* III)

the Sun most closely approaches their zenith — just as we too are accustomed to call the high solstice the *summer* solstice, because the Sun is then at its highest on the meridian above the horizon. They likewise have two *low* solstices, namely when the Sun is at the tropics, because then the Sun is most removed from the vertex of their head — just as we usually call the winter [brumal] solstice the *low* one, since the Sun then recedes farthest from us. But if we take "solstice" in its strict sense, that is, for the turning-back of the Sun (since at those points the Sun does not appear to change its declination from the equator), they will have only two low solstices, when the Sun is at the tropics — of which one is high for us and the other low. As for the verses of [Lucan] adduced to prove two *high* solstices, they are beside the point, since the circle of the high solstice is called by Lucan the Tropic of Cancer, as we said above when treating of the rising and setting of the signs in the right sphere.

III. They have a perpetual equinox.

IV. They have two summers in the year, and as many winters — provided "summer" denotes an excess of heat and "winter" a slackening of heat. The summers occur when the Sun is on the equator, the winters when it holds the tropical points. Hence, says [al-Farghānī] (Differentia 6), the difference is this: that our summer and winter are, for them, of one and the same character, because our summer is for them likewise a winter. By the same reasoning we might say that they have a double spring and a double autumn, namely in the seasons intermediate between the summers and the winters.

V. They have four kinds of shadow: one toward the west, when the Sun rises; a second toward the east, when the Sun sets; a third at midday toward the south [Auster], while the Sun is in the northern signs; and a fourth at midday toward the north, when the Sun holds the southern signs. But when the Sun is on the equator, they cast no shadow at all at midday.

VI. All the stars and all the points of the heaven, except the poles, rise and set for them — because their horizon cuts all the parallels described for the primary motion, since it passes through the poles themselves. All this is plain on the material sphere. As for the verses that he adduces from the poets on this matter, how much force they have and how aptly and fittingly they are brought in here, let others judge.

[Margin: Properties of those whose zenith is between the equinoctial and the Tropic of Cancer.]

[Lemma — Sacrobosco:] But for those whose zenith is between the equinoctial and the Tropic of Cancer, it happens twice in the year that the Sun passes through the zenith of their head. This is shown as follows. Let a circle be conceived parallel to the equinoctial, passing through the zenith of their head. That circle will intersect the zodiac in two places equidistant from the beginning of Cancer. Therefore the Sun, when it is at those two points, passes through the zenith of their head. Hence they have two summers and two winters, four solstices, and four shadows, just like those who dwell under the equinoctial. And in such a situation some say Arabia lies. Whence Lucan, speaking of the Arabs coming to Rome to aid Pompey, says:

You Arabs, you came into a world unknown to you, marveling that the shadows of the groves did not fall to the left.

[Lemma continues:] For in their own regions the shadows were sometimes to their right, sometimes to their left, sometimes perpendicular, sometimes eastern, sometimes western. But when they came to Rome, on the near side of the Tropic of Cancer, they always had northern shadows.

COMMENTARIVS

The second location is that of those whose zenith is between the equinoctial circle and the Tropic of Cancer. To these he assigns four properties.

I. Twice in the year they have the Sun above the zenith of their head.

II. They have two summers and two winters; but one winter is colder than the other, namely the one in which the Sun is farther removed from their vertex — which happens when the Sun is in Capricorn.

III. They also have four solstices, two high and two low.

IV. They likewise have a fourfold shadow, like those who dwell under the equator. Add to this that they have an inequality of days and nights throughout the whole year, except on the days at the time of the equinox; and also that not all the stars, or points of the heaven, rise and set for them — as is clearly seen on the material sphere. As for his statement that Arabia, according to some, is placed in this situation, this must be understood of Arabia Felix, for this, for the greater part, lies between the equator and the Tropic of Cancer.

[Margin: Properties of those whose zenith is on the Tropic of Cancer.]

[Lemma — Sacrobosco:] For those, indeed, whose zenith is on the Tropic of Cancer, it happens that the Sun passes once in the year through the zenith of

their head — namely when it is in the first point of Cancer; and then, in one hour of one day of the whole year, they have a perpendicular shadow. In such a situation the city of Syene is said to lie. Whence Lucan:

...with Syene nowhere bending the shadows.

[Lemma continues:] Understand this of midday, that is, of a single day — a day whose shadow in the morning is thrown to the west and in the evening to the east — while through the remainder of the whole year a northern shadow is cast for them.

COMMENTARIUS

The third location is that of those whose zenith is directly on the Tropic of Cancer. To these he ascribes two properties.

I. Once in the year the Sun passes over the vertex of their head, namely when it is at the beginning of Cancer.

II. They possess three kinds of shadow: an eastern one in the evening, a western one in the morning, and a northern one at midday — though when the Sun is at the beginning of Cancer they have no shadow at all at midday. In such a situation is said to be the Egyptian city of Syene, where, on the authority of [Pliny], the astronomers built a very deep well, in which, when the Sun is at the beginning of Cancer, no shadow is seen, but the whole is lit by the Sun. To these we may add that they have an inequality of days, except at the equinoxes; that they have only two solstices, one high, the other low; that they have one summer and one winter; and finally, that not all the points of the heaven rise and set for them. All of which is plain on the material sphere.

[Margin: Properties of those whose zenith is between the Tropic of Cancer [?] and the arctic circle [remainder of gloss abraded — ?].]

[Lemma — Sacrobosco:] But for those whose zenith is between the Tropic of Cancer and the arctic circle, it happens that the Sun never at any time passes through the zenith of their head, and a shadow is always cast for them toward the north. Such is our own situation. Note also that Ethiopia, or some part of it, lies on the near side of the Tropic of Cancer, according to some. Whence Lucan:

...and the land of the Ethiopians, which would be pressed by no region of the sign-bearing pole [the zodiac], did not, with its knee sunk down, the outermost hoof of the bent Bull [Taurus] jut forward.

[*Lemma continues:*] For some say that "sign" is here taken equivocally — for the twelfth part of the zodiac, and for the figure of the animal, which for the greater part of itself lies within the sign it names. Hence the Bull [Taurus], although it lies for the greater part of itself in the zodiac, nevertheless extends its foot beyond the Tropic of Cancer, and so presses upon Ethiopia, even though no part of the zodiac presses upon it. For if the Bull's foot, of which the poet speaks, were extended toward the equinoctial, so as to be directly over Aries or some other sign, then Ethiopia would be pressed by Aries or Virgo or other signs — as is evident from a circle drawn parallel to the equinoctial, carried around through the zenith of those Ethiopians' head, and through Aries and Virgo or other signs. But since physical reasoning is opposed to this (for they would not be so blackened, were they born in a temperate and habitable region), it must be said that the part of Ethiopia of which Lucan speaks lies under the equinoctial circle, and that the Bull's foot of which he speaks extends toward the equinoctial. A distinction must then be drawn between the *cardinal signs* and the *regions*. For the two signs in which the solstices occur and the two in which the equinoxes occur are called cardinal signs, while the intermediate signs are called regions. And on this understanding it is clear that, since Ethiopia lies under the equinoctial, it is pressed by no region, but only by the two cardinal signs, namely Aries and Libra.

COMMENTARIUS

The fourth location is that of those whose vertex is placed between the Tropic of Cancer and the arctic circle. To these too he assigns two properties.

I. They never have the Sun over the vertex of their head.

II. They have three kinds of shadow, like those who dwell in the preceding situation, with this one difference: that they never have a perpendicular shadow. In this situation, he says, some have supposed Ethiopia to be placed, which they proved from Lucan. But he himself refutes this, explaining Lucan otherwise, as is clear from the text. Yet whatever the truth about Lucan, it is certain that a great part of Ethiopia lies under the equinoctial circle. How fitting our author's exposition is, let others judge — for by many, and especially by [Scaliger] in his *Poetice*, Lucan is censured. It is nonetheless true, as the author says, that the Bull's hoof reaches out toward the equator. To these two properties one may add that those living in this situation of the earth have two solstices, one high, the other low; that they have one summer and one winter, and an inequality of days and nights; and that not all the stars rise and set for them.

[Margin: Properties of those whose zenith is on the arctic circle.]

[Lemma — Sacrobosco:] But for those whose zenith is on the arctic circle, it happens on any day and time of the year that the zenith of their head is the same as the pole of the zodiac; and then they have the zodiac, or ecliptic, for their horizon. And this is what [al-Farghānī] means when he says that there the circle of the zodiac is bent [flattened] over the circle of the hemisphere. But since the firmament is continually moved, the circle of the horizon will intersect the zodiac in an instant; and since they are great circles on the sphere, they will cut each other into equal parts. Hence at once one half of the zodiac emerges above the horizon and the other is suddenly depressed below it. And this is what [al-Farghānī] means when he says that there six signs set at once and the other six rise. Since the ecliptic is also their horizon, the whole Tropic of Cancer will be above the horizon and the whole Tropic of Capricorn below it; and so, when the Sun is at the first point of Cancer, they will have a single day of 24 hours and a night lasting scarcely an instant, because in an instant the Sun crosses the horizon and at once re-emerges, and that touching is for them a night. The reverse befalls them when the Sun is at the first point of Capricorn: for then they have a single night of 24 hours and a day lasting scarcely an instant.

COMMENTARIUS

The fifth location is that of those who have the vertex of their head precisely on the arctic circle, to whom he assigns a single property: namely that on any day of the year the vertex of their head becomes identical with the pole of the zodiac.

From this it follows that the zodiac then takes the role of the horizon; and therefore, virtually in the blink of an eye — as soon as the pole of the zodiac, by the motion of the primary mobile, has withdrawn from the vertex of the head — the zodiac and the horizon will cut each other mutually in two, since they are great circles, so that (as [al-Farghānī] says, *Differentia* 7) one half of the ecliptic rises at once — that is, six signs appear above the horizon — while the other half sets at once, that is, the remaining six signs are suddenly hidden and descend below the horizon. Hence too it comes about that the whole Tropic of Cancer stands above the horizon, while the Tropic of Capricorn, together with the beginning of Cancer and the beginning of Capricorn, touch and, as it were, graze the horizon. Therefore, when the Sun is at the beginning of Cancer, they will have a day of 24 hours and a night lasting scarcely an instant, because in an instant the Sun, as it were, crosses the horizon and at once re-emerges — indeed it never then perfectly sets, but merely touches the horizon. And when the Sun is at the beginning of Capricorn, for the same reason they will have a night of 24 hours

and a day lasting scarcely an instant. All of which is most clearly seen on the material sphere. Add that not all the stars rise and set for them.

[Margin: Properties of those whose zenith is between the arctic circle and the arctic pole of the world.]

[*Lemma — Sacrobosco:*] But for those whose zenith is between the arctic circle and the arctic pole of the world, it happens that their horizon intersects the zodiac in two points equidistant from the beginning of Cancer; and in the revolution of the firmament it happens that the portion of the zodiac intercepted [between them] is always left above the horizon. Hence it is clear that, as long as the Sun is in that intercepted portion, there will be one continuous day without night. Therefore, if that portion is of the extent of one sign, there will be a continuous day of one month without night; if of the extent of two signs, a continuous day of two months without night; and so on. Likewise it happens for them that the portion of the zodiac intercepted by two other points equidistant from the beginning of Capricorn is always left below the horizon. Hence, when the Sun is in that intercepted portion, there will be one continuous night without day, short or long according to the extent of the intercepted portion. As for the remaining signs, which rise and set for them, they rise and set in reverse order [praepostere]. They rise in reverse: as Taurus before Aries; Aries before Pisces; Pisces before Aquarius [and so on]; and yet the signs opposite to these rise in the correct order and set in reverse — as [Libra? ♎] before [Virgo? ♍] before [Leo? ♌] — these three zodiac glyphs abraded and only partly legible, ?] — while the signs opposite to these set directly, namely those which were rising in reverse, such as Taurus, and so on.

COMMENTARIVS

The sixth location is that of those who dwell between the arctic circle and the arctic pole of the world, to whom he assigns two properties.

I. The horizon cuts the zodiac each day in two points equally removed from the beginning of Cancer, and the portion intercepted between those two points never descends below the horizon by the motion of the primary mobile, but always remains in view. From this it follows that, while the Sun traverses that portion, there is a continuous day without night — so that if the portion were 30 degrees, that artificial day would be nearly 30 natural days. By the same reasoning, the zodiac will be cut by the horizon at two other points equally distant from the beginning of Capricorn, and the segment of the zodiac comprehended between those two points never rises above the horizon by the motion of the primary

mobile, but lies perpetually hidden, and is equal to the prior segment that is always in view. Hence, while the Sun traverses the said segment, they will have a continuous night without day — so that if that segment were 30 degrees, that night would be composed, as it were, of 30 natural days, and so on. This is made manifest on the material sphere, if it be so arranged that the solstitial colure coincides with the meridian, and Cancer be placed toward the arctic pole — that is, toward the north, above the horizon — and Capricorn toward the antarctic pole, that is, toward the south, below the horizon. For if a parallel be then conceived as drawn tangent to the ecliptic, the ecliptic will be cut in two points, which will intercept a non-setting arc; and this is manifest, if the position of the sphere is rightly conceived. And the said arc will be greater or smaller according as the beginning of Cancer is raised more or less above the horizon, when it has been placed on the meridian on the northern side.

[Margin: Which signs rise and set in reverse order.]

II. The remaining signs, which rise and set for them, rise and set in a reversed order [*praepostero ordine*] — that is, they do not rise and set in the order in which they rise and set in other parts of the world. So that whereas, for example, Aries always rises and sets before Taurus [*elsewhere*], the signs situated near the vernal equinox rise in reverse, that is, Taurus rises before Aries, and Aries before Pisces, and so on. But they set in the correct order, namely Pisces before Aries, and Aries before Taurus, and so on, as in other positions of the sphere. On the other hand, the signs situated near the autumnal equinox set in reverse, that is, Libra sets before Virgo, and Virgo before Leo, and so on. But they rise in the correct order, as in other positions of the sphere — that is, Leo before Virgo, and Virgo before Libra, and so on. All of which is plain on the material instrument. To these add also that not all the stars rise and set for them.

[Margin: How to inquire how great the continuous day is between the pole and the arctic circle.]

If you wish to know how great the continuous day, and likewise the night, is in the aforesaid place — where the vertex of the head is set between the arctic circle and the arctic pole — you will achieve this by the following method. Subtract the altitude of the pole (which will necessarily be greater than $66^{\circ} 30'$) from a quadrant, that is, from 90° ; and the remainder will be the declination of the beginning of the always-apparent arc. Then from the table of declinations you will easily find the beginning of that arc, whose midpoint lies between that beginning and the beginning of Cancer; and doubling this will give the whole perpetually conspicuous arc, while the arc opposite to it is perpetually hidden.

Having obtained the arc, you will easily know from the Sun's true motion how many natural days it takes to traverse it, and consequently you will have the length of the continuous day, and likewise of the continuous night. EXAMPLE. Where the arctic pole is elevated $69^{\circ} 48'$, I subtract this altitude of the pole from 90° , and there remains the declination of the beginning of the always-apparent arc, $20^{\circ} 12'$, to which in the table of declinations corresponds the beginning of Gemini, or the end of Cancer. Therefore the arc from the beginning of Gemini to the end of Cancer will always be apparent, and the arc from the beginning of Sagittarius [♐, ♐] to the end of Capricorn [♑, ♑] will be perpetually hidden, and so on. For greater convenience, however, I have appended the following little table from [Oronce Fine], in which you have the always-apparent arcs and the continuous days for each degree of the pole's altitude, beginning from 67° up to 90° .

The arcs that are always hidden are equal to the arcs that are always visible; but the continuous nights are not equal to the continuous days, because the Sun passes more quickly through the arcs near Capricorn [♑] than through those near Cancer [♋]. For at the present epoch the point opposite the apogee [Aux, the apogee] lies there [near Capricorn], while here [near Cancer] lies the apogee itself, as will be explained in the Theorics [of the Planets]. For this reason the continuous nights will be somewhat shorter than the continuous days. Understand this to hold where the Arctic pole is raised above the horizon; for where the Antarctic pole is seen above the horizon, then, for the reason just given, the continuous days will be shorter than the continuous nights, as is evident.

[Margin: That the continuous nights are not equal to the continuous days, and why.]

If anyone should wish to obtain the continuous nights more accurately, let him find out — whether from astronomical tables — in how many days and hours the Sun traverses the arcs that are always hidden, which of course are equal and opposite to the arcs that are always visible. This, however, is not strictly necessary, since it is enough to know the continuous nights approximately, especially as they differ little from the continuous days. Only near a pole elevation of 90 degrees is a discrepancy of several days observed. Therefore, so as to stray less from the truth, one may assign a single day to each degree of the arcs that are always hidden.

TABLE OF THE GREATEST DAYS, where the pole is elevated by more degrees than $66\frac{1}{2}$.

Elevation of the pole [Eleuatio poli] — G. (°)	Arc always visible [Arcus semper apparens] — G. (°)	M. (')	Continuous day [Dies continuus] — D. (days)	H. (hour s)	M. (min)
67	22	52	22	1	40
68	40	0	42	1	16
69	52	0	54	16	25
70	61	26	64	13	46
71	70	26	74	0	0
72	78	22	82	6	39
73	84	56	89	4	58
74	92	12	96	17	0

76	105	16	110	7	27
77	111	20	116	14	22
78	117	6	122	17	6
79	122	46	127	9	55
80	128	22	134	4	58
81	133	50	139	31 [?]	36
82	139	6	145	6	43
83	144	22	151	2	6
84	149	36	156	3	3
85	154	42	161	5	23
86	159	50	166	11	23
87	164	52	171	21	47
88	169	58	176	5	29
89	174	58	181	21	58
90	180	0	187	6	39

For those whose zenith falls at the Arctic pole, it happens that their horizon is the same as the equator [Aequinoctialis]. Hence, since the equator cuts the zodiac into two equal parts, so too their horizon leaves one half of the zodiac above itself and the other half below. And so, when the Sun runs through that half which reaches from the beginning of Aries to the end of Virgo, there will be one continuous day

without night; and when the Sun runs through the remaining half, which reaches from the beginning of Libra to the end of Pisces, there will be one continuous night without day. Therefore one half of the whole year is a single artificial day, and the other half is night; and so the whole year there is one natural day. But since the Sun there is never depressed more than 23 degrees below the horizon, it seems that they have a continuous day without night — for with us too it is called day before the rising of the Sun above the horizon. This, however, is as regards common perception. For it is not artificial day, as regards physical reasoning, except from the rising of the Sun to its setting below the horizon. To this point, then — that the light seems to be perpetual there (since it is day before the Sun is raised above the earth by 18 degrees, as Ptolemy says, though other teachers say 30, that is, by the extent of one sign) — it must be answered that the air there is cloudy and thick. For the Sun's ray, being there of weak power, raises more from the vapors than it can consume; and so it does not clear the air, and it is not day.

[Margin: The properties of those who have their zenith at the Arctic pole.]

COMMENTARY.

The seventh and last location is that of those who dwell under the Arctic pole, to whom he assigns one property: namely that in the whole year they have a single natural day — for half the year one artificial day, and for the remaining half of the year one artificial night. This is to be understood on the assumption that the Sun moves uniformly in the zodiac. For since it is carried more swiftly through the southern semicircle of the zodiac than through the northern — as is established from the Theorics of the Planets — the artificial day will be a little longer than 6 months, and the night somewhat shorter than 6 months. He then resolves a tacit objection. For since, according to Ptolemy and the more common opinion, day begins (including also twilight) when the Sun is 18 degrees below the horizon, and since the Sun there is never depressed more below the horizon than by $23\frac{1}{2}$ degrees — which is indeed the greatest declination of the Sun — it seems that the day there would be greater than the night in the whole year. For the common people call "day" the Sun's stay above the horizon together with the morning and evening twilight. The Author answers this difficulty: on account of the cloudy air existing there, and because of the weakness of the solar rays, which are nearly equidistant from the horizon, the twilights cannot be so bright as to render the air clear and make day. One could also reply — whatever be the case regarding the twilights (and in the earlier treatment we dealt with twilights, with the hiding of the Sun below the horizon at the beginning of the morning

twilight and the end of the evening twilight, namely by how many degrees the Sun is distant from the horizon at the beginning

of the morning twilight, or the end of the evening twilight: namely 18 degrees or thereabouts, but on no account 30) — that the astronomers speak of artificial day and night in the strict sense, that is, insofar as artificial day is the Sun's stay above the horizon. For on this reckoning it will be true that under the pole there is day for about half the year, and likewise night, as is clear from the material sphere. Add to this that not all the points of the heaven rise and set for them; rather, half of them is perpetually visible, while the other half lies hidden below the horizon.

[Margin: In what way the same properties are to be understood in the southern hemisphere [sphæra Australis].]

These same seven locations are to be conceived and understood also in the other half of the heaven, from the equator toward the southern pole. But everything that has been said in these regarding the northern signs is to be understood in those regarding the southern signs, and conversely.

On the Division of the Climes [DE DIVISIONE CLIMATVM]

Now let a certain circle be conceived on the surface of the earth, set directly beneath the equator. Let another circle also be understood on the surface of the earth, passing through the East and West and through the poles of the world. These two circles intersect each other in two places at right spherical angles, and they divide the whole earth into four quarters. One of these is our habitable quarter — namely that which is intercepted between the semicircle drawn from East to West on the surface of the equator, and the semicircle drawn from East to West through the Arctic pole. Yet not even that quarter is wholly habitable, since the parts of it near the equator are uninhabitable on account of excessive heat, and likewise the parts of it near the Arctic pole are uninhabitable on account of excessive cold. Let there be understood, therefore, one line equidistant from the equator, dividing the parts uninhabitable on account of heat from the habitable parts that lie toward the North. Let another line also be understood, equidistant from the Arctic pole, dividing the parts of the quarter that lie toward the North and are uninhabitable on account of cold from the parts that lie toward the equator. Between these two extreme lines let there be understood six lines parallel to the equator, which together with the two former ones divide the whole habitable part of the quarter into seven portions, which are called the seven climes [Climata].

COMMENTARY.

This is the fourth part of this chapter, in which the Author describes the climes of the world — for the reason that, when the clime is varied, there is also necessarily varied the rising and setting of the signs, as well as the length of the artificial days and nights. So, in order to make clear what he himself means by a "clime," he says that one must conceive a circle on the surface of the earth set directly beneath the equator; likewise another passing through the poles of the world and through the points of the East and West — understand, the absolute East and West, that is, through the Canary Islands, which mark the West, and through the point which, eastward from them on the same parallel, is 180 degrees distant; for this marks the East. For so great did the length of the habitable earth appear to the ancients, as may be seen in Ptolemy. By these two circles the whole surface of the earth is divided into four quadrants, of which one is this our habitable one — namely that which is contained by a semicircle of the equator and another northern semicircle, described through the East, the West, and the Arctic pole. Not that, as the Author says, this whole quadrant is inhabited — for he says this is false, since both the part near the equator, on account of excessive heat, and the part near the Arctic pole, on account of excessive cold, cannot be inhabited. Hence he adds that a line must be conceived equidistant from the equator, which separates the part uninhabitable on account of heat from the part habitable toward the North. By parallel reasoning, another line must be conceived equidistant from the equator, or equally removed from the Arctic pole, which separates the part uninhabitable on account of cold from the part habitable toward the South. For only the part of the earth's quadrant comprised between the said two lines is inhabited. And if between these two parallel lines six other parallels be drawn, the whole habitable part of the earth will be divided into seven parts, which are called the seven climes of the world. How far one line ought to be distant from another, in order that the climes may be constituted, will be evident from what follows.

A clime is defined as just so much space of the earth as suffices for the day-measure [horologium — the length of daylight as read from the clock or sundial] to vary perceptibly. For one and the same summer day, of some length, which occurs in one region, is perceptibly shorter in a region nearer the South. The space, then, so great as that within which the same day begins to vary perceptibly, is called a clime. Nor is the same day-measure found at the beginning and at the end of this space; for the hours of the day vary perceptibly, and hence the day-measure too.

[Margin: What a clime is.]

COMMENTARY.

He now teaches more clearly how much space, interposed between two parallel lines, there ought to be for a clime to be constituted, saying that a clime is just so much space on the surface of the earth within which the summer day — namely the longest — notably varies, that is, by half an hour. So that a clime is nothing other than a certain space of the temperate and habitable zone, between whose beginning and end (proceeding from the pole to the equator, and conversely) the length of the greatest summer day, or of the winter night, is increased or diminished by half an hour — so that if, for example, the longest day at the beginning of some clime toward the South contains 15 hours, at the end toward the pole it comprises 15½ hours. But if we do not wish to take account of the temperate zone, a clime may be said in general to be a space of the earth comprised between two parallels within which the longest day either increases or decreases by half an hour. On this reckoning more climes will have to be constituted than seven, as we shall shortly say.

The middle of the first clime, then, is where the length of the longer day is 13 hours, and the pole of the world is raised above the circle of the hemisphere by 16 degrees and two thirds of one; and it is called the clime dia Meroes [Greek: διὰ, "through" — through Meroe]. Its beginning is where the length of the longer day is 12 hours and a half and a quarter of one hour, and the pole is raised above the horizon by 12 degrees and a half and a quarter of one degree. And it extends up to the place where the length of the longer day is 13 hours and a quarter of one hour, and the pole is raised above the horizon by 20 degrees and a half; and this space of earth is 440 miles [milliaria, Roman miles].

[Margin: The first clime.]

The middle of the second clime is where the longer day is 13 hours and a half, and the elevation of the pole above the horizon is 24 degrees and a quarter part of one degree. And it is called the clime dia Syenes [through Syene]. Its latitude runs from the boundary of the first clime up to the place where the day becomes longer — 13 hours and a half and a quarter part of one hour — and the pole is raised by 27 degrees and a half. And this space of earth is 400 miles.

[Margin: The second clime.]

The middle of the third clime is where the length of the longer day comes to 14 hours, and the elevation of the pole above the horizon is 30 degrees and a half and a quarter of one part; and it is called the clime dia Alexandrias [through Alexandria]. Its latitude runs from the boundary of the second clime up to that place where the

longer day is 14 hours and a quarter of one, the pole's altitude being 33 degrees and two thirds; and this space of earth is 350 miles.

[Margin: The third clime.]

The middle of the fourth clime is where the length of the longest day is 14 hours and a half, and the altitude of the axis is 36 degrees and two fifths, and it is called dia Rhodon [through Rhodes]. Its latitude runs from the boundary of the third clime up to that place where the length of the longest day is 14 hours and a half and a quarter part of one, and the elevation of the pole is 39 degrees; and this space of earth is 300 miles.

[Margin: The fourth clime.]

The middle of the fifth clime is where the longest day is 15 hours, and the elevation of the pole is 41 degrees and a third of one; and it is called the clime dia Romes [through Rome]. Its latitude runs from the boundary of the fourth clime up to that place where the length of the greatest day is 15 hours and a quarter of one, and the elevation of the axis is 43 degrees and a half; and this space of earth is 255 miles.

[Margin: The fifth clime.]

The middle of the sixth clime is where the longer day is 15 hours and a half, and the pole is raised above the horizon by 45 degrees and two fifths of one; and it is called the clime dia Boristheneos [through the Borysthenes, i.e. the Dnieper]. Its latitude runs from the boundary of the fifth clime up to that place where the length of the longer day is 15 hours and a half and a quarter of one, and the elevation of the axis is 47 degrees and a quarter of one; and this distance of earth is 212 miles.

[Margin: The sixth clime.]

The middle of the seventh clime is where the greater length of the day is 16 hours, and the elevation of the pole above the horizon is 48 degrees and two thirds. And it is called the clime dia Riphæon [through the Rhipæan Mountains]. Its latitude runs from the boundary of the sixth clime up to that place where the greatest day is 16 hours and a quarter of one, and the pole of the world is raised above the horizon by 50 degrees and a half [?]; and this space of earth is 185 miles.

[Margin: The seventh clime.]

Beyond the boundary of this seventh clime, although there are many islands and dwellings of men, yet whatever there is, because it is of poor habitability, is not reckoned under any clime.

[Margin: Why there are not more climes than seven.]

COMMENTARY.

In this place he runs through all seven climes, teaching how great is the longest day in the middle of each clime, how great likewise is the elevation of the pole, and in what way any given clime is named. For the middle of each clime is named either from some notable city, or from an island, a river, or a mountain, through which, of course, passes the parallel that is described through the middle of the clime. Finally, how many miles the latitude of each clime comprises — assigning to each terrestrial degree $56\frac{2}{3}$ miles, just as al-Farghānī granted, as we said above. Then he also determines the length of the greatest day and the elevation of the pole, both at the beginning and at the end of each clime. But all these things are plain in the text, and are seen distinctly in the following table. He adds, however, that even if there are other habitations outside these seven climes, they are not reckoned among the climes by the authorities, because they are not very suitable, but either too hot or too cold.

[Margin: What the Author explains for each of the individual climes.]

[Table of the Climes according to the Ancients — continued from the preceding page]

[The table is untitled on this page; its heading (evidently *Tabula climatum secundum antiquos*) stood on the preceding page. It gives, for each of the seven climes, the beginning (*Princip.*), middle (*Medium*), and end (*Finis*): the longest day in hours and minutes, the elevation of the pole in degrees and minutes, the width in miles, and the naming-place of the clime.]

[*Lemma — Sacrobosco:*] The whole difference, then, between the initial boundary of the climes and their final boundary is three and a half hours [of longest day], and, from the elevation of the pole above the horizon, 37 degrees and 45 minutes. Thus it is clear that the width of each clime runs from its beginning, on the side toward the equinoctial, up to its end, on the side toward the Arctic pole; and that the width of the first clime is greater than that of the second, and so on. The length of a clime, on the other hand, may be called a line drawn from east to west, equidistant from the equinoctial. Hence the length of the first clime is greater than that of the second, and so on, which happens because of the narrowing of the sphere. The space, too, between the beginning of the first clime and the end of the seventh is 2142 miles.

[Margin: Diversity in respect of hours and of the pole's elevation among the seven climes, and some other comparisons between them.]

COMMENTARIUS

He gathers five points from what has been said.

I. That the difference between the longest day of the first clime at its beginning and the longest day of the seventh clime at its end is 3 hours 30 minutes.

II. That the excess of the pole's elevation at the far edge of the seventh clime over the pole's elevation at the start of the first clime amounts to 37 degrees 45 minutes. These points are clear from what has been said and from the table set out above.

III. That the width of the first clime is greater than the width of the second, and the width of the second greater than that of the third, and so on, as may be seen in the aforesaid table. The geometrical cause of this we shall shortly disclose.

IV. That the length of the first clime from east to west is greater than the length of the second, and the length of the second greater than that of the third, and so on — which indeed happens, as he says, because near the pole the sphere is in a certain way drawn in, as is evident in the parallel circles, which are smaller near the poles than near the equator.

V. That the terrestrial space from the beginning of the first clime all the way to the end of the seventh, proceeding always directly from the equator toward the pole, comprises 2142 miles, as is established from what has been said.

But let us now demonstrate what we promised, together with Pedro Nunes of Portugal [Petrus Nonius Lusitanus], namely that a change of a single half-hour in the length of the longest day requires less space in a more northerly region than in a less northerly one — that is, that the days take on a greater increment if one moves, say, three degrees toward the pole, than the increment they take if one approaches the equator by the same number of degrees.

[Margin: Why the more northerly climes are narrower than the less northerly climes.]

For let the tropic of Cancer [tropicus ♋], in which the longest days occur, be ABCD, whose center is E. Let the straight line AC be the common section of the meridian and of the tropic of Cancer, in its proper position, such that the diameter BD — which will be the common section of the same tropic and of the right horizon [Horizontis recti] — cuts it at right angles. For since both the right horizon and the tropic of Cancer are perpendicular to the meridian, their common section too will be perpendicular to the same meridian, and hence (by Euclid, *Elements* XI, definition 3) also perpendicular to the straight line AC lying in the meridian. Since, then, both the meridian and the right horizon pass through the axis of the world — and therefore through E, the center of the tropic of Cancer, because the axis of the world is drawn through that same center of the tropic of Cancer — and since AC is taken as the common section of the meridian and of the right horizon and of the same tropic: therefore BAD will be the diurnal arc in the right sphere.

Let there be conceived, under the same meridian, an oblique horizon above which the Arctic pole is visible, making with the tropic of Cancer the common straight section FG, which will likewise be perpendicular to AC, the common section of the meridian and of the same tropic — which will be proved in no other way than has been shown for BD, the common section

[Margin, keyed to superscript letters in the demonstration: a = *Elements* I.28; b = scholium to [proposition] 27.]

of the right horizon and of the tropic, being perpendicular to AC: since both the oblique horizon and the tropic are perpendicular to the meridian, and so on. From this it follows that the straight lines BD, FG are parallel; and hence that the arcs BF, DG are equal; and consequently that the diurnal arc is FAG.

Let there be conceived again two more horizons, more oblique, under the same meridian, making with the tropic of Cancer the common straight sections IK, MN — which by the same reasoning will be perpendicular to AC, and therefore parallel to one another, and will cut off equal arcs FI, GK and IM, KN. And the diurnal arcs will be IAK, MAN. Now the arcs IF, KG will be the excesses of the diurnal arc IAK over the diurnal arc FAG; and the arcs MI, NK will be the excesses of the diurnal arc MAN over the diurnal arc IAK. Let the elevation of the pole above the horizon of the line IK be posited as much greater than the elevation of the pole above the horizon of the line FG as the elevation of the pole above the horizon of the line MN is greater than the elevation of the pole above the horizon of the line IK, so that the pole's elevation increases uniformly. I say that the arcs MI, NK — which are the excesses of the diurnal arc MAN over the diurnal arc IAK — are greater than the arcs IF, KG, which constitute the excess of the diurnal arc IAK over the diurnal arc FAG.

For let P be the center of the sphere, from which are drawn the straight lines PE, PH, PL, PS, PO. PE will be part of the world's axis — because the axis passes through the center of the sphere and through the center of the tropic of Cancer — while the remaining straight lines will be parts of the common sections of the oblique horizons and of the meridian, since both the meridian and the oblique horizons pass through the center of the sphere P and through the points H, L, O. Now since the axis of the sphere, and the common section of the meridian and of any oblique horizon, intercept in the meridian the arc of the pole's elevation above that horizon, and constitute at the center of the sphere the angle standing on that arc — as is evident from a material sphere — EPH will be the angle of the pole's elevation above the horizon of the line FG; EPL the angle of the pole's elevation above the horizon of the line IK; and EPO the angle of the pole's elevation above the horizon of the line MN; because the axis PE, produced, falls upon the pole, while any of the other straight lines is the common section of the meridian and of its own horizon. And since the arcs of the pole's elevation in the meridian, on which those angles stand at the center P, are posited equal — (for the elevation of the pole above the horizon of the line IK is posited as much

greater than the elevation of the pole above the horizon of the line FG as the elevation of the pole above the horizon of the line MN is greater than the elevation of the pole above the line IK) — the angles HPL, LPO will also be equal; and therefore the angle HPO will be bisected by the straight line PL into two equal parts.

Now since the axis PE is perpendicular to the tropic of Cancer, the angle PEH will (by Euclid, *Elements* XI, definition 3) be right; hence PHE is acute, and therefore PHO is obtuse, and POH is acute; and thus the straight line PO is greater than PH. Therefore, since PL bisects the angle HPO, as we have demonstrated, OP will be to PH as OL is to LH. And since the straight line OP is greater than PH, OL too will be greater than LH. Hence, by the corollary of proposition 1 of *On Twilights* [de Crepusculis], the arcs MI, NK will be greater than the arcs IF, KG; and consequently the excess of the diurnal arc MAN over the diurnal arc IAK will be greater than the excess of the diurnal arc IAK [over FAG], even though the excesses — or the differences of the pole's elevations — are posited as equal. Which was the proposition to be established.

Diagram. A circle representing the meridian, with vertical diameter AC (A at top, C at the bottom) standing for the axis / meridian line. A series of parallel horizontal chords descend the circle, each the common section of a successively more oblique horizon with the tropic of Cancer; P is a point on the axis-side interior, upper right, from which lines are drawn to the points where the chords meet the axis (E, H, L, S, O), producing the radiating pencil PE, PH, PL, PS, PO.

- A (top of circle): apex of the vertical diameter (axis / meridian).
- C (bottom of circle): foot of the vertical diameter.
- B (left, upper) — D (right, upper): endpoints of the chord BD through E (right horizon / equatorial section).
- E (on axis, upper): center of the tropic of Cancer, where BD meets AC.
- F (left) — G (right): endpoints of the chord FG through H (first oblique horizon).
- H (on axis, below E): where FG meets the axis.
- I (left) — K (right): endpoints of the chord IK through L (second oblique horizon).
- L (on axis, below H): where IK meets the axis.
- S (on axis, below L): where the chord QR (a further oblique-horizon section) meets the axis.
- O (on axis, near bottom): where the chord MN meets the axis.

- Q (lower left) — R (lower right): endpoints of the lowest labelled chord (QR).
- M (lower left, near C) — N (lower right, near C): endpoints of the chord MN through O.
- P (interior, upper right): center of the sphere; vertex of the pencil PE, PH, PL, PS, PO.

[Margin, keyed to superscript letters in the demonstration: c = Theodosius, *Sphaerica* I.10; d = *Elements* III.27; e = Theodosius, *Sphaerica* I.10; f = *Elements* I.17; g = *Elements* I.13; h = *Elements* I.17; i = *Elements* I.19; k = *Elements* VI.3.]

From this appears the reason why the more northerly climes are narrower, as the author said. For since a clime is a stretch of the earth extending from south to north, within which the longest day takes on an increment of one half-hour: if two neighboring climes were equal to each other, the differences of the pole's elevations [at their bounds] would also be equal — since a clime is said to comprise as many miles of width as are contained in the width of the other. Therefore, as has been demonstrated, the increment of the longest day would be greater in the more northerly clime than in the less northerly one. Hence in the two the longest day would not [each] increase by a half-hour — which is contrary to the definition of climes. And so it is necessary that the more northerly clime be narrower.

This too appears plainly from the figure above. For since it has been demonstrated that the arcs MI, NK are greater than the arcs IF, GK — the angles HPL, OPL being equal — if there are taken arcs QI, RK equal to the arcs IF, KG, and if the straight lines QR, PS are drawn, then QR will be the common section of the tropic of Cancer and of a certain oblique horizon; and the angle LPS — by which the elevation of the pole above the horizon of the line QR differs from the elevation of the pole above the horizon of the line IK — that angle is indeed smaller than the angle OPL, or HPL. From which it results that the elevation of the pole above the more oblique horizon increases less, when the increments of the longest days are equal; and therefore the clime that is more northerly is narrower than the clime that is less northerly, which was to be demonstrated.

Although among the Ancients only seven climes — the aforesaid ones — were established, nevertheless by more recent [astronomers] many more are now set up. For it is not true, as the Author says here, that only a certain part of one quarter of the earth is habitable; since it has now been ascertained that the whole sea is intermingled with the land, so that everywhere — whether continents or islands — are found, in whatever direction navigation is undertaken in the ocean;

and that there is no region so hot or so cold that human beings cannot live in it; indeed, in any place whatsoever both human beings and other animals are found dwelling. Add to this that it is not necessary, for the constitution of climes, that all parts of the earth be habitable; it suffices to observe a certain fixed rule in the increase of the longest days at the various elevations of the pole. And so astronomers, following Ptolemy in *Dictio* 2, chapter 6 [*Almagest* II.6], describe on the surface of the earth circles parallel [to the equator], proceeding from the equator toward the Arctic pole, spaced at such intervals from one another that the longest day of one differs by a quarter of one hour from the longest day of the next parallel. From which it follows that three such parallels enclose a stretch of earth that is called a clime. For if you proceed from one parallel to the third, you will find that the longest day has changed by a half-hour. And the middle one of the three is called the parallel through the middle of the clime — not because the clime is bisected by it (for this is false, since it cuts off a greater part of the clime toward the equator and a smaller part toward the pole, as has been demonstrated), but because the interval of time by which the longest day at

[Margin: The habitable part of the earth is greater than the Author posits.]

[Margin: In how great a space the parallels on the earth are described by Ptolemy and by other astronomers.]

the beginning of a clime differs from the longest day at its end — namely, a half-hour — it divides into two equal quarters of one hour.

By this reasoning the more recent [astronomers] establish 23 climes, beginning from the first clime of the Ancients and proceeding toward the Arctic pole, until they find the longest day to comprise 23 hours — as will be clear from the following table, in which are contained also all the parallels, and the longest days of all the parallels, and the pole elevations (that is, how far they recede from the equator). Likewise, how many degrees each clime comprises from the equator toward the pole; whence the miles that a clime contains are easily found, by assigning to each degree $62\frac{1}{2}$ miles, according to Ptolemy.

[Margin: The more recent [astronomers] establish 23 climes.]

Further, these same parallels and climes are to be understood in the other hemisphere as well, from the equator toward the Antarctic pole — but in such a way that they receive opposite names. For example, let the Fifth Clime of the South be called the Opposite of the clime through Rome, and so on.

From what has been said it is easily understood what the difference is between a clime and a zone. For a zone is called a stretch of the earth lying between the two tropics, or between one of the tropics and the neighboring polar circle, or between one of the polar circles and the nearest pole of the world. By this reckoning five zones are found, of which two are called frigid, one torrid, and two temperate, lying between the torrid and the frigid. But a clime embraces a stretch of the earth in which the variation of the longest day amounts to a half-hour. From which it comes about that within a single zone several climes can be contained.

If anyone should wish to know more fully the properties of all the parallels, let him read chapter 6 of *Dictio* 2 of Ptolemy [*Almagest* II.6].

Finis tertij capitis. — End of the third chapter.

CHAPTER FOUR

On the Circles and Motions of the Planets, and on the Causes of Eclipses of the Sun and Moon

(Caput Quartum. De Circulis, et Motibus Planetarum, et de Causis Eclipsium Solis, & Lunæ.)

[Sacrobosco's text (lemma):] Note that the Sun has a single circle, along which it moves on the surface of the ecliptic line, and it is eccentric. Now, not every circle is called eccentric, but only such a one as, while dividing the earth into two equal parts, does not have its own center at the center of the earth, but outside it. The point on the eccentric that comes closest to the firmament is called the *aux* [apogee], which is interpreted as "elevation"; while the opposite point, which is at the greatest distance from the firmament, is called the point opposite the *aux*. The Sun has two motions from west to east. One is proper to it, in its own eccentric circle, by which it moves each day and night nearly 60 minutes [of arc] above the poles of the axis of the circle of the signs [the zodiac]. The other, slower, is the motion of the sphere itself, and is equal to the motion of the sphere of the fixed stars — namely, one degree in 100 years. From these two motions, then, is compounded its course through the circle of the signs from west to east, by which it traverses the circle of the signs in 365 days and a quarter of one day, apart from a small amount that is of no perceptible account.

COMMENTARY

[Margin: *Argumentum 4. cap.* — Argument of chapter 4.]

In the preceding chapters the Author dealt with the motion of the *primum mobile*, which runs from east to west, and with what follows from that motion — namely the rising and setting of the signs, days and nights, and so on. Now, in the last chapter of this work, he discusses the motion of the other heavens, which runs from west to east, and especially the motion of the Sun and Moon, so as to open up for us the causes of lunar and solar eclipses. But since the Author touches on all this very briefly, we too shall be very brief in this part — the more so because this subject, if it is to be treated as it deserves, calls for a longer discussion, and belongs to the *Theories of the Planets* [*Theoricæ Planetarum*], which, God willing, we shall shortly bring to light.

The eccentrics and epicycles: by what appearances the astronomers discovered them in the heaven

(*Eccentrici, et Epicycli, quibus* [Greek: φαεινομένοις (phainomenois, "appearances," dative plural — i.e. "by what phenomena")] *ab Astronomis inventi sint in cælo.*)

Since in this passage the Author teaches, following the received doctrine of the astronomers, that the planets move on eccentric orbs and epicycles — which some of the philosophers, together with Averroes [Averroës, Ibn Rushd], try to abolish altogether as being at odds with Aristotle and with natural philosophy —

before I interpret the Author's text, I think it worth my while to set out briefly here (to satisfy those who have earnestly demanded it of me) the various observations that most moved Ptolemy, Alfraganus [al-Farghānī], Thebit [Thābit ibn Qurra], and nearly all the other astronomers to believe that there are eccentric orbs and epicycles in the heavens. Next I shall present the strongest arguments of Averroes and his followers, by which they attack orbs of this kind and try to destroy them entirely. Finally I shall dissolve those same arguments and show them to be worthless, so that anyone may understand that the astronomers discovered these orbs in the heavens not without reason, but with great diligence and remarkable success — whereas the philosophers who follow Averroes rashly assail them with so much vehemence. But before all else it must be explained briefly in what way the eccentric orbs and epicycles are to be conceived in the heaven, so that it may afterward be more easily understood that the phenomena observed by astronomers everywhere can, once those orbs are posited in the heaven, be defended without difficulty, whereas if those same orbs are removed the phenomena have no place and everything collapses utterly.

[Margin: *What the eccentric orb "simply so called" is.*]

The eccentric orb, then, in the heaven of any planet — the one that is called eccentric *simply* (*eccentricus simpliciter*) — is that whose concave surface and convex surface alike have their center distinct from the center of the universe, that is, of the whole heaven; so that it is of uniform thickness, like any celestial sphere, is immersed within the thickness of the whole heaven, and surrounds the earth itself. From this it follows that (since the whole heaven of any planet is of uniform thickness in every direction, and has a center common with the whole world) around the eccentric orb there stand two other orbs of non-uniform thickness, one above it and the other below — such that the upper one is thinnest at the part where the eccentric orb recedes furthest from the center of the world, but thickest at the opposite part, where the same eccentric is nearest the earth; while in the lower orb, on the contrary, its thickest part lies beneath the thinnest part of the upper, and its thinnest beneath the thickest. For in this way both the convex surface of the upper orb and the concave surface of the lower will have the same center as the whole heaven of the planet — namely the center of the world, as the case requires; whereas the concave surface of the upper orb and the convex surface of the lower will have the same center as the eccentric orb. And so the whole heaven [of the planet] will be equally distant from the center of the world on both its concave and its convex side — which would not be the case unless these two latter orbs, of unequal thickness, were placed around the eccentric orb.

[Margin: *What the eccentrics "in a qualified sense" are.*]

These latter are usually called by the authorities eccentrics *in a qualified sense* (*eccentrici secundum quid*), because on one of their outer surfaces they have the same center as the whole universe, but on the other a different one — just as the former is called eccentric *simply*, because on both its surfaces it has a center distinct from the center of the whole universe. And so, if the heaven of any planet

is cut by a plane through the two points of the eccentric simply so called — one of them the furthest from the earth, the other the nearest to the earth — there will result a cross-section such as the accompanying figure shows. In it the eccentric simply so called is represented by the white orb, whose center, both on its convex and on its concave side, is H. The two black orbs surrounding it represent the eccentrics in a qualified sense; the convex surface of the upper of these is ABC, and the concave surface of the lower is DEF, and its center is G, which is also the center of the whole world — so that the whole heaven is concentric with the world in the simple sense, that is, both on its convex and on its concave surface. But the concave surface of the upper orb and the convex surface of the lower are both described from H, the center of the eccentric simply so called. This being so, the whole heaven of each planet will be composed of three partial orbs: the eccentric simply so called, and two eccentrics in a qualified sense — except for the heaven of Mercury and the heaven of the Moon, each of which is made up of several orbs, as will be set out in the *Theories*.

Diagram. A circular schematic of the three partial orbs of a planet's heaven (the eccentric simply so called, flanked by the two eccentrics in a qualified sense), with the epicycle/Sun-circle drawn on the line of the aux. The two outer, shaded (black) rings are the eccentrics *secundum quid*; the inner clear (white) ring is the eccentric *simpliciter*; the small circles at top and bottom, on the vertical line, are the epicycle positions at apogee and perigee. A straight vertical line (A–C) runs through the centers, and is the line of the aux.

- A (top, on the vertical line): outermost point of the figure, at the aux [apogee] side.
- I (upper small circle, just below A): center of the upper epicycle position, where the Sun's center lies at the aux.
- M (left, on the middle circle): point on the eccentric (Sun's-center) circle IMO.
- D (upper center, top of the inner white ring): on the vertical line of the aux.

- H (upper center dot, within the white ring): center of the eccentric simply so called.
- E (left of center, on the horizontal): inner point on the white ring's boundary.
- G (center dot): center of the world (also center of the eccentrics *secundum quid*).
- N (on the vertical line, just below G): point on the line of the aux.
- F (lower center, bottom of the inner white ring): on the vertical line of the aux.
- O (lower small circle): center of the lower epicycle position, the point opposite the aux, nearest the earth.
- L (bottom, below the lower small circle): lowest point on the vertical line.
- B (lower left of the outer black ring): point on the convex surface ABC.
- C (bottom, on the vertical line): point on the convex surface ABC.

[Named points used in the surrounding text: convex surface of the upper eccentric = ABC; concave surface of the lower = DEF; center of the eccentrics *secundum quid* and of the world = G; center of the eccentric *simpliciter* = H; eccentric (Sun's-center) circle = IMO, with aux at I and its opposite at O; line of the aux = AC through G and H. One faint mark on the vertical line between the upper epicycle and D could not be resolved [?].]

An epicycle, on the other hand, is a small solid sphere immersed within the thickness of the eccentric simply so called, in such a way that it can revolve about its own center. Such a small sphere is represented in the said figure by the circle described from center O. Fixed on the epicycle is the planet, and it is carried along by the epicycle's motion about center O; and for this reason Ptolemy called it "the orb that carries the star or planet round" [*orbis revolvens stellam, seu planetam*]. The epicycle, in turn, is carried around the earth by the motion of the eccentric simply so called — with the exception of the Sun, which has no epicycle but, fixed in the eccentric simply so called, is carried around by that orb's motion. Hence the eccentric orb simply so called is named by practitioners the "carrier" (*deferens*) of the epicycle or of the planet.

[Margin: *What the eccentric circle, the aux, the point opposite the aux, and the line of the aux are.*]

Moreover the circumference IMO, described in the eccentric orb by the motion of the Sun's center, is usually called the eccentric circle. Its point furthest from the earth — such as I, which is placed beneath A, in which the Sun's center lies, and

which is marked by the straight line drawn through the centers G and H — is called the *aux* [apogee]; the opposite point O, nearest the earth, is called the point opposite the *aux*. Finally, the straight line AC, drawn through the centers G and H, is customarily named the line of the *aux*, because on it are found the *aux* and its opposite — that is, the point of the eccentric circle furthest from the earth and the point that comes nearest the earth, as is demonstrated in the *Theories*. But let us now come to explaining the phenomena that most impelled the astronomers to discover eccentric orbs and epicycles in the celestial spheres.

[Margin: *Why the ancients thought the stars were carried by chance.*]

To begin the matter a little further back, then: when the men of antiquity observed that the stars — especially the wandering ones, which are called planets — are carried by various motions, so that now they seemed to quicken their course, now to check it, now appeared almost to lack all motion (so that you would think they stuck fast in the same place of the heaven), now to move backward in the zodiac; and that at one time they came very close to the earth, at another withdrew to the greatest distance from it; and, in short, when they detected six hundred other varieties of this kind and, as it were, irregularities in the planets — they fell into the greatest and least tolerable errors about the motions of the heavenly bodies, supposing that these lacked fixed and settled laws in their motions, and that such varieties of motion befell them by some chance rather than by any firm and certain principle. But later men, of sounder mind, once they had begun to examine the celestial things more correctly, more subtly, and more scrupulously, came to the view that it is the height of madness to think that any irregularity, non-uniformity, or inequality can be found in the motions of the heavenly bodies; and that, on the contrary, the highest equality, uniformity, and regularity must be assigned to them. For since we see very many things in these lower and perishable regions move in orderly fashion and by a fixed, observed law, why should the same be denied to the heavenly bodies, which are the noblest of all? Indeed, natural reasoning too seems to persuade us that there can be no irregularity in the celestial motions.

[Margin: *That there is no irregularity in the motions of the heavens.*]

For if the heavens moved irregularly and unevenly, this would happen either at the beginning of the motion — as occurs with projectiles, which move faster at the start — or in the middle, as we see in animals, or finally at the end, as happens in natural [motions, i.e. falling bodies]. Since, then, the motions of the heavenly bodies have none of these limits, it is impossible that any inequality or irregularity should be found in them. Again, if the heavens moved irregularly, so

as to be driven now more slowly and now more quickly, this could not come about unless their motive powers were rendered now weaker and now stronger, or at least their resisting powers were now increased and now diminished. For a motion is made slower when, the resisting power in the moved body or in the medium remaining the same, the moving power is weakened; or when, the moving power remaining the same, the resistance in the moved body or medium is increased. A motion, on the other hand, is made faster when, the resistance in the moved body or medium remaining the same, the motive power is increased; or when, the motive power remaining the same, the resistance in the moved body or medium is diminished. But neither of these can be found in the celestial motions. For the Intelligences that, according to the common doctrine of the philosophers, move the heavens are wholly unchangeable; and the celestial bodies too, if we believe Aristotle and his followers, are free of all corruption, growth, and diminution, and are untiring. Therefore the celestial bodies are not driven by any irregular motion, but are carried around by fixed, perpetual, and constant laws. This the experience and the phenomena of the astronomers most clearly declare. For it has been established that the Sun always completes its period in the space of 365 days and nearly a quarter of one day; that Mars, too, circuits the whole zodiac in the space of about two years; Jupiter in 12; and so on for the remaining planets. It is proof, therefore, that the planets have fixed and settled laws of their motions; for otherwise it could not be that they kept such constant periods in their motions.

Although reason thus persuaded them that this was so, yet since many irregularities, as we have said, were daily observed by skilled astronomers in the motion of the heavens, they had to consider from where irregularities of this kind might arise. And the first thing that came into their minds was that each planet is carried around not by one motion, but by several.

If it had only a single motion, none of the appearances mentioned above — nor the others we shall explain further on — could be accounted for, since one and the same motion cannot at once be both regular and irregular. The conclusion, then, was that various motions had to be assigned to the individual planets: each motion, considered on its own, regular and uniform, as reason requires, yet all of them together producing that apparent irregularity, as will shortly become clear. And since, according to the decrees of Aristotle and the philosophers, it is impossible that one and the same celestial orb — being a simple body — should contain several motions, they were compelled to assign to the sphere of each planet several partial orbs, out of which the whole sphere is composed, so that from the multiplicity of the motions of these orbs they might explain the causes of

that apparent irregularity. Hence, the more varied the motion of a given planet appeared, the more motions and orbs had to be assigned to it.

[Margin: The sphere of the planets was divided into concentric orbs by Eudoxus and Callippus.]

These partial orbs, however, were not all set up in the same way by every astronomer. Eudoxus and Callippus — whose view was famous in Aristotle's day, as is clear from *Metaphysics* XII, and which even Averroes [Averroes] strives in many places, together with his followers, to defend — divided each of the total orbs of the planets into several concentric partial orbs, that is, orbs sharing a common center with the whole heaven and the universe. These, they held, were moved about different poles in different directions. From this arrangement it follows that, although each partial orb considered on its own moves regularly, nevertheless, because one retards or drives the other in some way, the planet itself appears to move irregularly. This opinion — which among more recent writers Girolamo Fracastoro [Fracastoro] strives with all his might to defend in the little book he entitled *On Homocentrics*, and which Lucillo Filalteo [Lucillo Filalteo] seems to approve in his books *On the Heaven*, with certain modifications — can indeed uphold some of the appearances that pertain to the slowness and speed of motion; but it can in no way give an account of all the appearances that daily experience detects in the planets, as we shall presently show.

[Margin: Ptolemy, with other astronomers, divided the spheres of the planets into eccentric orbs and epicycles.]

For this reason Ptolemy [Ptolemy] — easily the foremost of astronomers (though there are those who say the Pythagoreans did the same earlier, if less clearly and accurately, and that Hipparchus [Hipparchus] afterward imitated them) — together with al-Battānī [al-Battānī], Thābit [Thābit ibn Qurra], and a great many other astronomers, considering the defect of these homocentric orbs (that is, orbs having a common center with the whole heaven), was forced to devise another way to defend all the phenomena [φαινόμενα, *phainomena*, the observed appearances] observed in the planets, by which everything that appears in the motions of the planets might be maintained. After long reflection he saw — for he was of the keenest intellect — that this could be accomplished in no way more easily and conveniently than by eccentric orbs and epicycles, which have a center different from the center of the whole heaven, as we explained above. And so he divided each of the orbs of the planets into eccentric partial orbs, adding to each planet — with the Sun alone excepted — its own epicycles, because by eccentrics alone no account of all the appearances could be given. Averroes too, in his

commentaries on Ptolemy's *Almagest*, asserts that there are eccentric orbs and epicycles in the celestial spheres. The appearances that drove Ptolemy and other astronomers to believe that there are eccentric orbs and epicycles of this kind in the heavens were not few, and were altogether striking and remarkable; some of these we shall now bring forward.

[Margin: I. An appearance proving that eccentrics exist.]

I. The Sun, the Moon, and any other of the wandering stars — as has been most carefully observed by the more skilled astronomers — appears now farther from the earth, now nearer. Likewise (a consequence of the former point) its diameter appears now larger, now smaller, and thus the star itself seems now larger, now smaller. For the Sun (to leave aside the other planets for now), when it is in Capricorn or in the other southern signs, appears larger than when it is in Cancer or lingers in the other northern signs; so that at the present epoch it is largest in Capricorn and smallest in Cancer, its diameter being greatest there and least here. This inequality is gradually removed, and the Sun is seen at various magnitudes, according as it moves away from Capricorn or Cancer; and so its apparent diameter cuts off various arcs from the zodiac. Since, then — as is demonstrated by the writers on optics [Perspectivi] — the same object appears larger the nearer it is, and smaller the farther it withdraws from our sight, there is no doubt that the Sun, the Moon, and the rest of the planets are carried in orbs having a center different from the center of the earth, so that they can now approach nearer the earth and now recede farther from it. For if they were carried in orbs having the same center as the earth, they would always be equally distant from the earth, and would thus always present themselves to the gaze of our eyes at the same magnitude — which experience utterly contradicts.

To make this clearer: let the zodiac be ABCD, whose center E is also the center of the universe; and from another center, F, let the eccentric circle GHI be described, with three solar bodies, of which G, at apogee [Auge], is farthest from the center of the universe; I is nearest; and H is at a middle distance. Suppose, then, that the center of the Sun is moved in the eccentric circle GHI. It is clear that the body of the Sun, though in itself always of the same magnitude, nevertheless — because of its various and unequal distances from the earth, the cause of which inequality is the eccentric in which it is carried — appears to our sight now smaller, now larger, according as it holds a greater or lesser distance from us.

Diagram. The eccentric circle of the Sun set within the zodiac. The outer circle is the zodiac ABCD; the inner (eccentric) circle carries three positions of the Sun.

Lines are drawn from E (the world's center) as tangents to each solar position, marking off the arcs KL, MN, OP on the zodiac.

- A (top of outer/zodiac circle): with K (left) and L (right) flanking it — the tangent points EK, EL for the Sun at apogee.
- B (right of zodiac): with M (above) and N (below) flanking it — tangent points EM, EN.
- C (bottom of zodiac): with O (right) and P (left) flanking it — tangent points EO, EP.
- D (left of zodiac): opposite B, endpoint of the horizontal diameter DEB.
- E (center): the center of the universe / earth.
- F (just above E): the center of the eccentric circle.
- G (small circle at top, inside near A): the Sun at apogee (in Cancer), farthest from E.
- H (small circle at right, near B): the Sun at middle distance (in Aries, or in Libra).
- I (small circle at bottom, near C): the Sun at perigee (in Capricorn), nearest to E.
- Small zodiac-sign glyphs are engraved around the outer ring [individual glyphs too fine to resolve securely: ?].

Thus, when it is at G — namely in Cancer — its diameter, seen along the lines EK, EL that are tangent to the solar body, cuts off from the zodiac the arc KL, which contains four parts, of which about ten are contained in the arc OP that the tangent lines EO, EP cut off from the zodiac when the Sun is at I, that is, in Capricorn; and of which six, and a little more, are included in the arc MN, which is intercepted in the zodiac between the tangent lines EM, EN when the Sun is placed at H, that is, in Aries, or in Libra.

Now if the circle GHI, which carries the Sun beneath the zodiac from west to east, were described about E, the center of the universe (or of the zodiac), this appearance would have no place, since the Sun would always be equally distant from us. And the same must be said of the other planets. This appearance is granted by Averroes (so that it is remarkable how inconsistent he was on this point) in *Meteorologica* I, where he says:

It seems that Nature has equalized matters in this. For when the heat that comes by reflection is diminished — as when the Sun is in Capricorn — an equalization occurs in the heating on account of nearness; and, on the contrary, when intense heat occurs through reflection at right angles, or nearly so, while the Sun is in

Cancer, the Sun is then farther from the center of the earth, so that the heat is diminished. The same author, in *Metaphysics* XII, comment 45, admits that the Moon is sometimes farther off and sometimes nearer.

But to this appearance the adversaries reply, conceding that it is true that the Sun is sometimes seen larger and sometimes smaller — yet not because of a smaller or greater distance of it from the earth (for it is always equally distant, since, as they say, it is carried in a concentric orb), but on account of vapors that are interposed between the Sun and our sight and that scatter the visual rays, so that we behold the Sun now larger, now smaller, even though it is always carried in a concentric orb and at an equal distance from the earth. And the same, they say, must be maintained about the other planets.

Diagram. A reprint, on this page, of the same eccentric-Sun woodcut described above (fig-p304-1): the zodiac ABCD with the inner eccentric circle GHI carrying three solar positions (G at apogee, H at middle distance, I at perigee), center E (world) and F (eccentric), and the tangent points K, L / M, N / O, P marking the apparent-diameter arcs. All letter-labels identical to fig-p304-1; only the tiny peripheral zodiac-sign glyphs are unresolved [?].

But this reply is of no weight. For the Sun and the other planets were seen larger not only when the air abounded in vapors, but also when the sky was perfectly clear and the planet itself had the same altitude above the horizon. For example, the Sun, when it is in Cancer — where today the Sun's apogee is found — and has an altitude above the horizon of 20 degrees, so that its distance from the zenith is 70 degrees, always appeared much smaller to the most learned astronomers than when it is in Capricorn, where now the opposite of the apogee lies (granting the same clearness of air, and its altitude above the horizon likewise 20 degrees, and its distance from the zenith 70 degrees, as before). Nor, again, is there any force in what they say: that although the Sun keeps the same altitude and the sky is always clear, nevertheless, because when the Sun is in Capricorn (where we place the opposite of the apogee) it is winter, and hence the air is thicker, whereas when it is in Cancer (where we set the apogee) it is summer, and thus the air becomes rarer and finer, the Sun appears larger in Capricorn and smaller in Cancer. There is no force in this, I say, because sometimes in summer the sky is much hazier than in winter, and yet there the Sun was seen smaller and here larger. Further, because when the sky is clear the thickness of the air cannot be so great as to produce so great an inequality in the Sun's magnitude — especially since on two consecutive days, of which one was clear and the other hazy, so great a difference is never detected. Besides, let them say what they will about the

Sun; in the case of the Moon they are necessarily refuted. For the Moon, as is explained in its *Theorica*, changes its apogee every month, so that in the space of any one month its own apogee and the opposite of the apogee come to lie under each of the signs of the zodiac. And so, both in summer and in winter, it is found twice at apogee each month and twice at the opposite of the apogee; nevertheless it appears now smaller, now larger. Therefore the solution has no place in the case of the Moon. Moreover, the Sun does not always have its apogee fixed in the same sign, but a changeable one, as is demonstrated in its *Theorica*: its apogee moves always and continually toward the more eastern parts of the zodiac; and it will one day come about that its apogee is in Capricorn and the opposite of the apogee in Cancer. Yet the Sun, hitherto, like the Moon, has always appeared smaller at apogee than at the opposite of the apogee. And truly it would seem remarkable that, when the planets are at the opposite of the apogee, there should always be so much haze, but at the apogee so much clearness, that there they always appear larger in the same way, while here they appear smaller.

Seeing that this solution cannot at all satisfy the appearances adduced, Girolamo Fracastoro, examining the matter more subtly, devised another contrivance besides the interposed vapors. For he says that the planets appear larger not only because of thicker air interposed while they are in that region of the heaven where we place the opposite of the apogee, but also, and chiefly, because those parts of the heaven in which the opposite of the apogee is set are denser, so that the visual rays are refracted there, and on that account the planets appear larger and nearer to us. A subtle idea, to be sure, but an utterly futile fiction. For if the planets were seen larger on account of the density of those parts of the heaven, they would not appear of the same brightness and clearness through those denser parts and through the other, less dense parts; rather they would have less brightness there and more here — inasmuch as that density is so great that they appear sensibly larger — which is absurd. For the same planet, other things being equal, is just as bright and splendid when it appears larger as when it appears smaller. Add to this that, if that density existed, the same fixed stars in the zodiac would appear larger to us at one time — namely when those denser parts are supposed to lie beneath them — than at another; which conflicts with experience. Indeed, since the Moon is twice at apogee and twice at the opposite of the apogee each month, this appearance cannot be referred to that density, unless someone should say that the whole heaven of the Moon beneath the zodiac is sprinkled with such densities. Which is absurd. For it would follow that the Moon ought always to appear of the same magnitude. Therefore those denser parts cannot be placed in the heaven of the Moon.

[Margin: II. An appearance proving that eccentrics exist.]

II. The Sun is moved beneath the zodiac about the center of the earth, or of the universe, irregularly and unequally, as appears more clearly than the Sun's own light in the northern semicircle of the ecliptic and in the southern semicircle. For every year we find by experience that the Sun takes more days while it traverses the six northern signs contained in the former semicircle than while it lingers in the other six southern ones contained in the southern semicircle. For to be carried from the vernal equinox — that is, from the beginning of Aries — through Taurus, Gemini, and the other northern signs up to the autumnal equinox, that is, to the beginning of Libra, requires 187 days. But to be carried from the autumnal equinox — that is, from the beginning of Libra — through Scorpio, Sagittarius, and the remaining southern signs up to the vernal equinox, or to the beginning of Aries, only 178 days are needed. This anyone will easily discover if in the calendar he counts the days from 21 March inclusive, on which the vernal equinox falls in our epoch, up to 24 September exclusive, on which the autumnal equinox falls at this time. For there will be found 187 days there, but here only 178 days. From which it clearly fol-

—lows that the Sun moves unequally beneath the zodiac, since it traverses equal arcs of it — namely the two semicircles — in unequal times. But since the Sun, like the other stars, must (as we said above) be carried regularly by its proper motion in its own orb, it is clear that by its proper motion it is not carried about the center of the zodiac, or of the universe, since about this center it moves unequally, as has been said. Therefore it must be carried regularly about another center, different from the center of the universe, and thus in an eccentric orb — that is, one described from that other center. For it follows necessarily from this that the Sun moves irregularly beneath the zodiac and about the center of the universe, as experience teaches. For any star whatever, if it moves regularly about the center of an eccentric different from the center of the universe, must be carried irregularly about the center of the universe; and if it is carried about the center of the universe irregularly, it moves regularly about the center of the eccentric, that is, about another center.

For let the zodiac be ABCD, whose center E is the same as the center of the universe; let the eccentric be GHIK, whose center F is different from center E. Now let the line of the apogee, AC, be drawn through the centers E, F; and let the straight line BD cut it at right angles at center E. This BD will necessarily divide the zodiac into two equal semicircles BAD, BCD, since it is drawn through its center, but the eccentric into two unequal arcs, since it does not pass through its

center. Of these the greater will be HGK, in which the center of the eccentric and the apogee are found, and the lesser HIK, in which the opposite of the apogee lies. And so, if the Sun is supposed to move regularly in the eccentric circle about center F, it will traverse the greater portion HGK in a greater time than the lesser portion KIH. Now in the same time, with respect to the center of the earth E, the Sun completes the semicircle of the zodiac BAD in which it traverses the eccentric portion HGK; and in the time in which it passes through the eccentric portion KIH, it traverses the other semicircle of the zodiac DCB with respect to the center of the earth. For when the Sun is at point H of the eccentric, it stands, with respect to the center of the earth E, at point B of the zodiac; and while it is at point G of the eccentric, it appears at point A of the zodiac; and finally, while it is at point K of the eccentric, it is seen from the earth at point D of the zodiac. So that the Sun, while it traverses the eccentric portion HGK, is seen from the center of the earth to complete the semicircle of the zodiac BAD; and consequently it is seen to traverse the remaining semicircle of the zodiac DCB while it completes the other eccentric portion KIH. Therefore the Sun will traverse the semicircle of the zodiac BAD in a greater time than the semicircle DCB; and on that account it will move unequally beneath the zodiac — more slowly, namely, under the semicircle BAD, and more swiftly under the semicircle DCB.

Again, if the Sun is supposed to move unequally beneath the zodiac about the center of the universe E — so that, for example, it is carried more swiftly about point C than about point A — it will come about that it is necessarily driven regularly about another center, and in some eccentric orb. For since it is supposed to be carried more swiftly in the semicircle about point C than in the semicircle about point A, it will complete the former in a shorter time than the latter. Therefore in equal times it will traverse unequal portions of the zodiac — a greater one, namely, about C than about A. Let LCM, then, be the greater portion that the Sun traverses in the same time in which it traverses the lesser portion MAL. Now from E, the center of the universe (or of the zodiac), let the straight lines EL, EM be drawn; let equal segments EN, EO, of whatever size, be cut off between them; let the straight line NO be joined; from E let the perpendicular EF be raised to it; and let it be extended in both directions as far as the points A, C in the zodiac. And since in the triangle ENO the sides EN, EO are equal, [a] the angles N, O will be equal. But also the right angles at F are equal, and the sides EN, EO — which are opposite the right angles in the triangles EFN, EFO — are equal. [b] Therefore the sides FN, FO also will be equal. And so, taking F as center, a circle GNIO, described from F at the interval FN, will pass through point O. In this eccentric circle, then, about center F, different from the center of the universe, I say that the Sun moves regularly. For since the semicircles NIO, OGN are equal,

and the Sun traverses them in equal times — the very same times, namely, in which it passes through the unequal arcs of the zodiac LCM, MAL (for when the Sun is at point N, it appears in the zodiac, from E the center of the universe, under point L; and while it is at point O, it is seen under point M; and consequently the Sun is observed to traverse the portion NIO in the eccentric circle in the same time in which it traverses the arc of the zodiac LCM, and the remaining portion OGN in the same time in which it traverses the arc of the zodiac MAL) — it clearly stands established that the Sun moves uniformly and regularly in the eccentric circle GNIO, since it completes equal semicircles in equal times.

[Margin: a — [Euclid,] *Elements* I.5.]

[Margin: b — [Euclid,] *Elements* I.26.]

Diagram. A zodiac wheel with the twelve signs engraved around the outer ring, and within it the geometric construction of the Sun's eccentric circle GNIO about center F.

- A (top of outer circle): the beginning of the apogee diameter AC.
- C (bottom): opposite A; the vertical diameter AC (line of the apogee).
- B (right): endpoint of the horizontal diameter DB.
- D (left): opposite B.
- E (center): the center of the universe / earth.
- F (just above E): the center of the eccentric circle GNIO.
- G (top, inner): point of the eccentric on the apogee side.
- I (bottom, inner): point of the eccentric opposite G.
- N (inner, left of center): endpoint of segment EN.
- O (inner, right of center): endpoint of segment EO.
- K (lower-left, near center): point on the eccentric.
- H (lower-right, near center): point on the eccentric.
- L (outer, upper-left): point of the zodiac where the Sun at N appears.
- M (outer, upper-right): point of the zodiac where the Sun at O appears.
- The twelve zodiac-sign glyphs run around the outer ring [individual glyphs too fine to resolve securely: ?].

You see, then, that it is no wonder the Sun should move for more days from the vernal equinox to the autumnal equinox than from the autumnal to the vernal, if it is supposed to be carried in an eccentric orb; for it follows necessarily from this that it moves irregularly about the center of the universe and beneath the zodiac,

as we have shown. The same will be demonstrated for the other planets as well, as is plain.

Now this appearance of the irregularity of the planets' motion is so striking and clear that Ptolemy derives from it, by geometric reasoning, the eccentricity of the Sun — that is, the distance of the center of the Sun's eccentric orb from the center of the universe — and the place of the apogee in the zodiac; and, in the case of the other planets, the magnitudes of the diameters of the epicycles, and many other things, as we shall make clear, God willing, in the *Theorics*. This same appearance had such force with Averroes that it compelled him to admit, in *Meteorologica* I, that the Sun must move regularly in an eccentric orb, since about the center of the earth it moves so irregularly. So that even from this passage his inconsistency appears, since elsewhere he did away with eccentrics entirely by that same means.

[Margin: III. An appearance proving that eccentrics exist.]

III. It has been observed many times over that eclipses of the Sun have been unequal, even though in each the Sun and Moon held the same position; and this inequality could arise from no other cause than an eccentric. To make this clearer, we must take a point from the writers on optics: whenever some luminous body illuminates another smaller one, the nearer these two bodies are to each other, the greater the part of the smaller that is illuminated, and the more intensely; but the far-

COMMENTARY ON CHAPTER IV OF THE *SPHERE*

(*Christoph Clavius [Christoph Clavius], commentary on Sacrobosco's De sphaera, Chapter IV — continued: the arguments that the planets move on eccentrics and epicycles.*) a smaller shadow is produced than when they are separated by a greater distance. For in that case a smaller portion of the smaller body is lit, but a larger shadow is produced. Conversely, when some luminous body illuminates another that is larger, the smaller the distance between them, the smaller the portion of the larger body that is illuminated, but the more extensive the shadow that is cast — more so than when the one stands farther from the other. For in that case a larger portion of the larger body is lit, but a smaller shadow is produced.

Diagram. A solar-eclipse cone. At the right is a large circle marked **A** (the Sun, the luminous and larger body). At the far left is a large hatched (shaded) circle marked **L** (the Earth). Between them stand two small circles, each marked **B** (the

Moon, shown at two distances — one nearer the Earth, one nearer the Sun). Straight tangent lines are drawn from the Sun A past the edges of the Moon B, converging into a shadow cone that reaches toward the Earth L.

- A (large circle, right): the Sun (luminous, larger body)
- L (large hatched circle, left): the Earth
- B (small circle, nearer L): the Moon, in its farther-from-Sun / nearer-Earth position
- B (small circle, nearer A): the Moon, in its nearer-Sun / farther-Earth position
- E (top of the nearer B): upper tangent point on the first Moon-position
- F (bottom of the nearer B): lower tangent point on the first Moon-position
- I (top of the farther B): upper tangent point on the second Moon-position
- K (bottom of the farther B): lower tangent point on the second Moon-position
- G (top edge of A): upper tangent point on the Sun [an adjacent, faintly-inked second tangent point appears alongside it, possibly a repeated G or a C — [?]]
- H (bottom edge of A): lower tangent point on the Sun
- D (bottom edge of A, beside H): second lower tangent point on the Sun

All of this is set before the eyes in the figure provided, in which the luminous and larger body is A, while the opaque and smaller one is B — at one moment drawing nearer to A, at another standing farther from it. You see, then, that at the nearer distance the luminous body A lights up a larger portion of the smaller body B and produces a smaller shadow, whereas at the greater distance the same luminous body A illuminates a smaller portion of the smaller body B and casts a larger shadow. And again you see that if A, the larger body, is taken as opaque, and B, the smaller, as luminous, then a smaller portion of the opaque body A is illuminated by the nearer luminous body B, and a larger shadow is cast, than by the body B when it is farther off; for then a larger portion of body A is illuminated, and a smaller shadow cast — as is plain from the lines drawn tangent to both the Sun and the Moon.

With this established, it has been observed by the most skilled astronomers, more than once, that with the luminaries — the Sun, namely, and the Moon — remaining in the same position (for example, in the head or in the tail of the Dragon [in capite vel cauda Draconis], where both must necessarily be for an eclipse to occur, as we shall teach below), and the same parallax [diuersitate

aspectus] between our line of sight and the Sun being preserved, the solar eclipses (which arise from the interposition of the Moon between our sight and the Sun) have at one time been larger and lasted longer, appearing over a larger portion of the earth and obscuring a larger part of the Sun, than at another time. Now this could in no way happen unless we grant that those two planets sometimes have a smaller distance from the earth, or from each other, and sometimes a greater one. For when the Sun is farther from the Moon, then, as has been said, a larger shadow is cast upon the earth by the Moon — which is smaller than the Sun — and a smaller part of the Moon is illuminated by the Sun. From this it follows that at the time of a solar eclipse a larger tract of the earth is darkened, and the eclipse lasts a longer time. The contrary happens if the Sun has a smaller distance from the Moon: for then a smaller shadow is produced by the Moon upon the earth, and a larger part of the Moon is lit by the Sun; and accordingly, at the time of a solar eclipse a smaller surface of the earth is darkened, and the eclipse lasts a shorter time. As can be seen in the adjacent figure, in which the Sun's body is A, the earth L, and the Moon B — now farther from the Sun and nearer the earth, now nearer the Sun and farther from the earth. Since, therefore, these two luminaries cannot have a smaller or larger distance from each other, or from the earth, unless they are supposed to move on eccentrics — for if they were carried on concentrics they would always keep the same distance both from each other and from the earth, as is evident — it is entirely reasonable that there are in the heavens eccentric orbs in which the planets move, so that they may sometimes be more, and sometimes less, distant from each other or from the earth, and so that a cause can be assigned for that inequality in the solar eclipse.

And to bring forward, for the common benefit, what I too have myself observed on occasion in this matter, I shall recount two remarkable eclipses of the Sun that happened in my own time, not long ago. One of them I observed in the year 1560 at Coimbra [Conimbricæ] in Portugal [Lusitania], about noon; in it the Moon was interposed directly between our sight and the Sun, so that it covered the whole Sun for no small interval of time, and the darkness was somehow deeper than that of night. For one could not see where to set one's foot, and the stars shone out most brightly in the sky, and — a marvellous thing — birds fell from the air to the ground out of dread at so foul a darkness. The other I witnessed at Rome [Romæ] in the year 1567, likewise about noon; in it the Moon was again set between our sight and the Sun, yet it did not obscure the whole Sun as in the former eclipse, but (what perhaps never happens otherwise) there was left in the Sun a certain thin ring encircling the whole Moon on every side. From these two eclipses it is plainly gathered that the Sun and the Moon did not have, in both

eclipses, the same distance from the earth, or from each other. For if they had had the same distance both from each other and from the earth, who does not see that the Sun ought to have been obscured in the same way in both eclipses? This is easily demonstrated from the science of optics [à Perspectiuis], and the matter is as plain as a thing held in the hand. For if a hand keeps always the same distance from some wall and from the eye, being placed between the wall and the eye, it will always take the same portion of the wall from view, and not now a larger and now a smaller one. Therefore it can in no way be said that these two luminaries move on concentric orbs, since on that supposition they would always be equally distant from each other and from the earth, and so this observed appearance of solar eclipses could have no place at all.

Again, it has not seldom been noticed that, with the same luminaries remaining in the same position — namely, with the one in the head of the Dragon and the other in the tail, and the Moon having the same latitude — the lunar eclipses (which occur from the interposition of the earth between the Sun and the Moon, because the Moon then enters the earth's shadow, so as to be no longer lit by the Sun's rays, as we shall say hereafter) have at one time begun earlier and been larger, and lasted a longer time, than at another. This could by no means have happened unless the Moon had entered a larger shadow of the earth in one eclipse than in another. For it is thus that in the one it needed a longer time to extricate itself from the shadow than in the other, and so the eclipse of the Moon there proved larger than here. But the earth cannot make a larger shadow at one time than at another unless the Sun approaches it now more, now less — as we taught at the beginning of this third appearance. Nor again could the Moon, if the earth's shadow were always the same, pass now through a larger shadow and now through a smaller, unless it approached the earth more at one time than at another. Since, then, neither the Sun nor the Moon can come nearer the earth at one time than at another unless we assign to each planet an eccentric on which it is carried around — as is evident — it will not be foreign to the truth to hold that eccentric orbs exist among the celestial spheres. An example of this

you have in this adjoining figure, in which A signifies the Sun, now nearer to the earth B, now farther removed from it. From this it comes about that the earth's shadow is sometimes smaller and sometimes larger — the shadow, indeed, through which the Moon, represented by the letter C, passes in the eclipse. And this appearance had such force even with Averroes [Averroes] that

Diagram. A second eclipse-cone figure. At the right stand two large circles side by side, each marked A (the Sun, at two distances from the earth). In the middle is a

hatched (shaded) circle marked **B** (the earth), from whose edges tangent lines run leftward to form the earth's shadow cone. At the left, three small circles, each marked **C**, are ranged along the axis of the cone (the Moon, shown at three positions as it passes through the earth's shadow).

- A (large circle, right): the Sun, in its position nearer the earth
- A (large circle, right of the first): the Sun, in its position farther from the earth
- B (hatched circle, centre): the earth, casting the shadow cone
- C (small circle, upper left): the Moon, first position on the shadow axis
- C (small circle, middle left): the Moon, second position
- C (small circle, lower left): the Moon, third position

he sincerely asserted, in *On the Heavens* Book II, comment 32 [Averroes, *De Caelo* II, comm. 32], that perhaps this appearance concerning the lunar eclipse could be defended in no other way than by an eccentric orb — a thing which nonetheless he elsewhere denied. Behold another inconsistency of Averroes!

[Margin: IV. An appearance proving them to be eccentric.]

IV. In the Moon, Mercury, and Venus astronomers have not always found the same parallax [diuersitas aspectus], but now a larger and now a smaller one, even when the planet held the same position: so that in the Moon, for example, the parallax has sometimes amounted to $1^{\circ}6'$ [grad. 1. min. 6], and sometimes only to $0^{\circ}50'$ [grad. 0. min. 50], as Gemma Frisius [Gemma Frisius], no undistinguished writer among the moderns, says — and this with the Moon at the same altitude above the horizon. It is therefore necessary that the planet becomes now higher, now lower with respect to the centre of the earth. For when a planet is lower — that is, nearer the earth — it admits a larger parallax [aspectus diuersitatem], but when it is borne higher and farther from the earth, a smaller one; provided that it has the same altitude above the horizon there as here, as we demonstrated above

Diagram. A parallax graticule. A semicircular fan is drawn, ruled with radial lines running out from a common centre and crossed by concentric arcs, forming a grid (a graticule of altitude). At the bottom centre, at the fan's apex, sits a small hatched (shaded) half-circle representing the earth (the observer's globe). Straight lines are drawn from the centre of the world and from the observer's eye through the star's centre, illustrating the difference between the true and the apparent altitude. No point-letters are lettered on this figure.

in Chapter I, when we disputed on the order of the celestial spheres; and it also appears plainly in this present figure, in which, to the left, the star — now farther from the earth, now nearer it — keeps the same altitude with respect to the straight line drawn from the centre of the world through the star's centre; that is, it keeps the same true altitude, or the same true place. To the right, however, the star — now less, now more distant from the earth — keeps the same altitude with respect to the straight line drawn from the eye, or from the surface of the earth, through the star's centre. Now one and the same star cannot become now nearer the earth and now farther from it if it is carried on a concentric orb, but only if it is carried on an eccentric, as is clear from what has been said. Not without reason, therefore, did the astronomers affirm that the planets are carried around on eccentric orbs.

These are the four appearances (many others being left aside) by which the astronomers rightly strive to establish that the spheres of the planets are composed of eccentric orbs, on which they are borne by their proper motions from west to east. And these same appearances, in the same order, prove and convincingly show that in all the planets except the Sun alone there are also epicycles, on which the planets themselves revolve — as will become clear from what now follows.

[Margin: I. An appearance proving that there are epicycles.]

I. The planets, the Sun excepted, when they are at the apogee of the eccentric [in *Auge Eccentrici*] — that is, at the point of the eccentric most remote from the earth — do not always keep the same relation to the earth. For they are borne now higher, now lower; and (as follows from the first appearance) their diameters are now smaller, now larger; and consequently the planets themselves appear now smaller, now larger, and cut off with their diameters now a smaller, now a larger portion of the Zodiac. The very same thing happens to the planets when they are at the point opposite the apogee of the eccentric. But this variety cannot come about by reason of the eccentric alone. For since the apogee of the eccentric is always at the same distance from the earth, a planet situated at the apogee would always appear the same as regards nearness and distance, largeness and smallness; and the same would happen to a planet situated at the point opposite the apogee. For a planet ought always to be most remote from the earth at the apogee, and nearest at the point opposite the apogee (as we find in the Sun, which is carried on an eccentric orb alone) — whereas it in fact appears sometimes more remote and sometimes nearer, both at the apogee of the eccentric and at the point opposite the apogee. There will therefore be, immersed

within the thickness of the eccentric, an epicycle by whose motion the planet revolves. For in this way we shall assign the cause of the aforesaid variety without any difficulty. Let the Zodiac, then, whose centre is the same as the centre of the world, be A; and let the eccentric that carries the planet be B C D E, whose centre F is distinct from the centre of the world; and let the apogee of the eccentric be B, and the point opposite the apogee D. Now if the Moon, for example, moved on this eccentric alone, it would without doubt always be seen at its most remote and smallest at the apogee B, and would always appear nearest and largest at the point opposite the apogee, D. But the contrary of this has been found to happen by the astronomers. Yet if an epicycle G H I is posited, on which the planet is fixed at the point G or I, it plainly follows that the Moon (and understand the same of the other planets too), although it be at the apogee of the eccentric or at the point opposite the apogee, nonetheless appears more remote from us — because it is then found, for example, on the epicycle at the point G — than when it stood on the epicycle at the point I. But perhaps someone will say that the eccentrics were granted in vain, if by means of the epicycle we can maintain that the planets are now more remote from the earth, now less distant. To this the answer is that, just as by the eccentric alone this appearance

Diagram. The eccentric-and-epicycle construction. A large circle (the Zodiac) is drawn with a horizontal and a vertical diameter crossing at the centre A (the centre of the world). Within it an eccentric circle is drawn whose centre is F, offset above A along the vertical. On this eccentric: B marks the top (the apogee), D the bottom (the point opposite the apogee), E the left, and C the right. At the apogee B sits a small epicycle lettered G (top), H (right), I (bottom); and at the opposite point D sits a second small epicycle lettered I (top), H (right), G (bottom).

- A: centre of the world (= centre of the Zodiac), at the crossing of the diameters
- F: centre of the eccentric, offset above A on the vertical
- B: apogee of the eccentric (top)
- D: point opposite the apogee (bottom)
- E: left point of the eccentric
- C: right point of the eccentric
- G, H, I: points on the epicycle (upper epicycle: G top, H right, I bottom; lower epicycle: I top, H right, G bottom)

cannot be defended, so likewise the same appearance cannot be defended by the epicycle alone. For it has been ascertained by the mathematicians that the Moon, for example, when situated at the point G of the epicycle — most remote from the

earth — did not always keep the same distance from the earth, nor always appear of the same magnitude. They found the same thing to happen while the Moon was at the point I of the epicycle, nearest the earth. And they observed the same in the other planets. It is necessary, therefore, that the epicycle be carried on an eccentric orb, and not on a concentric, in order that so great a variety may find a place. Hence not in vain is an eccentric set up in the planets besides the epicycle, since both orbs are necessary for us to save the aforesaid appearance. I myself certainly saw, a few years ago, Mars of such magnitude that it then appeared, under a most serene sky, twice as large as at another time, and many marvelled, supposing that a new star had blazed out in the heavens. This I have said for the purpose that the studious reader may see how conspicuous is this appearance concerning the magnitude of the planets — an appearance which cannot be defended without eccentrics and epicycles — so that of its own accord it sometimes presents itself to our very eyes without the aid of instruments.

[Margin: II. An appearance proving that there are epicycles.]

II. All the planets, the Sun excepted, when situated at the apogee of the eccentric — although of themselves they move more slowly there with respect to the centre of the earth, as was said above concerning the Sun — nonetheless have been found to possess yet another irregularity there. For the Moon, for example, has sometimes been seen to move more quickly at the apogee, and sometimes more slowly; and the same has been ascertained at the point opposite the apogee: so that the Moon sometimes traverses in the Zodiac about 15° [gr. 15] in one day, but on another day only 11° [gr. 11]. And this indeed cannot be defended by the eccentric alone (for otherwise the same appearance would have to be found in the Sun, which is false, since the Sun always moves with the same slowness while it is at the apogee, and with the same speed while it is at the point opposite the apogee); but we shall maintain it very easily if we suppose the Moon to move on an epicycle, and the epicycle on an eccentric, as is clear from the figure above. For if the eccentric of the Moon moves in the order of the signs (as in fact it does move) — that is, from ♈ [Aries] into ♉ [Taurus], and from ♉ [Taurus] into ♎ [the printed sign reads as Libra; the succession of the signs would give Gemini ♊ — [?]], and so on, namely in the said figure from C into B, and from B into E, and so on — while the epicycle of the same is borne, in its upper part (as is shown in its *Theorica*), against the order of the signs, that is, with a motion contrary to the motion of the eccentric — say from G into H, taking the upper epicycle in the figure, or from H into G, taking the lower — but in the lower part of the epicycle in the order of the signs, just like the eccentric, namely, on the upper epicycle of the named figure from H into I, and on the lower from I into H: then it is plainly

understood that the Moon, while it revolves in the upper part of the epicycle, is carried more slowly, since it is borne against the motion of the eccentric; but in the lower part more swiftly, since its motion is, as it were, doubled toward the same quarter. There is added, moreover, that the Moon moves uniformly on its own eccentric about the centre of the earth (as we shall demonstrate with Ptolemy [Ptolemy] in its *Theorica*); so that without the epicycle we cannot render the reason for this slowness and swiftness. This variety has been noted, in its own way, in the other planets too, the Sun excepted; and hence they too revolve on epicycles.

Furthermore, an epicycle has been found much more evidently in the three superior planets, Mars, Jupiter, and Saturn, and also in Mercury and Venus. For these planets are seen now to go forward in the Zodiac from the western parts toward the eastern, now to go backward from the eastern parts toward the western. For while they are in the upper part of the epicycle, they are turned in the order of the signs, just as is the motion from west to east, and thus they appear to go forward: so that if, for example, one of them is in the 1st degree of Leo [grad. 1. ♌], it will presently be in the 2nd, then in the 3rd, and so on. But while they are engaged in the lower part of the epicycle, they are moved against the order of the signs — that is, against the motion which the epicycle has on the eccentric — and so they appear to go backward: so that if, for example, one of them is at the 4th degree of Leo [gr. 4. ♌], it will presently be at the 3rd, then at the 2nd, and so on. All of which will be more clearly explained in the *Theoricae*. But why this retrogradation does not appear in the Moon, although it too is moved into diverse and dissimilar parts on its own epicycle, we shall show in its *Theorica*. And so, since this appearance can in no way be defended without an epicycle, but very easily with one posited, as is clear from what has been said, it will be probable that every planet, the Sun excepted, moves on an epicycle.

Diagram. A second copy of the eccentric-and-epicycle construction, identical in lettering to the figure on the preceding page. A large circle (the Zodiac) has horizontal and vertical diameters crossing at the centre **A** (centre of the world). Within it is the eccentric circle, centre **F** (offset above **A**); on it **B** is the apogee (top), **D** the point opposite (bottom), **E** the left, **C** the right. A small epicycle at the apogee **B** is lettered **G** (top), **H** (right), **I** (bottom); a second epicycle at **D** is lettered **I** (top), **H** (right), **G** (bottom).

- **A:** centre of the world / centre of the Zodiac
- **F:** centre of the eccentric (offset above **A**)
- **B:** apogee of the eccentric (top)

- D: point opposite the apogee (bottom)
- E: left point of the eccentric
- C: right point of the eccentric
- G, H, I: epicycle points (upper epicycle G top / H right / I bottom; lower epicycle I top / H right / G bottom)

[Margin: III. An appearance proving that there are epicycles.]

III. The ancient and diligent observers of the stars considered, on occasion, two lunar eclipses with the Sun and Moon remaining in the same position in both — for instance, with the Sun in the head of the Dragon and the Moon in the tail — and with the Sun in both being at the same point of its eccentric, so that in both it had the same distance from the earth, and accordingly cast the same shadow of the earth in both cases. And they found that one of the eclipses lasted a longer time than the other. Now the cause of this inequality cannot be assigned to the eccentric of the Sun. For the greater or lesser duration of an eclipse comes about from the Moon's entering a larger or a smaller shadow of the earth; but at that time the earth's shadow was in both eclipses always the same, since the Sun is supposed to be equally distant from the earth in both. It is necessary, therefore, that the Moon itself was in one of the eclipses less remote from the earth, and in the other more remote. For since the earth's shadow is extended into a cone (because the earth is smaller than the Sun), it comes about that the nearer the shadow is to the earth, the broader it is, but the farther from the earth, the narrower and less broad. From which it follows that the Moon, the nearer it is to the earth, the larg-

Diagram. The lunar-shadow (umbra) figure combined with the eccentric-and-epicycle. At the right is a large circle marked **A** (the Sun). To its left a smaller circle **F**, and then the system of concentric circles about the centre **E** (the earth). The outer circle carries **B** at the top and **D** at the lower left; inner circles carry **K** (upper), **I** (above centre), **H** (below centre), and **L** (lower). From the earth's region a hatched (shaded) shadow cone runs leftward to a point; within the cone stands **G** (the Moon, in the earth's shadow), and above the left end of the cone is **C**.

- A (large circle, right): the Sun
- F (circle between A and E): intermediate circle / centre between Sun and earth
- E (centre): the earth
- B (top of the outer circle): apogee point
- D (lower left of the outer circle): point opposite the apogee

- C (upper left, at the end of the shadow cone): boundary point of the shadow cone
- G (within the shaded cone, left): the Moon, in the earth's umbra
- K (below B): point on a middle circle (upper)
- I (above E): upper epicycle point
- H (below E): lower epicycle point
- L (below H): point on a middle circle (lower) ...[the Moon] passes through a greater portion of the shadow, but a smaller one the farther it has receded from the earth; and so eclipses turn out unequal in magnitude and duration. But this smaller or greater distance of the Moon from the earth during a lunar eclipse cannot in any way be attributed to its eccentric.

Diagram. A composite eclipse figure illustrating the theory of the Sun's eccentric, the Moon's eccentric, the ecliptic, and the Moon's epicycle at the two nodes. Three roughly concentric circles are drawn about a common region, with the earth E near the centre, a shaded wedge (the earth's shadow-cone) tapering to the left toward C, and small circles (the Moon's epicycle) shown at the right and within the shadow at the left.

- B (top of the outer circle): a point on the Sun's eccentric *ABCD*.
- D (bottom of the outer circle): a point on the Sun's eccentric *ABCD*.
- C (far left, apex of the shaded wedge): a point on the Sun's eccentric *ABCD*; the earth's shadow narrows to a point here.
- A (right, inside the small circle at the right): the Sun, located at the head of the Dragon [caput Draconis].
- E (centre): the earth.
- F (right, on the ecliptic and the Moon's eccentric): the head of the Dragon [caput Draconis], a node.
- G (left, within the shaded shadow-cone): the tail of the Dragon [cauda Draconis], a node, and the centre of the Moon's epicycle shown there.
- I (upper, on the Moon's eccentric *FIGL*): a point on the Moon's eccentric.
- L (lower, on the Moon's eccentric *FIGL*): a point on the Moon's eccentric.
- K (upper, on the ecliptic *FHGK*): a point on the ecliptic.
- H (lower, on the ecliptic *FHGK*): a point on the ecliptic.

For by reason of the eccentric the Moon has one and the same distance from the earth in every eclipse, whether solar or lunar; this is because the Moon (as will be shown in its Theory) always stands at the aux [apogee] of its eccentric, both at its conjunctions with the Sun and at its oppositions. For every solar eclipse occurs at

some conjunction, and every eclipse of the Sun [the print reads *Solis*; the sense requires the Moon — *Lunæ*] at some opposition. We must therefore have recourse to the epicycle. For in this way we shall account, without great labor, for this inequality of lunar eclipses, even though the two luminaries have the same position with respect to the head and tail of the Dragon [the nodes], the Sun is always equally distant from the earth, and the Moon stands at the aux of its eccentric. For in one eclipse the Moon can be at the point of the epicycle nearest the earth, and in another at the point most remote from the earth. Hence the former eclipse will be greater and will last longer than the latter, because in the former the Moon passes through a larger portion of the earth's shadow, in the latter a smaller.

You have an example in the figure above, in which *ABCD* represents the Sun's eccentric; *FIGL* the eccentric that carries the centre of the Moon's epicycle; and *FHGK* the ecliptic, which cuts the Moon's eccentric at the points F and G, of which F, say, is called the head of the Dragon, and G the tail. A is the Sun located at the head of the Dragon; E is the earth; and G is the centre of the epicycle located at the tail of the Dragon, and so on.

But should someone object that it follows from this that we did not rightly infer above, from eclipses, that a solar eccentric exists — since, as we have just said, a greater and a lesser eclipse can be produced by the epicycle — the reply is that the Moon's epicycle does not suffice. For two lunar eclipses have been found unequal to each other, although the luminaries were in the same position (as we said) with respect to the head and tail of the Dragon, and the Moon remained in the same part of the epicycle — say, either the upper or the lower part. Now no cause of this inequality can be assigned unless we say that in one eclipse the luminaries had a smaller distance between them, or at least that one of the two [luminaries, printed *Planetarum*] had come nearer to the earth or receded farther from it than in the other. Since, then, this smaller or greater distance cannot be referred to the Moon's epicycle — because the Moon is assumed to be always in the same part of the epicycle, that is, to have been so in both eclipses — an eccentric too must necessarily be granted.

[Margin: IV. An appearance proving that epicycles exist.]

IV. It has been observed that the Moon, when situated at the same point of its eccentric — at the aux [apogee], for example, or at the point opposite the aux — does not always have the same diversity of aspect [parallax], but now a greater, now a smaller one. This can happen in no way unless, at the same point of the eccentric, the Moon at one time comes nearer the earth and at another is more

distant from it. For this reason an epicycle must be granted to the Moon as well; for once this is posited, the said appearance will present no difficulty whatever.

Diagram. A semicircular construction (drawn as the upper half of a circle) with straight lines radiating from the centre of the base to the arc, and two small circles (representing the epicycle) set on these lines with intersecting sight-lines drawn through them. It illustrates the argument that follows: on the left, two opposite points of the epicycle are taken *as seen* (along the line from the eye through the epicycle's centre); on the right, two opposite points are taken *as they truly are* (along the line from the earth's centre through the epicycle's centre). No lettered labels are visible on the figure.

As can be seen clearly in the figure here presented: on the left two opposite points on the epicycle are taken *as they are seen* — namely, along the straight line drawn from the eye through the centre of the epicycle; whereas on the right two opposite points on the epicycle are taken *as they truly are* — that is, along the straight line drawn from the centre of the earth through the centre of the epicycle. At these points the lunar body is placed. The rest is clear from the figure itself.

[Margin: Further reasons confirming that eccentrics and epicycles exist. First reason.]

To these appearances, and to many others which we deliberately pass over here, three further arguments are added which seem to confirm that eccentric orbs and epicycles do exist in the celestial spheres. Let the first be as follows.

It is accepted by all astronomers and philosophers, as evident and self-evident, that every higher celestial orb draws along with it, by its own motion, the lower orb that is contiguous and concentric to it. This we have learned — with experience herself as our teacher — to be perfectly true. For we see the spheres of all the planets, together with the Firmament and the ninth heaven, swept from east to west in the space of 24 hours by the diurnal motion of the primum mobile. Again, we find that these same planetary spheres, together with the Firmament, are drawn from west to east by the motion of the ninth sphere — though very slowly, namely in the space of 49,000 years according to Alfonso [the Alphonsine reckoning], or, according to Ptolemy, in the space of 36,000 years. Finally, it has been noticed that all the heavens of the planets are also moved little by little with the motion of trepidation — that is, the advance and retreat of the eighth sphere. A sign of this is that the greatest declination of the Sun and of the other planets has changed.

Since, therefore, the greatest individuality of motions is found among the planets — so that no proper motion of any higher body is communicated to a lower planet (as can be known to any astronomer even slightly experienced, adversaries included, and is denied by no one: for Jupiter has nothing whatever from Saturn's 30-year motion, and likewise nothing is communicated to Mars from Jupiter's 12-year motion, and so on for the rest, as all affirm) — it seems clear that the orbs which carry the planets are not concentric. Otherwise the motion of any higher body would be communicated to all the lower planets, just as we see happen in the total spheres, as we said. Since we do not see this happen — as the adversaries themselves testify — it cannot be said that the planets are carried in concentric orbs, but rather in eccentric ones. For in this way that experience just cited, concerning the individuality of the planets' motions, will very easily find its place.

For the diversity of centres is what prevents the eccentric orb of any planet from sweeping along with it the immediately lower orb contiguous to it — whose concave surface is concentric with the whole world — unless a penetration or splitting of the heavens were admitted, as can readily be perceived from a material instrument [an armillary model]; and in any case it is understood from the first figure of this question. For how can it happen — if the matter is considered more attentively — that a simply eccentric orb *IMO*, [turning] about its own centre H, should draw along the next lower orb, one that is eccentric only in a qualified sense [secundum quid], whose concave surface, together with the whole heaven, is equally distant from the centre of the world G, unless this lower orb penetrates or cuts the heaven of the lower planet, which is contained within the concave of the said orb that is eccentric in the qualified sense?

I know that the authors of concentric orbs invent, within the orbs of each individual planet, certain "restoring" orbs — which Fracastoro [Girolamo Fracastoro] calls *Circitores* — whose office is that, by however much the higher planets draw the lower ones along by their motions, by just so much these restoring orbs carry the lower planets back in the opposite direction. But this seems very like a fiction. For, apart from the fact that in this way the greatest confusion is introduced into the motions, I do not see how the *primum mobile* could communicate the diurnal motion to all the lower spheres, since those *Circitores* are placed in between and wholly prevent the lower spheres from being swept along by the higher — unless someone says that the individual planetary spheres have their own diurnal motions from east to west, completed in the space of 24 hours: which is novel, unheard of, and hitherto granted by no one.

[Margin: Second reason.]

The second argument is this. If the planets are not carried from west to east in eccentric orbs, then they must be conveyed either through concentric orbs, or else move by themselves in the heavens, like fish in the sea or birds in the air. But they do not move in either of these two ways. Therefore they are carried in eccentrics. The inference is manifest; the major premise, too, is clear from a sufficient enumeration of the parts; and the minor is proved with respect to each part.

That the planets do not move by themselves (to begin with the latter part) like fish in the sea or birds in the air, Aristotle strives to prove by many arguments in his book *On the Heavens* [*De Caelo*]; and it was confirmed by us above by an evident argument, when in chapter 1 we showed, along with the Author [Sacrobosco], that the heaven turns from east to west; and it is the common teaching of all philosophers and astronomers. Indeed, if they moved in that way, and not rather by the motion of the orbs in which they are, we could have no certain knowledge of their motions. For since, as was said among the appearances above, the planets are sometimes farther from and sometimes nearer to the earth; sometimes move more swiftly, sometimes as it were check their course; now seem to stand still, now to advance beneath the Zodiac from west to east, now to move backward — who does not see that, if the planets moved like fish or birds, they would sometimes have to abandon the circles they describe from west to east (so as to be able to recede farther from the earth and approach it again); sometimes to neglect their proper course and strive backward in the opposite direction; and finally sometimes to halt their course altogether in the heaven, so as not to move at all? And if these things happened, by what means, pray, could their periods be determined? By what method, likewise, could one know in which part of the heaven the planets would depart higher from the earth and again return toward it, and so on?

That the planets are likewise not carried around from west to east in concentric orbs will become clear as follows. First, because on this supposition the phenomena adduced above cannot be saved — especially those observed concerning the greater and lesser distance from the earth, and the greater and lesser apparent size of the planets. And if they contend that they can save the other appearances — namely the slowness and speed of motion, and the direct motion, retrogradation, and station of the planets — by means of concentric orbs, they seem to accomplish this only in a general way and very confusedly. For they say that all these things come about because one concentric orb now retards

another, now advances it more, now leads it backward; but in what part of the heaven these things ought to happen they do not teach.

Next, because many absurdities and awkward consequences follow from positing concentric orbs. The first, indeed, is that — as was said a little earlier — the motions of the higher orbs would be communicated to the lower planets, which conflicts with experience. And further, because, wishing to save everything by concentric orbs, they invent certain orbs within the spheres of the planets to carry them from north to south and vice versa. Once this is posited, who is so dull and sluggish as not to see that the Sun could not always travel beneath the Ecliptic — chiefly beneath the Ecliptic of the *primum mobile* — since it is not carried by that [north–south] motion, seeing that of itself it is set in motion from east to west, whereas one simple body can have only one motion? Indeed, if it were moved from north to south, or the reverse, then in the same city the altitude of the pole would perpetually change — which is contrary to the most manifest experience. And who, again, is so crude and ignorant as not to perceive, once this is granted, that the Sun would sometimes come to be at the Arctic pole, and sometimes set in the very place where we now see it rise? This, indeed, Hieronymus Fracastorius [Girolamo Fracastoro], the foremost champion of concentric orbs, candidly admits — and it readily appears on a material sphere — that such a thing would sometimes have to follow from this kind of north-to-south motion of the heavens, and the reverse. He even affirms that, according to certain Egyptians, this has already happened twice since the founding of the world.

But how false and ridiculous this is, who does not see? For from the histories and traditions of mathematicians and philosophers we have known that, for a span of 2,000 years and more, down to the present (to say nothing of the ages before that), the Sun and the other wandering stars have, on the fixed days of the year, risen and set at nearly the same point of the horizon in the same city, have had the same meridian altitude, and the same length of day and of night. Yet all these things must necessarily have changed over so great an interval of years, if that motion really existed in nature. If, then, since the beginning of the world — according to the common opinion — not yet 7,000 years have elapsed, how will it not be exactly like an old wives' tale that so great a change in the Sun has already occurred twice?

I pass over very many other absurdities that follow from this. Nor let anyone object to us the motion of *trepidation* — by which, in the opinion of some, all the stars and planets are set in motion — for since this motion is so imperceptible

that it is scarcely detected by the most expert astronomers, no notable change can occur in the stars and planets, as is evident in the maximum declination [obliquity], which from Ptolemy's time down to our own age has not yet decreased by half a degree. Add to this that this motion does not carry the stars around in a circle from north to south, but only makes the planets, as it were, tremble with that motion — now borne little by little from north to south, now again from south to north, by an imperceptible change.

Finally, from concentric orbs there arises the greatest confusion, on account of the enormous multitude of them that their defenders introduce. From this, too, there necessarily follows a remarkable derangement of the motions.

[Margin: How many concentric orbs are posited by Fracastoro.]

For they posit — as is plain in Fracastoro — 77 or 79 movable orbs or spheres: eight indeed bearing stars, but all the rest devoid of stars, six of which they place above the Firmament. This not only runs counter to the majority of astronomers, who hitherto have found only three starless celestial spheres above the Firmament, but also conflicts with all the Peripatetics, who, following Aristotle's view, are unwilling to admit even a single orb above the Firmament.

[Margin: How many orbs are posited by those who admit eccentrics.]

Those who posit eccentric orbs in the heavens avoid so great a confusion; for in all they grant only 33 orbs — 27 that surround the earth, and 6 epicycles, which stand wholly outside the earth. Hence there will not be so great a multitude of motions, especially since two qualifiedly-eccentric [secundum quid] orbs always advance together proportionally, as is explained in the Theorics — so that a proper motion is denied to eight qualifiedly-eccentric orbs (two in Mercury, and one in each of the other six planets), and each pair of qualifiedly-eccentric orbs is like a single orb, since both are always carried with one and the same motion. And so, since — according to the famous axiom of the philosophers — "it is done in vain by means of more what can be done equally well by means of fewer," and since we posit nearly three times fewer eccentrics than the adversaries do concentrics; and since all the phenomena [φαινόμενα, Greek: *phainomena*, the observed appearances] are saved by eccentrics not only equally well but far better than by concentrics (for the account of hundreds of appearances cannot be given by concentrics, as is clear from what has been said) — who will doubt that eccentric orbs and epicycles are rather to be established in the heavens than concentric ones, especially since eccentrics are in no way repugnant to natural

philosophy, as will be established from the solutions to the arguments of Averroes and his followers?

[Margin: Third reason, proving that eccentrics and epicycles exist.]

Finally, one may conclude the thesis in this way. Just as in natural philosophy we arrive at a knowledge of causes through their effects, so too in astronomy — which deals with the heavenly bodies most remote from us — we must come to a knowledge of them, and of their arrangement and constitution, from their effects: that is, from the motions of the stars as perceived by our senses. For just as, from the mutual generation and corruption of natural things, the natural philosophers, together with Aristotle, inferred prime matter along with the other two principles of natural change, and many other things besides, so too the astronomers, from the various motions of the heavens in general — from east to west and from west to east — investigated a definite number of celestial spheres. Some, indeed, recognized eight [spheres] from only eight distinct motions considered in general; others, from ten distinct motions, established through other phenomena the order among the celestial spheres, as was noted in general in chapter 1; and likewise, by the same method, this has been set forth by us at length through other phenomena.

Therefore it is fitting, and most agreeable to reason, that from the particular motions of the planets and their various appearances the astronomers should inquire into the number of the partial orbs which carry the planets around with such varied motions, and into their constitution and configurations — but on this rule and condition: that the causes of all the motions and appearances can be conveniently assigned, and that no absurdity repugnant to natural philosophy can be inferred from them. For this reason, since eccentric orbs and epicycles are such that by their means astronomers save all the phenomena without any labor (as is partly clear from what has been said, and will be understood more plainly from the Theorics), and since no absurdity or difficulty in natural philosophy follows from them (as will presently be established from the solution of the arguments usually brought against orbs of this kind by the adversaries) — the astronomers have rightly decreed that the planets are carried in eccentric orbs and epicycles, and not in concentric ones, since by these latter we cannot save so manifold a variety in the motions of the planets.

[Margin: The adversaries' reply to the third reason.]

But the adversaries try to weaken this argument, saying that they grant that, once eccentric orbs and epicycles are posited, all the phenomena can be saved — yet

that it does not follow from this that the said orbs are really found in nature; rather, that they are wholly fictitious. This is so, first, because perhaps all the appearances can be saved by a more convenient route, though that route is as yet unknown to us; and second, because it is possible that the appearances are genuinely saved by the said orbs even though the orbs themselves are entirely fictitious and in no way the true cause of those appearances — just as one may indeed infer a truth from a falsehood, as is established from Aristotle's *Dialectic* [Logic].

To this a confirmation may be added, in the following way. Nicolaus Copernicus, in his work *On the Revolutions of the Celestial Orbs* [*De Revolutionibus orbium coelestium*], saves all the phenomena by another route — namely, by positing the Firmament as immobile and fixed, the Sun likewise fixed at the centre of the universe, and by assigning to the earth, which is placed in the third heaven, a threefold motion, and so on. Hence eccentrics and epicycles are not necessary for saving the phenomena in the planets. Again, Ptolemy accounts by an epicycle for all the appearances in the case of the Sun which he [elsewhere] defends by an eccentric. Therefore it cannot be inferred from our third argument that the Sun moves in an eccentric, since perhaps it is carried on an epicycle.

[Margin: A refutation of the adversaries' reply.]

Nevertheless it must be said that our third argument retains its force, and that the adversaries' reply proves nothing. For, first, if they have a more convenient route, let them show it to us; we shall be content, and shall give them our warmest thanks. For astronomers contend for nothing else than that all the phenomena in the heaven be saved as conveniently as possible — whether this be done by eccentric orbs and epicycles, or in some other way. And because no more convenient route has hitherto been found than the one which defends everything by eccentrics and epicycles, it is highly credible that the celestial spheres are composed of orbs of this kind. But if they cannot show us a more convenient route, they surely ought to rest content with this one, gathered from so many varied phenomena [φαινόμενοις] — unless they wish utterly to destroy not only the natural philosophy that is taught in the schools, but also to bar the way to all the other arts, which investigate causes through their effects.

For whenever anyone infers some cause from manifest effects, I shall say exactly the same thing they do — namely, that perhaps some other cause of those effects, unknown to us, might exist. Or else, if we are to rest content with the cause once found, on the ground that it has a certain connection with the effects from which it was inferred, then eccentrics and epicycles too must be granted, since they

have so close a connection with the appearances that all of them can be defended, by the motions of these orbs, with little trouble. Next: if, for the reason that a truth can be inferred from a falsehood, it is not correctly concluded from the appearances that eccentrics and epicycles are found in the heavens, then the whole of natural philosophy will collapse. For in the same way, whenever someone concludes from a known effect that this or that is its cause, I shall say that this is not true, on the ground that a truth may be inferred from a falsehood; and thus all the natural principles discovered by the philosophers would be destroyed. Since this is absurd, it appears that the force and strength of our argument is not rightly weakened by the adversaries.

It can also be said that that rule of the logicians, *"From the false there follows the true,"* is not to the point; because a truth is inferred from a falsehood in one way, and the phenomena are defended by eccentrics and epicycles in another. For in that case a truth is inferred from a falsehood by force of the syllogistic form. Hence, once the truth of some proposition is known, false premises can be arranged in such a form that, by force of the syllogism, that true proposition is necessarily concluded. For example, because I know that an animal is sentient, I can construct the following syllogism: *"Every plant is sentient; every animal is a plant; therefore every animal is sentient."* But if I were in doubt about some conclusion, I would never rest content on false premises...

I would acquire certainty of it, even if it were correctly inferred by the force of a syllogism. Suppose, for instance, that I am in doubt whether every star is round: although by the force of this syllogism — *Every star is a stone. Every stone is round. Therefore every star is round* — I may correctly infer that conclusion from false premises, I shall nevertheless never be made certain of it, but remain in doubt about the aforesaid conclusion. But from the eccentric orbs and epicycles not only are appearances already known of old defended, but future ones are also predicted, whose time is otherwise entirely unknown. Thus, if I am in doubt whether, say, at the full moon of September in the year 1587 there will be an eclipse of the Moon, I am made entirely certain from the motions of the eccentric and epicyclic orbs that an eclipse will occur, so that I no longer doubt it. Indeed, from these same motions I know at what hour that eclipse will begin and how great a part of the Moon will be obscured. In the same way all eclipses, both solar and lunar, can be predicted, together with their time and magnitude — even though they keep no fixed order among themselves, so that no determinate interval of time is set between two successive ones, but sometimes two occur in one year, sometimes one, and sometimes none. Now it is not credible, if the eccentrics and epicycles are fictions (as the adversaries would have it), that we

constrain the heavens — and we would indeed seem to constrain them, if the eccentrics and epicycles are fictions — to obey our fabrications and move as we please, or as suits our own principles.

As for what concerns Nicolaus Copernicus [Copernicus], we say that he did not reject the eccentrics and epicycles as fictitious and repugnant to philosophy. For he himself likewise posits the earth as an epicycle, and in the case of the Moon he sets up an epicycle upon an epicycle; but he did this only in the attempt to emend the periods of the planetary motions, which he had found to be limping. For it is exceedingly difficult to define the periods of the motions in such a way that they do not, over many centuries, deviate from the truth, since no mortal has ever been able to determine the period of a single planet so exactly that there are not some minutes in excess or defect which, over a great interval of years, introduce a notable error. So that it is truly a wonder that God, the Best and Greatest, willed to obstruct the motions of the planets with such great difficulties that no one can perfectly attain them, but always finds something left over — the more so that everyone may admire the supreme skill displayed in bodies so noble and in the great harmony and concord of their motions, celebrating with perpetual praises their Creator and Mover. And especially because of the constitution of the heavens and their motions — in which there always seems to remain something beyond us — it seems to have been written by the Preacher [Ecclesiastes], ch. 3, that the highest diligence should be devoted to their investigation by the most skilful searchers of celestial things: *And he delivered the world to their disputation* [Et mundum tradidit disputationi eorum] — lest, namely, if men had at some time perfectly understood the number, order, constitution, and motion of the heavens, they should cease, and, the works of God no longer being investigated and admired and their talents left unexercised, grow torpid through inactivity. Therefore, that Copernicus defended the φαινόμενα (the appearances) by another route is no wonder. For since he knew from the motions of the eccentrics and epicycles the time, the quantity, and the quality of the appearances, both future and past, he was able — being most ingenious — to devise a new way by which those appearances could be defended more conveniently (as he thought), and the periods of the motions emended in some part, which he had noticed to limp. This seems to have been the chief aim of Copernicus's study, as we said — just as we too can infer a known conclusion by several syllogisms, even from false premises. But so far is it from being the case that, on account of Copernicus's teaching, the eccentrics and epicycles should be removed, that on that very account they are all the more to be posited.

For the astronomers devised these orbs precisely because they discovered, with the greatest certainty, from various phenomena, that the planets are not always carried at an equal distance from the earth. This indeed Copernicus willingly admits, since according to his teaching the planets always have an unequal distance from the earth, as is clear from the position of the earth outside the center of the world, in the third heaven. Only this is gathered from his position: that it is not entirely certain that the constitution of the eccentrics and epicycles is such as Ptolemy [Ptolemy] makes it, since many appearances can be defended by another route. Nor indeed do we contend in this question to persuade the reader of anything else than that the planets are not always carried at an equal distance from the earth; and hence that either there are in the heavens eccentric orbs and epicycles in the order in which Ptolemy placed them, or at least that some cause must be posited for these effects equivalent to the eccentrics and epicycles.

[Margin: The chief point proposed in this question.]

And if Copernicus's position involved nothing false or absurd, it would indeed be doubtful to which opinion — Ptolemy's, or rather Copernicus's — one should adhere (as far as concerns defending appearances of this kind). But since many absurd and erroneous things are contained in Copernicus's position — for instance, that the earth is not in the middle of the firmament and moves with a threefold motion (by what reasoning this can happen, I scarcely understand, since according to the philosophers one simple motion is due to one simple body); and that the Sun is set at the center of the world and is devoid of all motion —

[Margin: The absurdities that follow from Copernicus's position.]

all of which conflict with the common doctrine of the philosophers and astronomers, and seem to contradict what Holy Scripture teaches in very many places, as we have treated more fully in chapter 1: therefore Ptolemy's opinion seems to be preferred to this invention of Copernicus. From all of which it is clear that it is just as probable that there are eccentric orbs and epicycles as it is probable that there are eight, or ten, or even eleven moving heavens, since both the number of the heavens and the said orbs were discovered by the astronomers from the appearances and the motions.

Now, from the fact that Ptolemy defends the appearances of the Sun both by an epicycle and by an eccentric, it is only gathered that it is uncertain whether the Sun is carried on an eccentric or on an epicycle. But whichever be said, it is clear that the Sun is unequally distant from the earth and is by no means carried on a concentric orb — which is enough for us, as we said. Ptolemy, however, chose an

eccentric orb for the Sun, because an eccentric surrounds and encircles the center of the earth. But let us now set forth the arguments of Averroes [Averroes] and his followers and refute them, so that from this too it may appear that eccentrics and epicycles are not monsters or portents, and are in no way repugnant to natural philosophy, as the adversaries falsely think.

[Margin: Arguments against eccentrics and epicycles.]

First, then, the adversaries argue with Averroes as follows. According to Aristotle's [Aristotle] opinion in the books *On the Heavens*, simple motion is threefold: from the middle, to the middle, and about the middle; of these the first two belong to the elements, the last to the celestial bodies.

[Margin: 1st objection.]

But if eccentrics and epicycles were granted, some celestial body would move toward the middle and from the middle, since one part of them approaches nearer to the earth and another less so. Since therefore this is absurd — seeing that the celestial bodies are neither heavy nor light, so that they could have a natural inclination to a motion toward the middle and from the middle — eccentric orbs and epicycles will not be granted.

2. A celestial body, on the authority of Aristotle, is perfectly spherical. But the eccentric orbs "in a certain respect" [secundum quid] that surround the simply eccentric orb are not perfectly spherical, since they are thicker on one side and thinner on the other. Therefore they are not to be conceded.

[Margin: 2nd objection.]

3. If eccentric orbs "in a certain respect" were granted, they could not be moved without penetration or splitting of the heavens, since the thicker part of the one would have to enter the thinner part of the same. By parity of reasoning, when the subtler part slips beneath the place of the thicker, either a vacuum will result — since the thinner part cannot fill the place of the thicker — or else a rarefaction of the heaven. And since these are absurd, it will also be absurd to posit eccentric orbs.

[Margin: 3rd objection.]

4. Aristotle, in book 2 *On the Heavens*, affirms that all the φαινόμενα (appearances) of the planets can be defended by a plurality of motions. In vain, therefore, are eccentrics and epicycles posited, and they are repugnant — at least to Aristotle.

[Margin: 4th objection.]

5. The place of the whole and of the part is the same. But the place of the heaven, as Averroes holds, is the center of the world. Therefore the center of the total spheres and of the partial ones will be the same. All the orbs, therefore, are concentric, and none is eccentric.

[Margin: 5th objection.]

6. The more a sphere is distant from the first principle, the more motions it needs in order to attain or preserve its perfection, as Aristotle holds. Therefore eccentrics and epicycles are not to be conceded, since, once they are posited, the Sun would have fewer motions than Saturn, Jupiter, and Mars, which are nearer to the First Being.

[Margin: 6th objection.]

7. If eccentrics exist in the nature of things, they will certainly be moved about their own centers. But at every center about which the motion of a heaven takes place, there is an earth at rest, since everything that is moved needs something at rest, as Aristotle holds. Therefore, as many as are the eccentrics and epicycles, so many will be the earths at rest — which is absurd.

[Margin: 7th objection.]

8. If eccentrics are granted, there will be in the nature of things (as Augustinus Niphus [Agostino Nifo] says) something superfluous and idle, namely one of the two eccentric orbs "in a certain respect" that carry the Aux (apogee) of a planet. For either of them is sufficient to carry the Aux and its opposite, as is clear. Therefore one will be superfluous, since it has no use.

[Margin: 8th objection.]

These are the reasons by which the adversaries strive to prove that eccentric orbs and epicycles should be done away with. To them we shall add three others that Girolamo Fracastoro [Girolamo Fracastoro] adduces at the end of his little book *On Homocentrics* [Homocentricorum], as demonstrations that cannot be refuted. The first of these, showing that in the case of the Sun an eccentric can in no way be granted, is as follows.

[Margin: 1st objection of Fracastoro.]

If an eccentric orb were granted in the case of the Sun — one point of which, of course, recedes farthest from the earth (that is, from the center of the world, which is the center of the Equator), and one approaches nearest — then that most-remote point, and hence the Sun existing in it, would by the daily motion describe a parallel more distant from the Equator than would the other point nearest the earth. Hence the maximum declinations of the Sun would not be equal to one another; rather the northern one — where today the Aux, or most-remote point, lies — would be greater than the southern, where now the opposite of the Aux, or point nearest the earth, is found. And yet all astronomers have observed that the maximum northern declination of the Sun is equal to the southern. Again, in an oblique sphere, when the Sun is at the Aux — namely in Cancer [♋] — the diurnal arc would be greater than the nocturnal arc when it is at the opposite of the Aux, that is, in Capricorn [♐]; which is contrary to common experience. For when the Sun is in opposite degrees of the ecliptic, two parallels are described, the diurnal arc of the one being equal to the nocturnal arc of the other.

Then, of the latter arguments, which do away with the epicycles of Venus and of the Moon, the first is of this kind.

[Margin: 2nd objection of Fracastoro.]

If the epicycle of Venus were of such magnitude that its semidiameter comprised 43 degrees — and the whole diameter 86 degrees — it would reach nearly to the center of the earth. For if the semidiameter contained precisely 45 degrees, the epicycle would pass exactly through the center of the earth — which he tries to prove geometrically. Since therefore this is absurd and contrary to experience, there will be no epicycle of Venus in the nature of things.

[Margin: 3rd objection of Fracastoro.]

Lastly, if the Moon is revolved on an epicycle, we should not always see the same half of the Moon; rather, when it is in the lower part of the epicycle one half would appear to us, and when it is in the upper part, the other — as is evident from this adjoining figure. For while the Moon is in the lower part of the epicycle, the half marked with the letter A will appear to us; but while it turns in the upper part, the other half, marked with the letter B, will be presented to us. But this is contrary to daily experience, for we see the spots [maculae] of the Moon perpetually turned toward us. From which it follows that we always behold the same half. The emptiness of the epicycle in the case of the Moon is therefore

apparent. Fracastoro does indeed bring forward other reasons in the passage cited, which, since they are of no weight, we deliberately pass over.

Diagram. An uncaptioned woodcut set in the left-center of the page, illustrating Fracastoro's third objection (that a Moon carried on an epicycle would show us both of its halves). Two circles are drawn, internally tangent at the top: a small circle above and a large circle below.

- A (top of the small upper circle): one hemisphere ("half") of the Moon.
- B (just within the small upper circle, below A): the other hemisphere.
- B (upper-central region of the large lower circle): the hemisphere facing away when the Moon is high on the epicycle.
- A (near the center of the large lower circle, below B): the hemisphere that would face the earth when the Moon is low on the epicycle.

The letters A and B mark the two "halves" of the Moon referred to in the text. All four labels (A, B, B, A) are legible.

[Margin: Solution to the 1st objection.]

We shall easily satisfy all these arguments. To the first, then, we reply that the eccentrics and epicycles are moved about their own middle, that is, about their own centers. That by this motion they now approach nearer to the earth, now move farther from it, is not absurd, because this approach and recession does not occur along a straight line — which alone Aristotle excluded from the celestial bodies, since it belongs only to the elements, which are heavy and light. And if anyone should contend that Aristotle thought the contrary, this must be pardoned in him; for he spoke only of those motions that were known in his own time, namely, from the middle and to the middle along a straight line, and about the middle of the world. And if the motions of the eccentrics and epicycles had been known in his time, I do not doubt that he would have spoken otherwise about motion around the middle. But if this solution does not satisfy the adversaries, they will have to prove that every celestial motion must take place about the center of the world — which they will never achieve. For it does not belong to them to prescribe laws to the celestial motions, but to God the Best and Greatest, who by his infinite goodness and providence judged it fitting that the planets should not be carried about the earth on concentric orbs.

[Margin: Solution to the 2nd objection.]

We shall resolve the second objection if we say that all the eccentric orbs — even those "in a certain respect" — and the epicycles are most perfectly spherical with

respect to their own centers. For the outermost surfaces of all these orbs are equally distant from their own centers on all sides. Nor indeed is it an obstacle that the eccentric orbs "in a certain respect" are thicker in one part than in another, since no natural reason can persuade us that all the celestial orbs must be of uniform and equal thickness. And if Aristotle taught the contrary, we do not believe him on this point.

[Margin: Solution to the 3rd objection.]

As for the third argument, I greatly wonder that Averroes and the Averroists — whom in this matter you might more truly call "Errorists" [Erroistae] — are borne with so hostile a spirit against the eccentrics and epicycles that they have been unwilling to understand by what manner they are moved. For those two eccentric orbs "in a certain respect" are not moved in such a way that the thinner part of the one takes the place of the thicker, and vice versa, as they falsely imagine; rather they are borne together proportionally, so that perpetually the thicker part of the lower lies beneath the thinner part of the upper, and vice versa, and together they carry around the simply eccentric orb, in such a way that they have no motion other than that of the whole heaven of the planet. The argument would have force only if the simply eccentric orb were at rest and the eccentrics "in a certain respect" surrounding it were moved — which is not the case.

[Margin: Solution to the 4th objection.]

To the fourth objection it must be replied that Aristotle was always of the opinion that in astronomical matters the astronomers should be consulted. Hence he then followed the astronomers of his own time, namely Eudoxus [Eudoxus] and Callippus [Callippus], who strove to defend all the φαινόμενα (appearances) by concentric circles. But I do not doubt that, had he lived in Ptolemy's time, he would have embraced the eccentrics and epicycles, since all things are most conveniently defended by that method. For he always affirms that in astronomical matters faith is to be placed in the astronomers.

[Margin: Solution to the 5th objection.]

To the fifth argument we say that the opinion that the heaven is in place by its center is proper to Averroes. Hence, if we choose not to accept it, the argument concludes nothing against us. Yet if anyone wishes to defend that opinion, he can say that the eccentric orbs and epicycles too are in place by their own centers, and that the center of the world is the place of the total heavens, but not of the partial orbs. And if someone presses that the place of the whole and of the parts is

the same, that must be understood of the common place, not of the proper place. For any part of a stone has the same place in common with the stone, but not the same proper place, since the place must be equal to what is placed in it. So then, if one wishes to defend Averroes's opinion, he will be able to say that the common place of all the spheres, both partial and total, is not the center of the world, but the center absolutely — whatever that may be — or certainly the aggregate of all the centers; and thus that they have the same common place, namely a center, while each orb nevertheless has its own proper place, namely its own center.

[Margin: Solution to the 6th objection.]

To the sixth argument we reply that the Sun has fewer motions than the superior planets not only on the system of eccentric orbs and epicycles, but also on that of the concentrics, as is clear from Fracastoro, chapter 24, where he reviewed the number of the orbs. Hence we deny that the celestial orbs, the lower they are, must be stirred by the more motions, and the higher they are by the fewer, since experience has taught the contrary, as the adversaries themselves admit.

[Margin: Solution to the 7th objection.]

To the seventh objection it must be denied that an earth at rest is necessary at every center in order that the celestial orbs may be moved about it. For although God the Best and Greatest were to remove this earth altogether, or drive it elsewhere outside the center of the world, the heavens would still be carried by the daily motion about the middle of the world.

[Margin: Solution to the 8th objection.]

To the eighth argument it must be said that the two eccentric orbs "in a certain respect" are necessary, so that they may make up and complete the whole heaven of the planet, which is concentric with the world. Hence neither of them should be reckoned superfluous, for the whole heaven that is composed of them has its own proper motion. These orbs are not posited solely in order to carry the Aux and its opposite, as the objection falsely assumes.

[Margin: Solution to the 1st objection of Fracastoro.]

Now, as for the three arguments of Fracastoro, we say that the first concludes nothing in the case of the Sun. For since the Sun is at so great a distance from the earth that it admits either no parallax [aspectus diversitas] at all, or certainly an imperceptible one, it comes about — since the plane of its eccentric always lies in the plane of the ecliptic (as will be explained in the *Theorics* [Theoricae]) — that it always appears on the ecliptic, if it is viewed from the earth. Hence, when it is at

the beginning of Cancer [♋] or Capricorn [♏], it will appear to describe by the daily motion the same parallels that the beginnings of Cancer and Capricorn describe in the *primum mobile*, which are equal. Nor is it an obstacle that the Sun is at the Aux when it is in Cancer, and at the opposite of the Aux when it is in Capricorn. Otherwise Saturn, while it is on the ecliptic and at the beginning of Cancer, would describe a parallel more remote from the Equator than Jupiter, since Saturn is farther from the earth than Jupiter — which is false. For each planet, while it is on the ecliptic and at the beginning of Cancer, has been found to have a declination of $23\frac{1}{2}$ degrees and to describe by the daily motion the Tropic of Cancer [♋]. Therefore it does not follow that the maximum northern declination of the Sun is greater than the maximum southern declination, nor, in an oblique sphere, that the longest day in summer is longer than the longest night in winter. All these absurdities would indeed follow if the Sun had a notable parallax. Nevertheless it is true that the center of the Sun, when it is at the Aux, describes by the daily motion in its own orb a parallel more distant from the Equator than when it is at the opposite of the Aux, because there it describes a less distant one. But since each parallel, on account of the excessive distance of the Sun from the earth, seems to be described by the points at which, in the *primum mobile*, the straight lines drawn from the center through the Aux and through the opposite of the Aux terminate, it comes about that they are judged to be equally distant from the Equator, as far as the senses go.

[Margin: Solution to the 2nd objection of Fracastoro.]

To the second argument of Fracastoro we reply that the astronomers do not lay down that the semidiameter of Venus's epicycle contains 43 degrees, but 43 of those parts of which 60 are contained in the semidiameter of the eccentric circle. From this it comes about that the lines drawn from the center of the earth and touching the epicycle cut off from the *primum mobile*, on both sides of the line of the Aux, about 45 degrees — which is precisely the amount by which, at most, Venus is seen to recede from the Sun, both toward the east and toward the west. But it does not follow from this that the epicycle reaches almost to the earth. For since, as Fernellius of Amiens [Jean Fernel] reports in his *Cosmotheoria*, the semidiameter of the eccentric circle contains nearly 689 [?] earth-radii, the semidiameter of the epicycle will comprise about $435\frac{2}{3}$ [?] earth-radii. If we subtract this number from the distance of the earth to the opposite of the Aux — which comprises about $674\frac{1}{3}$ [?] earth-radii — the interval between the center of the earth and the opposite of the Aux of the epicycle, while the epicycle is nearest the earth (namely at the opposite of the Aux of the eccentric), will contain about 179 earth-radii. This distance contains more than 640641 miles. We, however,

following Maurolico [Francesco Maurolico] in chapter 1, make this distance of the concave surface of Venus somewhat smaller, namely $167\frac{2}{3}$ earth-radii, that is, 600167 $\frac{14}{33}$ miles. Therefore the epicycle of Venus does not touch the earth, but is separated from it by so great an interval that within it the heaven of Mercury and the heaven of the Moon, together with all the elements, can conveniently be enclosed. Moreover, Fernel himself depicted the proper figure, with the proportions of the diameters of the eccentric and the epicycle, in the *Theoric of Venus*; so that from it too it may easily appear that the epicycle of Venus cannot reach the earth, but is immersed within the thickness of the eccentric orb.

[Margin: Solution to the 3rd objection of Fracastoro.]

Lastly, in defense of the epicycle of the Moon, Fernelius of Amiens replies, in the book cited, that the Moon has on its epicycle a proper motion about its own center, conformable to the motion of the epicycle, but in the contrary direction.

From this motion it follows that the Moon always turns the same spotted face toward us. Nor should this seem surprising or absurd, even though Aristotle denied that the stars have motions of their own. For since the phenomena [Greek: φαινόμενα (phainomena, "appearances" — the observed phenomena)] show that the Moon is carried on an epicycle and always turns the same face toward us, it must be that it revolves by its own motion about its own center, so that it perpetually remains in a certain stable equilibrium.

From all these considerations, then, I take it to be established that eccentrics and epicycles are not so monstrous and absurd as our opponents pretend, and that astronomers introduced them not without good reason. Suppose they are to be judged absurd because they have different centers, and because eccentrics have, in a certain respect, an unequal thickness. Why then should we not say the same absurdity attaches to the fact that the Moon does not have a uniform density, but has parts that are denser in some places than in others, as its spots indicate? Had the opponents not seen these spots with their own eyes, I have no doubt that, if astronomers had proposed them, they would have hissed them off the stage. Let them, then, make it a point of religious scruple to admit anything into the heavens that seems to depart even in the slightest from the most perfect uniformity. And yet — in the Firmament itself, which the followers of Aristotle are forced to assert is, as it were, the standard for all the other spheres — there nonetheless appears the greatest unevenness, both from the stars and, if we follow the truth, from the Milky Way. Since, therefore, this great inequality throughout the whole depth of the heavens, in respect of density and rarity, is not denied even by the opponents, why should eccentrics and epicycles be reckoned

absurd and monstrous merely on account of the difference of their centers and their unequal thickness? But enough has now been argued about eccentrics and epicycles for the present occasion. Let us now return to the author's exposition, which we set aside.

It should be noted that the Sun has a single circle, etc.

COMMENTARIVS.

[Margin: Of what the Sun's heaven is composed.]

First, then, the author treats of the Sun's orb and motion, saying that the Sun has a single eccentric circle, on which it is perpetually carried beneath the Ecliptic from west to east. To understand this, we must recall to mind what we said a little earlier: namely, that the whole heaven of the Sun — which has its center in common with the center of the world — is divided by Ptolemy and the more recent astronomers into three partial orbs, contiguous to one another. Of these, the highest is, along its convex surface, concentric with the world — that is, its center does not differ from the center of the world — but along its concave surface it is eccentric, that is, it has a center other than the center of the world. The lowest orb, conversely, is concentric with the world along its concave surface, and eccentric along its convex surface. The third, finally, which is placed in the middle of these, is eccentric along both surfaces, convex as well as concave, because it is contiguous with the concave surface of the upper orb and the convex surface of the lower. Hence the first two orbs are usually called eccentric in a certain respect [*eccentrici secundum quid*], because they have a center different from the center of the world along one surface only; but the third, the intermediate one, is called eccentric absolutely [*eccentricus simpliciter*], and in it the Sun is fixed and moves about its center from west to east, so that the center of the Sun describes in the course of a year a certain circle beneath the Ecliptic, whose center is the same as the center of the orb that is eccentric absolutely. This, then, is the circle that the author here calls the Eccentric, on which the Sun moves by its own motion.

[Margin: What the Aux of the Sun and the opposite of the Aux are.]

Now since this circle has a center distinct from the center of the world (that is, of the Firmament), it follows that one of its points — namely the one indicated by a straight line drawn from the center of the world through the circle's own center — is farthest from the earth and nearest to the Firmament; while the other, which lies opposite to it, is nearest to the earth and farthest from the Firmament.

That first point, he says, is called by the Arabs the Aux of the Sun [Aux Solis — the apogee]; and the opposite point, the opposite of the Aux [the perigee].

[Margin: The Sun has a double motion from west to east.]

Next he teaches that the Sun has a double motion from west to east. One is its own motion, on its eccentric, on which it completes each day about 59 minutes and 8 seconds. Hence that eccentric orb is usually called the deferent of the Sun, because by its motion the Sun is carried beneath the Ecliptic from west to east. It then has a second motion, an extremely slow one, by which it is moved — along with the motion of the whole heaven of the Sun — from west to east by 1 degree in 100 years, according to Ptolemy; but according to Alfonso, by 1 degree 28 minutes in 200 years. And because by this motion those two eccentric-in-a-certain-respect orbs carry the Aux of the Sun and the opposite of the Aux to different and different points of the Ecliptic — though very slowly — they are called by astronomers the deferents of the Aux of the Sun. In the year 1592 the Aux of the Sun stood at about 9 degrees 13 minutes of Cancer, according to the Prutenic Tables, and its opposite at 9 degrees 13 minutes of Capricorn. From these two motions, then, he says, the annual motion of the Sun is compounded. But the arrangement of these three orbs of the Sun, and their motions, are usually explained more fully in the Theorics of the Planets.

[Margin: Which are the orbs that carry the Aux of the Sun.]

[Margin: Of what the heavens of the other planets, besides the Sun, are composed.]

Every planet, however, except the Sun, has three circles: namely the Equant, the Deferent, and the Epicycle. The Equant of the Moon is a circle concentric with the earth, and lying in the plane of the Ecliptic. But its Deferent is an eccentric circle, and does not lie in the plane of the Ecliptic; rather, one half of it inclines toward the north, the other toward the south. And the Deferent intersects the Equant in two places; and the figure of the intersection is called a Dragon [Draco], because it is broad in the middle and narrower toward the ends. That intersection through which the Moon moves from south toward north is called the Head of the Dragon [caput Draconis]; the other intersection, through which it moves from north to south, is called the Tail of the Dragon [cauda Draconis].

[Margin: What the Head and Tail of the Dragon are in the case of the Moon.]

The Deferent and the Equant of every planet are equal. And it should be known that the deferent and equant of Saturn, Jupiter, Mars, Venus, and Mercury are all

eccentric and outside the plane of the Ecliptic — and yet the two of them lie in the same plane.

[Margin: In the five planets the deferent and equant are eccentric, and lie in the same plane, which declines from the Ecliptic.]

Every planet also, except the Sun, has an Epicycle. Now the Epicycle is a small circle, along whose circumference the body of the planet is carried; and the center of the Epicycle is always carried on the circumference of the deferent.

[Margin: What the Epicycle is.]

COMMENTARIVS.

Secondly, he treats of the orbs and motions of the other planets, saying that each of them has three circles: namely the Equant, the Deferent, and the Epicycle. The Equant of the Moon is a circle concentric with the earth, and lies in the plane of the Ecliptic. This circle is called the Equant of the Moon because, as is established from the Theorics, it is from its motion that the true motion of the Moon is known adequately and precisely. The Deferent of the Moon, however, is a circle eccentric absolutely, like that of the Sun, with this one exception: that this eccentric does not lie in the plane of the Ecliptic, as the Sun's does, but one half of it inclines away from the Ecliptic toward the north, the other toward the south. Hence it comes about that the Moon, carried along on this circle, is found sometimes outside the Ecliptic toward the north, sometimes toward the south, but never exactly beneath the Ecliptic except at those two points where the Ecliptic — or Equant — and the Deferent circle of the Moon intersect one another. This Deferent, which is eccentric absolutely, is surrounded by two other orbs eccentric in a certain respect, just as was said of the Sun. Of the two points at which the Equant and the Deferent of the Moon intersect, the one through which the Moon is carried northward on the Deferent is called the Head of the Dragon; the other, through which it tends southward, the Tail of the Dragon. And these two points are carried from east to west by the Equant of the Moon; for this Equant orb is the highest in the sphere of the Moon. For this reason astronomers usually say that it carries the Head and Tail of the Dragon, and that it is larger than the eccentric that carries the Moon.

[Margin: Why equant orbs were devised in the planets.]

The Deferent and the Equant of every other planet are equal to one another, and eccentric absolutely, and each lies outside the plane of the Ecliptic, although both exist in one and the same plane. Now equant circles were devised in these planets

— for they are not real orbs and parts of the planetary spheres, as the Deferent and the eccentrics-in-a-certain-respect are, but only imaginary — in order that the irregularity of the Deferent of each planet might be reduced to uniformity by the aid of its own Equant, as will be clearly established from the Theorics. Each deferent of a planet also has two other eccentrics-in-a-certain-respect, one above it and the other below, as we said of the Sun, which are called the deferents of the Aux. Mercury alone has four eccentric-in-a-certain-respect orbs, of which two are called the eccentric deferents of the Aux, which carry Mercury, and the other two the deferents of the Aux of the Equant. Although the first two — the eccentric deferents of the Aux, or the deferents of Mercury — may also be called eccentric absolutely, since their convex and concave surfaces have a center different from the center of the world, yet with respect to the deferent of Mercury, which is absolutely eccentric, they may in a certain way be called eccentric-in-a-certain-respect. For the concave surface of the upper and the convex surface of the lower have the same center as the eccentric that carries Mercury, while the convex surface of the upper and the concave surface of the lower have a different one.

Furthermore, every planet except the Sun has, besides the said circles, an epicycle as well — that is, a tiny orb immersed in the deferent orb, in which the planet is carried. For the body of the planet is fixed in the epicycle; yet the center of the epicycle is perpetually carried by the motion of the eccentric, or deferent. But these things can scarcely, or only with difficulty, be understood without the instruments of the Theorics. We shall, however, set all these matters out more fully in the Theorics of the Planets.

ON THE STATION, DIRECT MOTION, AND RETROGRADATION OF THE PLANETS.

If, then, two lines are drawn from the center of the earth so as to enclose the epicycle of some planet — one on the eastern side, the other on the western — the point of contact on the eastern side is called the first station; the point of contact on the western side is called the second station. And when the planet is at either of those stations, it is said to be stationary. The upper arc of the epicycle intercepted between the two stations is called direct motion [directio]; and when the planet is on it, it is said to be direct. But the lower arc of the epicycle intercepted between the two stations is called retrogradation; and the planet situated there is said to be retrograde. To the Moon, however, no station, direct motion, or retrogradation is assigned; hence the Moon is not called stationary, direct, or retrograde, because of the speed of the motion of the center of the epicycle on the eccentric.

[Margin: The various affections [passiones] of the planets.]

COMMENTARIVS.

He now treats of certain affections of the planets, namely the station, direct motion, and retrogradation of the planets. He says, then, that if two straight lines are drawn from the center of the earth touching the epicycle — one on the eastern side, the other on the western — those points of contact are called stations: the point on the eastern side the first station, and the one on the western side the second station. A planet situated at either of those stations is therefore called stationary, because then the planet appears to us, as it were, to stand still on its epicycle and not to change its place in the Zodiac through its motion on the epicycle, since at that moment it is either ascending or descending. But if we wish to understand "station" in the strict sense — that is, to understand the point of the epicycle at which, when the planet is there, the motion of the eccentric and the motion of the epicycle bear such a proportion to one another that the planet seems to stand altogether at the same place in the Zodiac — then this occurs a little below those points of contact, as is explained in the Theorics. Next, he says, the upper arc of the epicycle intercepted between the two stations is called the direct motion of the planet, and a planet situated on it is called direct, because it then moves according to the succession and order of the signs — that is, from west to east, say from Aries to Taurus, from Taurus to Gemini, and so on. But the lower arc is called retrogradation, and a planet placed on it is termed retrograde, because it then advances against the succession and series of the signs — that is, from east to west, namely from Aries to Pisces, from Pisces to Aquarius, and so on. All of which is to be understood of the planets that have an epicycle, the Moon excepted, so that in the Sun and the Moon these do not apply. For the epicycles of the planets, the Moon excepted, move in their upper part according to the succession of the signs, but in their lower part against the series of the signs; whereas the Moon's epicycle, on the contrary, moves with the succession of the signs in its upper part, and according to the series of the signs in its lower part. Hence the Moon ought to be called direct when it is in the lower part of the epicycle, because there it moves according to the series of the signs, and retrograde when placed in the upper part of the same. Nevertheless the Moon is called neither direct nor retrograde, on account of the swift motion of the Moon itself on the eccentric. For the Moon is carried, along with the motion of the center of the epicycle on its deferent, most swiftly from west to east. Hence it cannot be called stationary, nor direct, nor retro-

[Margin: Why the Moon is not called stationary, direct, or retrograde.]

grade, because the motion of the center of the epicycle on the deferent overcomes the proper motion of the epicycle. Yet when placed in the lower part of the epicycle it is said to be swift, and in the upper part slow, since there its motion from west to east is, as it were, doubled, whereas here it is in a manner retarded, as will be clear in the Theorics.

ON THE ECLIPSE OF THE MOON.

[Margin: The earth's shadow is conical.]

[Margin: What the Nadir of the Sun is.]

[Margin: When an eclipse of the Moon occurs.]

[Margin: Why an eclipse of the Moon does not occur at every full moon.]

Since the Sun is larger than the earth, it is necessary that half the sphere of the earth is always illuminated by the Sun, and that the earth's shadow, extended in the air and turned as on a lathe, diminishes in its roundness until it comes to nothing at the surface of the circle of the signs [the zodiac], inseparable from the Nadir of the Sun. Now the Nadir of the Sun is the point directly opposite the Sun in the Firmament. Hence when, at full moon, the Moon is at the Head or the Tail of the Dragon, beneath the Nadir of the Sun, then the earth is interposed between the Sun and the Moon, and the cone of the earth's shadow falls upon the body of the Moon. And since the Moon has no light except from the Sun, it is in truth deprived of light. And it is a general eclipse over all the earth, if the Moon is exactly at the Head or Tail of the Dragon; but a particular eclipse, if it is near, within the determined limits of the eclipse. And an eclipse always happens at, or about, full moon. Hence, since it is not at every opposition — that is, full moon — that the Moon is at or near the Head or Tail of the Dragon, nor placed beneath the Nadir of the Sun, it is not necessary that the Moon suffer an eclipse at every full moon.

COMMENTARIVS.

Here he explains in what manner an eclipse of the Moon occurs, and why the Moon does not suffer an eclipse at every full moon. For since the Sun is much larger than the earth, as we taught in chapter 1, it is necessary — as Witelo [Vitellio] demonstrates in Book 2 of the *Optics* [*Perspectiva*], proposition 27 — that more than half of the earth be illuminated by the Sun, and therefore that the earth's shadow resemble a cone, or spinning-top, whose apex never departs from the plane of the Ecliptic. For neither does the center of the Sun deviate from that

plane, and the apex is always opposite the Sun, since the earth lies at the center of the Ecliptic, that is, of the whole world. From which it is manifest that, since a full moon occurs when the Sun and Moon stand at diametrically opposite degrees, but the Moon is not beneath the Ecliptic except when it is at the Head or Tail of the Dragon (as we said a little before), the Moon suffers an eclipse only at that full moon at which it is found either at the Head or at the Tail of the Dragon. For thus it comes about that the Moon enters the earth's shadow and is prevented from being lit by the Sun. Hence, since it borrows its light from the Sun, it must then fail and be deprived of light, because then the earth is interposed precisely between the Sun and the Moon. The whole Moon will indeed be darkened over the whole earth, if at full moon it stands exactly at the Head or Tail of the Dragon, because it will be wholly plunged into the shadow; but not the whole of it, if at full moon it is found near the Head or Tail of the Dragon — in such a way, however, that the earth's shadow covers some part of the Moon. From these things it is clear why the philosophers say that an eclipse of the Moon is the interposition of the earth between the Sun and the Moon; because truly, in an eclipse of the Moon, the earth lies on the same diameter on which the said planets are placed at that time, and along which they are in opposition. But since for the most part the oppositions of the luminaries occur while the Moon is not at the Head or Tail of the Dragon, nor even so near that it can be covered by the shadow, an eclipse of the Moon therefore does not always occur at every full moon. For the Moon must be either at the Head or at the Tail of the Dragon for an eclipse to occur. All these matters will indeed be clearer in the Theorics of the planets.

ON THE ECLIPSE OF THE SUN.

[Margin: When an eclipse of the Sun occurs.]

[Margin: An eclipse of the Moon occurs over the whole earth, but an eclipse of the Sun does not.]

[Margin: The eclipse of the Sun at the Passion of the Lord was miraculous.]

But when the Moon is at the Head or Tail of the Dragon, or near, or within the aforesaid limits, and in conjunction with the Sun, then the lunar body is interposed between our sight and the solar body. Hence it will overshadow for us the brightness of the Sun, and thus the Sun will suffer an eclipse — not because it fails in light, but because it fails for us, on account of the interposition of the Moon between our sight and the solar body. From these things it is clear that there is not

always an eclipse of the Sun at conjunction, that is, at new moon. It should also be noted that when there is an eclipse of the Moon, it is an eclipse over all the earth; but when there is an eclipse of the Sun, by no means so: rather, in one clime there is an eclipse and in another there is not. This happens on account of the difference of aspect [parallax of sight] in different climes. Hence Virgil most elegantly touched on the natures of both eclipses in a brief compass, saying: "The various failings of the Moon, and the labors of the Sun." [Virgil, Georgics II.478; the received text reads "defectus solis varios lunaeque labores," with Sun and Moon in the reverse arrangement to that printed here.]

From what has been said it is clear that, since there was an eclipse of the Sun at the Passion of the Lord, and that same Passion was at full moon, that eclipse was not natural but rather miraculous and contrary to nature, because an eclipse of the Sun ought to occur at new moon, or thereabouts. On which account we read that Dionysius the Areopagite said, at that same Passion: "Either the God of nature is suffering, or the machine of the world will be dissolved."

COMMENTARIVS.

[Margin: Why an eclipse of the Sun does not occur at every new moon.]

Finally, he explains in what manner an eclipse of the Sun occurs, saying: Whenever the Moon, in conjunction with the Sun — that is, at new moon — stands at the Head or the Tail of the Dragon, or at least near, yet within the limits of eclipse, it will be interposed between our sight and the Sun; hence it will hide from us the brightness of the Sun, and an eclipse of the Sun will occur — not that the Sun itself is deprived of light, but only with respect to us, on account of that interposition of the Moon between our vision and the solar body.

But an eclipse of the Sun will not occur at every conjunction of the Moon with the Sun — that is, at every new moon — because it is not at every conjunction that the Moon interposes itself between the Sun and our sight, but only when the Moon is so joined to the Sun (that is, exists in the same sign and degree in which the Sun is) that a line going out from our eye and drawn through the center of the Moon reaches the Sun. And this will happen when the Moon, at new moon, is found at the Head of the Dragon, or the Tail, or at least near.

Commentary on Chapter 4 of the *Sphere* (conclusion) — and the beginning of the *Theorica planetarum* arranged in tables

Conclusion of the eclipse commentary

He then teaches that there is this difference between an eclipse of the Sun and one of the Moon: an eclipse of the Moon is universal over the whole earth, so that its light fails in every region; but an eclipse of the Sun is by no means universal. Rather, there can be a solar eclipse in one clime and not in another—indeed, it can be greater in one and smaller in another. This is because a solar eclipse depends on our line of sight [aspectu], which differs in different climes, as is explained in the *Theorica*; a lunar eclipse, however, does not, but depends only on the earth's shadow, which is always the same in every clime.

From what has been said, the Author finally infers that, since a solar eclipse necessarily occurs at new moon—that is, at the conjunction of the Moon with the Sun—the eclipse of the Sun that took place at the Lord's Passion, when it was in fact full moon, was not natural but miraculous, and against the course and order of nature. For by divine power the Moon, abandoning its own proper course, moved toward the Sun and hid it from us. And on this account, as the histories attest, blessed Dionysius the Areopagite [Dionysius Areopagita] exclaimed at that time: "*Either the God of nature is suffering, or the fabric of the world is being dissolved.*" Because of this they raised an altar consecrated to the unknown God, whom shortly afterward St. Paul made known to them, and so led them to faith and to the knowledge of the true God, who is blessed and glorious for ever and ever, Amen.

Since, however, what the Author has written in this chapter about the motions of the planets and the eclipses of the Sun and Moon is so obscure that it cannot be explained in a few words, it has seemed good at this point—something that many people have told me would be most welcome to the studious reader, and have even urged me to undertake—to append certain tables that set the whole theory of the planets before our eyes, as if in a mirror. These tables were once composed by a certain learned man, but I have recast them into a more convenient form. To them I have added, from approved writers, the distances of the centers of the eccentric orbs and of the epicycles from the center of the world, and the magnitudes of the semidiameters of those same orbs in parts of which the Earth's semidiameter is one. The methods by which all these things may be investigated

and tested will be explained in my *Theorica*. (For I did not have the time here to examine the distances of the centers and the magnitudes of the semidiameters for myself, but took them from other authors as they stand written.)

THEORICS OF THE PLANETS, ACCORDING TO THE TENETS OF THE ALPHONSINES [Alphonsinorum], ARRANGED IN TABLES

(*THEORICÆ Planetarum iuxta placita Alphonsinorum per tabulas digestæ.*)

THEORICA OF THE ORBS AND MOTIONS OF THE SUN

(Two-page table spread. The caption runs across the opening: verso "*THEORICA ORBIVM*", recto "*ET MOTVVM ☉ SOLIS*" = "*Theory of the orbs and motions of the Sun.*" Left marginal brace, set vertically: "*Sphæram ☉ constituunt orbes tres*" — "*Three orbs constitute the sphere of the Sun.*")

The nine columns of the spread give, for each partial orb: (1) the particular orbs of which the whole solar sphere consists; (2) their names and positions relative to the center of the world; (3) the centers of the orbs and their distances from the center of the world; (4) the axes on which they turn; (5) the poles on which they turn; (6) their proper motions or revolutions; (7) the semidiameters of the orbs, in parts of which the Earth's semidiameter is one; (8) the plane surfaces of the orbs as inclined to the plane of the ecliptic; (9) the apogee [aux] of the eccentric for the year of Christ 1554.

Theory of the Orbs, Set Out in Tables (continued)

These pages give the synoptic "theory of the orbs" [*theorica orbium*] for the three superior planets together (Saturn ♄, Jupiter ♃, Mars ♂), then for Venus ♀, then Mercury ☿, and finally the outermost spheres. Each planet's full table occupies one opening: the **structural** columns (orbs, names/positions, centres, axes) stand on the verso, and the **quantitative** columns (poles, motions, semidiameters, surfaces, aux) on the facing recto; the two halves share the same orb-rows and are stitched here per orb.

THEORICA ORBIVM — Saturn ♄, Jupiter ♃, Mars ♂

Structural half

[Margin (running down the left edge): For the spheres ♄, ♃, ♂, four orbs each constitute the individual spheres; moreover a fifth is to be conceived, the **equant eccentric** [*aequans eccentricus*], which is only a circle.]

Column headings:

1. **Particular orbs** of which the whole spheres of h , a , o consist.
2. **Names and positions** of the particular orbs with respect to the centre of the world.
3. **Centres of the orbs, and the distances of the centres** from the centre of the world.
4. **Axes of the orbs** on which they move.

Particular orb	Name & position (rel. to centre of world)	Centre & its distance from the centre of the world	Axis of motion
Two eccentrics carrying the aux [<i>duo augem eccentrici deferentes</i>]	Partly concentric , and eccentric in a certain respect, like the deferents of the aux of the Sun $\odot$ and Moon C .	Of the world , as to the outermost surfaces; for the surfaces contiguous to the Eccentric have the same centre as the Eccentric.	Of the ecliptic of the eighth sphere .
Eccentric carrying the epicycle [<i>eccentricus deferens epicyclum</i>]	Eccentric, absolutely, or a deferent.	Its own centre, distant from the centre of the world in earth- semidiameters: in h 980, min. 53; a 532, min. 12; o 503, min. 12. — Or in parts: h 3, min. 25; a 2, min. 45; o 6, min. 0; of which the semidiameter of the Eccentric holds 60.	Cutting the axis of the ecliptic, but outside the centre of the world.
Equant circle [<i>aequans circulus</i>]	The equant eccentric .	Its own centre, distant from the centre of the world by twice the distance of the	Equidistant from the axis of the deferent, or of the eccentric.

Particular orb	Name & position (rel. to centre of world)	Centre & its distance from the centre of the world	Axis of motion
		centre of the Eccentric from the centre of the world.	
Epicycle [<i>epicyclus</i>]	Wholly outside the centre of the world.	Its own centre, unequally removed from the centre of the world; but [equal] in magnitude to the semidiameter of the Eccentric, or of the Deferent, [measured] from the centre of the Eccentric.	Mobile , on account of the motion of latitude.

Quantitative half

Column headings: 5. **Poles of the orbs** on which they move. 6. **Proper motions, or revolutions of the orbs.** 7. **Semidiameters of the orbs in parts**, of which the semidiameter of the earth is one. 8. **Plane surfaces of the orbs, inclined to the plane of the ecliptic.** 9. **Aux of the eccentric, for the year of Christ 1554** (S[igns] · G[degrees] · M[inutes]).

Orb	Poles	Proper motion / revolution	Surface	Aux (1554): S · G · M
Two eccentrics carrying the aux	Of the ecliptic of the eighth sphere.	From west to east, i.e. according to the series of the signs, in 49000 years.	Under the ecliptic of the eighth sphere.	♄ 8 · 13 · 28 ♊ 5 · 23 · 52 ♂ 4 · 15 · 27
Eccentric	Unequally	From west to	Declining	—

Orb	Poles	Proper motion / revolution	Surface	Aux (1554): S · G · M
carrying the epicycle	declining from the poles of the ecliptic; for the northern pole is more distant than the southern.	east, i.e. according to the succession of the signs, in years: ♄ 29 y · 155 d · 8 h; ♃ 11 y · 313 d · 17 h; ♀ 1 y · 321 d · 22 h.	from the ecliptic, with a fixed declination, such that the auges always incline to the north and never cross the ecliptic, and describe circles parallel to the ecliptic of the eighth sphere, by virtue of the motion of the eighth sphere.	
Equant circle	Equidistant from the poles of the Eccentric, or of the Deferent.	From west to east, to the motion of the Eccentric, or of the Deferent. According to the order of the signs, i.e. from west to east in the upper part; but in the lower part the contrary, i.e. from east to west; in days:	Declining from the ecliptic, and never receding from the plane of the eccentric.	—

Orb	Poles	Proper motion / revolution	Surface	Aux (1554): S · G · M

<i>eccentrici deferentes]</i>		as to the outermost surfaces; but as to the other, middle ones, the same as the Eccentric.	sphere, on account of the motion of the eccentric in latitude.
Eccentric carrying the epicycle	Eccentric, absolutely, or a deferent.	Its own centre, movable — describing, at the motion of the [orbs] carrying the aux of the eccentric, a small circle, and standing unequally distant from the centre of the world. The minimum distance contains 3 parts ; the maximum, however, 9 , of which the semidiameter of the Eccentric holds 60. Or the minimum has earth- semidiameters 5 , min. 48 ; the maximum, however, 17, min. 24.	Equidistant from the axis of the [orbs] carrying the aux of the eccentric.
Equant circle	The equant	Its own centre,	Equidistant from

Particular orb	Name & position	Centre & distance from centre of world	Axis of motion
	eccentric.	distant from the centre of the world according to the minimum distance of the centre of the Eccentric.	the axis of the [orbs] carrying the aux of the eccentric.
Small circle [<i>circulus paruus</i>]	Wholly outside the centre of the world.	The same as [that] of the [orbs] carrying the aux of the Eccentric.	The same as that of the [orbs] carrying the aux of the eccentric.
Epicycle	Wholly outside the centre of the world, and is moved.	Its own centre, distant from the centre of the Eccentric according to the magnitude of the semidiameter of the Eccentric; but from the centre of the world, unequally.	Mobile , both for the motion of inclination and of reflexion.

THEORICA ORBIVM, ET MOTVVM — Primum Mobile, Ninth Sphere & Eighth Sphere

Begins PDF p. 324 / printed p. 312 (verso, lower table); continues into the next opening

For the three outermost, simple spheres the structural and quantitative columns are combined into a single table ("Theory of the orbs and motions"). Only the first two columns fall on this page; the remaining columns (centres, axes, poles, motions, semidiameters, surfaces) continue on the facing recto of the next opening. **Table continues.**

Column headings (visible portion): 1. Orbs of which the whole spheres consist.
2. Names & positions of the orbs with respect to the centre of the world.

Sphere	Orb	Name & position
[Margin: One single orb constitutes the Primum Mobile .]	A single orb , in which ten circles, and several others besides, are conceived, of which the chief are the Equinoctial and the Zodiac .	Concentric with the world. The Primum Mobile .
[Margin: One orb constitutes the ninth sphere .]	One orb , in which — besides the Zodiac and two small circles — no other circle is understood.	Concentric . The ninth sphere [<i>nona sphaera</i>]. The Second Movable.
[Margin: A single orb constitutes the eighth sphere .]	A single orb , in which the Zodiac (called the Movable) exists together with the fixed stars. It is divided, moreover, into 48 celestial images [constellations].	Concentric . The eighth sphere . The Firmament [<i>firmamentum</i>].

Theoricæ Planetarum per tabulas digestæ (continued)

Theorica of the orbs and motions of Mercury (concluding columns)

[This recto (printed p. 313) carries the right-hand column-group of the Mercury *Theorica orbium* whose left-hand (identity/centre) columns stood on the facing verso. Table caption, spanning the opening: ...**ET MOTVVM ꝯ MERCVRII** — "... and of the motions of Mercury." Six orb-rows.]

Column headers (verbatim):

- **POLI orbium, super quibus moventur.** — Poles of the orbs, upon which they are moved.

- **MOTVS proprij, sive revolutiones orbium.** — Proper motions, or revolutions of the orbs.
- **SEMIDIAMETRI orbium in partibus, quarum semidiameter terræ est una.** — Semidiameters of the orbs in parts of which the earth's semidiameter is one (sub-columns *PAR.* | *MIN.*, given *quoad concavum* / *quoad convexum* = "as to the concave [surface]" / "as to the convex").
- **SVPERFICIES planæ orbium ad planum Eclipticæ inclinatæ.** — Plane surfaces of the orbs, inclined to the plane of the ecliptic.
- **AVX Eccentrici, ad annum Christi 1554.** — Aux of the eccentric, for the year of Christ 1554 (sub-columns *S.* | *G.* | *M.* = signs | degrees | minutes).

		SEMIDIAMETRI (concave PAR/MIN; convex PAR/MIN)

		through midnight to the east in 24 hours; and it is called the <i>motus raptus</i> [the rapt/diurnal motion].)		distant 23°30'.)
Ninth sphere	ECLIPTICÆ vel Zodiaci primi mobilis. (Of the ecliptic or zodiac of the primum mobile.)	AB Occidente in Orientem recurrens in annis 49000. & vocatur Motus Augium. (From west to east, recurring in 49,000 years; and it is called the <i>motus augium</i> [the motion of the auges].)	45225 / 0; Et adhuc maior, minor tamen quam semidiameter primi Mobilis. (And still greater, yet less than the semidiameter of the primum mobile.)	SVB Ecliptica primi mobilis, ecliptica ista perpetuo manens. (Beneath the ecliptic of the primum mobile, this ecliptic remaining fixed forever.)
Eighth sphere	ACCEDENTES, & recedentes ad motum Axis. (Accessing and receding, to the motion of the axis.)	A Septentrione versus Ortum, recurrendo in Septentrionem in annis 7000. super duobus circulis parvis, & vocatur motus Trepidationis. (From the north toward the east, recurring to the	45225 / 0 quoad convexum; At quoad concavum 22612 / 30. (...as to the convex; but as to the concave, 22,612;30.)	DECLINANS frequenter ab ecliptica tam nonæ sphæræ, quam primi mobilis. (Declining frequently from the ecliptic both of the ninth sphere and of the primum mobile.)

Sphere	POLI orbium	MOTVS proprij	SEMIDIAMETRI (PAR / MIN)	SVPERFICIES
		north in 7,000 years, upon two small circles; and it is called the <i>motus trepidationis</i> [the motion of trepidation].)		

AVX communis, ad annum Christi 1554: S. 0 · G. 20 · M. 15 (0 signs, 20°, 15').

[Internal check: the eighth sphere's concave semidiameter 22612;30 is exactly half of 45225 — consistent, not flagged.]

Definitions of the terms (DEFINITIONES TERMINORVM)

[This opening (printed pp. 314–315) is a single wide comparative table. Its leftmost column names the term; the definition columns are headed by the planetary symbols and, for most terms, distinguish the Sun and Moon (☉ ☽) from the five planets (♄ ♀ ♂ ♃ ♅). Many definitions are marked *in omnibus* / *OMNIBVS* ("in all") and run continuously across the opening as one cell; a few (the top **Habitus** row, and the last three rows) give genuinely distinct wordings per planet-group. The type is very small and the wording is split across the gutter; intricate brace-grouped rows are transcribed as far as they resolve, with [?] marking uncertain stitches.]

Habitus Planetarum ad Solem — the relation of the planets to the Sun

Per-group cells (header symbols as printed):

- ☉ **Sol:** *SOL, tanquam reliquorum Planetarum princeps, ad nullum, sed omnes ad ipsum quendam motus respectum habent.* — The Sun, as chief of the remaining planets, [is directed] to none; rather all have a certain regard of motion toward it.
- ☽ **Luna:** *DEFERENTES Augem Eccentrici ita quotidie contra signorum ordinem retrocedunt (Eccentrico tamen Epicyclum interim secundum seriem signorum protrudente) ut linea medij motus ☉ in medio inter Augem Eccentrici & Epicyclum semper reperiatur. Quare in omni [conjunction ♂?] &*

oppositione Epicyclus est in Auge; in quadratura vero in Augis opposito. — The [orbs] carrying the aux of the eccentric retrograde daily against the order of the signs (while the eccentric meanwhile pushes the epicycle forward following the order of the signs), so that the line of the Sun's mean motion is always found midway between the aux of the eccentric and the epicycle. Hence at every conjunction and opposition the epicycle is at the aux; but in quadrature, at the point opposite the aux.

- ♃ ♄ ♂ **(the three superiors):** *SINGVLI horum Planetarum tanto tempore revolvuntur in suis Epicyclis, quantum est à [conjunction ♂?] media cuiusque eorum cum ☉ [Sole; symbol unclear], usque in sequentem. Unde in qualibet tali [conjunction ♂?] Planeta in Auge media sui Epicycli reperitur.* — Each of these planets revolves upon its epicycle in as much time as there is from one mean conjunction of each of them with the Sun to the next. Hence at any such conjunction the planet is found at the mean aux of its epicycle.
- ♀ **Venus:** *AVX Eccentrici Augi ☉ perpetuo cohæret. Sed & medius ♀ motus semper [?] idem est, qui medius motus ☉. Hinc media eorum [conjunction ♂?] semper esse solet.* — The aux of the [Venus] eccentric perpetually coheres with the aux of the Sun. Moreover the mean motion of Venus is always [?] the same as the mean motion of the Sun. Hence their mean conjunction is always wont to occur.
- ☿ **Mercury:** *DEFERENTES Augem Eccentrici una cum centro Eccentrici [contra] signorum seriem in anno Solari revolvuntur. Eccentricus vero in [eodem] tempore secundum ordinem signorum movetur. Sed & cum ☉ semper [?]diam habet ut Venus.* — The [orbs] carrying the aux of the eccentric, together with the center of the eccentric, revolve against the order of the signs in one solar year; but the eccentric in the same time moves following the order of the signs. And with the Sun it always [behaves? holds a like arrangement] as Venus does.

Definitions of the remaining terms

Term (left column, verbatim)	Definition
AVX in 1. significazione (Aux, in the first sense)	<i>EST (in omnibus) punctum Eccentrici à centro mundi remotissimum, per lineam per utrumque centrum, mundi scilicet & Eccentrici, extensam designatum. Cuius oppositum est punctum eiusdem Eccentrici terræ vicinissimum, in omnibus etiam, præterquam in ☿, ut in eius Theorica declaratur.</i> — In all [planets], the point of the eccentric farthest from the center of the world, marked out by a line extended through both centers, namely of the world and of the eccentric. Its opposite is the point of the same eccentric nearest the earth — in all likewise, except in Mercury, as is explained in its Theorica.
AVX in 2. significazione (Aux, in the second sense)	<i>EST (in omnibus) arcus Zodiaci à principio ♈, secundum signorum successionem, usque ad lineam Augis computatus. In tabulis Aux simpliciter vocatur.</i> — In all, the arc of the Zodiac reckoned from the beginning of Aries, following the order of the signs, up to the line of the aux. In the tables it is called simply the "aux."
LONGITVDO media Eccentrici (Mean longitude of the eccentric)	<i>EST punctum Eccentrici, per lineam ex centro Eccentrici ad Augis lineam ad angulos rectos eductam [ostensum]; in quo maxima accidit æquatio. [?]</i> — The point of the eccentric shown by a line drawn from the center of the eccentric to the line of the aux at right angles, at which the greatest equation occurs.
AVX Epicycli media (Mean aux of the epicycle)	<i>EST punctum Epicycli, quod linea à centro Æquantis (id est, ex puncto</i>

Term (left column, verbatim)	Definition
	<i>centro Eccentrici opposito) per centrum Epicycli educta ostendit. — The point of the epicycle shown by a line drawn from the center of the equant (that is, from the point opposite the center of the eccentric) through the center of the epicycle.</i>
AVX Epicycli vera (True aux of the epicycle)	<i>EST punctum circumferentiæ Epicycli, quod indicat linea recta à centro mundi per centrum Epicycli educta, terminatum. — The point on the epicycle's circumference at which a straight line drawn from the center of the world through the center of the epicycle terminates.</i>
LINEA medij motus Planetæ (Line of the planet's mean motion)	<i>EST quæ à centro mundi ad Zodiacum educitur, lineæ ex centro Æquantis per centrum Epicycli exeunti æquidistans [in the 5 planets]; vel lineæ à centro Eccentrici ad corpus Solare excurrenti æquidistans. Vocaturque linea medij motus. — The line drawn from the center of the world to the Zodiac, parallel to the line issuing from the center of the equant through the center of the epicycle (in the five planets), or parallel to the line running from the center of the eccentric to the solar body; and it is called the line of mean motion.</i>
LINEA veri motus Planetæ (Line of the planet's true motion)	<i>EST quæ à centro mundi per corpus Planetæ educta, ad Zodiacum usque protenditur. — The line drawn from the center of the world through the body of the planet, extended all the way to the Zodiac.</i>
{Medius / Verus} Motus Planetæ	<i>EST arcus Zodiaci à principio ♈,</i>

Term (left column, verbatim)	Definition
(Mean / true motion of the planet)	<i>secundum successionem signorum, usque ad {Medij / Veri} Motus lineam numeratus.</i> — The arc of the Zodiac from the beginning of Aries, following the order of the signs, numbered up to the line of the {mean / true} motion.
Linea {Medij / Veri} Motus Epicycli (Line of the {mean / true} motion of the epicycle)	{mean:} <i>Exeunti à centro Æquantis ad centrum Epicycli [ductæ] æquidistans</i> — parallel to [the line] going from the center of the equant to the center of the epicycle; {true:} <i>Per centrum Epicycli [à centro mundi] transiens</i> — passing through the center of the epicycle [from the center of the world]. [?]
{Medius / Verus} Motus Epicycli (Mean / true motion of the epicycle)	<i>EST arcus {Zodiaci / Epicycli} interceptus inter {lineas medij [& veri motus] / Augem mediam [& veram]} ... secundum motum Planetæ in Epicyclo, usque ad corpus ipsius supputatus.</i> [?] — The arc of the {Zodiac / epicycle} intercepted between {the lines of mean [and true motion] / the mean [and true] aux} ... reckoned according to the motion of the planet on the epicycle, up to the planet's body.
CENTRVM {Medium / Verum} (Center — mean / true)	<i>EST arcus Zodiaci à linea Augis eccentrici, secundum seriem signorum, usque ad lineam {medij / veri} motus.</i> [?] — The arc of the Zodiac from the line of the aux of the eccentric, following the order of the signs, up to the line of the {mean / true} motion.
Æquatio centri {In Zodiaco / In Epicyclo} (Equation of center — in the Zodiac / on the epicycle)	<i>In Zodiaco: EST arcus Zodiaci inter lineam Augis Eccentrici, & lineam medij motus secundum seriem signorum [interceptus]. Et dicitur simpliciter</i>

Term (left column, verbatim)	Definition
	<i>centrum</i>. — the arc of the Zodiac between the line of the aux of the eccentric and the line of mean motion, following the order of the signs; called simply "the center." <i>In Epicyclo: EST arcus Epicycli inter Augem eius mediam, & veram [interceptus]. Et dicitur simpliciter Æquatio centri.</i> [?] — the arc of the epicycle between its mean aux and its true [aux]; called simply "the equation of center."
Argumentum {Medium / Verum} (Argument — mean / true)	<i>Medium: EST arcus Zodiaci inter lineam Augis, & lineam medij motus comprehensus. Et dicitur simpliciter Argumentum [medium].</i> — the arc of the Zodiac comprised between the line of the aux and the line of mean motion; called simply the [mean] argument. <i>Verum: EST arcus Epicycli ab Auge eius [media/vera] ... secundum motum Planetæ in Epicyclo, usque ad corpus ipsius supputatus.</i> [?] — the arc of the epicycle from its aux ... reckoned according to the planet's motion on the epicycle, up to its body.
Æquatio Argumenti (Equation of the argument)	<i>EST arcus Zodiaci lineis medij & veri motus Epicycli interiacens.</i> [and, for the Moon:] <i>EST arcus Zodiaci inter lineas medij & veri motus</i> › <i>cadens.</i> [?] — the arc of the Zodiac lying between the lines of the mean and true motion of the epicycle (for the Moon: the arc of the Zodiac falling between the lines of the Moon's mean and true motion).
Compositio tabularum Æquationum (Composition of the equation-tables)	[Sun & Moon:] <i>OMNIBVS Eccentrici sui locis communis existit.</i> — it is common to all places of its eccentric. [Five

Term (left column, verbatim)	Definition
DIVERSITAS Diametri (Variation of the diameter)	planets:] <i>AD Augem sui Eccentrici ...; ad situm, sive distantiam S. 2. G. 4. M. 30. ab Auge Æquantis.</i> [?] — at the aux of its eccentric ...; to the position, or distance, of 2 signs 4°30' from the aux of the equant. <i>EST differentia, qua Æquationes argumentorum in opposito Augis Eccentrici positæ, ad mediocrem Epicycli à terra distantiam, differunt ab Æquationibus in Auge, & minima [Epicycli] à terra distantia.</i> Related wording: <i>EST excessus, quo Æquationes argumentorum in opposito Augis Eccentrici super longitudes medias [positæ superant Æquationes] ... qui Propior vocatur; et longitudinum mediarum [super Æquationes] in Auge, qui Longior dicitur.</i> [?] — The difference by which the equations of the arguments placed opposite the aux of the eccentric, at the epicycle's mean distance from the earth, differ from the equations at the aux and at the least distance from the earth (the one called "nearer," the other "farther").
MINVTA Proportionalia (Proportional minutes)	[Sun & Moon:] <i>SVNT particulæ excessus lineæ Augis super lineam oppositi Augis, divisi in 60. partes æquales.</i> — the parts of the excess of the line of the aux over the line opposite the aux, divided into 60 equal parts. [Five planets:] <i>SVNT particulæ excessus lineæ Augis Æquantis super lineam mediocris à terra distantie: et rursus huius super minimam distantiam, in 60. partes æquales</i>

Term (left column, verbatim)	Definition
DIVERSITAS Minutorum Proportionalium (Variation of the proportional minutes)	<i>distributi</i>. — the parts of the excess of the line of the aux of the equant over the line of the mean distance from the earth, and again of this over the least distance, distributed into 60 equal parts. [Moon — <i>DVPLICIA</i>, "double":] <i>quia quædam ad Augem Eccentrici omnia sunt intra Deferentem, sed ad longitudes medias omnia extra: et dicuntur Minuta proportionalia longiora. Quædam autem alia ad longitudes medias omnia sunt intra Deferentem, sed ad oppositum Augis omnia extra: et dicuntur Minuta proportionalia Propiora</i>. — because some, at the aux of the eccentric, are all within the deferent, but at the mean longitudes all outside: these are called the "farther" proportional minutes; while certain others, at the mean longitudes, are all within, but at the point opposite the aux all outside: these are called the "nearer" proportional minutes. [Five planets — <i>TRIPLICIA</i>, "triple":] <i>Quædam enim ad Augem Æquantis omnia sunt intra Deferentem, & ad medias longitudes omnia extra: et dicuntur longiora. Quædam autem alia ad longitudes medias omnia sunt intra, & ad minimam à terra distantiam omnia extra: et dicuntur Propiora. Horum rursum ad oppositum Augis Æquantis nonnulla sunt intra, & nonnulla extra. Tertia denique minuta proportionalia sunt particulæ excessus lineæ oppositi Augis Æquantis super minimam à terra</i>

Term (left column, verbatim)	Definition
	<i>distantiam, &c. Qui excessus, quoniam insensibilis est, omittuntur; propterea in tabula hæc Minuta proportionalia [non ponuntur].</i> — for some, at the aux of the equant, are all within the deferent and at the mean longitudes all outside: called the "farther"; certain others, at the mean longitudes, all within, and at the least distance from the earth all outside: called the "nearer." Of these, again, at the point opposite the aux of the equant, some are within and some outside. A third kind of proportional minutes, finally, are the parts of the excess of the line opposite the aux of the equant over the least distance from the earth, etc.; and since this excess is imperceptible, they are omitted, and therefore in the table these proportional minutes are [not entered]. [Sun's cell (<i>simplicia</i>?) not legible on this scan — [?].]

Definitions of Terms — The Phenomena of the Planets [Passiones]

**

1. Planets [Planetæ] are said to be direct, retrograde, or stationary [Directi, Retrogradi, Stationarij]: namely when the line of the planet's true motion advances according to the succession of the signs (direct), moves back against the succession of the signs (retrograde), or appears to stand still in one place of the Zodiac (stationary).

- ☉ Sun: The Sun is always direct, since it has no epicycle.
- ☾ Moon: The Moon is always direct, because the centre of the epicycle traverses a greater arc of the Zodiac by the motion of the eccentric [eccentricus], from west to east, than the body of the Moon does by the

motion of the epicycle in its upper part, against the order of the signs, on any given day.

2. Station [Statio] (first / second): In its first sense it is the point of the epicycle at which the planet begins to go retrograde (first station) or to go direct (second station). In its second sense it is the arc from the aux [augis] of the epicycle up to the aforesaid point.

3. Arc [Arcus] (of direction / of retrogradation): It is the arc of the epicycle — from the point of the second station, through the aux of the epicycle, up to the point of the first station (arc of direction); or from the point of the first station, through the point opposite the aux of the epicycle, up to the point of the second station (arc of retrogradation).

4. Course [Cursu] (slow and diminished / swift and augmented): namely when the planet moves more slowly, or more swiftly, than the line of the mean motion [linea medii motus].

5. Augmented or diminished in number [Aucti / Minuti — Numero]: when the equation of the argument [aequatio argumenti] is added to the mean motion (augmented), or subtracted from the mean motion (diminished).

6. Augmented or diminished in light [Aucti / Minuti — Lumine]: when the Sun recedes from them, or they themselves recede from the Sun (augmented in light); or when the Sun approaches them, or they approach the Sun (diminished in light).

7. Oriental and morning stars / Occidental and evening stars [Orientales & Matutini / Occidentales & Vespertini]: when they rise in the morning before the Sun (oriental and morning stars), or set in the evening after the Sun (occidental and evening stars).

8. Rising [Orientes ortu] (morning / evening): In the morning rising: when, before sunrise, in the eastern region they begin to emerge from the Sun's rays and to become visible to us — that is, as the Sun recedes from Saturn, Jupiter, and Mars, or as Venus and Mercury recede from the Sun. In the evening rising: when they recede so far from the Sun that they begin to appear in the western region in the evening.

- ☾ Moon: The Moon lacks this kind of rising, because on account of its speed the Sun cannot recede from it; for after conjunction [♌] it recedes from the Sun only until it begins to be seen.

- ♄ ♃ ♀ (three superiors): These three, because on account of their slowness they cannot recede from the Sun, lack this kind of rising.

9. Setting [Occidentes occasu] (morning / evening): In the evening setting: when, after sunset, in the western region they begin to be covered by the Sun's rays and gradually hidden from us. In the morning setting: when they approach the Sun so closely that in the morning they cease to appear in the eastern region.

- ☾ Moon: When after opposition it approaches the Sun, beginning to be covered by its rays. The Moon lacks this setting, since on account of its speed it cannot approach the Sun.
- ♄ ♃ ♀ (three superiors): These three, on account of their slowness, lack this setting.

10. Aspect of the planets [Aspectus Planetarum] (trine / quartile / sextile): it occurs when they are distant by a third, a fourth, or a sixth part of the Ecliptic.

11. Conjunction [Coniunctio] (mean / true / visible): it occurs when the lines of the mean second motions, of the true second motions, or the lines drawn from our eye through the bodies of the planets, are joined into one.

12. Opposition [Oppositio] (mean / true): it occurs when the lines of the mean, or true, [second] motions are set opposite one another along the longitude of the Zodiac.

13. Place of a star [Locus Astri] (true / apparent): it is a point of the firmament, determined by a line drawn from the centre of the world through the star itself (true place), or shown by a line extended from our eye through the star (apparent place).

14. Parallax [Diuersitas aspectus] (simply, or in altitude / in longitude / in latitude / of the Moon relative to the Sun):

- Simply, or in altitude: the arc of a great circle passing through the zenith of the head, [through the true and the apparent place] of the star.
- In longitude: the arc of the Ecliptic bounded by two great circles passing through the true place and the apparent place [of the star] and through the poles of the Zodiac.
- In latitude: the arc of a great circle passing through the poles of the Zodiac and the true or apparent place of the star, intercepted between two circles parallel to the Ecliptic, of which one runs through the true place, the other through the apparent place.

- Of the Moon to the Sun: that by which the parallax of the Moon, as the greater, exceeds the parallax of the Sun, as the lesser.

15. Apparent latitude of the Moon [Latitudo Lunæ visa]: it is the arc of a great circle passing through the poles of the Zodiac and the apparent place [of the Moon], intercepted [between the Ecliptic and] the apparent place. [Some words of this cell are not fully resolved: ?]

16. Ecliptic digits [Digiti Ecliptici]: they are called the twelfth parts of the diameter of the eclipsed body [of the Sun or of the Moon].

17. Minutes [Minuta] (of incidence in a solar or lunar eclipse / of tarrying in a lunar eclipse): they are the minutes of the Zodiac which the Moon, as the swifter, traverses in overtaking the Sun — from the beginning of a solar eclipse up to its middle; from the beginning of a lunar eclipse up to its middle (if it be partial, or total without tarrying), or up to the beginning of total obscuration (if it be total with tarrying); and from the beginning of total obscuration up to the middle of the lunar eclipse.

18. Visual diameter [Diameter visualis] (of the Sun / of the Moon):

- Of the Sun: at the aux of the eccentric it subtends 31[?] minutes; at the point opposite the aux [of the eccentric], 34[?] minutes.
- Of the Moon: [at the aux of the eccentric and the aux of the epicycle] it subtends 29[?] minutes; [at the aux of the eccentric and the point opposite the aux of the epicycle] 36[?] minutes. [The exact pairing of each condition — "of the world / of the Zodiac" [Mundi / Zodiaci] — to its subtended value is not fully resolvable on the tile: ?]

19. Of a star [Stellæ] (declination / latitude): it is the arc of a great circle passing through the poles of the equator (for declination) or of the Zodiac (for latitude) and through the place of the star, intercepted between the star and the equator [Æquinoctialem], or between the star and the Ecliptic.

20. Latitude of the planets [Latitudo Planetarum]:

- ☉ Sun: The Sun lacks latitude, for the plane surface of its eccentric nowhere deviates from the plane surface of the Ecliptic.
- ☾ Moon: Simple [simplex], on account of the declination of its eccentric receding from the Ecliptic only, while it always keeps the plane of the epicycle with it.

- ♄ ♃ ♀ (three superiors): Double [duplex] — one [component] on account of the fixed declination of the eccentric from the Ecliptic; the other on account of the plane surface of the epicycle deviating from the Ecliptic by a mobile declination, by which it approaches and recedes from the plane surface of the eccentric. From these the latitude of the three superiors is composed.
- ♀ ☿ Venus and Mercury: Triple [triplex]. The first is called Deviation [Deuiatio], and it is the declination of the eccentric from the Ecliptic — the epicycle, however, of Venus always keeping toward the North, but that of Mercury always toward the South of the Ecliptic. The second is called Declination [Declinatio]: namely where the diameter of the true aux of the epicycle deviates from the plane surface of the eccentric, approaching and receding from the diameter of the mean longitudes of the epicycle; which motion, taking place upon [that] diameter, is called reflexion [reflexio]. The third is likewise a certain mobile turning-away [auersio] of the diameter of the mean longitudes of the epicycle from the plane surface of the eccentric, and it takes place upon the diameter of the [long] longitudes of the epicycle as upon an axis. From all these the latitude of Venus [and of Mercury] is composed.

21. Argument of latitude [Argumentum latitudinis] (mean / true): it is the arc of the Zodiac counted, according to the succession of the signs, from the line of the true motion of the head of the Dragon [caput Draconis, the ascending node] up to the line of the mean motion (mean argument) or of the true motion (true argument) of the Moon.

FINIS.

[This "FINIS" closes the appended Definitions of Terms and thereby the whole Commentary on the Sphere of Sacrobosco (In Sphaeram Ioannis de Sacro Bosco). What follows is the alphabetical index to the Commentary.]

A Most Abundant Index of the Matters and Words Contained in These Commentaries, Arranged in Alphabetical Order

[INDEX LOCVPLETISSIMVS RERVM ET VERBORVM, QVÆ IN HIS COMMENTARIIS CONTINENTVR, in ordinem Alphabeticum digestus.]

A.

Entry	Ref.
[A]braham taught the Egyptians arithmetic and astronomy [Braham Ægyptios docuit Arithmeticam, & Astronomiam]	2
The absurdities which follow from the opinion of Copernicus [Absurda quæ sequuntur opinionem Copernici]	301[?]
The various senses of "Zodiac" [Acceptiones Zodiaci variæ]	142. 143
How the access and recess of the eighth sphere comes about [Accessus & recessus Sphæræ octauæ quomodo fiat]	67
How the access and recess in the eighth sphere was detected [Accessus & recessus in octaua Sphæra quomodo deprehensus]	53
Achillini's opinion concerning the number and motion of the heavens, and its [refutation] [Achillini sententia de numero & motu cœlorum, eiusque con...]	[?]
...[the] girdle of the <i>primum mobile</i> [cingulus primi mobilis]	ibid. & seq.
The various names of the equinoctial circle [Æquinoctialis circuli varia nomina]	181
What the equinoctial points are [Æquinoctialia puncta quæ]	12. 157
What the equinoctial (or true) rising and setting is [Æquinoctialis siue verus ortus, & occasus quid]	182
What the equinoctial (or equal) hour is [Æquinoctialis siue æqualis hora quæ]	238
What the true and mean equinox is [Æquinoctium verum & medium quod]	39
Why the equinox occurs, the Sun being in the Equator [Æquinoctium cur fiat, Sole existente in Æquatore]	125

Entry	Ref.
How it is to be understood that the equinox occurs twice a year over the whole earth [Æquinoctium bis in anno fieri in vniuersa terra quomodo intelligatur]	ibid.
Why the equinox always occurs in the right sphere [Æquinoctium cur semper fiat in sphæra recta]	226[?]

[The index continues beyond this page.]

Index of Subjects and Terms (*Index rerum et verborum*)

Alphabetical subject index to the In Sphaeram commentary — continuation of letter A. Latin headword translated; page number(s) preserved exactly as printed.

- The circumference of the Earth according to Aristotle. — ib.
- That the circumference of the Earth according to Ptolemy is the more widely accepted. — 115
- The circumference of the Earth according to Alfraganus [al-Farghānī], Almeon [al-Ma'mūn], and Thebith [Thābit ibn Qurra]. — ibid.
- The circumference of the Earth according to the more recent navigators. — ibid.
- The circumference of the Earth according to Fernellius [Jean Fernel]. — ibid,
- The circumference of the heavens according to their concave and convex [surfaces]. — 117
- Who the *Amphiscii* are [those who cast shadows both ways]. — 189
- What the rising or setting amplitude is, and how it is found by means of Sines. — 182
- That the rising or setting amplitude is the same at the four points of the Ecliptic. — ibid.
- Anaximander [Anaximander], the first discoverer of the Zodiac. — 132

- What a spherical angle is. — 147
- The four principal ages of living creatures. — 136
- How many cycles of years the Great Year comprises. — 2
- That the year was adjusted to the course of the Sun by Julius Caesar [Julius Caesar]. — 2.5
- The Platonic Year. — 29
- The four seasons of the year — Spring, Summer, Autumn, and Winter — to which parts of the Zodiac they correspond. — 135
- The qualities of the four seasons of the year. — *ibid.*
- Why the year in the Roman Calendar begins at the winter solstice, and not at the vernal equinox. — 137
- That the year of Julius Caesar, and indeed the Ecclesiastical year, is greater [than the true year]. — 156
- What the anomaly of the obliquity of the Zodiac is. — 37
- What the circle of the anomaly of obliquity is. — 38
- What the mean motion, or argument, of the anomaly of obliquity is. — *ib.*
- The equation of the anomaly of obliquity: when it must be added to the mean obliquity, and when subtracted. — *ibid*
- What the anomaly of the precession of the equinoxes is. — 39
- What the mean motion, or argument, of the anomaly of the precession of the equinoxes is. — 40
- What the circle of the anomaly of the precession of the equinoxes, or of the motion of the eighth sphere, is. — 39
- The simple [anomaly] is called the anomaly of obliquity; but the doubled [anomaly] is called that of precession. — 40
- What the Antarctic circle is. — 12
- That the Antarctic pole has no stars around it. — 98
- The Antarctic pole, and its various names. — 10.126

- The Antarctic circle. — 184
- The Antarctic circle according to the Greeks. — *ibid.*
- What the cause is of the anticipation of the equinoxes and solstices in the Calendar. — 157
- Why the Antipodes do not fall off. — 107
- That our Antipodes have the same latitude as we do, but of a different name [i.e. opposite denomination]. — 166
- Why the ancients believed the stars are borne by chance. — 291
- What the apparent Horizon is. — 180
- What the apparent, and the true, rising and setting are. — 192
- Two appearances against the motion of the fixed stars from west to east over the poles of the Zodiac, and their solution. — 32
- The appearances proving that eccentrics exist. — 292
- The appearances proving that epicycles exist. — 296
- Why water is impure. — 17
- That it belongs to the nature of water that it should surround the Earth. — 16
- In what manner water withdrew from the Earth. — 16.17
- That water does not encircle the whole Earth, and what the cause of this is. — 16
- Why water is said to be heavy in a certain respect. — 19
- That water is proved to be round. — 56.57
- That water and Earth make up one globe. — 57
- Why water does not occupy the center of the world, as the Earth does. — 61
- That water is smaller than the Earth. — 64
- That a vessel holds a greater quantity of water at the foot of a mountain than at its summit. — 65

- Which the watery signs of the Zodiac are. — 123
- That Claudian [Claudian] described the marvelous sphere of Archimedes [Archimedes]. — 9
- Archimedes' demonstration proving that every liquid has a spherical figure. — 57
- Archimedes' ratio between the circumference of a circle and its diameter. — 11 [?]
- Archimedes' [rule that], given the ratio between the circumference of a circle and its diameter, one may derive a circumference too great from a known diameter, but a diameter too small from a known circumference, compared with what it really is. — 112
- Archimedes' proposition in the book *On the Number of the Sand* [*The Sand Reckoner*]. — 120
- What the Arctic circle is. — 13
- The Arctic pole, and its various names. — 10.126
- The Arctic circle according to the Greeks. — 184
- The Arctic circle. — 183. & seq.
- The arc of the firmament intercepted between two visual rays equally distant, one of which issues from the center of the Earth while the other touches the Earth — how great it is. — 72
- What the Complement of any arc is. — 182
- The arc of the Colure between the tropic of Cancer and the Arctic circle — how great it is. — 185
- What the ascension and descension of any arc, or point, of the Ecliptic, or even of a star, is. — 194
- What the right and oblique ascension of any arc of the Ecliptic is, both according to the author and according to Ptolemy [Ptolemy] and other astronomers. — 195

- That the whole arcs of the Ecliptic between the four Cardinal points are made equal to their ascensions in the right sphere, but their parts are by no means [equal]. — ib.
- The rising of the arcs of the Zodiac in the right sphere. — ib.
- Which arcs of the Zodiac have equal ascensions in the right sphere. — ib.
- That arcs of the Ecliptic that are equal, and equally distant from any of the four Cardinal points, have equal ascensions in the right sphere. — ib.
- That equal and opposite arcs of the Ecliptic have equal ascensions in the right sphere. — 196
- That the ascension of any arc of the Ecliptic is equal to the descension of the same in the right sphere: indeed, also to the culmination of the heaven in any sphere whatever, oblique as well as right. — 198
- How the ascension in the right sphere of any arc, or point, of the Ecliptic reckoned from either equinox is investigated by means of Sines. — ib.
- How the ascension in the right sphere of any arc, or point, of the Ecliptic is derived from the table of right ascensions. — 200
- That the whole arcs of the Ecliptic between the two equinoctial points are made equal to their ascensions in the oblique sphere, but their parts are by no means [equal]. — ib.
- That arcs of the Ecliptic reckoned from the beginning of Aries and Libra up to the end of Gemini and Sagittarius always give greater parts rising in the right sphere than the coterminal quadrants of the Equator; but arcs of the Ecliptic reckoned from the beginning of Cancer and Capricorn up to the end of Virgo and Pisces [give] smaller [parts]. — 197
- That arcs of the Ecliptic from the beginning of Aries up to the end of Virgo have smaller ascensions in the oblique sphere than in the right; but arcs from the beginning of Libra up to the end of Pisces [have] greater [ascensions], and greater precisely by as much as those others have smaller. — 201
- That two opposite and equal arcs together have their ascensions equal to the ascensions of the same in the right sphere. — ib.

- That arcs of the Ecliptic from the beginning of Aries up to the end of Virgo, when reckoned, always give greater parts rising in the oblique sphere than the halves of the coterminal Equator; but arcs of the Ecliptic from the beginning of Libra up to the end of Pisces, when reckoned, [give] smaller [parts]. — 200
- That arcs equal and equally remote from either of the solstitial points have, in the oblique sphere, their ascensions taken together equal to the ascensions of the same taken together in the right sphere. — 201
- That the ascension of any arc of the Ecliptic is equal to the descension of the opposite and equal arc, in any sphere whatever, whether right or oblique. — 202
- That arcs equal and equally distant from either of the equinoctial points have equal ascensions in the oblique sphere. — *ibidem*.
- That the ascension of any arc of the Ecliptic in the oblique sphere is unequal to the descension of the same. — *ibidem*.
- That the ascension and descension together of any arc of the Ecliptic are equal to the ascension and descension together of the opposite and equal arc, in any sphere whatever, right as well as oblique. — *ibidem*.
- How the ascension in the oblique sphere of any arc, or point, of the Ecliptic reckoned from either equinox is found from the ascensional difference. — 203
- How the ascensional difference in the oblique sphere of any arc, or point, of the Ecliptic is computed by means of Sines. — *ibidem*.
- How the ascension in the oblique sphere of any arc, or point, of the Ecliptic is derived from the table of oblique ascensions. — 204.
- How the descension in the oblique sphere of any arc, or point, of the Ecliptic reckoned from the beginning of Aries is found. — *ibid*.
- What the arcs of the artificial days and nights are. — 235
- That the ascensional difference of any arc, or point, of the Ecliptic is the same as [the difference] between the semidiurnal arcs of the right and oblique sphere, when the Sun tarries at that point of the Ecliptic. — 238
- How the diurnal arc is computed from the oblique ascension. — 239

- How the semidiurnal arc is found from the difference between the semidiurnal arc in the right sphere and the semidiurnal arc in the oblique sphere. — 238.239
- How the semidiurnal arc is computed from Sines. — 239
- By what art the table of semidiurnal arcs is constructed. — *ibid.*
- A table of semidiurnal arcs for all elevations of the pole. — 240. & sequent.
- How the arc of the Ecliptic that is always visible, or always hidden, in places between the polar circle and the pole is investigated. — 276
- That the arcs of the Ecliptic always visible are equal to the arcs always hidden in places between the polar circle and the pole; but the continuous days are unequal to the continuous nights. — 276
- By what art the area of any circle is found. — 112
- That the number of grains of sand is, according to some, infinite; but according to others indeed finite, yet exceeding any given number. — 120
- By what reasoning the number of grains of sand filling the whole world up to the concavity of the firmament is investigated. — *ibid.*
- What greater number is that of the grains of sand — of which 10000 equal a grain of poppy-seed — filling the whole world up to the concavity of the firmament. — 121
- The argument of the first chapter and its division. — 7
- Two arguments against the motion of the fixed stars from west to east over the poles of the Zodiac are refuted. — 32
- What the argument of the anomaly of obliquity is. — 38
- What the argument of the anomaly of the precession of the equinoxes is. — 40
- The argument of the 2nd chapter and its division. — 122
- The argument of the third chapter and its division. — 191
- The argument of the fourth chapter. — 290

- The arguments of Averroes [Averroes] against eccentrics and epicycles, and their solution. — 302. & seq.
- Why Aries is set down as the beginning of the Zodiac. — 136
- That the beginning of Aries is nobler than the remaining three Cardinal points. — *ibid.*
- Aristotle's [Aristotle's] reasoning proving that water is round. — 57
- Aristotle calls the fire beneath the concavity of the Moon an exhalation. — 65
- Aristotle's reasoning by which it is proved that the Earth is at the middle of the world. — 70
- Aristotle's opinion concerning the Milky Way is refuted. — 185
- Arithmetic is concerned with discrete quantity. — 1
- That the Egyptians learned arithmetic from Abraham [Abraham]. — 2
- The Phoenicians are thought to have handed down the first rudiments of arithmetic. — *ibid.*
- The art, discovered from a single meridian line, of finding innumerable other [meridian lines]. — 166
- What the artificial Horizon is. — 180
- By what reasoning the quantity of the artificial day and night is ascertained from the material Sphere. — 130
- What the artificial day and night are, and why their quantity is reckoned with respect to the Horizon. — 125
- What the arc of the artificial day and night is. — 235
- That all the artificial days and nights in the right sphere are equal to one another. — 236
- Any artificial day to which the artificial night is equal. — *ib.* & seq.
- That any two artificial days equally distant from either solstice are equal to one another in the oblique sphere. — 237

- That artificial days in winter are shorter in a more northerly city than in a less northerly city; but in summer longer; and why. — *ibid.*
- How the quantity of the artificial day is computed from the oblique ascension. — 239
- What the ascending and descending semicircle of the Ecliptic is. — 137
- What the ascension of any star, or even of any point of the Ecliptic, is. — 194
- What the ascension and descension of any arc, or point, of the Ecliptic, or even of a star, is among astronomers. — *ibid.*
- Why the ascension and descension of any arc of the Ecliptic is defined by astronomers by means of the Equator. — *ibid.*
- What the right and oblique ascension and descension of any arc of the Ecliptic is, both according to the author and according to Ptolemy and other astronomers. — 195
- What right, or oblique, ascensions are according to Ptolemy and the astronomers. — *ibid.*
- That the ascensions of equal arcs of the Ecliptic, equally distant from any of the four Cardinal points, are equal in the right sphere. — *ibid.*
- That the ascensions of equal and opposite arcs of the Ecliptic are equal in the right sphere. — 196.197
- That the ascension of any arc of the Zodiac in the right sphere is equal to the descension of the same in the same right sphere; and to the culmination of the heaven both in the right sphere and in the oblique. — 198
- By what reasoning the right ascension of any arc of the Ecliptic is to be investigated by means of Sines. — *ibid.*
- How the ascension in the right sphere of any arc, or point, of the Ecliptic reckoned from either of the equinoxes is explored by means of Sines. — *ibid.*
- How the table of right ascensions is composed. — *ibid.*
- The table of right ascensions. — 199

- How the ascension in the right sphere of any arc, or point, of the Ecliptic is known from the table of right ascensions. — 200
- How the right ascensions are derived from the Table of Right Ascensions. — *ibid.*
- A comparison of the ascensions in the oblique sphere with the ascensions in the right sphere. — 201
- That the ascensions of opposite and equal arcs of the Ecliptic taken together in any oblique sphere are equal to the ascensions of the same arcs taken together in the right sphere. — 201
- That the ascensions of equal arcs of the Ecliptic, equally remote from either of the solstitial points, taken together in any oblique sphere, are equal to the ascensions of the same arcs taken together in the right sphere. — *ibid.*
- That the ascension of any arc in the oblique sphere is equal to the descension of the opposite and equal arc in the same sphere. — 202
- That the ascensions of unequal arcs of the Ecliptic, equally remote from either of the equinoctial points, are equal in any oblique sphere. — *ibid.*
- That the ascension of any sign in the oblique sphere is unequal to the descension of the same sign. — *ibid.*
- That the ascension of any arc of the Ecliptic is equal to the descension of the opposite and equal arc, in any sphere whatever, right as well as oblique. — *ibid.*
- That the ascension and descension together of any arc of the Ecliptic are equal to the ascension and descension together of the opposite and equal arc, in any sphere whatever, right as well as oblique. — *ibid.*
- That the ascension and descension of any sign together are equal to the ascension and descension of the opposite sign in any sphere whatever. — *ibid.*
- That the ascension of any arc of the Ecliptic in the oblique sphere is unequal to the descension of the same. — *ibid.*
- That the ascension and descension together of any arc of the Ecliptic in the oblique sphere are equal to the ascension and descension together of the same arc in the right sphere. — *ibid.*

- How the oblique ascensions are found from the ascensional differences. — 203.
- That the ascension and descension of the same sign together in the oblique sphere are equal to the ascension and descension of the same sign together in the right sphere. — 202
- How the tables of oblique ascensions are constructed. — 203.204
- How the oblique ascensions and descensions are found from the tables of oblique ascensions. — 204.
- How the ascension in the oblique sphere of any arc, or point, of the Ecliptic is drawn out from the table of oblique ascensions. — *ibid.*
- A table of oblique ascensions from the 36th degree up to the 60th. — 209. & seqq.
- By what reasoning the ascensional differences are found by means of Sines. — 203. And how they are found from the table of ascensional differences. — *ibid.*
- A table of ascensional differences. — 205. & seqq.
- That the ascensional difference of any arc, or point, of the Ecliptic is the same as [the difference] between the semidiurnal arcs of the right and oblique sphere, when the Sun tarries at that point of the Ecliptic. — 238
- What the diversity of aspect [parallax] is. — 43
- That the parallax of the same star is the greater the nearer it is to the Horizon, so that a star existing on the Horizon has the greatest, but at the zenith of the head none at all. — *ibid*
- That the parallaxes of two stars in the same heaven having the same altitude above the Horizon are equal. — *ib.*
- That the parallax of a star nearer to the Earth, wherever it may exist in the heaven, is greater than that which a star more distant from the Earth has, though occupying the same true or apparent place as the former. — 44
- That a star has its greatest parallax on the Horizon. — 43
- What the diametrical, trine, quartile, and sextile aspects of the stars are. — 136

- What the aspects of the heavenly bodies are. — *ibid.*
- That the parallax of the Moon in different climes is the cause why an eclipse of the Sun sometimes occurs in one clime and not in another, and greater in one than in another. — 307
- The *Assus* [a division of the *as*] and its parts. — 140
- What an asterism, or constellation, is. — 73
- That the asterisms, or Constellations — 48 in number — are arranged in tables, in which are contained the longitudes, latitudes, and magnitudes of the stars. — *ibid.* & *seqq.*
- Why the stars appear larger when placed near the Horizon than in mid-heaven. — 53
- That all the stars are round and spherical. — *ibid.*
- Which the northern and southern stars are. — 127.144.145
- That the stars on the meridian have their greatest altitudes and powers [influences]. — 164
- What the stars are that neither rise nor set, and how they are recognized. — 181
- Why the ancients supposed the stars are borne by chance. — 291
- That the stars move regularly. — 292
- What the true place of a star is. — 43
- What the apparent place of a star is. — *ibid.*
- That astronomy is necessary for the science of navigation. — 2
- What astronomy is. — *ibid.*
- In what manner astronomy and astrology differ from one another. — 3
- What parts astronomy has. — *ibid.*
- The division of astronomy into Theoretical and Practical. — *ibid.*
- By whom Theoretical astronomy was first expounded. — *ibid.*

- What the subject of astronomy is. — *ibid.*
- How great the excellence of astronomy is. — *ibid.*
- The usefulness of astronomy for Theology. — 4
- The dignity of astronomy from its manner of demonstration. — *ibid.*
- The usefulness of astronomy for various disciplines. — *ibid.* & seq.
- Why astronomy is called by most people "natural theology." — *ibid.*
- The usefulness of astronomy for Cosmography. — *ibid.*
- That astronomy is necessary for ecclesiastical persons. — *ibid.*
- The usefulness of astronomy for the administration of the commonwealth. — *ibid.*
- What usefulness astronomy has brought to the leaders of armies. — 5
- That Abraham handed down astronomy to the Egyptian priests. — *ibid.*
- That the Pontiffs and Priests of the Egyptians cultivated astronomy. — *ibid.*
- That astronomy made Thales [Thales] rich. — *ibid.*
- That Kings and Emperors took delight in astronomy. — *ibid.*
- That astronomy was held in great esteem among the ancients. — *ibid.*
- That astronomy brings the greatest pleasure. — *ibid.*
- That Plato [Plato] asserted eyes were granted to man for the sake of astronomy alone. — *ibid.*
- What the subject of astronomy and of this book is. — 6
- The various astronomers. — 2
- That the scarcity of excellent astronomers delayed the correction of the Calendar. — 4
- Why astronomers at various times observed that the fixed stars move variously, and that the magnitude of the year and the greatest declination of the Sun are not the same. — 41

- How astronomers investigated the number of the stars. — 73
- Why astronomers use the sexagesimal division. — 139
- Why astronomers begin the day from the Meridian rather than from the Horizon. — 164
- How astronomers say that everything is in some Sign. — 194
- What the astronomical rising and setting is, and how it differs from the poetical. — 193
- Why astronomers define the rising and setting by means of the Equator. — 194
- By what phenomena, or appearances, astronomers were impelled to believe that there are eccentric orbs and epicycles in the heavens. — 290
- What the equal, or mean, astronomical day is. — 235
- What the rising and setting of a star is. — 191
- What the visual diameters of the stars are. — 46. & seq.
- How the declinations of the stars are computed by means of Sines. — 99
- The magnitudes of the stars, both in their diameters with respect to the diameter of the Earth, and in their solidity with respect to the Earth. — 100. & seqq.
- By what reasoning the distances of the stars from the Earth, their thickness and magnitudes, may be investigated. — 117. & seqq.
- By what reasoning the magnitudes of the stars are known. — 118
- That the nearer a star is to the Horizon, the greater the parallax it has. — 43
- That a star on the Horizon has the greatest parallax. — ib.
- That a star existing at the zenith has no parallax at all; but of two stars having the same apparent or true place, the one that is nearer to the center of the Earth has the greater parallax. — ibid.

Index of Subjects and Terms (continued)

(Two-column alphabetical index to the In Sphaeram commentary. Each entry gives the topic followed by the page reference(s) exactly as printed; "ib." / "ibid." = ibidem, "& seq." / "& seqq." = and following.)

A (continued)

- Judicial astrology is a superstitious matter, condemned by St. Augustine [Augustine]. — 3
- Why the study of astronomy has been neglected. — 1
- Astronomy treats of continuous movable quantity. — 1
- Astronomy extends most widely among the mathematical disciplines. — 1
- Astronomy was cultivated by the ancient philosophers above all other disciplines. — 1
- Those who gave it luster are called the first inventors of astronomy. — 2
- Astronomy is a most ancient science. — 2
- Who were the first inventors of astronomy. — 2
- The Egyptians learned astronomy from Abraham. — 2
- Who are said to be the first inventors of astronomy. — 3
- Why the invention of astronomy is attributed to the Sidonians. — 3
- Atlas was most skilled in astrology. — 3
- Atlas was not the same person as Enoch. — 3
- Where the fable of Atlas took its origin. — 3
- Some make Atlas the first inventor of astronomy. — 3
- The author's opinion concerning the new star that appeared in the year 1572, and concerning other new stars. — 104.105
- The author considers only 10 circles of the sphere. — 122
- What the line of the apogee [augis linea] is. — 291
- What the point opposite the apogee is. — 291
- The opinion of Augustinus Ricius [Augustinus Ricius] concerning the number and motion of the heavens, and its refutation. — 26
- Which is the southern part of the sky. — 126
- That the southern part of the sky near the Antarctic pole has no stars. — 98.156
- That the southern part of the world is less noble than the northern. — 135

- That the southern part of the world is the left, and the northern the right. — ib.
- Which is the southern and northern part of the sky and of the earth. — 144. & seq.
- Which are the southern and the northern stars. — 127.128.144
- Which is the southern and northern part of the zodiac, and the southern and northern signs. — 144
- What the apogee [aux] is. — 291
- What the apogee of the sun is. — 304
- What the axis of the sphere is. — 9
- Every axis is a diameter, but not conversely. — ib.
- Every circle in the sphere has its own axis. — ib.
- An axis is found only in solid bodies. — ib.
- The ancients imagined the heaven and the earth to be supported by an axis. — ibid.
- The axis of the world in the right sphere coincides with the horizon. — 15
- The axis of the world in the oblique sphere differs from the horizon. — ib.

B

- Which is the northern part of the sky. — 126
- Which is the northern and southern part of the sky and of the earth. — ib.
- That the northern part of the world is the right, and the southern the left. — 136
- That the northern part of the sky near the Arctic pole is adorned with more stars than the southern near the Antarctic pole. — ib.
- That the northern part of the world is more noble than the southern. — ib.
- Which is the northern and southern part of the zodiac, and the northern and southern signs. — 142.144
- Which are the northern and the southern stars. — 126.144

C

- Celestial bodies are the noblest of all. — 3
- The celestial orbs are contiguous with one another. — 10.42
- The harmony of the celestial motions. — 22
- Various opinions concerning the celestial motions, and their refutation. — 24. & seq.
- Our own opinion concerning the celestial motions. — 27. & seq.

- The periods of the celestial motions. — 29. & seq.
- The 48 celestial images [constellations], in which are contained the longitudes, latitudes, and magnitudes of the stars. — 76. & seq.
- The circles of the celestial houses. — 122
- How the terrestrial zones are placed beneath the celestial zones. — 188
- The theory of the celestial orbs and motions reduced into tables. — 308. & seq.
- Why the heaven is called the seat of God. — 3
- The heavens are the noblest bodies. — 3
- Why the heavens are called divine bodies. — 4
- The heavens commend the goodness, wisdom, and providence of God. — 4
- How the heaven is understood to move from east to west, and vice versa. — 21
- Those who posit a single heaven are refuted. — 22
- Those who held the heavens to be eight in number. — ib.
- Those who reckoned the heavens to be nine in number. — 23
- Those who, first of all, defined the heavens to be ten in number. — ibid.
- The empyrean heaven which the theologians posit cannot be known by astronomers. — 24
- The watery, glacial, or crystalline heaven. — ib.
- The empyrean heaven according to the theologians. — ib.
- By what evidence some prove that an empyrean heaven exists. — ib.
- In the judgment of the astrologers the heavens are twelve in number. — ib.
- Those who thought the heaven to be devoid of all motion are refuted. — ibid.
- That the motions of the heavens from west to east have no ordered proportion among themselves. — 26
- To which heaven the diurnal motion of the heavens is attributed. — 21.27
- That the lower heavens are swept along in the diurnal motion by the primum mobile. — ib.
- There are two principal motions of the heavens. — ib.
- The lower heavens move absolutely from east to west, and in a certain respect from west to east. — 28
- That all the heavens move absolutely from east to west. — ib. & seq.
- That the motions of the heavens from east to west and from west to east are not contrary. — 27.28

- In what way the motions of the heavens from east to west and from west to east can be called contrary. — 29
- The various motions of the heavens are illustrated by examples. — 28
- Why the heavens move upon the poles of the zodiac from west to east. — 29
- That the heavens can move upon the same poles from east to west and from west to east; indeed that some orbs do so move; and why they do not all move upon the same poles. — ib.
- That the eighth heaven moves with a threefold motion — from east to west, from west to east, and with the motion of trepidation, or of access and recess — according to some. — ibid.
- By what reasoning it has been established that all the heavens move absolutely from east to west. — 30
- By what reasoning the motion of the heavens from west to east has been established. — 31
- By what means it has been observed that the lower heavens move from west to east upon the poles of the zodiac. — ib.
- In what manner it has been established that the heaven of the fixed stars moves with the motion of trepidation, or of access and recess. — 33
- The moving heavens are ten according to Alfonso [Alfonso X]. — 34
- The moving heavens are eleven, according to Magini [Giovanni Antonio Magini] and our own opinion. — 36
- The heavens are immediately adjacent to one another. — 10.42
- The order of the heavens according to Aristarchus of Samos [Aristarchus of Samos] and Nicolaus Copernicus [Copernicus]. — 42
- The order of the heavens according to Plato, Aristotle, and the Egyptians. — ibid.
- The order of the heavens according to the more recent astronomers, and by what reasoning it is inferred. — ib. & seq.
- The order of the heavens is proved from the swiftness and slowness of their motion, and confirmed from eclipses. — 44
- That the heaven moves from east to west is proved from the stars that rise and set. — 47
- That the heaven moves from east to west is proved from the stars that neither rise nor set. — ib.
- That the heaven moves, but not the stars by themselves, is proved by two observations. — ib.

- The heaven is round because of its likeness to the archetypal world, and because of convenience. — 49
- That the heaven is round is proved from necessity. — 51
- That the heaven is not flat is proved. — 52
- Why the heaven appears to be farther from us near the horizon than near the vertex overhead. — 53
- The heaven is equidistant from the center of the earth, but not from any assigned point on the earth's surface — if we speak geometrically; it is so only as far as the senses are concerned. — *ibid.*
- Plato assigns to the heaven and the elements the figures of the five regular bodies. — 66
- In what sense a man is said always to see half of the sky. — 67
- By what method the distances of the heavens and stars from the earth, their thickness, and their magnitudes can be investigated. — 117. & seq.
- The distances of the heavens from the earth, their thicknesses, and their circumferences. — 116. & seq.
- By what means the distances and thicknesses of the heavens and the magnitudes of the stars can be investigated. — 117. & seq.
- Which is the northern and southern part of the sky. — 126
- All points of the sky are in some sign, in the third sense of the term. — 143
- The heaven is divided into a northern and a southern hemisphere: first by the equator, then by the zodiac, and finally by the vertical circle properly so called. — 144. & seqq.
- The right and left part of the sky according to various authors. — 187
- The heaven of each planet is composed of several orbs. — 192
- That every heaven, by its own motion, carries along with it the lower orb contiguous and concentric to it. — 29.298
- Of what the heaven of the sun is composed. — 304
- Of what orbs the heavens of the other planets besides the sun are composed. — *ib.*
- The calendar was corrected by the authority of Gregory XIII [Pope Gregory XIII]. — 4
- The calendar was corrected by the labor and diligence of the author. — *ibid.*
- Why the calendar was corrected so late. — *ibid.*
- Why the beginning of the Roman calendar is taken from the winter solstice rather than from the vernal equinox. — 137

- Why the Roman calendar does not indicate the equinoxes and solstices on the same days. — 157
- That Callippus [Callippus] and Eudoxus [Eudoxus] divided the celestial spheres into concentric orbs. — 292
- The channels which some attribute to the stars are rejected. — 48
- What the tropic of Cancer is. — 12
- Whence the whiteness in the Milky Way arises. — 185
- The argument of chapter 2, and its division. — 122
- What the head of the Dragon [ascending node] in the Moon is. — 304
- What the tropic of Capricorn is. — 12
- The cardinal points of the world. — 10
- Which are the cardinal points in the zodiac. — 136
- Verses and tables by which the sun's entry into the 12 signs of the zodiac is known. — 157.159
- What sign is called the fall [dejection] of each planet. — 138
- What the tail of the Dragon [descending node] in the Moon is. — 304
- The cause of the anticipation of the equinoxes and solstices in the calendar. — 157. & seq.
- What the center of the sphere is. — 9
- The center lacks all magnitude. — 15
- That the center of the earth and of the water is one and the same, as regards their convex surfaces. — 57. & seq.
- Those who established three centers: one of the earth, another of the water, and a third of the universe. — *ibid.*
- Those who posited two centers: one of the earth, and another of the water. — *ibid.*
- What the center of magnitude of each body is. — 59
- What the center of gravity of each body is. — *ibid.*
- How the center of gravity in any body is determined. — 60
- The center of gravity and of magnitude is the same both in the earth and in the water. — *ib.* & seqq.
- The Chaldeans taught the Egyptians arithmetic and astrology. — 2
- Which are the choleric signs of the zodiac. — 134
- The diligence and labor of Christophorus Clavius [Christoph Clavius] in these Commentaries. — 1

- Christophorus Clavius devoted much study and effort to the correction of the calendar. — 4
- What the temporal [chronic] rising is. — 190
- What the temporal [chronic] setting is. — ibid.
- By what art, with the aid of the compass, the distances of places are found. — 177. & seq.
- Every circle of the sphere has its own axis. — 9
- What the greater and the lesser circle of the sphere is. — 1 [?: single printed digit; content suggests 11]
- What a pole is in the circles of the sphere. — 12
- The circles of the sphere are ten. — 11
- Into how many parts a circle is divided by the astronomers. — 12
- What the Arctic circle is. — 13
- What the Antarctic circle is. — ibid.
- The circles of the sphere are set before the eyes in the figure of the sphere. — ibid.
- What the equant circle of the anomaly of obliquity is. — 38
- What the circle of the anomaly of obliquity is. — ibid.
- What the circle of the anomaly of the precession of the equinoxes is. — 39
- What the equant circle is. — ibid.
- That the visual circle of the Sun has a hundredfold proportion to the visual circle of Venus. — 47
- The various properties [dignities] of the circle. — 49
- What the proportion of any circle to its diameter is. — 111
- In what manner the circumference of a circle is found from a known diameter. — ibid.
- In what manner the diameter of a circle is derived from a known circumference. — ibid.
- By what art the area of any circle is found. — 112
- That the circle described by the pole star is of such magnitude that the whole sphere of the sun, placed within it, would not touch it. — 120
- What a greater and a lesser circle in the sphere is. — 122
- Which are the hour circles and the vertical circles. — ib.
- The author considers only 10 circles of the sphere. — ib.
- That the celestial circles are manifold among the astronomers. — ib.

- Which are the vertical circles, the hour circles, the circles of the celestial houses, and those of positions, declinations, and latitudes. — *ibid.*
- Which are the circles of declinations and of latitudes. — *ib.*
- Why the greatest and the not-greatest circles in the sphere are so called. — *ib.*
- Which are the circles of the celestial houses and of positions. — *ib.*
- The properties of the circles in the sphere. — 123
- What the greatest and the not-greatest — that is, the greater and the lesser — circle in the sphere is. — 122
- In what manner Proclus [Proclus] divides the circles of the sphere. — 123
- What the equinoctial circle is. — 124
- Which are the intrinsic and extrinsic circles of the sphere. — *ibid.*
- How the equinoctial circle is conceived to be described in the sky. — 126
- Where in the sky the circles of the sphere are chiefly to be conceived. — *ib.*
- Why the equinoctial circle is so called, and likewise why it is called the equator and the girdle of the primum mobile. — *ib.*
- That the celestial circles are to be conceived as in the primum mobile. — *ib.*
- The various names of the equinoctial circle. — *ib.*
- Why the celestial circles are divided into 360 degrees. — 139
- Every circle is divided like the zodiac. — 141
- The circle of latitude. — 145
- The circle of declination. — *ibid.*
- What the circle of declination of a star is. — *ib.*
- No circles in the right sphere can be called colures. — 146
- The colure of the solstices measures the greatest declinations of the sun. — 148
- The greatest circle of the ever-apparent and of the ever-hidden stars. — 182. & seq.
- The Antarctic circle. — 184
- The Arctic circle. — *ib.*
- The proportion of a greatest circle to a not-greatest one, and by what method it is known from the sines. — *ib.*
- Which are the polar circles, how far they are from the poles of the world, and how they are reckoned by the Greeks. — *ib.*
- The Milky Way is in the firmament, not in the air; and through which constellations it passes. — 185

- The polar circles enclose the regions toward the poles, which have their longest day greater than 24 hours. — 186
- The functions of the parallel circles in the sphere. — ib.
- The parallel circles indicate the equality of days and nights in the right sphere, but their inequality in the oblique; they determine the latitudes of places, and along them the longitudes are counted; they likewise indicate the declinations and altitudes of the stars. — ib.
- Which are the circles of the natural days, and the arcs of the artificial days and nights. — 237
- How many parallel circles are described by the sun in a year. — ib.
- That more parallel circles are described by the sun from Aries to Libra than from Libra to Aries, and why. — ib.
- At what interval apart the parallel circles on the earth are described by Ptolemy [Ptolemy] and other astronomers. — 288
- What the eccentric circle is. — 291
- What the equant circle of a planet is, and why it was devised. — 304.305
- The circumferences of circles described from the same center, contained between two straight lines going out from the center, are similar. — 110
- What the proportion of the circumference of any circle to its diameter is, according to Archimedes [Archimedes]. — 111
- By what method the circumference of a circle is derived from the diameter, and the diameter in turn from the circumference. — ib.
- In what manner the circumference of a circle is found from a known diameter. — ib.
- That the circumference of any circle, found from a known diameter, comes out greater than it actually is, according to Archimedes' proportion between the circumference of a circle and its diameter. — 112
- That several cities can have the same meridian, as far as the senses are concerned, both from east to west and from north to south. — 109
- Cities of which one is more easterly than another have different meridians. — ib.
- What the longitude of cities is. — ib.
- From what meridian the longitudes of cities begin. — ib.
- What the longitude and latitude of cities is. — 166
- The latitude of cities is twofold: northern or southern. — 167
- Which cities have the same latitude or longitude. — ib.

- The longitudes and latitudes of very many cities arranged in a table. — 138. & seq.
- In what manner the distances of cities are investigated. — 177
- That the distances of cities are to be taken along a great circle. — ib.
- How the distance between two cities, of both of which the longitude and latitude are known, is to be investigated. — ib. & seq.
- When cities are situated beneath the equator, and when they have different longitude and latitude. — ib. & seq.
- Which cities are distant from one another by a semicircle, and which by a quadrant. — ib.
- That the latitude of each city is equal to the altitude of the pole there. — 181
- For a given city, in what manner it is known in which zone it lies. — 386 [?: hundreds digit uncertain]
- Claudian [Claudian] described the sphere of Archimedes. — 5 [?: single digit uncertain, 5 or 9]
- How many climes were established by the ancients. — 284
- What a clime is. — ib.
- On what the division of climes depends. — ib.
- A table of climes according to the ancients. — 286
- Why the more northerly climes are narrower. — ib.
- Why the climes are not more than seven. — 285
- Comparisons of the climes with one another, as regards hours and the altitude of the pole. — 286
- The moderns establish 23 climes. — 288
- A table of climes according to the moderns. — ibid.
- How a clime and a zone differ. — ibid.
- A stone column, on which the science of the stars was inscribed, was preserved in Syria down to the age of Josephus [Josephus]. — 2
- Two columns, on which the sons of Adam inscribed the sciences, lest they perish. — 2
- Which are the colures of the solstices and of the equinoxes. — 12.146
- The colures of the primum mobile are called not mean but true. — 36
- The true etymology of the colures. — 146
- What function the colures have, and whence they are so named. — ibid.
- What circles the colures are, and whence they are named. — 12.146
- That no circles can be called colures in the right sphere. — 146

- What the colure of the solstices is. — 147
- What the colure of the equinoxes is. — *ibid.*
- The two colures indicate the four cardinal points, and divide the zodiac, the equator, and all the parallels into four quadrants. — *ibid.*
- The colure of the solstices cuts the ecliptic into an ascending semicircle and a descending semicircle (148); it divides the zodiac into six signs that rise directly in the oblique sphere and six signs that rise obliquely. — 197
- The colure of the solstices measures the distances of the poles of the zodiac from the poles of the world. — 156
- The colure of the equinoxes indicates the two equinoctial points. — 157
- The colure of the equinoxes divides the ecliptic into a northern and a southern semicircle. — 163
- How great the arc of the colure between the tropic of Cancer and the Arctic circle is. — 185
- How great the arc of the colure between the tropics and the polar circles is. — *ib.*
- The possible combinations of the primary qualities are only four. — 17. & seq.
- Which are the useless combinations of the primary qualities. — *ibid.*
- Various rules of combination, by which it is known in how many ways many things can be combined with one another. — *ibid.*
- Which are the common signs of the zodiac. — 135
- A comparison of the ascensions in the oblique sphere with the ascensions in the right sphere. — 201
- What the complement of any arc is. — 182
- The construction of the material sphere. — 13
- Why cavities have been made in the earth. — 16
- That not all phenomena can be maintained by concentric orbs. — 290. & seq.
- That, if concentric orbs are posited, as Fracastoro [Fracastoro] wishes, many absurdities follow. — 299
- How many concentric orbs are posited by Fracastoro. — *ibid.*
- That the shadow of the earth is conical. — 305
- Why the ancients imposed fixed names on the constellations. — 73
- What a constellation or asterism is. — *ibid.*
- The 48 constellations or asterisms, in which are contained the longitudes, latitudes, and magnitudes of the stars. — 76. & seq.

- The heavens are contiguous. — 15.42
- In what manner the convex surface of any sphere is found. — 57
- The opinion of Copernicus concerning the motion of the eighth sphere. — 35
- The absurd hypotheses of Copernicus. — 36
- What absurdities follow from the opinion of Copernicus. — 301
- Bodies, the higher they are, the nobler they are. — 3
- What a body is. — 7

Index of Subjects and Terms (continued)

[Alphabetical subject index to the commentary on Sacrobosco's Sphaera. Each entry preserves its printed page reference verbatim; "ibid." / "ib." repeat the preceding number, and "& seq." means "and following."]**

C (continued)

- Why a body has only three dimensions. — 8
- What heterogeneous bodies are. — 16
- What homogeneous bodies are. — *ibid.*
- The number and order of all the bodies that make up the universe. — 47
- We are accustomed to judge the shapes of bodies from their convexity. — 49
- The figures of the five regular solids, and how Plato [Plato] assigns them to the elements and to the heaven. — 66
- That the simple bodies are five, composing the whole universe. — *ibid.*
- What the cosmic rising and setting of the stars is according to the poets. — 190. & seq.
- What the cosmic rising is. — *ibid.*
- What purpose the cosmic rising and setting serves. — 193
- Astronomy is useful for cosmography. — 4
- The equator is useful to cosmographers. — 130
- How great the thickness of the air is. — 64
- By what method the thicknesses of the heavens and of the stars can be investigated. — 118.119
- That the Cross, which the stars near the Antarctic Pole are commonly said to form, is in the Centaur. — 98

- Treatment of the twilights. — 256. & seq.

D

- The ten circles of the sphere. — 11.122
- The proper motion of the tenth sphere. — 36
- From where the libration of the tenth sphere takes its beginning. — *ibid.*
- How great the maximum declination of the ecliptic of the primum mobile is, and why it is called the mean declination. — *ibid.*
- How much the maximum declination of the Sun can increase and decrease, and where it becomes greatest, and where least. — *ibid.*
- By what method the declinations of the stars may be investigated. — 99
- By what method the declinations of the stars are computed by means of sines. — *ibid.*
- What the circles of declination are. — 122
- What declination is. — 127
- What the declination of any given star is. — *ibid.* & 145
- That the declinations of points of the ecliptic equally distant from the equinoctial points are equal. — *ibid.*
- The various relations of the declinations and latitudes of the stars. — *ibid.*
- That the declination of four points of the ecliptic is the same. — *ib.*
- The circle of declination. — *ib.*
- What the maximum declination of the Sun is. — 147
- The various observations of the maximum declination of the Sun, and which one we think ought to be adopted. — 149
- By what method the maximum declination of the Sun is to be investigated. — *ib.*
- By what art the declinations of points of the ecliptic are computed. — *ibid.*

- By what method the declinations of points of the ecliptic are computed by means of sines. — *ibid.*
- A table of the declinations of all points of the ecliptic. — 150. & seq.
- How the declinations of all points of the ecliptic are found from the table of declinations. — 156
- That the greatest northern declination of the Sun is equal to the greatest southern declination of the Sun. — *ib.* & seq.
- That there is no tenfold proportion among the elements. — 63.64
- The deferent and equant in the five planets are eccentrics, and lie in the same surface, which is inclined away from the ecliptic. — 304
- Which orb is the deferent of the head and tail of the Moon's Dragon [i.e. the lunar nodes]. — 305
- The deferent orb of any given planet. — 305
- Why the descension and ascension of any given arc of the ecliptic is defined by astronomers by reference to the equator. — 140.141
- What the descending and ascending semicircle of the ecliptic is. — 139
- What the descension of any given star, or even of any point whatsoever of the ecliptic, is. — 141
- What the right or oblique descension and ascension of any given arc of the ecliptic is, both according to the Author and according to Ptolemy [Ptolemy] and other astronomers. — *ib.*
- That the descension of any given arc of the ecliptic is equal to the ascension of the opposite arc, and equal in any sphere whatsoever, whether right or oblique. — 202
- That the descension of any given arc of the ecliptic in the oblique sphere is unequal to the ascension of the same arc. — *ib.*
- That the descension of any given arc of the ecliptic in the right sphere is equal to the ascension of the same arc in the same sphere: indeed, equal also to the culmination of the heaven in any sphere whatsoever, whether oblique or right. — 198

- That the descension and ascension together of any given arc of the ecliptic in the oblique sphere are equal to the descension and ascension together of the same arc in the right sphere. — 202
- That the descension and ascension together of any given arc of the ecliptic are equal to the descension and ascension together of the opposite arc, and equal in any sphere whatsoever, whether right or oblique. — *ibid.*
- How the descension of any given arc or point of the ecliptic, counted from the beginning of Aries, is to be found in the oblique sphere. — 204
- How the oblique descensions are found from the tables of oblique ascensions. — *ibid.*
- The detriment of any given planet, which sign of the zodiac it is said to be. — 138
- Why God prolonged so long a life for the first parents. — 2
- In what sense God is said to be in heaven. — 3
- God is the maker of the world. — 15
- For what end God created his creatures. — 49
- That "right" and "left" are taken variously in the heaven. — 187
- The diameter encompasses more than the axis. — 9
- What the visual diameters of the stars are. — 45.46
- That the visual diameter of the Sun is tenfold the visual diameter of Venus. — *ib.*
- The proportions of the diameters of the stars to the diameter of the Earth. — 106
- How many times the diameter of any given star contains the diameter of the Earth, or the reverse. — *ib.*
- How the diameter of the Earth is derived from its known circumference. — 111
- What the proportion of the diameter of any given circle to its circumference is according to Archimedes [Archimedes]. — 111

- How the diameter of a circle is drawn out from its known circumference. — *ibid.*
- That the diameter of any given circle found from a known circumference comes out smaller, and the circumference found from a known diameter comes out larger, than it really is, according to Archimedes' proportion between circumference and diameter. — 112
- The magnitude of the Earth's diameter varies according to various authorities. — 114.115
- How great the artificial day is, and how it is ascertained from the material sphere. — 130
- Among astronomers the meridian determines the beginning of the day. — 164
- The various beginnings of the day among various peoples. — 164
- What the artificial day is. — *ib.*
- Why the natural days are unequal. — 234
- What the natural day is. — *ib.*
- By what art the natural days are reduced to equality by astronomers. — 235
- What the mean days are, which are called equal by astronomers. — *ib.*
- What the circles of the natural days are, and the arcs of the artificial days and nights. — *ib.*
- What the arcs of the artificial days and nights are. — *ib.*
- That the artificial days and nights in the right sphere are all equal among themselves. — 236
- Where the greatest and least day occurs in the oblique sphere; and where the days are longer than the nights, or the reverse. — *ib.*
- That the days are unequal to the nights in the oblique sphere, and why, except on the two equinoxes. — *ib.*

- The days in winter are shorter in a more northerly city than in a less northerly city; but longer in summer. — 237
- Any two artificial days equally distant from either of the solstices in the oblique sphere are equal among themselves. — ib.
- Which artificial days are equal to which nights in the oblique sphere. — ib.
- Which artificial day is equal to which artificial night. — ibid.
- How the length of the artificial day is computed from the oblique ascension. — 238. & seq.
- How the length of the continuous day between the Pole and the Arctic Circle is investigated. — 282
- That the continuous days between the Pole and the polar circle are not equal to the continuous nights. — 283
- How many semidiameters of the Earth the difference between the least distance of the Sun and the greatest distance of the Moon from the Earth contains. — 44
- The six differences of the magnitudes of the stars, and how many are contained in each difference. — 73
- What the difference of longitudes is. — 166
- What the difference of latitudes is. — 167
- How the ascensional differences are computed by means of sines. — 203
- A table of the ascensional differences. — 205. & seq.
- That the ascensional difference of any given arc or point of the ecliptic is the same as that which exists between the semidiurnal arcs of the right and oblique sphere, when the Sun is dwelling at that point of the ecliptic. — 238
- How the difference between the semidiurnal arc of the right sphere and the semidiurnal arc of the oblique sphere is found. — 239
- The various properties of the circle and the sphere. — 49
- A digression concerning that new star which appeared in the year 1572 and vanished in the year 1574, and concerning two others. — 103. & seq.

- Why measurements are made along a perpendicular line. — 7
- That the dimensions are only three in number is proved by demonstration. — 8
- Dionysius the Areopagite [Pseudo-Dionysius] was an astronomer. — 5
- What the direction of a planet is. — 305
- Why the Moon is not called direct, retrograde, or stationary. — *ibid.*
- When a planet is called direct. — *ibid.*
- From what sources the honorable disciplines drew their origin. — 2
- The distinction between rising and setting as regards the poets, and as regards the astronomers. — 193
- By what method the distances of the heavens and the stars from the Earth can be investigated. — 117. & seq.
- The distances of the heavens from the Earth, and their thicknesses and circumferences. — 116.117
- By what means the distances of the heavens, their thicknesses, and the magnitudes of the stars can be investigated. — 117. & seq.
- The distance of the poles of the zodiac from the poles of the world. — 132
- That the distances of the poles of the zodiac from the poles of the world are equal to the maximum declinations of the Sun. — 156
- The distances of places on Earth are taken along a great circle. — 177
- How the distance between two cities, of both of which the longitude and latitude are known, is to be investigated. — *ib.* & seq.
- By what method the distances of places on Earth are investigated, when both places are northern, or southern, etc. — *ib.*
- By what art the distances of places are found with the aid of the compasses. — 177.178
- How the distance between two stars is found. — 178

- That the distance of the zenith from the equator is everywhere on Earth equal to the altitude of the pole above the horizon. — 181
- The distance of the pole of the world from the pole of the zodiac is equal to the maximum declination of the Sun. — 184
- What the parallax [*diuersitas aspectus*] is. — 43
- That the parallax of the same star is the greater the nearer it is to the horizon, so much so that a star existing on the horizon has the greatest parallax, but at the vertex of the head none at all. — *ib.*
- That the parallax of a star which is nearer the Earth, wherever it exists in the heaven, is greater than that of a star lying farther from the Earth and occupying the same place, whether true or apparent, as the former. — 44
- That the parallaxes of two stars in the same heaven having the same altitude above the horizon are equal. — 43
- That the parallax of the Moon in different climes is the cause why an eclipse of the Sun occurs sometimes in one clime but not in another, and is sometimes greater in one than in another. — 306
- The division of the mathematical disciplines. — 2
- The division of the sphere according to substance. — 10
- The division of the sphere according to accident. — 11
- The various divisions of the circles of the sphere. — 11.122
- Why the division of the zodiac into 12 signs was made. — 134
- What the division of the zodiac according to longitude is. — 139
- The division of the zodiac into degrees, minutes, etc. — *ib.*
- Why astronomers use the sexagesimal division. — *ib.*
- The division of the zodiac according to latitude. — 141
- The division of a sign into 30 degrees, and of the whole zodiac into 360. — 138
- The division of the hours. — 238

- What the diurnal motion is. — 21
- Which are the circles of the celestial houses and of the positions. — 122
- Which are the principal houses. — 138
- The houses of the planets, which signs of the zodiac they are said to be. — *ibid.*
- The more principal house of any given planet, which sign of the zodiac it is, and which is the less principal house. — *ibid.*
- What the head and tail of the Dragon in the Moon are. — 305
- The dignity of the number twelve. — 136

E

- Given eccentric orbs and epicycles, how the phenomena can be defended. — 290. & seq.
- What an eccentric orb is, simply speaking. — *ibid.*
- What eccentric orbs are in a qualified sense. — 291
- What the eccentric circle in the planets is. — *ibid.*
- That eccentrics exist is proved by the appearances. — 292. & seq.
- That the spheres of the planets consist of eccentric orbs and epicycles according to Ptolemy. — *ibid.*
- That eccentrics exist is proved by reasoning. — 298. & seq.
- That the eccentric orbs, simply and in a qualified sense, together with the concentrics and epicycles in all the heavens, are only 33. — 300
- Why the Church begins the year from the winter solstice. — 137
- How necessary astronomy is for churchmen. — 4
- Why the Sun suffers eclipse from the Moon, but not from Venus. — 45.46
- Why the fixed stars and the three superior planets do not suffer eclipse through the interposition of the Earth between the Sun and themselves. — 103

- The ecliptic is the cause of eclipses. — 144
- Why an eclipse of the Moon does not occur at every full moon. — 306
- What an eclipse of the Moon is, and when it occurs. — *ibid.*
- That an eclipse of the Moon is the interposition of the Earth between the Sun and the Moon, and why. — 141
- An eclipse of the Moon occurs over the whole Earth, but an eclipse of the Sun does not. — 306
- What an eclipse of the Sun is, and when it occurs. — *ib.*
- Why an eclipse of the Sun does not occur at every new moon. — *ib.*
- The eclipse of the Sun at the Passion of the Lord was miraculous. — *ib.*
- The ecliptic of the primum mobile, together with its poles and tropics, is called the mean. — 36
- How great the declination of the ecliptic of the primum mobile is. — 36
- The ecliptics of both the ninth and the eighth sphere always intersect the equator at the beginning of Aries of the primum mobile, although they recede from the ecliptic of that same primum mobile. — 40
- What the ascending and descending semicircle of the ecliptic is. — 137
- What the ecliptic line is, and why it is so called. — 141
- How the ecliptic is conceived to be described in the heaven. — 142
- The various names of the ecliptic. — 141
- That the ecliptic is the path of the Sun, which it never leaves. — *ib.*
- What the northern and southern semicircle of the ecliptic is. — 142
- The various functions and uses of the ecliptic. — 144. & seq.
- The ecliptic is the cause of the inequality of days and nights, and of the alternation of the seasons. — *ib.*
- The ecliptic is the measure of the motion of the heaven from west to east. — *ib.*

- The ecliptic cuts the heaven into a northern and a southern hemisphere. — ibid.
- The ecliptic is the cause of eclipses. — ib.
- The ecliptic is the boundary from which the latitudes of the stars are reckoned. — 145
- Which points of the ecliptic have equal declinations, which greater, and which lesser. — 146
- That points of the ecliptic equally distant from the equinoctial points have equal declinations. — ib.
- That four points of the ecliptic have the same declination. — ibid.
- The ecliptic shows the true places of the stars in the zodiac. — ib.
- The ecliptic indicates the true motions of the stars. — ib.
- How the declinations of the points of the ecliptic are computed by means of sines. — 149
- That the two halves of the ecliptic set between the equinoctial points are matched by their ascensions in the oblique sphere, but their parts are not in the least so. — 200
- In what way the elements are said to be subject to generation and decay. — 3
- All the elements except Earth are mobile. — 15.17
- What the elements are, and how many. — 16.17
- Why the elements are called simple bodies. — 6
- What the cause of the order of the elements is. — 15
- What the order of the elements is. — 16
- The elements are mutually altered, corrupted, etc., by one another. — ibid.
- What the shapes of the elements are. — ib.
- The elements are not resolved into things of different forms. — ib.
- All the elements except Earth are moved from east to west. — ib.
