The Kids among themselves (Haedi inter se se)	<i>Gassendo</i>	0	44	40

The Great Table of Distances continues (Caput VIII), arranged alphabetically by constellation. The table gives, for each pair of fixed stars, the source siglum (Observers column) and the measured separation in degrees (Gr.), arcminutes (I), and arcseconds (II). The folio is laid out in two table-columns per page; the transcription below preserves that order (left half of the folio first, then right half).

BOÖTES, or ARCTOPHYLAX [Boötes]

ARCTURUS, and the stars listed below it

Star-pair	Observers	Gr.	I	II
The bright star of Boötes' shin [Tibia Boötis lucida]	Gassendo	[?]	16	30
	ex Tych. da.	19	12	0

The next- to-last star of Draco's Tail, and the stars listed	ex Tych. LL. Petavius, from the data given by Tycho, Bk. 3 of the <i>Uranologio</i>	14	35	0

Star-pair	Observers	Gr.	I	II
below [Caudae Draconis penultima, & infrascripta Stellae]	<i>n</i> , ch. 6 [Petavius ex Tychonis datis Lib. 3. Vranol. cap. 6.]			
Boötes' left shoulder [Bootae humerus sinistr.]		35	48	0
The southern Ass-Colt of Cancer [Cancri Asellus australis]		61	53	0

(Right half of folio, PDF p. 258 — DE FIX. STEL.)

This column continues the list of distances from **the next-to-last star of Draco's Tail** (per Petavius, from Tycho's data, *Uranologion* Bk. 3, ch. 6) to each star listed.

Star [from Draco's Tail penultima]	Gr.	I	II
The northern Ass-Colt of Cancer [Cancri Asellus borealis]	58	46	0
The preceding star of the northern part of Cancer, in the square	60	2	0

Star [from Draco's Tail penultima]	Gr.	I	II
[Cancri bor. praec. in □]			
The southern star of Cancer, in the square [Cancri austr. in □]	62	49	0
3rd, southern, in the right arm of Andromeda [3. Austr. in brach. dextr. Andr.]	73	24	0
The lowest star of Aquila's wing [Infima alae fin. Aquilae]	90	39	0
The southern star of the right arm of Andromeda [Australis. brach. dextr. Andr.]	67	27	0
The reins (loins) of Aries [Arietis renes]	85	30	0
The foot of Cassiopeia [Cassiopeae pes]	45	47	0
The breast of	45	47	0

Star [from Draco's Tail penultima]	Gr.	I	II
Cepheus [Cephei pectus]			
The peripheral stars of the Crater [Crateris borea peripheriae]	81	18	0
The northern handle of the Crater [Crateris ansa borealis]	84	2	0
The horn, the following wing [Cornu ala sequens]	86	12	0
The neck of Cygnus [Cygni collum]	64	5	0
The beak of Cygnus [Cygni rostrum]	68	47	0
The upper Crown [Corona superior]	49	58	0
The right wing of Cygnus [Cygni ala dextra]	43	5	0
The outermost star of Cygnus' left wing [Cygni alae sin. extrema]	73	47	0

Star [from Draco's Tail penultima]	Gr.	I	II
The bend of Cygnus' left wing [Cygni ancon. alae sin.]	68	37	0
The head of Draco [Draconis caput]	39	53	0
The head of Gemini, Castor's head [Geminorum caput Castoris]	56	49	0
The head of Gemini, Pollux's head [Geminorum caput Pollucis]	57	28	0
Auriga's right foot [Aurigae pes dexter]	64	49	0
Auriga's left foot [Aurigae pes sinister]	66	37	0
The bend of Hercules' right arm [Herculis dextrae ancon.]	61	4	0
The Heart of Hydra [Hydrae Cor]	83	27	0
The northern	83	26	0

Star [from Draco's Tail penultima]	Gr.	I	II
Balance [Lanx borea]			
Ophiuchus' left knee [Ophiuch. genu sin.]	90	30	0
Ophiuchus' right knee [Ophiuch. genu dext.]	97	57	0
Ophiuchus' right shoulder [Ophiuch. hum. dext.]	81	35	0
Ophiuchus' left shoulder [Ophiuch. hum. sinist.]	73	13	0
The Heart of Leo [Leonis cor]	62	2	0
Ophiuchus' head [Ophiuchi caput]	73	8	0
The middle star of Orion's belt [Orionis media balthei]	95	52	0
The mouth of Pegasus [Pegasi os]	95	21	0
Perseus' left shin [Persei Tibia sinistra]	67	58	0

Star [from Draco's Tail penultima]	Gr.	I	II
Perseus' left shoulder [Persei hum. sinist.]	58	35	0
The bright star of the Serpent's neck [Serpentis lucida colli]	61	9	0
Taurus' right knee [Tauri genu dext.]	92	33	0
The bright star of Ursa Major's southern right foot [Vrsae mai. austral. pedis dextri]	34	5	0
The more northern star of the same [eiusdem borealior]	33	41	0

	& Syllog.	21	14	0

Liber IV — De Fixis Stellis (continued)

Caput VIII — The Great Table of Distances (continued)

The distance table continues alphabetically by constellation. Columns are: **star-pair (Latin description)** | **Observers** (siglum) | **Gr.** (degrees) | **I** (arcminutes) | **II** (arcseconds). Where a star-pair entry has multiple observer rows, the pair-description is given once and the subsequent rows belong to the same pair.

The left column continues the block begun in the previous batch (entries under Gemini/Pollux), then runs through assorted star-pairs whose entries are arranged with their constellation cross-references.

Star-pair	Observers	Gr.	I	II
Lucidus pes ☐ (the bright foot of Gemini)	Gassendo	19	32	12

Star-pair	Observers	Gr.	I	II
	Nobis	19	32	10

<i>(same)</i>	Nobis	25	44	50

The remaining distances should be sought under BOÖTES, CORONA, GEMINI, & LEO.

Star-pair	Observer	Gr.	I	II
The bright star of the shoulder of Ursa Minor & Polaris	Nobis	16	30	0

URSA MINOR

Star	Observers	Gr.	I	II
<i>(heading)</i>	Ex Datis Tychonicis per Petantium l. 6. Uranolog. cap. 6.			

(This sub-table lists distances from the Pole [Dist. à Polo] of many stars, drawn from Tycho's data via Pétau's Uranologia Book 6, Chapter 6. Columns under URSA MINOR run: star-name | source | Gr. | I | II — but here the values are a single distance from the Pole.)

Star	Source	Gr.	I	II
The bright star of the shoulder, which in Eudoxus's age was the Pole-star, and the stars listed below	Ex Datis Tychonicis per Petantium l. 6. Uranolog. cap. 6.			
Of Andromeda, the right arm, southern		66	8	0
Of the same, the southern arm		66	8	0
Of the Eagle [Aquila], the southern wing-tip, left		80	3	0
Of Aries, the Horns [Arietis Renes]		83	46	0
Of Boötes, the left		36	18	0

Star	Source	Gr.	I	II
shoulder				
Of Cancer, the southern Aselli		72	58	0
Of Cancer, the northern Aselli		69	47	0
Of Cancer, the leading star [præc.] in the Square [□]		71	29	10
Of Cancer, the following star, southern, in the Square [□]		73	46	0
Of Cassiopeia, the foot		41	47	0
Of Cepheus, the breast		13	0	0
Of Crater, the northern handle		92	5	0
Of Crater, the northern rim [periph.]		90	47	0
Of Corona,		46	13	0

Star	Source	Gr.	I	II
the following wing				
Of Corvus, the upper wing		93	23	0
Of Cygnus, the right wing, upper		33	18	0
Of Cygnus, the wing-tip, left		63	42	0
Of Cygnus, the wing-joint [ancon.], left		57	16	0
Of Cygnus, the neck		52	30	0
Of Cygnus, the beak		57	51	0
Of Draco, the head		19	37	10
Of Gemini, the head of Castor		65	24	0
Of Gemini, the head of Pollux		67	16	0
Of Auriga [Heniochus], the right foot		70	10	0
Of Auriga		70	32	0

Star	Source	Gr.	I	II
[Heniochus , the left foot				
Of Hercules, the right Elbow [Ancon]		57	11	0
Of Hydra, the heart		93	45	0
The northern Scale [Lanx borealis]		83	14	0
Of Leo, the heart		73	11	0
Of Leo, in the neck, southern		68	33	0
Of Lyra, the upper star		43	44	0
Of Ophiuchus, the right shoulder		74	9	0
Of Ophiuchus, the left shoulder		67	36	0
Of Ophiuchus, the left knee		92	41	0
Of Ophiuchus,		46	26	0

Star	Source	Gr.	I	II
the head				
Of Orion, the middle of the belt [media balthei]		102	52	0
Of Pegasus		84	11	0
Of Pegasus, the bright star of the neck		84	24	0
Of Pegasus, the loins [lumbi]		87	23	0
Of Perseus, the right shoulder		56	32	0
Of Perseus, the left Shin [Tibia]		69	21	0
Of the southern Fish [Piscis], the middle, in the southern spine		83	21	0
Of the Serpent, the bright star of the neck [colli]		69	20	0

Parsing notes: This Ursa Minor sub-table gives each star's single distance from the Pole; the Gr./I/II triplet is one angle per row. The source-attribution cell ("Ex Datis

Tychonicis per Petantium...") spans the whole sub-table as a bracketing header. Several II-column entries are blank (printed as 0).

(Right column of folio 228 — the table continues and concludes:)

Star-pair	Observer	Gr.	I	II
Of Taurus, the right knee		95	45	0
Of Ursa Major, the southern star in the foot, preceding [antecedens]		44	33	0
The northern star of the same foot		41	39	0
The last of the Tail, now Polaris	Gassendo	16	28	0

The remaining distances — especially those which now concern Polaris — should therefore be sought under BOÖTES, AURIGA, CASSIOPEIA, CORONA, CYGNUS, LYRA, PERSEUS, & URSA MAJOR.

CONCLUSION

It is therefore established from what has been said that the Tychonic distances themselves disagree among one another by somewhat — to the extent of the first two minutes [of arc].

CAPUT IX

[Margin: 1]

We recall to four classes the declinations of the Tychonic fixed stars. **The first** is that of those which Tycho — either alone, or Tycho together with Paul Hainzel

[Paulus Hainzelius] at Göggingen near Augsburg — observed in the year 1572 (now complete) and at the beginning of 1573, at the place where the altitude of the Pole was, for Tycho, 48°22'. Tycho displays these in Volume 1 of the *Progymnasmata*, from page 361 and page 369, where he also has, for certain others, the 4-year distances of the Pole-star [Polaris] from the Pole.

(Table: Paul Hainzel's observations, at the beginning of the year 1574. Columns: star | Maxima/Minima | Altitudo Merid. [Gr. I II] | Declinatio [Gr. I II]. For each star a maximum and a minimum meridian altitude, and the corresponding declination.)

Star (Paulus Hainzelius, beginning of 1574)		Altitudo Merid.			Declinatio		
		Gr.	I	II	Gr.	I	II
Polaris of Ursa Minor	Maxima	51	22	15	86	59	45
	Minima	45	22	45	86	59	45
The right shoulder of Cepheus	Maxima	77	31	40	60	50	10
	Minima	19	11	40	60	50	40
The preceding star in the	Maxima	61	27	15	75	54	45
	Minima						

Star (Paulus Hainzelius, beginning of 1574)		Altitudo Merid.			Declinatio		
		Gr.	I	II	Gr.	I	II
side of Ursa Minor	Minim	34	37	0	75	55	0
	.						
In the right side of Cepheus	Maxim	69	38	30	68	43	30
	Minim	68	43	0	68	43	0
	.						
Of Ursa Major, 1st of the Tail	Maxim	78	55	30	59	26	30
	Minim	17	48	30	59	26	30
	.						
Of Ursa Major, 2nd of the Tail	Maxim	81	9	0	57	13	0
	Minim	15	36	0	57	14	0
	.						

Star (Paulus Hainz elius, begin ning of 1574)		Altitud do Merid.			Declin atio		
		Gr.	I	II	Gr.	I	II
Of Ursa Major, the bright should er-star	Maxi m.	74	18	0	64	4	0
	Minim	22	26	0	64	4	0
Of Ursa Major, the left Leg [Crus]	Maxi m.	82	16	30	56	5	30
	Minim	14	28	30	56	6	30
Of Ursa Major, the thigh [Ilia]	Maxi m.	79	41	0	58	41	0
	Minim	17	2	30	58	40	30
Of Cassio	Maxi m.	83	22	30	57	39	30

Star (Paulus Hainzelius, beginning of 1574)	Altitudo Merid.			Declinatio		
	Gr.	I	II	Gr.	I	II
peia, the Knee [Genu]	Minim 16	22	30	57	39	30

Parsing notes: Two-line rows (Maxima/Minima) per star. Some Declinatio cells appear constant between max and min (an internal Tyconic consistency check). A few digits in the gutter side are faint; transcribed as read.

(Folio 229, — three sub-tables in the left column, a long observation table in the right column.)

Left column — first sub-table: Hainzel & Tycho declinations, Anno Christi 1572 completo

Star (1572 complete)	Hainzelius Declinatio			Tycho Declinatio		
	Gr.	I	II	Gr.	I	II
First of Aries [Prima □]	17	11	0	17	10	30
The Eye [Oculus] of Taurus [□]	15	35	0	15	34	30

Star (1572 complete)	Hainzel ius Declina tio Gr.			Tycho Declina tio Gr.

The bright star of the Throne [Lucida Cathed.]	56	48	30

Left column — third sub-table: Polaris distance from Pole, by year

Polaris, the star (Tycho nic years)	Dist. à Polo Gr.	I	II	Declina tio Gr.	I	II
1577	2	58	50	87	1	10
1581	2	57	30	87	2	30
1585	2	56	10	87	3	50
1589	2	54	50	87	5	10

[Margin: 2]

The second class is that of those which, by order of the Emperor Ferdinand, Father Albert Curtz [Albertus Curtius] of the Society of Jesus — under the anagrammatic name *Lucius Barrettus* — took care to publish, from the types of David Hautt at Vienna, where he edited them in the year 1581. He sets the meridian altitudes at the Pole-altitude of Uraniborg, whose Pole-altitude, chosen by Tycho, is 55°54'40". From this, therefore, the declination is derived.

(Note: "the year 1581" here is as printed; the Curtz/Barrettus *Historia Coelestis* was in fact published in 1666 — but Riccioli's text and the date it gives are transcribed verbatim. See report.)

Ex Sylloge Ferdinanda — Observations of Tycho, Anno 1582, by Sextant, or by the Greater or Lesser Quadrant

(From the Sylloge Ferdinanda of Tychonic observations, year 1582, made with sextant, or with the greater or lesser quadrant. Columns: star-names | month/days | Altit. Merid. [Gr. I II] | Declinatio [Gr. I II].)

Star-names	Month / Day	Altit. Merid.			Declinatio

Parsing notes: Many stars have multiple dated sub-observations; the Declinatio is recorded only on certain rows (the others sharing the value above). "A" in the Declinatio column flags *australis* (southern) declination. "Q.", "Q. M.", "Sext." = quadrant / greater(?) quadrant / sextant instrument tags. Some altitude entries are faint in the gutter; transcribed as read, with [?] where uncertain.

(Folio 230, — two columns of the Anno 1582 / 1584 observation table, then a closing note and a new sub-table.)

[Margin: 3]

The third class is that of those fixed stars which Tycho, in the *Epistolae* page 53, exhibits — meridian altitudes captured toward the end of the year 1584 and as 1585 was running [labente], or about the end of the year 1586 and the beginning of the year 1587, at Uraniborg, where he says in the same place (and in Volume 1 of the *Progymnasmata*, page 28) that the Pole-altitude is 55°54'40". Hence, therefore, we shall easily subjoin their declinations.

(Sub-table: Tycho, year 1584 going out [exeunte], & 1585 running [labente].

Columns: star | Altitudo Meridiana [Gr. I II] | therefore [Ergo] Declinatio [Gr. I II].)

Star (Tycho, 1584 exeunte & 1585 labente)	Altitudo Meridiana Gr.	I	II	Ergo Declinatio Gr.	I	II
The First of Aries [Prima □]	51	19	0	13	49	40
The Second of Aries [Secun da □]	52	50	0	18	44	20
The Unform ed star above the Tail	59	36	0	18	25	0

	I	II		I	II	
sinistro] Leo, the lower star in the head [Leonis inferior in capite]	59	44	0	25	38	40

Parsing notes: This 1584/1585 sub-table is faint and partly in the gutter; the Pleiades penultima declination II-value is uncertain (read as 0). Two-letter instrument tags absent here (these are single meridian-altitude reductions). "Ergo Declinatio" = the declination derived from the meridian altitude given the Uraniborg pole-height.

Liber IV — De Fixis Stellis (continued)

Caput IX (continued) — The Tychonic declinations recalled to four classes

Class 3 (continued): Tycho's 1584/85 meridian altitudes at Uraniborg → declinations

The table continues the Class-3 derivation begun in the prior batch: Tycho's meridian altitudes observed at Uraniborg (pole 55°54'40") for the year 1584 drawing to a close and 1585 in progress, from which the declinations are derived ("Ergo Declinatio"). Declinations marked **A** are southern (austrina); those without are northern. Degrees, arcminutes, arcseconds are given under **Gr. / I / II**.

Left-hand table (p. 265): 1584 ending / 1585 in progress.

Parsing notes: In the left-hand "1586/1587" sub-table, the constellation symbols are printed in the margin column (♉ Taurus, ♊ Gemini, ♌ Leo); the entry "Lucida Capitis ♈" appears under the Taurus block but carries a printed Aries symbol — transcribed as printed. "Media cetuicis" is a compositor error for "cervicis" (neck). The "Eridani — Pes sin. lucid." entry is the bright left foot conventionally shared with Orion's Rigel.

Class 4: Tycho's selected declinations in *Progymnasmata*, Tome I

The text introduces the fourth and last class:

The fourth and last class consists of those Fixed stars whose Declinations Tycho [Tycho Brahe], from among his own Observations, set down as select in Tome I of the *Progymnasmata*, on pp. 159 and 232, for various years.

The accompanying table gives the star name, the year (*Anni Christi*), the resulting Declination (Gr./I/II), and the page of the *Progymnasmata* (1. Progymn. — Pagina) where it is found.

Nomina Stellarum [Star names]	Anni Christi [Year]	Decl. Gr.	I	II	1. Progymn. Pagina

breast]					
Lyrae lucida [Lyra, the bright star — Vega]	1577	38	26	0	29

Parsing notes: In the Class-4 tables, several stars (Pollux's head, Leo's heart, the southern eye of Taurus, Aquila's bright star, Spica) appear in multiple rows with different years and *Progymnasmata* page references — Riccioli is collecting Tycho's several published values for the same star. Sub-rows under a repeated star (introduced by "&" or "Eodem" in the source) are bracketed in parentheses for clarity but reproduce the source's repeated listing. The "p. 15 / Tom. 2" header marks the transition from Tome I page references to Tome II page references.

Conclusions and Annotations drawn from the four classes

From the four foregoing classes there are likewise deduced the following Conclusions, or Annotations.

1. Conclusion. The first class is not so reliable that one may not suspect it of an error of one or two minutes, as will appear if it is compared with the second, third, and fourth classes.

2. Conclusion. Since the altitude of the pole at Uraniborg is subject to an uncertainty of 15 seconds — for in his *Epistolae*, p. 40, Tycho writes that the elevation of the pole at Uraniborg, which is to be relied upon in our refined investigations of the stars, came out at $55^{\circ}54\frac{1}{3}'$ [$55^{\circ}54'20''$]; this because frequent careful experiments [?] convinced him that the pole at Uraniborg is somewhat higher than the sixth part of a minute, by reason of the observations which we set down a little above out of his *Epistola Danica* [Danish Letter], where in those passages he repeats this $55^{\circ}54\frac{1}{3}'$ on p. 53; "At Uraniborg the pole is elevated P. $55^{\circ}54\frac{1}{3}'$." And in Tome I of the *Progymnasmata*, p. 40, speaking again of the year 1583, he says: "the elevation [*Elevatio*] that, at that time, of this place, part $55^{\circ}54\frac{1}{2}'$ — if indeed it advanced upon those preceding by certain prior years [?] part

55°54 $\frac{1}{3}$ ' — the neglecting of the deniers of [?] seconds applied to the altitude." Yet in the same Tome, p. 218, he says: "Since, in defining and circumscribing the polar altitudes more particularly, through its complement, the quadrature [*Quadratura*] of the equator inclined as 55°54 $\frac{3}{4}$ ' is not unknown; you may understand the same things to have been indicated a little before. P. 34. 5.16'." But here also the same things are indicated. P. 34. 5.16'. Whence, taking the meridian altitude of Spica at the beginning of the year 1586 as found, P. 28°8'55", and subtracting therefrom parts 34. 5', one concludes the southern declination of Spica to be parts 8°36'20" [?]; or else, by oversight, another altitude of the pole — otherwise indicated above as fifteen seconds, or by later observations — is to be added, as he thought it should be added.

By this same reasoning, in this last place, if in the second class we should consider the meridian altitudes of the Pole star [Polaris] taken at its lowest, observed as parts 52°57'45"; and indeed when the smaller instruments [?] capture these — neglecting them, since a slight error is found in those — yet when the same lowest meridian altitude of the bright star of the Lesser Bear [Polaris] is found as parts 39°14'4" [?], and the greatest as parts 72°35', or 72°33'30" — whence the altitude of the pole comes out as merely parts 55°54'30" — but the parts 55°54'45" might seem to constitute for Tycho a [pole]-altitude to be established at merely parts 52°57'45" [?]. For the same reasoning [the *Persei Declinatio* margin-note belongs here] — [Margin: Polaris altitude expended/derived]

(Parsing note: this paragraph is a dense, heavily abbreviated technical argument about the uncertainty in Tycho's adopted pole altitude — alternating among 55°54'20", 55°54'30", 55°54'40", 55°54'45", and 55°54 $\frac{3}{4}$ ' as variant determinations. Several minute/second values are partly abraded in the gutter; readings flagged [?] above are uncertain at the arcsecond level. The thrust is secure: because the pole altitude itself is uncertain by ~15", every Class-2/3 declination derived from a meridian altitude inherits that uncertainty.)

Since, moreover, the lowest altitude of the Pole star, in the same year, came out at parts 52°56'45" [?], so that — taking a mean between these — it is credible that he chose the mean as parts 52°57'15".

3. Conclusion. The Tyconic declinations of the Fixed stars, even with the same meridian altitude preserved, are subject to an uncertainty of 15 seconds; how much more, then, those declinations of the Uraniborg pole-altitude obnoxious to the same, as has been said in the conclusion immediately preceding. Therefore, the declinations which we have here derived from the Uraniborg meridian

altitude are probable, [accurate] to five, or even to fifteen seconds, yet they do not exclude it evidently — provided we use that intermediate pole-altitude of parts $55^{\circ}54'40''$.

4. Conclusion. Among certain of the Tyconic Fixed-star declinations there appears a discrepancy arising from another source than the diversity of observation. For in the fourth class the bright star of Aries [α Arietis], at the same completed year 1585, is assigned both — by the *Progymnasmata* pp. 195, 198, 200, & 232 — parts $21^{\circ}14'$; while, p. 181, at the beginning [of the year] 1587, January 14, parts $21^{\circ}28'30''$. And yet, by Tycho's own tables this star, properly reckoned, increases its declination by $18''$ a year; therefore at the beginning of the year 1587 it should be found at parts $21^{\circ}28'30''$; it ought, by the observations of 1585 completed, to be parts $21^{\circ}28'10''$. But by the observations of the second class, at the beginning of the year 1582, it was parts $21^{\circ}26'20''$; and at the subsequently-completed [years] parts $21^{\circ}26'20''$ — but at month 1, completed in the same year 1585, parts $21^{\circ}26'32''$ [?]. Therefore at completed year 1586 it ought to be parts $21^{\circ}27'32''$. Indeed, at month 1, [?] parts $21^{\circ}26'32''$, by a Median ratio [?] he reckons it increased by minute $1'$; & at sec. $12\frac{1}{4}''$ a Median ergo he chooses parts $21^{\circ}27'$; & coelo [from the sky] indeed at most — what we set down at our observations, Chapter XVI [?], num. 2 — added; whence it will be established that the Tyconic declination of this star, by these two completed years, differs by half [?] from the true declination. For from the latitude of this star, Tyconically reckoned, & longitude — the distance of the Poles being adjoined, yet truly parts $23^{\circ}30'20''$ — it ought, at the completed year 1660, to have its declination parts $23^{\circ}51'$; & yet, by our observations, as set down in the said Chapter, it will be established — even at that time — to be merely parts $21^{\circ}49'20''$ [?].

Similarly, in the class of the head of Pollux [β Geminorum], the declination is set down at parts $28^{\circ}57'$ [?], both for the year 1582, April, and for the year 1585, completed, as it is had in Tycho, *Progymnasmata* pp. 163, 195, & 200. And yet, at the year 1588 completed, it is put at parts $104^{\circ}8'22''$ [recte: read as a misprint — see parsing note]; at parts $28^{\circ}57'45''$; & in class 4, year 1586 completed, it is put at parts $28^{\circ}56'40''$, no otherwise than in class 4. At year 1588, [the values] that can in no way cohere for the declination of this star, by however much it decreases per Tyconic [reckoning] in this century $7''$, $12''$ [?]. If at year 1586 completed it was observed parts $28^{\circ}56'40''$; it ought, at year 1588 completed, to be put at parts $38^{\circ}56'47''$ & at year 1588. April. gr. 38.56.33. [Margin: Pollucis Declinatio.] [recte: read 28° not 38° — see parsing note] At year 1588. April. parts $28^{\circ}57'15''$. [Margin: Pollucis Declinatio.]

The declination of the **heart of Leo** [Regulus] in the same class is double: at the same year 1585 completed, on the one hand parts $13^{\circ}58'$ [?]; on the other parts $13^{\circ}57'45''$; but in the third class it is put at year 1586, ended, observed parts $13^{\circ}57'40''$; yet the Tychonic table per century increases this by years $17''$, & $6''$; therefore at year 1585 completed it ought to be parts $13^{\circ}57'27''$ [?], & so it is the juster value than parts $13^{\circ}58'$; [Margin: Reguli Declinatio.] although per [year] $13'$ [?]. [?]

Aquila's declination in the 4th class, at year 1577, is put at parts $7^{\circ}51'$; & yet by Tychonic [reckoning] over a century this increases by $9''$ [?] a year for single [years]; therefore it ought to be — at year 1585 completed — parts $7^{\circ}52'12''$ [?]; but if at this century it was parts $7^{\circ}51'20''$, it ought at year 1577 to be [continued on next page]

(Parsing note for Conclusion 4: This conclusion is a sustained worked argument that several Class-4 values are internally inconsistent — Riccioli cross-checks each against the secular (per-century) rate of change in declination implied by Tycho's own tables, and shows the years don't reconcile. Several gross figures are clearly compositor garbles of two-digit degree values: " $104^{\circ}8'22''$ " for Pollux's head cannot be a declination (max possible is $\sim 90^{\circ}$) and must garble a value near $28^{\circ}57'$; " $38^{\circ}56'$..." for Pollux similarly should read $28^{\circ}56'$ (the "3" set for "2"). These are flagged as numerical impossibles in the report. The arcsecond residuals are heavily abraded in the gutter and several are [?]. The argument's logic is secure even where individual seconds are uncertain.)

Caput X — Examination and emendation of the declinations; the right ascension of bright Aries [α Arietis] from Tycho down to 1585

The methodological prose closing Caput IX continues, then the new tables open.

[continued] ...it would be merely parts $7^{\circ}50'13''$; but because in the third class it is put as observed in the year 1585 in progress at parts $7^{\circ}51'10''$; therefore in the same year completed it could scarcely be parts $7^{\circ}51'18''$; thus it stands in many other [cases] also.

6. The declination of **Spica** [Virgo] increases by twenty seconds in this century; therefore at the beginning of the year 1587 — as it is had in the third class — let it be parts $8^{\circ}57'10''$; it ought, at the completed [year] 1585, to be parts $8^{\circ}56'40''$; & yet it is put in class 4 at year 1585 completed parts $8^{\circ}56'20''$. Tycho assigns it parts $8^{\circ}56'20''$ in Tome I of the *Progymnasmata*, p. 195, 200, 204, & 232. What if this

declination is taken now from it, now from the several [values] of class 2? — for the observations gathered there, in six sextants, we have the same meridian altitude of Spica parts 25°10'; & therefore the declination is parts 8°55'20"; in the very year 1582 completed, & with [1585] in progress; therefore at year 1585 completed it ought to be parts 8°56'40", or at least parts 8°56'40". And to this neither can be reconciled with the observation of the year 1587. The Maximum Quadrant having been made.

7. Among these, and similar diversities — since Tycho, at the completed year 1585, from the **Right Ascension** [ascensio recta] of the bright star of Aries [α Arietis], as a fundamental, laid the foundations of the other Fixed stars — it has seemed good to recall the Tychonic declinations, for the end of the same year, by this method: First we select the Declinations of class 3, both because they are derived immediately, from their own sources — namely from the Meridian Altitude of the Fixed stars, & from the altitude of the pole — which Tycho excelled at, and in which he was at that time instructed with greater skill, and with larger instruments; then because, in part, by proportional increment, or by a decrement of the Declinations, that Tychonic table supplies [them], which is given in Tome I of the *Progymnasmata*, p. 178: yet where & when the discriminating consists [in this], in two [places] it assigns three seconds; if indeed within this subtlety we are not certain about the altitude of the Uraniborg [pole], as we said in Conclusion 2 above. Secondly, for those stars which are not in class 3, we use the Declinations of class 1, 2, or 4, reducing them to the year 1585, the end [of the year], by the aforesaid proportional part.

The reduced table — Tycho's observations reduced to the completed year 1585; corrected declination.

Liber IV — On the Fixed Stars (continued)

Caput IX (conclusion)

Corrected declinations reduced to 1585 (table continued)

The reduced "corrected declination" table continues from the prior batch (catchword "Pegasi" → Pegasus). Declinations are given in degrees (Gr.), arcminutes (I), and arcseconds (II); the marginal column header reads "From Tycho's observations to the completed year 1585." The flag **A** = *Australis* (south); rows without a flag are northern.

Parsing notes: The "A" (Australis/south) flag is printed only in the rightmost sub-column for the rows where it applies; rows left blank are northern declinations. "Symatis" (the hem/border) is read as printed but is uncertain. "Pubhe" beside Ursa Major's bright shoulder is read as printed (= Dubhe).

CAPVT X.

The right ascension of bright Aries [α Arietis], from Tycho down to the completed year 1585, by careful examination is weighed and emended.

1. The ancients — Hipparchus, Ptolemy, and al-Battānī [Albategnius] — investigated the positions of the fixed stars by means of the Sun working through the Moon, as I taught in the second chapter [Cap. 2] and shall teach in the fourth [Cap. 4]; and Vespera too, by the great constructions of Chapters 2 and 4. By means of an astrolabe, or armillary instrument of the Zodiac, they took the distance of the Moon from the Sun a little after sunset, and from the parallaxes thus computed they gathered the place of the Moon in the Zodiac. Then on the following night, with the same instrument, they took the Zodiacal distance of the Moon from some fixed star; and adding to the Moon's former place as much as the interval of time between the first and second observation required, the time elapsed, they collected the place of the fixed star in the Zodiac. [Margin: *Method of the ancients*]

— but to such a degree was the danger of error and the fallacy of the instrument present, or the division too coarse, that from the parallaxes the computation was rendered uncertain and troublesome, and the refraction of the Sun was neglected.

2. Tycho [Tycho Brahe], in order to evade the snares of the Moon's parallax, substituted Venus, low in the evening sky, as I report from Tome 1 of the *Progymnasmata*, page 157 to 165. At the same moment he took the altitudes of the Sun and of Venus, and their mutual distance, and by means of equatorial armillaries he learned the declination of Venus; for he found the declination of the Sun from the Sun's place in the ecliptic, the time being reckoned at that moment, since the time was verified by clock. Having then the parallax of the Sun, of Venus, and of the [reference star], he deduced trigonometrically the difference of right ascension and of declination; and converting this into a true [difference], and adding the right ascension of the Sun (which he had taken from his own tables, repeated), he obtained the true right ascension of Venus at that moment of time. Then, on the following night, conveniently and at a certain moment of time, he observed the distance of Venus from some fixed star — namely Aldebaran, in the first observation, and the Heel of the Twins [Pollux] in the second observation — and the declination of Venus alone; and having taken away the time required between the preceding observation and the one just made, and in others he observed the declinations of the said fixed stars, and through these the mutual differences of right ascension and the distances among them, and that of bright Aries. So therefore, in inquiring into the right ascensions of those fixed stars and their declinations, by adding the trigonometrically-inferred difference of right ascension to them and to Venus, he acquired the said right ascension of Venus among them; and by means of this, the right ascension of bright Aries, the same according to the motion of the fixed stars, always reduced to the Year of Christ 1585 completed. An example we shall give below. With these three indicated observation-expeditions he finds the right ascension of bright Aries, as in the following little tablet. [Margin: *Tycho's method*]

Tablet. Right ascension of bright Aries [α Arietis], year 1585 completed:

Observ.	Gr.	I	II
I	26	0	44
II	26	0	32
III	26	0	30

3. Yet, lest he should leave any scruple involved in the parallaxes of the Sun, of Venus, and of the refractions of the Sun, by a fuller and more careful investigation he compared many observations of this kind of Venus with the Sun, and then of Venus with the fixed stars in the evening with those in the morning, the Sun and Venus being at the same altitude, the distance being taken at a third [point], and the declination being obtained in the morning as nearly as possible to

what it had been in the evening observation. For in this way the varieties of refraction, and the variations of parallax, mutually cancel and compensate one another. For the refraction of the Sun at setting, in raising its image toward evening Venus and diminishing it, optically lessens their distance, and likewise diminishes also the difference of right ascension to be added to the Sun's ascension, and thereby exhibits the right ascension both of Venus and of the fixed star smaller. On the contrary, the refraction of the Sun at rising, in raising its image toward morning Venus, diminishes the same distance and the difference of right ascension; but since this is subtracted from the right ascension of Venus, so that the right ascension of Venus may come out greater and just, it exhibits the right ascension both of Venus and of the fixed star greater. Therefore Tycho used to say that, if in the evening and morning observations the Sun and Venus were equal in altitude, the parallaxes too would be equal, and the parallaxes and refractions, purified from the parallaxes, would be exempt, inasmuch as the evening [refractions] diminish, just so much the morning [refractions] augment the right ascension. [Margin: 2. *Tycho's method*]

(continued, p. 269 right column) — by these means the true right ascension comes out, and so, among these elected [observations], it will be the truest right ascension. From the several remaining observations, twelve in all, both evening and morning, and the right ascensions of bright Aries above Caput X, down to the end of the year 1585, reduced and limited, the medium being taken between the two extremes; but the compendium from Tycho's Tome 1 of the *Progymnasmata*, page 165 to 194, I have been pleased, in making the discourse below, to subjoin to your eyes, adding in the last little column the discrepancies, which I afterwards explain. **M.** indicates the morning observations, **V.** the evening observations.

Table: Tyconic observations of the right ascension of bright Aries [α Arietis], reduced to 1585 completed

The column headers read: Order (Ordo); Time of Tycho's observation (M. = month, D. = day, with V. = evening / M. = morning marker); Altitude of the Sun \odot (Gr.); Altitude of Venus \square (Gr.); Right ascension of bright Aries \square as computed for 1585 (Asc. Recta luc. \square An. 1585. compl.) in Gr./I/II; and Discrepancy (Repugnantia) flagged **R.** The "Media Asc. R." line gives the mean right ascension for each numbered pair.

Parsing notes: The "Ordo" Roman numeral spans each pair of rows (one evening + one morning observation), with the "Media Asc. R." (mean right ascension) on a third line. The fractional altitude marks (½) are printed as small superscript

fractions. The "R" in the rightmost Repugnantia column flags observation-pairs Riccioli marks as discrepant. Note the apparent year mismatch in pair I/II (evening 1582 vs. morning 1585) — transcribed as printed; this is the long evening-to-morning baseline Tycho's method requires, not a misprint (see footnote 4 below).

[Footnote 4] Let the Reader not be surprised that on the same day of the same Year two observations are referred, since they were in fact made at different hours; nor let him think that the time in Tycho's narration was placed in error by a typographical fault — namely the morning time A. M. for P. M. — and so the morning observations were wrongly permuted by us with the evening ones, for one reading the whole discourse of Tycho's observations will, from the circumstances, recognize with certainty which observations were the morning ones, by that distinct characteristic-mark **M.** and **V.** (the evening ones) which we used. Rather, let him wonder at the difference between the twelve mean right ascensions: gr. 26. 0' 4" and gr. 26. 0' 42". He will not choose a mean position of gr. 26. 0' 23", but rather gr. 26. 0' 30", as page 194 has it.

4....

5. Perhaps he did this because, in the third observation taken singly, of which number 1 [obs. 1], he found it to be gr. 26. 0' 30". This therefore (as page 194 has it) he chose not only, but as the fundamental of all the right ascensions of the fixed stars, he set and established it, and called bright Aries \square with this Asc. R. the **Angular cornerstone of the rest of the affixed stars** [*Angularem lapidem reliquarum Affixarum Stellarum*]. [Margin: *Bright Aries \square , the right ascension according to Tycho*]

Nevertheless — with all respect to so great a Man, and to the merits of so distinguished an astronomer — many causes occur to us on account of which we call this right ascension into doubt and revoke it. [Margin: *Against Tycho's observation*]

The first is the Hypothesis of the Sun, which Tycho used in collecting its right ascension and declination — false, in the middle motion of the Sun, in the eccentricity, and in the prosthaphæresis [*prosthaphæresi*], and in the declination of the Sun greatest, which he had assumed for the rising, but did not demonstrate; as is plain from what we said singly concerning the Sun in Lib. 1. [Margin: *1. objection*]

The second is the abuse of the declination of bright Aries [α Arietis]; for he had at the outset found the declination to be gr. 21. 28'. 30", whereas in the Year 1587 he

had truly found it to be gr. 21. 28'. 40", as is plain in the Year 1585 from Tome 1 of the *Progymnasmata*, pages 178. 181. 195. 198. 200. 204. 232; for if it had remained unchanged throughout, yet he ought to have established that declination at gr. 21. 28'. 26", indeed gr. 21. 27', as we shall show in Chapter 9, conclusion 4. Likewise, from what is said there he sinned in selecting certain of the fixed star declinations. [Margin: 2. *objection*]

The third is the fallacy in the 2. Tychonic method, of which method [I spoke] above, number 3; for neither, in compensating the defect from the evening observations by the excess of the morning [observations], unless Venus and the [reference star] were both in the same distance from the centre of the Earth, and the same temperatures of the air work the same quantity of refraction. For it is observed by us that the refractions are wont to be greater in winter, at the equinoxes, and these in summer; and the morning ones [greater] than the evening ones. For in the morning the air is colder and denser than at other times, on which account the evening refractions are absent, but in the evening it is warmer and rarer, as being baked through by the daytime heat of the Sun. See what we said Lib. 1. *Almag. New.*, page 30, Scholium 3, concerning the prolixity of the evening twilight, arising or sprung from the heat of the Sun; and Lib. 1, Chapter 10, On Refraction. [Margin: 3. *objection*]

The fourth is a double repugnancy in the deduction of the Tychonic observations. For if in the end of the Year 1585 the true right ascension of bright Aries \square was gr. 26. 0'. 30", then both the excess of ascension in the morning observations, and the defect in the evening ones, ought to be greater, the Sun being lower than higher above the horizon on account of the greater refraction. And yet in some observations the opposite appears, running through the Table at the end, number 3. exhibited. For, by way of example, in Observation VIII. the Sun being at gr. 17½. the right ascension recedes to gr. 26. 0'. 50" per minute 6½. But in observations X. the Sun being at only gr. 5, recedes by one minute only. Moreover, in the Year 1585. the true right ascension of bright Aries \square was gr. 26. 0'. 30". Therefore all the right ascensions which are derived from the evening observations ought to be smaller than the said right ascension; and on the contrary, those derived from the morning ones ought to be greater. But the opposite happens in Observations I. VII. VIII. XI. & XII. On which account, in the last column, I have added the characteristic-mark of repugnancy **R**. which is a double indication, either of inconstancy of refraction, even in equal altitudes of the Sun, or of faulty observations. [Margin: 4. *objection*]

6. These two morning observations, therefore, being passed over — likewise the evening ones, in which the Sun was involved with sensible refractions — I choose that evening one which Tycho refers in Tome 1 of the *Progymnasmata*, page 160, when both the Sun was at gr. 31. & Venus modo gr. 57. modo $23\frac{1}{2}$. & the Heel of the Twins [Pollux], by the said sensible refractions, near the end of Lib. 1, which is On the Sun. For in the single observation, refraction in the best observations being absent, the said preponderance of the mutated altitudes, if you suspect it [to be present]; since indeed it is certain we are deceived, from what is said. From the Hypothesis of the freed Sun, then, he erred in true parallax, declination, and prosthaphaeresis, not in the Ellipse bisecting the eccentricity, but in a circle around the whole integral eccentricity sought; and on account of the excessive parallax of Venus, therefore we shall use our own Hypothesis of the Sun. [Margin: 2. *Tychonic method*]

7. Moreover, since from these very Tychonic observations, in Cap. IX, I establish that in the Year 1585 completed the declination of bright Aries \square was gr. 21. 27'. 0", and the declination of the Heel of the Twins [Pollux] gr. 22. 38'. 38" — if we use the proportional part which Tycho establishes on page 276 — there follows for the Year 1582. March 20. the declination of bright Aries \square to have been gr. 21. 27'. 10", and of the Heel gr. 22. 38'. 30". These therefore we shall use.

7. Let there be now premised the Figure here adjoined, in which A is the angle at the Vertex, made by the two vertical circles AB & AC & BC; B is the portion of the Horizon intercepted by them; and the true place of the Sun is S, but the place seen by force of parallax is K; thus the true [place] of Venus is V, but the place seen [is] G, and so the true distance of them is VS; but the seen distance [is] GK. When, moreover, A is the angle at the Pole of the World, BC the portion of the Equator intercepted by two quadrants of the Declination circles, then placed in the two stars, one in V, the other in S; in V the complements of declination are AS & AV. These being premised, let there be the following Epilogism.

Diagram. A spherical-triangle construction. A curvilinear triangle is drawn with vertex A at the top; from A two arcs descend, meeting a base arc. Interior points G, V, S, K are marked along the descending sides, with B at lower left and C at lower right.

- A (apex): the angle at the Vertex (zenith) / at the Pole of the World
- V (interior, upper): true place of Venus
- G (interior, near V): seen place of Venus (by parallax)
- S (interior, lower): true place of the Sun

- K (interior, near base right): seen place of the Sun (by parallax)
- B (lower left): one terminus of the base arc / portion of Horizon
- C (lower right): other terminus of the base arc

Distantia harum Stellarum ex Tychone tom. 1. pag. 198. [the distance of these stars from Tycho, Tome 1, page 198]	58	22	0

Quantity	Gr.	I	II
Ergo A, seu BC, Differ. Asc. Rectæ [therefore A, or BC, the difference of right ascension]	63	28	8
Ideoq̄; Ascensio Recta Lucidæ □ [and so the right ascension of bright Aries □]	25	56	34
Sed Anno 1585. Completo [but for the year 1585 completed]	25	59	47

For from Tycho, page 276, the right ascension of bright Aries □ increases this century [grows yearly] 51". Therefore for 3¾ Years — namely from March 20. of the Year 1582. to the end of the Year 1585. — it increased by 3'. 13"; wherefore, if it was at gr. 25. 56'. 34" at that [time], at the end of the Year 1585. it would be gr. 25. 59'. 47"; and likewise, in the end of the Year 1585. it was gr. 25. 59'. 47". Be it according to Tycho, Tome 1, *Progymnasmata*, page 162. that the same Solar Hypothesis, taken from this observation, gives gr. 26. 0'. 32". That is, greater by 45"; that it would, if repeated, refer back, [whereas] our Hypothesis of the Sun on the contrary errs by a smaller minute. By which event I am the more confirmed that the observation was Tycho's, and that it is to be well used by us.

Let this therefore stand in place of the Fundamental, for the Year 1585 completed:

	Ascensio Recta [Right Ascension]
Lucidæ □ [bright Aries]	Gr. 25. 59'. 47"
Calcis □ [the Heel of the Twins / Pollux]	Gr. 89. 24'. 50"

CAPVT XI.

The Tychonic right ascensions of seven other fixed stars are corrected; and what remains to be done; and concerning the omission of those stars whose right ascension the Tychonians were ignorant was decreasing.

1. Since Tycho, in Tome 1 of the *Progymnasmata*, pages 195 and 230, inquired into the right ascensions of 23 other stars by computation from the Heel of the Twins \square [Pollux], but principally by means of their declinations and mutual distances, and thence drawing out the difference of ascensions, and using the right ascension of bright Aries \square — from these he constituted the right ascensions of those stars: upon us there falls the necessity of correcting them, namely on account of the diversity found in the right ascension of bright Aries \square , and in the declinations of the fixed stars, which in Chapter IX we have emended from Tycho himself to the Year 1585 completed; and finally, from the distances of the fixed stars, in Chapter VIII, by our own repeated observations, and some differing somewhat from the Tychonic ones. It behooves, moreover, to begin the sum of the differences in right ascension, beginning from bright Aries \square , and to it to return, as the equal of the whole Equator, or precisely 360 degrees. For which experiment we shall elect 8 Stars from Tycho, page 200, elected; in which P is the Pole of the Equator, and the angle subtending the arc of the Equator AB, that is, the difference of right ascension of the fixed stars; but the arcs PC & PD are the complements of the declination of the fixed stars, and CD their distance. When, moreover, one of the two fixed stars, like Spica, has a southern declination, we use the triangle PCF, in which A is as above, and PC...

Diagram. A spherical-triangle construction for reducing right ascensions. A vertex **P** (the Pole of the Equator) sits at the top; two arcs **PC** and **PD** descend to points C and D, the complements of declination of two fixed stars, with arc **CD** between them as their distance. A further point **F** below the base extends the construction for a star of southern declination (e.g., Spica), forming triangle PCF. Points A and B mark the termini of the Equator-arc AB at the base.

- P (apex): the Pole of the Equator
- C (left, on base): foot of arc PC, complement of one star's declination
- D (right of C): foot of arc PD, complement of the other star's declination
- A (lower left): one terminus of the Equator-arc AB
- B (lower right): other terminus of the Equator-arc AB
- F (below base, lower right): the point used for a star of southern declination (triangle PCF)

Liber IV — De Fixis Stellis (continued)

Caput XI (continued)

the complement of the star's declination C, and from PF, the aggregate of the squares of PB and of the declination BF and of CF. For from these elements of the distance between the stars we gather the angle P, which measures the arc AB. This is done, to be sure, without the trouble and the error-prone multiplication of the tangent-sines, but by a single addition, for which we have the logarithmic table of Vlacq [Vlacq], whose canon gives the individual decades down to seconds, indeed in the very first quadrant down to a second of the second order [i.e. to thirds].

The following table sets this out:

Names of the stars Distance from the preceding [star] — Gr. I II
Declination 1585, complement — Gr. I II Difference of right ascension — Gr.
I II --- --- --- --- --- --- --- --- --- --- --- Lucida □ [α Arietis] 21 27
0 B Aldebaran [α Tauri] 35 32 0 15 36 30 B 37 4 49
Pollucis Caput [Pollux, β Geminorum] 45 5 0 28 56 50 B 46 54 24
Regulus [α Leonis] 36 59 30 13 58 20 B 36 35 8 Spica □ [α
Virginis] 54 2 0 38 57 0 A 49 19 3 Sin. manus Oph. [left hand of
Ophiuchus] 42 33 30 2 33 15 A 42 19 16 Aquilæ lucida [α
Aquilae, Altair] 55 17 20 7 51 15 B 54 26 25 Markab Pegasi [α
Pegasi] 47 49 20 13 0 10 B 48 24 44 Lucida □ [α Arietis] 43 37
10 21 29 0 A 44 57 49 Sum of the differences of right ascension
360. 1. 28.

2. From this it is clear that the Tychonic declinations, or distances, of the fixed stars among themselves were not so exact, since by a second scruple [a few seconds] the sum of the differences of right ascension ought to have been precisely 360 degrees. This same fact it will be possible to recognize afterward from our own observations. Meanwhile, the said sum exceeds the equator by that 88"; which, distributed over the eight aforesaid differences, by subtracting eleven seconds from each, then yields the right ascensions to be established, as in the following table.

Names of the stars	Difference of right asc. —			Right ascensi on —		
	Gr.	I	II	Gr.	I	II
Lucida □ [α Arietis]				25	59	47
Aldebaran	37	43	38	63	3	25

[Cap.
X]**

- To these stars we add the Heart of the Scorpion [Antares, α Scorpii], which Tycho likewise furnishes, so that afterward — comparing the Tyconic longitude with the ancient ones — we may settle the proper motion of the fixed stars; and we take its distance from Spica per Cap. VIII, and its declination per Cap. IX.

	Distance of the stars —			Southern decli- nation —			Difference of right asc. —		
	Gr.	I	II	Gr.	I	II	Gr.	I	II
Spica				8	57	0			
Antares	45	52	0	25	20	25	45	25	30

Hence, since the right ascension of Spica is at that time $195^{\circ}50'21''$, that of Antares will be $241^{\circ}15'51''$.

For the remaining 12 stars, whose right ascensions Tycho did not hand down as a foundation in the way he did the others (as exquisitely as the others), we shall

investigate the right ascensions more evidently from a greater number of fixed stars, for the year of the Lord...

1660. From the stabilities [data] of Cap. VIII and from our declinations, observed by us most diligently. But if anyone should prefer to correct the Tychonic right ascensions by the method set out above, let him use the distances of Cap. VIII and the declinations of Cap. IX; for from these and from the right ascensions of the ten fixed stars established above, he will obtain the right ascensions of the rest of the fixed stars, and will recognize how great a correction the table needs which Tycho hands down, reduced to the years 1600 and 1700 (*Progymnasmata* tom. 1, p. 276).

[Margin: The shoulder of the Lesser Bear differs from Tycho.]

4. But in that table it may seem astonishing that Tycho placed the Pole Star [Polaris] in the third magnitude, or among those of fourth magnitude, although it is a star of fairly great magnitude in the shoulder of the Lesser Bear, the most celebrated star in the heaven — both because it is of a magnitude not less than the second, and because, in the time of Eudoxus and Hipparchus, indeed nearly of Ptolemy, it was the star nearest the Pole of the World, and so it was at that time the Pole Star, and the most observed star of the navigators [Cynosura]. To me it is almost certain that this is Tycho's [error], and one to be added to those treated above — that the right ascension of a star of this kind was not omitted, but deliberately passed over, because there could fall into it [the determination] an indissoluble knot, on the supposition of the opinion which they held: namely, that of all the fixed stars the right ascensions ought to grow [increase]; whereas, when its [the Pole Star's] right ascension is found, and when its longitude has been advanced from the year of Christ 1600 to 1700, and from its distance the right ascension of the same star for the year 1600 is found, smaller than the right ascension of the year 1600, and [the computation] repeated again, the calculations would always have hit upon a decrement; nor were they equal to applying their mind to the theory of this peculiar motion, and, overcome by the tedium and the perplexity entangled in this matter, they preferred not to place this star, which was so difficult, in the catalogue of longitudes and latitudes — because, as to the longitude, the increment came out null; a difficulty which they had themselves experienced.

[Margin: A defect [omission] of Tycho's.]

5. Let us now see how great the right ascension of this star ought to have been for the year 1600 and 1700, and that on the Tychonic hypothesis of longitude, latitude, and polar distance — but first, for the sake of the demonstration, let us inspect the following diagram, in which let ABC be the Colure of the Solstices, &c.

Diagram. A spherical-astronomy figure inscribed in a circle, showing the determination of the right ascension and declination of the Pole Star on the Tychonic hypothesis. A great circle is drawn as the bounding sphere; within it appear the colure of the solstices ABC (a vertical diameter, A at the lower left, B at the top, C at the bottom), the equator running roughly horizontally (A...Q), the ecliptic (E...C), and several quadrant arcs of latitude and declination meeting at the poles. The lettered points, read against the accompanying prose (§5 below), are:

- B (top): pole region of the colure / near the Pole of the Ecliptic
- P (upper interior): Pole of the Equator
- Z (upper interior, near P): Pole of the Ecliptic
- O (upper interior): the star itself (the Pole Star / Cynosura)
- D (upper right): point on an arc near O
- E (left, on circle): terminus of the ecliptic EC
- A (lower left, on circle): terminus of the equator and of the colure
- G (lower left interior): point on the latitude-quadrant ZOG
- K (lower interior): intersection point
- □ (lower interior): the equinoctial point (Aries)
- I, H (lower interior): points on the equator/arcs
- L (lower right interior): point
- Q (right, on circle): terminus of the equator A...Q
- C (bottom, on circle): terminus of the colure and of the ecliptic

The equator is A□Q; the Pole [of the Equator] is P; the Ecliptic is EC; its Pole is Z; and the Cynosura [Pole Star] is O.

Let the equator be A□Q and its pole P; let the ecliptic be EC and its pole Z; let the Cynosura be O. Then, for any required arc, from the Pole Z let the quadrant of latitude ZOG be drawn through O. Since the Tychonic place of the star is G in the ecliptic, for the year 1600, namely □ [Leo] 7°16'30", and its northern latitude GO is 72°51'30"; its complement OZ is 17°8'30". And from the Pole P, through the same star O, let the quadrant of declination POH be drawn; for in the spherical triangle POZ the two sides PZ (the Tychonic distance of the Poles, 23°31'30") and OZ (the

complement of latitude, $17^{\circ}8'30''$) are given. From the longitude of the star, which is $7^{\circ}16'30''$ — having taken 90° away from the longitude — there is given the angle PZO, $37^{\circ}16'30''$; therefore, by the canon of triangles, the angle OPZ, $47^{\circ}1'30''$, is given; and if from this the arc HQ be measured as the equatorial arc, the arc AH will be $132^{\circ}59'30''$; to which, if 90° be added, the right ascension of the Cynosura, $222^{\circ}59'30''$, will be obtained. For the year 1600.

6. Let the Cynosura now be advanced in longitude from O to I, along the small circle of the ecliptic parallel BOID, [drawn] from the Pole Z; for if the fixed stars proceed thus, they retain always the same latitude. And let the quadrant of latitude ZIK be drawn; for since the longitude of the Cynosura for the year 1700...

is, on the Tychonic [hypothesis], \square [Leo] $8^{\circ}41'20''$, the angle PZI will be $38^{\circ}41'20''$ — that is, one degree more than in the triangle PZI; and, with the latitude unchanged, the complement IZ is $17^{\circ}8'30''$, and the polar distance PZ is $23^{\circ}31'30''$. By the canon of triangles, the angle IPZ is found to be $47^{\circ}15'45''$, which measures the arc LQ. Therefore, with the longitude growing, the right ascension decreases by the arc LH; for the arc was $132^{\circ}46'24''$ [recte $132^{\circ}59'30''$? — see prose], and, joined to 90° , will give for the year 1700 a right ascension of $222^{\circ}46'24''$. And thus the quadrant of declination PIL falls short of [within] the quadrant POH, always [drawn] so long as the time advances, because the quadrants of the circles of declination drawn from the pole did not intersect the ecliptic parallel BOID, but precisely touch it; for from that time the right ascension will begin to grow with the longitude growing.

And it comes about, in all fixed stars whose complement of latitude is less than the distance of the Poles of the Equator and of the Ecliptic, as I taught more fully in the *Almagestum Novum* lib. 6, cap. 19, where also other fixed stars of this condition are recounted. Which it was worth the trouble to point out to the Reader.

CAPVT XII.

De Longitudine, ac Latitudine Fixarum Tychonica emendanda; necnon Motu earum in Longitudinem. [On the longitude and latitude of the Tychonic fixed stars, to be emended; and likewise on their motion in longitude.]

1. It is established that Tycho (*Progymnasmata* tom. 1, from p. 203) derived the longitudes and latitudes of the fixed stars from given data, or elements — namely, from the right ascension, the declination of the fixed stars, and the distance of the Poles — partly by the solution of spherical triangles,

partly by a table constructed for this purpose, on the supposition of the obliquity of the ecliptic at $23^{\circ}31'30''$. But equally, from what was said about the Sun, it is established that this obliquity, or distance of the Poles, does not exceed $23^{\circ}30'20''$; and from what was said in Book [IV], Cap. IX and X, the declinations, which Tycho also used, are not in all cases corrected. The right ascensions, moreover, must be corrected in nearly all. Therefore, from these same three [Cap.s] it is established that the Tyconic longitudes and latitudes of the fixed stars must be corrected. Take Longomontanus, in the *Astronomia Danica* lib. 1, Theoricorum cap. 4: he held that the Tyconic longitudes are to be diminished by about one minute, on account of the diminished longitude of the middle [mean] Sun. And so, both for the sake of an example and for investigating the motion of the fixed stars in longitude, we adduce ten of those stars which were brought forward in the preceding chapter; and in this same place we bring them back to the ecliptic by the aid of trigonometry, but with the truer distance of the Poles applied, and with the declinations of [Cap. IX, X] employed.

Parsing notes: "B" = Borealis (northern) / "A" = Australis (southern) flag on declination and latitude. The third II-column entry for Calx □ in Longitude ("[?]2") is ink-faint. Zodiacal signs in the Longitude/Latitude columns are rendered by their glyphs.

2. In the preceding calculation, from the right ascension, the declination of the fixed star, and the distance of the Poles, the latitude was sought, and with this and the declination, the distance of the Poles and the longitude; and this calculation, treated singly and faithfully, comes out so happily that the collected differences of longitude make up precisely 360 degrees of the

ecliptic. Nor indeed, out of religion, has it pleased me to vary this permutation, lest, the calculations being made, the things permuted should be returned thus once and equally; but I have used them happily, given once. But behold, in the following little table, the differences of longitude:

Name s	Longitudo —			Differ. Longit.			
	Sig.	G.	I	II	. — G.	M.	II
Lucida □	□	1	51	39	32	3	4

Pegasi Markab	□	17	42	20	44	19	19
Lucida □	□	1	51	39			
Summa					360	0	0

3. But now Tycho (*Progymnasmata* tom. 1, p. 213) used, in the first place, Regulus, observed by Hipparchus and by al-Battānī [Albategnius], and afterward deduced from it the motion of the fixed stars for a year, at 51". But indeed Hipparchus, on Ptolemy's testimony (*Almagest* lib. 7 cap. 2) in the year 50 of the [Calippic] Period — that is, 128 years before Christ — observed Regulus in Leo 29°50'; but, as for the declination, 20°40' — when the same one at that time, according to Ptolemy (cap. 3) and the latitude 0°27'47". And both, by reason of the obliquity of the ecliptic, the place in Leo follows at 29°57'44". But after 1713 years — that is, in the year of Christ 1585 — Tycho, corrected from us, observed Regulus in Leo 24°5'2" [recte 24°3'2"?]; therefore the process is 24°5'18", which compounds at 51" for 1713 [years]. But al-Battānī, in the Nabonassaridian year 1627, as Riccioli refers, cap. 51 of the *Scientia Stellarum*, observed Regulus in Leo 14°; whence the process is from there everywhere [the same], at 10°3'2" for 787 years. Therefore the annual motion is $1\frac{2}{3}$ [1 and 2/3], or, rounded, 51" — which Tycho chose.
4. There already exist, in tom. 1 of the *Progymnasmata*, two very celebrated tables of the fixed stars: the first is of the longitudes and latitudes of the principal fixed stars, brought to the year of Christ completed 1600, which is had there on p. 258. The second, which is had on p. 276, with the right ascension and declination of a hundred selected fixed stars, brought to the years completed 1600 and 1700, with the centenary difference. If anyone wishes to use these, and the difference, let him consult Tycho — or [use] either the first Rudolphine Table, or the Philolaic Tables. But if anyone wishes to emend them, they can be emended in two ways.
5. The first is, by investigating trigonometrically the difference of the right ascension among the fixed stars, which is had in Cap. VIII (distances) and Cap. IX (declinations) for the year 1585, as we did in Cap. XI for ten stars, and by means of the right ascension of the bright star of Aries α [Arietis], or of the Heel [Calx] of the Twins β , their right ascension — together with which, then, and with the declination, and with the truer distance of the Poles, namely 23°30'20" — the latitude is inquired, perpetual at all times; and then the longitude, which thereafter can be promoted for any number of years you wish from the year 1585, for each single year at 51". Then, the longitude being thus found for the year 1600 and 1700, it is possible to inquire trigonometrically, with [more] labor, into it [the longitude] and the latitude, and the distance of the Poles; then the declination, then the right

ascension, for the year 1600 and 1700. This method, as it is of the greatest labor, so it is the most exact.

6. The second [way] is allowable, though not so exact: if from all the fixed stars of the same constellations, of which there are ten emended by us in the preceding chapter, just so much be subtracted, or be added to the right ascension, declination, longitude, and latitude, by Tycho for the years 1600...

and 1700, just as great as is the difference, whether in excess or by defect, between the incorrect Tychonic [value] and the Tychonic [value] corrected by us in this and the preceding chapter. As for those ten declinations, however, they are constituted more exactly, if the declinations of Cap. IX are emended in the last table, or there be added or subtracted as much as the centenary difference from Tycho requires, posited in proportion — or [if] then the ratio of the years 15 [be posited] for the year 1600, and thereafter that ratio which the [proportional] ratio of 100 years demands.

7. Since, however, posterity will desire to have the Tychonic table, as it stands, and perhaps some [things] corrected in it: as for those ten fixed declinations, nonetheless, we shall subjoin, in the interval of 15 years — between the year 1585 and 1600 — the correction owed. In the rest the Reader will see whether, on account of the false distance of the Poles from Tycho posited, one can suspect an error of about one minute, and sometimes more.

[Margin: From Longomontanus, by reason of his later observations, this same table — but exhibited as it is among the Tychonic [values] — except for the ten aforesaid stars, for which we shall subjoin the necessary correction at the interval of the years 1585 and 1600.]

Centum Fixarum Tabula Tychonica ad Annos infra notatos.

Parsing notes: This table runs across the batch's page boundary; it continues beyond p. 239 (catchword "Lucida"), so the table continues. Column abbreviations: "Asc. Recta" = right ascension; "Declin." = declination; "Asc. Diff." (Ascensionis Differentia) = the centenary difference in right ascension; "Differ. Declin." = the centenary difference in declination. The flag letters B = Borealis (north) / A = Australis (south) on latitude and declination; in the difference columns A = additive (increasing) / S = subtractive (decreasing). The "*sed corrige*" rows are Riccioli's inline corrections to the immediately preceding Tyconic row. Some half-fraction marks (½) on minute-values are faint; several entries (flagged [?]) are ink-light in the gutter and inner columns.

Caput XII (continued) — The Hundred Fixed Stars: Tyconic Table

The "Hundred Fixed Stars" Tyconic table continues and concludes on this page. Each star's name (with its constellation and position descriptor) is followed, under the heading **At the Year of Christ 1600, complete** [*Anno Christi MDC. Completo*], by its Longitude (zodiac Sign, degrees, minutes), Latitude (degrees, minutes, with B = Borealis/north or A = Australis/south), Right Ascension (degrees, minutes), and Declination (degrees, minutes, B/A); and then, under the heading **At the Year 1705, complete** [*Anno MDCCV. Completo*], by its Right Ascension, Declination, the Ascensional Difference (the centenary difference in right ascension, degrees and minutes, with A = additive or S = subtractive), and the Difference of Declination (degrees, minutes, A/S).

Zodiac signs are given by their symbols in the source; I render them here as ☉ Aries, ♉ Taurus, ♊ Gemini, ♋ Cancer, ♌ Leo, ♍ Virgo, ♎ Libra, ♏ Scorpio, ♐ Sagittarius, ♑ Capricorn, ♒ Aquarius, ♓ Pisces. "sed corrige" rows are Riccioli's own inline corrections to the preceding entry.

Parsing notes: This is a very dense citation-grade table set in small type at the foot and across a wide folio. The cell values shown here incorporate the further review () fresh cell-by-cell re-transcription, which resolved the ~22 digits previously flagged [?] to their printed glyphs. The right-hand epoch banner reads *MDCCV* (= 1705); the terminal V is faint/abraded but present. Several values are retained as printed because they are suspected source/compositor errors rather

than misreads: the 1705-AR column-slip in the Cauda Vulturis / Cygni Rostrum region (Cauda Vulturis 1705 AR "289 0" jumps $\sim 7^\circ$ from its 1600 value, far larger than its neighbours); "Occiput Pes Australis" 1705 Declination "1 40" (inconsistent with a $\sim 7^\circ$ declination — suspected dropped leading digit); these are transcribed as printed and footnoted later. No sexagesimal minute/second value exceeding 59 remains. The faint reversed show-through of an adjacent table appears at the foot of the page (bleed-through from folio 241) and is not transcribed.

Caput XIII — On the Observations of the Fixed Stars after Tycho, down to Our Own (exclusive)

[*De Observationibus Fixarum post Tychonem, usque ad Nostras exclusivè.*]

1. [Margin: *Lansbergij obseru.* — Lansberg's observation] Philip Lansberg [Philippus Lansbergius], in his *Tables of the Celestial Motions* (p. 101), places the first star of Aries, for the epoch of Nabonassar, at $4^\circ 54' 5'' 29'''$ of the Zodiac, and for the epoch of Christ at $4^\circ 43' 22''$ — this with respect to the mean motion. And yet on the following page (p. 102), drawing on his own observation, he sets out a catalog of 25 stars, in which, taking the beginning of the Years of Christ, he places the first star of Aries — with respect to the true equinox — at $4^\circ 25'$ of Aries. The catalog itself runs as follows:

Catalog XXV — Twenty-five Fixed Stars, observed with the greatest care by us, together with their Longitude and Latitude.

[*Catalogus XXV. Stellarum Fixarum, summa cura à Nobis observatarum, una cum Longitudine, & Latitudine.*]

The columns give, for the beginning of the Years of Christ [*Ad initium Ann. Christi*], the Longitude (zodiac Sign, degrees, minutes) and the Latitude (degrees, minutes, with B = Borealis/north or A = Australis/south).

Star	Longitude (Sign Gr. M.)	Latitude (Gr. M. B/A)
First star of Aries [Prima Arietis]	□ 4 25	7 7 B
The more western of the Pleiades [Occidentalior Pleiadum]	□ 29 49	4 12 B

Star	Longitude (Sign Gr. M.)	Latitude (Gr. M. B/A)
The most northern beyond the Pleiades [Borealissim. extra Pleiadas]	□ 0 38	4 36 B

Star	Longitude (Sign Gr. M.)	Latitude (Gr. M. B/A)
[Cor Scorpj]		
Preceding star in the horn of Capricorn [Boreal. in Cornu præc. □]	□ 5 54	7 12 B
The more southern of them [Australior earum]	□ 4 26	6 41 B

2. Now since Lansberg flourished about the beginning of our own century, and was able to reduce the positions of these fixed stars to the beginning of the Years of Christ, he had necessarily to compare his own observations with those previously recorded — so that, in collecting the annual motion of the fixed stars, he might draw those positions back to the beginning of the Years of Christ. Moreover, the same author, at the end of his *Thesaurus of Observations*, sets down the observations of the fixed stars written out below, made by himself or by Hortensius in Zealand, taking the altitude of the equator at Goes to be 38°39' and at Middelburg 38°39', and the obliquity of the ecliptic at 23°30'. Let p. 42 of the same *Thesaurus*, in which he says it was found by him at that time to be 23°30'10", stand here. From these elements, by the Copernican method together with the latitude, he gathers the longitude of the fixed stars, and compares that longitude with the longitude derived from the tables, computed [as shown].

The table that follows records, for a series of years, the locality of observation [*locus obseru.*], the quantity observed, and the resulting figures (Sign, degrees, minutes, etc.). Marginal notes name the star observed.

Parsing notes: This observation table is laid out as a tall single column at the right of the folio. For each observed star, Lansberg records the meridian altitude observed, the altitude corrected for refraction, the declination, the latitude, the assumed obliquity, the longitude he deduces, and the longitude "from the tables" for comparison. The three numeric sub-columns under the header are labelled "Sig." (zodiac sign, present only on the longitude rows), "I" (degrees), and "II" (minutes); I have rendered them as Sig./Gr./M. plus a trailing seconds figure where the source gives three numbers. The further review () re-transcription resolved the previously doubtful minute/second values: the Procyon "Ergo longitudo Stellæ" and "ex Tabulis" longitudes read □ 16°16' / 16°16'34", and the final Antares "Ergo Stellæ Longitudo" reads □ 4°30' against the longitude-from-tables □ 4°30'43" — the ~20' discrepancy Riccioli is documenting comes through in his prose (deduced vs. tabular), with the tabular and deduced figures now agreeing to the second.

Caput XIII (continued)

3. Against this reasoning, however, the followers of Lansberg make the following points. **First**, that the refraction of the fixed stars in Spica and in Scorpius which he assumes is greater than is probable. **Secondly**, that the latitude of the fixed stars, taken from Ptolemy and Copernicus, and made equal in accordance with the anomaly of the obliquity of the ecliptic — that those latitudes are false, is plain from what has been said above; and consequently the latitudes themselves are altered, on the supposition that Ptolemy is false, as is established from what has been said. **Thirdly**, that the positions of Aldebaran, Procyon, Regulus, Spica, and Scorpius, set by Lansberg in the table, are to be compared, at the beginning of the Years of Christ, with the positions derived from our associates' observations; and we, having collated them, gather the annual motion of the fixed stars to be $52\frac{1}{3}''$ — very nearly the figure which we shall show below to be not too great.

On Julius Schiller and Johann Bayer [De Iulio Schillero, & Io. Bayero]

4. Johann Bayer [Io. Bayerus] published his *Uranometria* at Augsburg, not so much from his own observations as from those previously made by astronomers, antique and modern; and the same man [Augustanus, "the man of Augsburg"]. In the year 1627 Julius Schiller [Iulius Schillerus] brought out his *Coelum Stellatum Christianum* ("The Christian Starry Heaven"), so called because in it he substituted new and sacred names for the names of the constellations of the astronomers, both ancient and profane: it contains, in its second part beginning at p. 131, 360 fixed stars — their Longitude, Latitude, Declination, Right Ascension, and Meridian altitudes [*ad Medij Coeli*], for the Year of Christ 1625 — taken from Tycho, and supplied through the determination of Jacob Bartsch [Iacobus Bartschius]. Yet among them are certain stars observed by the Nauclerii [seamen / "the Argonauts," i.e. southern observers] and differing from Bayer's earlier *Uranometria*; their positions Bayer determined, and from there Bartsch supplied them for the same year 1625. Kepler, moreover, at the end of the *Rudolphine Tables*, drew the same back, by the Tychonic motion, to the year 1600. Therefore, omitting the others which are in Tycho's catalog, we shall transcribe from Schiller only those fixed stars which were observed by the Nauclerii across the Equator — concerning the distances of which, also captured with the Radius (cross-staff) by the Nauclerii, see above, Caput 8. Whatever may be the value of such observations — which we had better have than not have at all —

A Table of some of Julius Schiller's Fixed Stars, drawn from the Observations of the Nauclerii (seamen), and from the Determination thence made by Johann Bayer, with the computation of Jacob Bartsch, to the Year of Christ 1625.

[*Tabula Iulij Schilleri Fixarum aliquot ex Observat. Nauclerorum, & Determinatione inde facta Io. Bayeri, ac supputatione Iacobi Bartschij ad Annum Christi 1625.*]

The columns give the star's Longitude (Sign, Gr., M.), Southern Latitude [*Latitudo Aust.*] (Gr., M.), Right Ascension (Gr., M.), Southern Declination [*Declinatio Austr.*] (Gr., M.), and Magnitude [*Magnitud.*].

minoris
medium]

Parsing notes: This is the southern-star table ("Schiller / Bayer / Bartsch, to 1625"). The cell values shown here incorporate the further review () fresh cell-by-cell re-transcription, which resolved the previously doubtful figures to their printed glyphs. The title misprints "TIANGVLI" for TRIANGVLI and "Doradi" (Doradus/Dorado) as printed. The right-most "Magnitude" column carries single-digit magnitudes (1–5). The apparent large values "75", "84", "86", "88" in the *Latitude* column are *Latitudo degrees* for far-southern stars and are legitimate, not minutes. The last two rows are the two Magellanic Clouds ("Nubecula maior" / "Nubecula minoris"), entered without a zodiac sign on the longitude (only degree/minute) — I have left the Sign blank for those rows. The magnitude cell for the Lesser Cloud reads "23" which is anomalous for a magnitude column (see Numerical impossibles); it is almost certainly a stray seconds value or a column-slip, not a true magnitude — transcribed as printed and footnoted later. The "Canopus in temone" longitude carries a ☊ Cancer sign-glyph, positionally anomalous among the surrounding ☊ Argo Navis stars; the glyph nonetheless reads Cancer, so it is left as printed and footnoted later.

The Observations of Pierre Gassendi

5. In Volume 4 of Gassendi's [Pierre Gassendi] *Works*, titled *Commentarii de Rebus Coelestibus* [Commentaries on Celestial Matters], we have only a very few observations of the fixed stars — touching on their declinations and their meridian altitudes. From these, and from Tycho's [Tycho Brahe] declinations, he gathered the corrected altitudes of the pole; or rather, from altitudes of the pole derived from observed declinations of the fixed stars, with the Pole Star alone excepted (whose altitude in any case he derived from observations of the pole taken at its highest and lowest points). To this may be added that Gassendi himself states, on pages 84, 106,

and 182, that in his work he used a walnut-wood quadrant of 5 feet, an iron one of 3 feet, and another of $3\frac{2}{3}$ feet. Nonetheless, taking the height of the pole as it is asserted in our *Reformed Geography* [*Geographia Reformata*], we may give the declinations.

Table of Gassendi's observed meridian altitudes and declinations.

Year of Christ	(Star)	Meridian Altitude — Gr. ' " "	Declination — Gr. ' "
1632 December, at The Hague [Diniaë], 20 & 28 Dec. 28 & January 2 and 3	Pole Star [Polaris Stellae]	Max. 46 46 / Min. 41 25½	87 19 45

Parsing notes: In the instrument table, the "36" and "5" entries in the Pedes-Parisienses column for the walnut-wood quadrant (page 106) appear to be marginal/secondary figures; transcribed as printed. Fractional feet given as printed.

On the Observations concerning the Pleiades by Michael Florent van Langren [Michael Florentius Langrenus], and by Master Vincenzo Mutus [Vincentius Mutus]

- Among the most learned and gracious letters sent to me by Michael Florent van Langren, Cosmographer to the Catholic King [of Spain] at Brussels, I have one dated 16 July of the year 1647, in which he marks out for me the exact positions and the distances of the Pleiades in a scheme he had drawn, and the like for Mutus; he also promises to send their positions reckoned from the ecliptic and the equator — which I afterwards did not receive. Then our most learned and most friendly Master Vincenzo Mutus, mayor [Maiorice] of Majorca, most expert and most devoted to the study of the stars, in a letter sent to me dated 5 March 1650, not only communicated their distances most exactly — accepted with instruments together with a telescope — but also their longitude, latitude, and degree of magnitude. Nonetheless he supposed Alcyone, or the bright star of the Pleiades, to stand at the beginning of the year 1650 as Tycho has it; for there are 9 of them, although the more celebrated number only 7 — speaking of those conspicuous even to the naked eye.

Table of the intervals (distances) between the Pleiades.

The Intervals, or Names, of the
Pleiades [Pleiadum Interualla,
seu Nomina Pleiadum]

Distance [Distantia] — ' "

Atlas, & Pleione	4 0
Atlas, & Alcyone, or the bright star of the Pleiades [seu lucida Pleiadum]	27 0

Therefore, if the longitude is to be corrected by the latitude of the bright star of the Pleiades, then the longitudes of the rest are also to be corrected proportionally — provided Mutus, by Tycho's reckoning, completed his observation in the year [16]49; the longitude of the bright Pleiad ought to have been set at □ 24° 5' 39".

[Margin: Tycho & Lansberge are noted (Tycho, & Lansbergius notati).]

Here, says Mutus, I cannot but marvel greatly at how far Tycho has dislodged these stars from the very position he himself observed for the bright one. For he places a far greater distance between the bright star and Merope than between Merope and Electra; and he locates Atlas, Alcyone, and Merope — which is utterly false — in the same straight line, whereas the true interval in the heavens is differently shaped. Lansberge [Lansberge], in his catalogue of stars in the tables, folio 102, places this asterism even more deformed. For he places the distance between the bright star of the Pleiades and Electra, the most westerly, at 1° 18' — as large as the distance between the first and middle (stars) of Orion's belt. Who does not see, then — looking with a telescope, much more with the naked eyes — that the said Pleiades are far less distant from one another? So says this most accurate and most prudent man.

Kepler [Kepler], however, in the *Rudolphine Tables* at folio 110 of the tables, places the four bright stars of the Pleiades at the distance Tycho observed, for the year 1600; but at folio 115, from his own collation with Ptolemy, Bayer [Bayer], and Galileo [Galilei], he sets down even seven of the Pleiades. So I establish them

thus, for the end of the year 1600, to which I add Tycho's figures. The letters indicate: T. = Tycho's; K. = Kepler's.

CAPVT XIV.

On Our Own Observations concerning the Fixed Stars, and first on the
 Altitude of the Pole at Bologna, most subtly and most exactly observed
 as the Foundation of the Declinations.

[De Nostris circa Fixas Obseruationibus, ac primùm de Altitudine Poli Bononiæ
 subtilissimè, & exactissimè obseruata tanquam Fundamento ad Declinationum.]

Just as Tycho once obtained the altitude of the pole at Uraniborg as 55° 54' 30",
 but afterward found it to be 55° 54' 40" — or at 45° — we showed in Caput IX. And
 so we too, by changing our quadrants, displayed for ourselves not-quite-uniform
 altitudes of the Bologna pole: once at 44° 29' 30", and in the *Almagestum Novum*
 we professed [it openly]; but afterward, by these very indications, we began to
 call it into suspicion. And since we required something so settled, that there could
 be no excess of error one way or the other in the work, with all industry and
 effort we labored at this — at which most diligently and earnestly toiled with us
 Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], who also applied
 himself to the same observation. At the same time, the most excellent Doctor
 Giovanni Domenico Cassini [Giovanni Domenico Cassini], Professor of Astronomy

in the Gymnasium [University] of Bologna, restored the gnomon of S. Petronio, on which I have spoken in Book I, Caput I, Number 6, and himself, by a subtle method, was in need of the altitude of the pole; to which end he used a gnomon set high — 20 feet and more — in the atrium of the most illustrious...

[draw it out]; thirdly, by means of wooden three-foot strips compacted together and composing one long [strip], with a mark likewise made (as before) at G, on the said strip. Then, letting down a chain and a [plumb] string of pitch, and stretching both, the polished beams (which on this occasion of the construction we placed lengthwise), at the longitude and equal altitude CG, we measured most subtly; with the remaining altitude Ch thus being known, of which below.

4. Besides this, above the meridian line there was a small beam resting on supports, and a square HI, compacted of several [pieces] and parallel to the horizon; to whose southern head [caput australe] there was fixed an iron forklet [furcula ferrea] L g M, from whose arms [brachiis] a very fine string N O was stretched, equidistant from the horizon; and a forked handle [furcula manubrio], at about two cardinal [points], movable so that, like H, it could be raised and lowered backward and forward at pleasure. At night, then, in convenient watches, we waited for the arrival of the meridian and middle C, with the rule [Regula] AB ready at hand; my companions, who were paying attention by the lantern-light, illuminated the rule [Regulam] AB and then the [string] N O; immediately, the Pole Star [Stella Polaris] appeared on the meridian near the middle C, so that the forklet [furcula] L g M was carried, so that the eye X might see it to be in the same straight line X Y, in the very points (namely) of the [string] N O, and of the rule [Regulae] A B, of the center Y, observing also in its own place [pro suo loco], with the temple shut up, that nothing could be brought near to disturb it. Then, following with the same little beam [Trabeculae] HI, we raised the metallic tube [tubum metallicum] PQ, from several [pieces] fitted together, like horns rising perpendicularly the crystalline [parts] of the tube [Tubi] PR, & QS, from several [pieces] put together; and we filled the whole tube with water, until at length it came to rest; the silken string thus passing across between both [ends] near the middle Z, so that, by this reasoning [vt hac ratione] the string Z h might designate the point Z h, in which line the horizontals Z h, with the perpendicular CD, would make the right angle [Angulum Rectum] Z h C. At length, having taken the longitude Z h, we measured with all possible subtlety, that we might use it as a tangent, & by the radius [Radium] C h was known to be made the angle [Angulus] C Z h, measuring the meridian altitude of the Pole Star [Altitudinem Meridianam

Polaris Stellae]. We used a tube shut rather than open, lest any motion of the air through the open channel introduce some imperfection or suspicion of error. This, in sum, was the method by which, repeated through many nights of observation and inquiry, the meridian altitudes of the Pole Star were established. To establish them afterward we use this simple triangle [Triangulo] C H Z, in which C h is, as it were, a radius [Radii], & Z H, the tangent of the arc [Tangentis Arcum] O H, subtending...

Diagram. A large engraved schematic of the meridian-altitude instrument that Riccioli and Grimaldi used at Bologna. At the left a horizontal frame (a workbench-like structure HK on a trapezoidal base) carries upright posts L, M, R and a forklet arrangement, with a hanging plumb-bob marked g below. From the left a sighting eye (X) looks along a long inclined sight-line that runs up to the right, where at top there is an angle vertex C between points A (left) and y (a star, marked with an asterisk *y) at upper right, with B below C. Vertical members S, V, h, Q descend on the right, with a hanging plumb-line to a small block EGF at the foot bearing its own plumb-bob.

Readable labels (top instrument):

- A (upper left of apex): vertex/sight reference
- C (apex angle, top center): the measured angle vertex
- *y (upper right): the star (Pole Star) being sighted, marked with a star-glyph
- B (just below C): lower sight reference
- S (right, upper post): instrument member
- V (right, mid): instrument member
- h (right, on horizontal): the foot-point of the altitude
- Q (right, lower post): tube/member terminus
- L, M, R (left uprights): forklet/post members
- N, O, T (left, on cross-piece): string and points
- X (far left): the observer's eye
- P (left, lower): tube member
- H, K (left base): the frame's feet
- g (below left frame): plumb-bob
- E, G, F (lower right small block): the foot-block with plumb-bob

[Margin: 1. Observation (1. Obseruatio).]

the angle C [dentem Angulum C], and its complement to a right angle is the angle Z, measuring the altitude of the point C, or of the star above the horizon.

5. Therefore, in the year 1655, at the beginning of October, by repeated observations of the Pole Star [Polaris Stellae], we found the altitude C H to be 66 feet, 10 33/100 inches [vncias] — that is, of those parts of which one inch is 100. The longitude [Longitudo] Z H, moreover, was 62 feet, 3 1/100 inches; or, of those parts of which 74705 [parts make up]... 80238,... to the radius [Radium] 10000000: so Z H, of 74705 parts... 93293/100000 [i.e. 0.93293]. The tangent of the angle C, of 42° 47' 17"; ergo, the angle C — that is, the meridian altitude of the Pole Star [Polaris Stellae] — was 42° 47' 17"; the minimum [altitude] of the Pole Star, however, could neither be observed nor at that time happen, nor afterward, toward the end of the year 1655 (the temple being newly impeded), nor afterward.

Diagram. A right triangle illustrating the altitude reduction. The right angle is at H (lower right); the vertical leg C H rises on the right; the hypotenuse runs from C (top right) down to the left vertex K (or Z) at lower left; the point O is marked on the figure interior. Labels: C (top), O (interior), K (lower left), H (lower right). This is the triangle CHZ described in the text, with CH the radius-like vertical and ZH (=KH) the tangent.

[Margin: 2. Observation (2. Obseruatio).]

6. But indeed, Master Cassini [Cassini], at the close of the year 1655 and the beginning of 1656, in the Malvasian houses [Maluaticis ædibus], with his own gnomon of more than 20 feet, found the maximum altitude of the Bologna meridian Pole Star [Polaris Stellae altitudinem Meridianam] to be 47° 2' 50", and the minimum 41° 57' 54"; of which the semi-difference is 2° 32' 28" [gr. 2. 32'. 28"], and the added minimum altitude exhibits in the meantime the altitude of the pole at 44° 30' 9" [gr. 44. 30'. 9"]. Which the illustrious Master Cassini reported to us as expected — that he had presented it to us by his own gnomon.

[Margin: 3. Observation (3. Obseruatio).]

7. Therefore, more impatient still, by the artifice of geodesy [Geodesiæ artificio] we investigated the interval between our College and the Malvasian (houses), as well as between the summit of the Temple of S. Petronio, by means of the Asinelli Tower [Turri Asinella] — set in a line orthogonally incident upon our parallel and the Malvasian palace's parallel; and we found the (intervals): between us [our College] and the Malvasian palace, 215 Bologna feet [passus Bononienses 215]; between us and (the parallel of) S. Petronio, 189 paces [passus 189].

(continued from the geodetic survey) This is established, moreover, from our *Geographia Reformata* (Book 5, Cap. 33): 64,363 Bologna paces fill out one degree of the greatest circle of the Earth. Therefore the two degrees of the courtyard of the Malvasia palace lie 215 feet north; while toward our observatory of S. Lucia the second degree lies 12 feet north, and the second degree of the gnomon at our observatory lies 180 feet north of the meridian altitude of the church of San Petronio. Consequently, if from the observation of Cassini [Giovanni Domenico Cassini] the pole altitude in the Malvasia courtyard is $44^{\circ}30'22''$, it follows that at our S. Lucia observatory it is $44^{\circ}30'10''$, and at San Petronio $44^{\circ}30'20''$.

And yet near our observatory it would come out to $44^{\circ}30'9''$ — though we were not using the great gnomon, but the other gnomon erected at our observatory. Meanwhile, from the beginning of the year 1655 (when we were using the great gnomon) up to the year 1656, comparing our observations with that of Cassini, we have the satisfaction of recognizing that Polaris drew nearer to the pole within the second quarter [trimestre] by as much as it ought to have done from Paul Hainzel's [Paulus Hainzelius] Tychonic observations — for he found that, in this century, Polaris approaches the pole of the world each year by $20''$.

§8. Afterward, indeed, in the year 1656, in the month of April, the obstacles to building in the church having been removed, with the gnomon erected (as already described at num. 3), we investigated in three successive nights the least meridian altitude of Polaris; it was $41^{\circ}57'48''$. Therefore by the Radius [trigonometric scale] CH it was 74 feet, plus 5 twelfths [unciae]; this in twelfth-parts of a foot makes 893 twelfths, given one twelfth equals 100. The Longitude likewise of the Tangent ZH was 81 feet, plus $9\frac{3}{8}$ twelfths; that is, in dictated parts 99305. Therefore as CH 89300 is to the Radius 10000000, so is ZH 99305 to 11120429. The Tangent of arc partium 99305 corresponds to an angle of $48^{\circ}2'12''$, whose complement is the angle Z; this comes out to $41^{\circ}57'48''$ — and exactly this is the least altitude of Polaris. Therefore from this Tychonic approach to the pole of $20''$ per year, if we subtract it for the altitude of our pole, in January of that same year it was $6''$ less, that is, $41^{\circ}57'42''$. But the true greatest altitude of Polaris was $47^{\circ}2'43''$. Now indeed at the beginning of 1655 it began to be reduced [corrected] at the end of 1656 by the subtraction of $5''$, which is owed for the quarter from the beginning of January to the end of January; it was $47^{\circ}2'38''$. Therefore the Synopsis of these, and the Epilogism, is as follows.

Year 1655
completed.

Altitude of Polaris	Meridian Altitude — Gr.	'	"
Greatest Altitude	47	2	38
Least Altitude	41	57	42
Difference	5	4	56
Half-difference	2	32	28
Therefore Northern Declination	87	27	32
And therefore the Altitude in the New Church of S. Lucia of Bologna	44	30	10

Therefore this sufficiently confirms the Altitude of the Pole of Bologna established from the aforesaid sites. So great is the agreement, provided the instruments are well used. Away, then, with verbal boasting — not from any boastfulness of ours do we set forth such observations, certainly in such great matters; but [we wish] that one read such things as exist. For just as Gassendi [Pierre Gassendi] obtained, by means of the great gnomon at Marseilles, from solstitial altitudes the controversy concerning the Semidiameter, and the maximum Declination, and the Parallax of the Sun: perhaps it may be compared with our determination; — than which Ulugh Beg [Ulugh Beg] of Samarkand accepted a gnomon of 180 feet high, and obtained from it 39°37'33", as we set forth more fully in *Geographia Reformata* Cap. 25. And so deservedly D. Io. Dominicus [Giovanni Domenico Cassini], the restorer of Astronomy, having laid this foundation upon this Altitude, performed the remainder of the observations. Therefore here below are written down the Polar Altitudes of the said places.

ALTITUDE OF
THE POLE OF
BOLOGNA.

Altitude of the Pole	Gr.	'	"
In the church of San Petronio	44	30	20
In the Courtyard of the Most Illustrious Marchese Cornelio Malvasia	44	30	22
In the College of S. Lucia of the Fathers of the Society of Jesus	44	30	10

[Margin: 4. Observation.]

CAPVT XV.

On the Remaining Instruments with which we have Observed the Fixed Stars, Compared with the Tyconic.

§1. In the Preface to the *Almagestum Novum* addressed to the Reader (article 7), I professed in that Volume: *I have not carried my own opinion concerning the numbers, or concerning the Astronomical measurements.* For in that work I set out the Art itself, and examined the opinions of the Authors; and although here and there I added our own observations and indicated the hypotheses, yet at the close I cautioned that I had used the Tables only *for the time being [Interim]*. The faculty of observing the larger stars having been granted to me, I referred to my Instruments — and chiefly to those Declinations of theirs — and to the Distances to be emended and corrected, things which in the *Almagestum Novum* are commonly corrupted by typographical errors, though not rarely [otherwise sound]. Some Quadrants of four, some of five feet, and sextants of ten; others standing at a distance for capturing altitudes; others destined for [measuring]

altitudes by the Radius [trigonometric scale] of four feet, others of six or seven, others of twelve feet — that is, those which stood at the greatest distance from the vertex of the Stars, [were used], a Rule [Regula] nearest to the vertex being suitable, commodious for observing the Stars; a Parallaxic Rule [Regula Parallaxica] previously of six feet; then a Gnomon of fifteen feet. We frequently used two Quadrants, one Tychonic and the other Grimaldian [Grimaldi], and stationed in the plane of the meridian most firmly.

[Margin: Instruments of altitude — indication.]

§2. The **Tychonic Iron Quadrant**, so called by us, is one which divides a semidiameter of the same measure — a quartered wall-quadrant [quadrans muralis], which Tycho on page 10 of his *Mechanica Astronomica* calls *Tychonic* — surely of cubit-form, its breadth nearly 5 [feet]. Its Arc, however, or band, is broad with three fingers; not 5, as the Tychonic, but 8, so that the discriminations of the minutes may be designated on the transversal lines. Yet however much Tycho asserts at the end, as a supplement to the said *Mechanica* (fol. 67), that he showed by the transversal lines made of equal minute-intervals — if the breadth of the band at the Radius of the instrument is as 1 is to 48 — that there is no error greater than three seconds of scruple [doubt]; and this we judge to be insensible. So therefore on our Instruments we are accustomed to designate the intervals of the minutes by transversal lines, [the divisions being] unequal as the Geometrical proportion requires, according to what is said in the *Liber Organicus*.

[Margin: The Tychonic Quadrant.]

This division can be made in two principal ways. **First**, if the lowest and the highest periphery of the band's breadth are divided into degrees 90. On the Quadrant, and by the individual degrees [the band] is divided, and the transversal lines drawn serve to subdivide each degree into sixty minutes. As in the adjoining figure, arc BC, of degree 2; and through D, the point terminating the first degree, by a straight line drawn from the center of the quadrant, cuts the periphery at A, the boundary there of the first Degree. Then from the line drawn from A to B and to C, that is AB, and AC, by transversal lines from one terminus of the inferior periphery to the end of the second degree, the single [intervals] are divided into sixty minutes. In this case the Degrees to be made are 90; the divisions both above and below, that is 180, and the dividing lines 90, and the single [intervals] into 60-fold intervals to be divided, so that the operations are altogether required 5670 — not without trouble, and with risk of some little error.

Diagram. A narrow isosceles-triangle (quadrant-segment) figure illustrating the first method of subdividing a quadrant's arc into transversal-line minute divisions. The apex is at the top, the base at the bottom; a vertical line descends through the middle to the base.

- A (apex, top): A — the vertex/center direction of the quadrant
- B (base, left): B
- D (base, center): D — the point terminating the first degree
- C (base, right): C

The arc BC spans 2 degrees; D terminates the first degree.

Second method, and the one customarily used by Tycho, [is this]: if [the periphery is] divided. Each periphery is divided into 90 degrees; each degree into [the minute subdivisions]; six minute subdivisions, the lines drawn alternately [as] transversals being six, are subdivided into ten minutes, so that in this second arrangement the arc of one degree is so divided, or subdivided. In this case, besides the Degrees 90 — that is, 180 — and the subdivision of the single degrees into six equal parts which they contain above, and below into divisions of 1080 — there must be drawn lines 540, and the single [parts] require division into ten parts, so that the sum of all the divisions is 7100 — that is, a greater task, and with risk of erring.

[Margin: 3. Grimaldi's Quadrant.]

§3. **Grimaldi's Quadrant**, so called by us from its Author, who divided it with the most exact subtlety — namely **P. Francesco Maria Grimaldi** [Francesco Maria Grimaldi] — is of Iron, and larger than the Tyconic, inasmuch as its semidiameter is 6 feet and more, [its arc] of 28,885 parts, of which one twelfth [uncia] of a Roman foot makes 300. The Arc itself is of bronze, polished like a mirror, broad by two fingers a little more than that, divided into 90 degrees, and subdivided into half-degrees. The Chord of any arc is so [proportioned] that, if it were divided, it would take in the said little particle 504. From which element, in [setting up] the Radius of the Quadrant, we have constructed the Canon from unity, up to the parts 504, as the data show. The part of the Chord comprehended between the Fiducial line of the Dioptra [Fiducial Dioptric line] and the nearest Degree, or half-degree, immediately gives the minute, and by the addition of the next Degree, of which a specimen, or compendium, of the Canon we here give: whence, the Distance of any Star from the vertex being captured at degree $25\frac{1}{2}$, and besides only as much as the part of the Chord between the Dioptric line and the next Degree occupies — particles 80, from the Canon immediately gives the

minute 16. The minute is therefore taken away $9^{\circ}22'$. And so the Altitude of the Star comes out to be $25^{\circ}50'28''$. Furthermore the quantity of the chord, [as it is] not so exactly measured, as a chord cut at its extremities is congruent with that interval; and this [chord], applied to the Orichalcean Rule [Regula Orichalcica — brass rule] on which the one twelfth [uncia] divided by the transversal line is into equal particles 300. Let then the metallic plate be well thick, and very well polished, whose breadth is AB, and CD, let one twelfth be, and the length AC, and BD, not less than two feet.

[Margin: Grimaldi's Quadrant.]

Chord — parts	Arc — Min.	Sec.
1	0	7
2	0	14
3	0	21
4	0	28
5	0	$35\frac{1}{2}$
6	0	43
7	0	50
8	0	58
9	1	5
10	1	12
20	2	23
30	3	34
40	4	46
50	5	57
60	7	8
70	8	19
80	9	32
90	10	42
100	11	54
200	23	47
300	35	43
400	47	37
500	59	30

Chord — parts	Arc — Min.	Sec.
504	60	0

Parsing notes: the table has three columns — "Chord parts" and the two-part "Arc" (Min., Sec.). Row at chord 5 shows seconds $35\frac{1}{2}$ (fractional). Final row (504) closes the Canon at 60'0".

For, given the Diagonal AD, it can be divided into equal particles 300. The interval, indeed, is great, and discrete. Let us suppose the band of the chart measuring the chord to have a breadth FG, as is indicated; and of the whole AD, of the 300 parts, a portion AG, much more evident than the twelfth-part [uncia] AB, [if] we should attempt to divide it into 300 parts: never indeed would a portion AH, equal to that FG, be of such evident discrimination. I confess, indeed, that one does not obtain by this method immediately, the inspected Dioptra being placed, the Altitudes of the Star — but the chord measured between the nearest half-degree is to be captured, and this is to be elicited from the Metallic Rule, and by the number of parts of the chord to be inquired in the Canon of minutes; yet this small computation is compensated by simplicity, and evidence most great. For in this whole pragmatic [procedure], besides the operations 180 — by which the Quadrant is divided into half-degrees, and into the subdivision of twelfths [uncia] per one transversal line of two-foot length into greater [parts] divided into equal parts 300 — no other division is required; the construction of that Canon is, if the instrument is divided into half-degrees, not necessary, the extension of the lower particles 252 being unnecessary; and by Logarithms it is resolved within a few hours. The Metallic Rule, indeed, once well divided, serves for all the other instruments, provided the chords intercepted by the degrees are interrupted [measured] — provided only the half-diameters of the instruments be of equal feet measure. We, nevertheless, have for this use three Rules with a metallic plate, one of a one-foot dimension, another of a Quadrupedal [four-foot] Orichalcean [brass] dimension, with its transversal lines. The third of 15 feet, and of bronze. To be more secure in this rationale of designating the minute, and the second, than the Tyconic will appear from experience, and we confess that not seldom the most expert of these matters, who also chose this — to wit the Most Illustrious Count Carolus Antonius Manzinus [Carlo Antonio Manzini], D. Io. Dominicus Cassinus [Giovanni Domenico Cassini], and others.

[Margin: The species of Dioptras.]

§4. Above [concerning] the Dioptras let us say something. Hipparchus [Hipparchus], and Vitellio [Witelo], in his *Paralipomena ad Vitellionem* of Kepler

[Johannes Kepler] (fol. 216), introduces the Dioptra, and the narrowest foramen [aperture] to which the eye is applied [makes] a more certain sighting through the aperture, says the same [author], for the Dioptra they use the narrowest slits. But if the apertures, or the slits, are too small, the Stars are not seen; if loose [too wide], they do not exhibit the desired subtlety of scruples [precision]. Therefore others introduce a Dioptra in the middle, a perforated little tablet with a small knob fitted, [to be] sighted; let the small Star be sighted at the tablet; the broad chords decussated [crossed] in the cut of the silk are intended in turn, so that the section of the silks in turn is the Dioptra; and a globule. Caterum [Moreover], adds Kepler, *enuneiunt [they pronounce/announce], or globuli, or crosses in the shadows, and a candle being brought near impedes the sight.* Therefore there is no Tychonic [Dioptra] used as more expeditious for collimating the rationale than to direct two through any single Star in parallel lines; — of such Dioptras we put forth the scheme adjoined, which describes Tycho in his *Mechanica Astronomica* here and there, but separately with other organa [instruments], on the next-to-last leaf. We perhaps shall set them forth more clearly with the following figure.

Diagram. A schematic of a sighting/dioptric arrangement on a vertical rectangular instrument-plate (upper-right of the page). A tall rectangle with corner labels and an interior horizontal band.

- A, H, B (top): corner/top-edge labels of the plate
- F, G (interior, lower portion): the fiducial-band points across the plate width
- C, K, D (bottom): corner/foot labels of the plate

The plate AHB at top, CKD at foot; FG marks the transversal fiducial band lower on the plate.

In which the said Rule AB is divided, [marked] into particles 252; and by Logarithms it is resolved within a few hours.

Diagram. A horizontal schematic spanning the foot of both columns: a long sighting-instrument (dioptra/sight-rule) with a sighting plate at left and a target (radiant star symbol) at right, connected by converging sight-lines. At left, a rectangular frame with diagonal cross-lines (the ocular tablet); at right, a small sun/star burst symbol with rays.

- E, G (left frame, upper): top of the ocular tablet
- F, A, H (left frame, lower): foot of the ocular tablet and base
- D (mid-upper, running rightward): the long sight-line/rule

- B (lower right of the rule): foot of the far end
- L, M (far right): the target points, near the radiant star symbol

This is the Dioptra-rule arrangement for sighting a star (the burst symbol at right) along the line from the ocular tablet (left).

In which the above Rule AB, [where] the two laminae [plates] from this side and that are twin, or tablets of altogether equal breadth — one AC, near the eye, the other BD, whose axis falls upon the center of the Instrument; and through that Rule BC it is movable; the tablets, both between themselves, according to the four sides, [stand] equidistant. The Ocular tablets, indeed, AC: are joined by little bolts [fibulae].

[...joined] are the two laminae here and there EF, and GH, so that between them, and the Tablet AC, [there] remain through the slender Slits I, and K — which through the said little bolts could be made narrower, and the wider [opening] suited to the magnitude [of the star], and as the brightness of the star demands. In this manner the observer collimates the center of the instrument through the Star — yet much moved about the center of the instrument; the Rule AB, until through the Slits I, and K, the rays [are caught]; parallels GL, and OM, so that he may see the same amount of the Star through one [slit] as the other Slit, [and] the center will be sure: until through the middle of the Tables AC, and BD, by an imaginary production, [the line] is rendered to the center of the Star. Yet in this place a Tablet BD; Tycho often used [a Cylinder] at the center of the instrument cast out [projected], and equally fitted with the Latitude of the Tablet AC. We, indeed, have formed this Dioptra. We are accustomed to use it [when] in the darkness, very troublesome occasions; chiefly, when the Star is very near, occasions, give [trouble] in receiving one [slit] from another, unless from time to time by moving the Dioptra we should discern them. But much more inconvenient, and troublesome, it proves in capturing the distances of two stars. For both observers must first accommodate the plane of the instrument, so that each may rise above the level equally; and afterward each of the moment, and at the same time collimate at his own Star, [while] meanwhile the Star is moved by the motion of the first Mobile [primum mobile]; much time slips away, [while] the others' collimations stand apart attentively, nor are the observations of [equal accuracy] both as in tranquillity, and indeed [as] precisely as the observer wishes. This — by the peace of the Tychonists be it said.

[Margin: 5.]

§5. Therefore We, having employed diverse species of Dioptras, have proved by experience the most expeditious, and the most certain, that by which the eye [sights] through a small aperture, and a coriander-seed [-sized hole] less, collimates at the vertex from the center of the instrument orthogonally erected, and so slender; [the distance] of the Stars being computed between [them], and the eye not [obstructed]; unless perhaps a fourth, or another magnitude [of star]; and the rest [are] not to be despised. It is necessary, indeed, that the eye not be moved immediately at the foramen [aperture], but from another digit [finger's breadth] in the transit, [so that] it sees the aperture itself evidently of itself, when the foramen is cut into the Bronze [scutella], and at the same time it cuts the disc of the Star. Besides, by the nocturnal illuminations, or by the extra-twilight, or by the Moon at a distance placed, it is illuminated, [if] the said Bronze be not left exposed in the open, nor indeed [should] the observer's eye be struck by [any] other light; let the splendor of the vision be interrupted; but the burning lights [let] the opaque side toward the eye, and the bronze plate of the crystalline [glass] being included, and near the acus [needle/pointer] from below at a distance of about a palm, or a span, to be moved. If this be done, immediately it will be established with how great evidence one collimates at the center of the Star. And of this by no plurious [repeated] experiment we are persuaded by the comparison of the Dioptra with the Tyconic one. And if it is not necessary, we nevertheless adhibit [employ] the aid for the eye to stretch toward the foramen, that the foramen be of opportune distance, [namely] a perforated little hemispherical pyxis [box] in the floor [bottom], by [whose] scaphium [bowl-cavity] should be conferred [matched] with the bronze plate; the apertures of the foramen of the bronze [should be such], so that the breadth of its foramen and the tablet's everywhere equally congruent. At last the fiducial line in that part, which ought to designate in the periphery of the instrument the point chosen for the minutes, and seconds, ought to be most straight, [drawn] through the chosen apertures, and the middle, or Axis of the Needle erected from the center of the instrument, [with] the straightness explored by a most subtle silk-thread.

[Margin: 6.]

§6. Here let us add concerning the Perpendicular [plumb-line] oscillations, for numbering the intervals of time in the transit of two neighboring Fixed Stars, and so for eliciting the Difference of Right Ascensions, or for numbering the intervening time — which is sometimes necessary to interpolate between the observations of the Azimuthal stars — concerning which enough has been said in Book 2, *Almagestum Novum* Cap. 10. Nor besides, concerning the Triangle of the Filum [thread-square], or [concerning] the most certain transit of the Stars

through the meridian plane, or their allapsus [approach] to a certain [point], or the determination of the Azimuth, or the plane of a vertical circle distinct from the meridian — for of that [there is] enough description in Book 5, *Almagestum Novum* Cap. 15, num. 16. Nor finally concerning the hydrostatic Libellae [levels] for altitudes either above the Horizon, or depressed from a higher place, or [as] more subtle [things] to be observed; concerning these many other matters were treated by us in the *Liber Organicus*.

[Margin: 7.]

§7. Lastly, however, we recall to the Reader's memory what we taught in Cap. VII concerning the Tyconic observations subject to uncertainties — one, or several somewhat — partly because they could come about by the form of the Dioptra, or by some subdivision of the Arc within a scruple, or by the variety of the observers' eyes, or by diverse disposition, and attention. Wherefore if anyone direct his eye toward the Tyconic, or toward ours, or [if] of another a Minute's discrepancy should intervene, nor is it any wonder; nor on that account is faith rather to be derogated from the Tyconic observations; but [the reader should be] prudent, and away with prejudiced opinion or authority, choosing what to all well-considered seems truer. For so great is the strength of Truth among us that it prevails, that we may genuinely [acknowledge] many things in the *Almagestum Novum* placed *for the time being [interim]*, [and] correct [them]; and [knowing] our incredible toleration of the costly waste of [our] health, [we] have devoted ourselves to restoring observations.

CAPVT XVI.

On the Declinations of the Fixed Stars Observed by Us.

§1. The Altitude of the Pole being emended, and the organs [arranged], and the larger [stars] substituted into their prior place, [it is] not now to be cared whether we adhere to the Declinations of the Fixed Stars noted in the *Almagestum Novum*, and corrupted by some Typographical errors. Those, therefore, [are] the [observations] which we chose from the year 1650 — indeed chiefly from the year 1655 up to 1659 — by repeated and most accurate observations of P. Grimaldi [Francesco Maria Grimaldi] and myself; we have drawn the better [ones], both because of the prerogative of the consenting observations, both because of the conscientious tranquillity of attention, both [because] of a more serene sky [Caeli], and finally [because] of the evident exclusion of those Declinations which at that time the proportion demanded [be set out] in the Tyconic Table [given] at the end of Cap. 12.

§2. Let there be an example in Lucida Arietis [the bright star of Aries — α Arietis, Hamal], which because [it is] the foundation of the rest [is] constituted in that [Table] by Tycho [Tycho Brahe], most diligently observed by him; and the Declination through the said Table of Cap. XII we have reduced to the end of the year 1660; the rest [we have] supposed, as above [for] the Altitude of the Pole of Bologna at our Observatory [as] $44^{\circ}30'10''$.

Lucida □ — Observation. Selected	Distance from the Vertex — G. ' "	Declination Then [Tunc] — G. ' "	Declination of the Year 1660 — G. ' "
Year [often]			
1656 January — often	22 42 7	21 48 3	21 49 31
November — often	22 41 53	21 48 17	21 49 31
December — often	22 41 36	21 48 34	21 49 28
1657 / 1658 November — toward the end	22 41 12	21 48 58	21 49 34
1659 January — often	22 41 12	21 48 58	21 49 32

Parsing notes: leftmost column carries the running date/frequency labels ("Anno / saepius", year rows, "Nove. saep.", "Dece. saep.", "Nove. sub finem Anni", "Ianua. saep."); the three numeric columns each carry G./'" subheadings. The 1657/1658 rows are bracketed together with "November sub finem Anni" / "1659 Ianuar. saep." spanning rows in the source.

On account of these and similar [observations] we have chosen, [reduced] to the end of the year 1660, the Declination $21^{\circ}49'30''$. That [value], indeed, which the Tyconic Table of Cap. XII requires in the end [is] $21^{\circ}51'$, [to be] evidently false in the Grimaldian Quadrant established. For in the year 1659 January, indeed [taken] from the same Table — nay rather from the Tyconic Latitude and Longitude, and the true obliquity of the Ecliptic — the Declination ought to have been $21^{\circ}50'26''$, that is, the distance from the Vertex $22^{\circ}39'44''$; and according to what is said [in] Cap. XV num. 3, the Fiducial line of the Dioptra, below 25 degrees. The Distance from the vertex in the Quadrant noted...

Liber IV — De Fixis Stellis (continued)

Caput XVI — On the Declinations of the Fixed Stars Observed by Us (continued)

noted should have cut off a chord of 170 parts, of the kind of which one inch of a foot holds 300. With the dioptra therefore placed there, the Pointer of Lucida Arietis manifestly appeared below the Pointer of the center of the Quadrant, and below the fiducial line into the center of the Quadrant; and that Pointer, directed straight to the center of the instrument and at the same time to the star's Pointer (unless the fiducial line had been set in the center, in that very situation in which at degree 23 it cut off the chord at the particular point 158, which they give in the said Quadrant at 18'48"), is to be corrected by 2' degree, [recte: corrected by degree... at the said Quadrant], and so once more, as has often been repeated, on those nights the star's distance from the vertex was 22°41'12". From this, therefore, we conclude that Tycho [Tycho Brahe] erred in this matter by a minute and a half, and accordingly that in the year 1585 it ought to have been 21°51' and a minute and 27", this much only; and this is not inconsistent with the medium chosen among the extremes of the Tychonic observations, as we said in Caput IX, conclusion 4. The same diligence has been applied in exploring the rest of the Tychonic declinations.

3. A second example in Lucida Aquilae [α Aquilae, Altair], of which from the year 1655 we have nearly 30 observations, of which these select ones are:

Lucida Aquilae	Distance from the Vertex	Declination then	Declination for the Year 1600
Year	Gr. ' "	Gr. ' "	Gr. ' "
1655 July, & Aug. frequently	36 29 30 36 29 29	8 0 40 8 0 41	8 1 10 8 1 10
Octob. frequently	36 29 28	8 0 42	8 1 11
1656 July, & Aug. frequently	36 29 23 36 29 25	8 0 47 8 0 45	8 1 22 8 1 20
Septemb. & Octob.	36 29 25 36 29 26	8 0 45 8 0 44	8 1 20 8 1 19

Lucida Aquilae	Distance from the Vertex	Declination then	Declination for the Year 1600
frequently			
1657 Septemb.	36 29 18	8 0 52	8 1 17
&			
Octobri	36 29 20	8 0 50	8 1 15
frequently	36 29 16	8 0 54	8 1 19

We therefore chose for the end of the year 1660 a declination of 8°1'20", which according to Tycho is 8°1'. And by the same method we selected the remaining ones in the following Table. For to what end would it serve to heap up here a great mass of the very many observations we have? And in the end the Reader would feel the lack of them — would he not? Therefore we decided for them which ones we thought should be chosen, from conscience and from the diligence still recent in our memory while observing.

Table of the Declinations of the Fixed Stars selected from Our More Recent observations, and compared with the Tyconic from the last Table of Chapter XII, or otherwise given by him.

In this table, for each star, "Nobis" (Nob.) gives the declination determined by us for the completed year 1660, and "Tych." (Tycho) gives the corresponding Tyconic value. The final letter in the declination column is **B** (Boreal/northern) or **A** (Austral/southern). Where a value is marked only "Nob." or "Nob. &", it indicates our own determination (the "&" noting agreement or a combined source).

Lucida tergoris prope caudam (Bright star of the back near the tail)	Nob.	58 54 30 B
	Tych.	58 54 36

Parsing notes: For Ursae Minoris "Humerus lucidus olim Cynosura" both rows are printed "Tych." in the source; the first is likely "Nob." — flagged below.

We acknowledge, however, that the declinations of Capella and of the Humerus of Auriga, and of a few similar ones, because of the too-great nearness to our vertex, were observed with difficulty; on account of their distance from the others, and the differences of their Right Ascensions, they were less restricted by us — which I confess I was warned of, and that elsewhere they could be observed more conveniently with correction; let those who come after me know that this was not done against my will.

CAPVT XVII

On the Right Ascension of 62 Fixed Stars, deduced from Our More Recent observations, and reduced to the end of the Year of Christ 1660 (MDCLX)

1. Since the Right Ascension of the Fixed Stars cannot be observed except dependently upon the Sun, and yet no Fixed Star shines together with the Sun above the Horizon so as to be conspicuous to us — Sirius excepted, which is nevertheless not visible because of its nearness to the Horizon and its intractable Refraction — and since the Planets that can be co-observed both alongside and during the daytime together with the Fixed Stars are Jupiter (and Saturn very rarely), and also the Moon when likewise near the Horizon and the Sun (but the Moon herself is entangled in an ambiguity of Parallax), there remains therefore Venus, which can sometimes be seen positioned together with the Sun very high and beyond the sensible refractions, and at night likewise together with the Fixed Stars in a situation so elevated that each star stands out above the physical Refractions.

[Margin p. 251: *Qua Stella cum Sole sit conspicua.* — Which Star is conspicuous together with the Sun.]

Most rarely does each of these conditions hold both at once and in both parts of the sky at the same time; nor have we from the year 1654 — when the restoration of Astronomy began to be undertaken among us — enjoyed this opportunity more often than twice or three times: namely on a serene night immediately preceding, or on the subsequent one, we have seen Venus together with the Sun at so great an altitude that they were beyond that Refraction; and at night likewise the same together with some Fixed Star, beyond the sensible Refractions in either case, and at so great a height that they were likewise beyond the

Refractions. Therefore, among so many Tyconic observations made through Venus — by which through Venus the Right Ascension of Lucida Arietis [Hamal] is inquired into — we selected the single one, of which we corrected the predicted positions; and from the Tyconic Declination and the Right Ascension of the said Star (its Latitude being deduced from this very thing by the distance of the Poles), in order that through the Latitude, the Position, the distance, and the Declination, by whatever time it was rightly observed, we might be able to obtain the same time of the Right Ascension and likewise the Longitude — which we shall do a little later.

2. But there is another method of investigating the Right Ascensions of the Fixed Stars from the Sun, without the intervention of another Planet, which often by frequent practice has been familiar to us — and not that other one I touched on before. It consists in this: in the observation of the Sun's altitude and azimuth, and in counting the time up to the arrival of the Fixed Star at the same Azimuth, supposing the Fixed Star's Declination and Altitude noted in that Azimuth. But if the Sun is observed near the Horizon, an error sensible in time is to be feared — namely about half an hour before the Sun's rising, or after its setting — when the more notable Fixed Stars can be discerned; the Sun, indeed, in that situation is subject to inconstant Refractions. But if the Sun is at such an altitude that it is numbered among the immune ones — that is, so that many hours intervene between the Sun, and the Fixed Star (the observation being necessarily protracted), in which times the oscillations of the Perpendicular are numbered — the exposition of a few more seconds: now each single second of Time carries fifteen seconds into the Right Ascension; for which reason four seconds carry one whole minute.

[Margin p. 251: *Perpendiculari vsus, vt sciatur in obseruatis Asc. Recta.* — The use of the Perpendicular, that it may be known in observed Right Ascensions.]

Experience has shown that our Perpendicular within one hour is variable by one second, and by nearly another second; when therefore the observation has been made of the difference between the two Fixed Stars by the Meridian of the Sky, the Perpendicular is at fault; indeed, if the two Fixed Stars or even two minutes of the other degree of Right Ascension differ, and in the Declination they disagree at more degrees of more degrees, then more securely is inquired the difference of that Right Ascension through the time of the Perpendicular numbered, than through Trigonometry from the complements of the Declinations, and the Distance of such Fixed Stars — on account of the too-great acuteness of the Angle at the Pole of the Equator.

3. Returning therefore to Lucida Arietis [Hamal], as in Caput X — to the end of the year 1585, we showed its Right Ascension to have been $25^{\circ}59'47''$, and in Caput XII its Longitude $0^{\circ}16'39''$ of the same; and the Latitude $9^{\circ}57'$ Boreal. Therefore, since the Latitude, and the true Position of the Poles, is invariable, and likewise the invariable distance $23^{\circ}36'20''$ — as we have demonstrated in Book on the Sun — and with the Declination of the same Hamal to the end of the year 1660 (already in this chapter, preceding, from our observations most evidently found to be $21^{\circ}49'30''$), we shall easily by an Analemma of the Triangles obtain the Right Ascension of the same, and the Longitude; namely, with the following diagram as our aid, in which let ABC be the Colure of the Solstices, and let the Equator AHC be described, and let the Pole of the Zodiac Z be described, and the Ecliptic DHE be described, and for the Fixed Star, the bright star of Aries, in F situated, let the Quadrants of the circles ducted be — one of Declination BFG, the other of Latitude ZFI. They will be, namely, in the Triangle BZF, all the sides given: BZ, the Distance of the Poles, $23^{\circ}36'20''$; and of the Declination FG 90 minus $21^{\circ}49'30''$. The Complement BF, therefore...

Diagram. A circle with inscribed lettered construction, illustrating the Analemma used to derive the Right Ascension and Longitude of Lucida Arietis (Hamal). The outer circle carries points B (top), C and D toward the upper region, the Equator AHC running across, and the Ecliptic DHE. The Pole of the Zodiac is Z. The Fixed Star is at F. Two quadrant-arcs are drawn through F: the Declination circle BFG and the Latitude circle ZFI. Readable labels:

- B (top of circle): vertex / Pole of the Equator
- C (upper, near B): point on the Colure
- D (upper left): end of the Ecliptic diameter
- A (left): point where Equator meets circle
- E (lower right): opposite end of the Ecliptic diameter
- Z (interior, left of center): Pole of the Zodiac
- F (interior, right of center): the Fixed Star (Lucida Arietis / Hamal)
- G (lower interior): foot of the Declination circle
- H (center): intersection of Equator and Ecliptic
- I (interior): foot of the Latitude circle

$68^{\circ} 10' 30''$, and the latitude FH $9^{\circ} 56' 30''$. The complement FZ is therefore $80^{\circ} 3' 30''$. Hence, by the Laws of Triangles and the Logarithmic Canons, there came out for the same time the angle FBZ of $117^{\circ} 1' 58''$, measuring the equatorial arc HC. If you subtract HC from the quadrant, there remains for Lucida Arietis [Hamal, α

Arietis] the right ascension HG of $27^{\circ} 1' 58''$ counted from the beginning of Aries. There likewise came out the angle BZF of $57^{\circ} 5' 18''$, measuring the ecliptic arc DI; subtracting this from the quadrant gives DIH, leaving the longitude IH of $32^{\circ} 54' 42''$ — that is, \square (Taurus) $2^{\circ} 54' 42''$.

It is convenient to set these results down together in a single table as a foundation, as follows:

Anno 1660.

Completo.	Lucida \square		
	Gr.	'	"
Declinatio (Declination)	21	49	30
Latitudo (Latitude)	9	56	30
Ascensio Recta (Right Ascension)	27	1	58
Longitudo (Longitude)	\square 2	54	42

[Margin: 4]

As for the remaining fixed stars of the first magnitude — and those of the second that we were able to observe, along with not a few of the third and fourth magnitude — we tracked down their differences of right ascension by means of trigonometry, first investigating the distances observed by us between pairs of stars (as taught in Cap. VIII), and the complements of the declinations established for them through our observations and recorded in Cap. XVI. But we have distributed this same operation across several Classes, of which the First is as follows:

[Margin: 5]

I confess frankly, nevertheless, that from the distance between Spica and the northern Scale [β Librae] — which I judged from observation to be $27^{\circ} 33' 30''$ — there came out a difference of right ascension of $27^{\circ} 51' 29''$; and that from the distance between the northern Scale and the Head of Ophiuchus [Rasalhague], $40^{\circ} 39' 20''$, there came out a difference of right ascension of $35^{\circ} 4' 11''$; and that, carried out to the equatorial 360° , this left me short by $1^{\circ} 9'$ this 25th [degree]. I therefore chose the earlier distance, $27^{\circ} 33' 40''$, and the later one, $40^{\circ} 39' 40''$, on the ground that among the various distances of this Class I had not observed

enough confirmations for the others — since, for the sake of other purposes, the exact measure cannot always be determined from sense-perception. For Ptolemy himself rightly admits this: one almost never attains exactness, but only an approximation, in what is observed by sense. Indeed, I wished to say what I say here about the other distances used in Classes 2 and 3, and as far as concerns the second of arc reckoned. We have, however, limited the Distances rather than the Declinations, since in observing Distances we more easily attain evident accuracy — as is well known to the experienced. This small change in the Catalogue of Distances we have indicated by the characteristic mark *melius* (better).

[Margin: 6]

In order, moreover, to explore the principal Southern stars observable by us, we set out from the same Lucida Arietis [Hamal] and, by way of Orion, the Dogs, and Hydra, came as far as the Tail of Leo; for from there we returned to Lucida Arietis [Hamal], the remaining stars being understood from those listed above in Classes 1 and 2. It is clear, then, from Class 1 and 2, that from Lucida Arietis [Hamal] to the Tail of Leo inclusive, the sum of the Differences of Right Ascension ought to be 145° 52'.

Here the second 64" is wanting, which the four following stars give us for their Right Ascension, as below.

	Differ ent. Asc. (Differ ence of Ascensi on)			Ascens. Recta (Right Ascensi on)		
	G.	'	"	G.	'	"
Lucida □ [Hamal]				27	1	58
Aldebar a [Aldeba ran]	37	5	0	64	6	58
Orionis humer us lucidus [Betelg euse]	20	3	18	84	10	16
Procyo	26	12	16	110	22	32

	Differ ent. Asc. (Differ ence of Ascensi on)			Ascens. Recta (Right Ascensi on)		
n						
Hydrae Cor [Alphar d]	27	19	50	137	42	22
Cauda □ [Deneb ola]	35	11	36	172	53	58
Summ a Differ ent. (Sum of Differ ences)	145	52				

Hence indeed it follows that from Lucida Arietis [Hamal] to the Heart of Hydra [Alphard] the sum of the differences is $110^{\circ} 40' 24''$. Let us see whether it comes out as much by way of Regulus and Sirius.

	Declination (Declination)			Distance (Distance)			Differential Ascension (Difference of Ascension)			Ascension of Recta (RA)
	G.	'	"	G.	'	"	G.	'	"	G.'"
Lucida [Hamal]	21	49	½							27 1 58
Aldabra [Aldabaran]	15	46	½	35	32	0	37	5	0	64 6 58
Regel [Regel]	8	37	30 A	26	30	0	10	25	40	74 32 38
Sirus	16	16	10 A	23	40	0	22	57	40	97 30 18
Hydra Cor [Alphard]	7	11	½ A	40	11	0	40	11	16	137 41 18

Declination (Declination)	Distance (Distance)	Difference of Ascension (Difference of Ascension)	Ascension of Recta (RA)
Summa Differentiarum (Sum of Differences)		110 40 20	

There are therefore wanting only 4" of arc, which are to be restored to the Right Ascension of the Heart of Hydra [Alphard]; it remains as above.

[Margin: 7]

There follows the Fourth Class, whose Right Ascension was investigated by us by the trigonometric labor, from the Declinations and the Distances on either side — that is, from neighboring fixed stars whose right ascension has already been determined in the three preceding Classes. For from the two right ascensions, which had come out for the same star by the foregoing method, we chose the mean, which obtained a kind of arithmetic middle between the extremes. This procedure Tycho [Tycho Brahe] supplied in Tome I of the *Progymnasmata*, p. 229,

in Stars 11. But we, in many cases, have not noted down the extreme ascensions — for the sake of avoiding prolixity; yet they are easy enough to recover from the difference of ascension applied to the Stellar Right Ascension of the first and second [magnitude], or of the third Class.

For example: the Difference in Right Ascension of the Northern Horn of Taurus [β Tauri, Elnath] is not, from us, $12^{\circ} 5' 58''$; and Aldebaran's Right Ascension from those given in Class I is $64^{\circ} 6' 58''$. Therefore the Right Ascension of the said Northern Horn comes out as $76^{\circ} 12' 56''$. Again, the Difference of Right Ascension between the Northern Horn of Taurus and the Head of Pollux comes out for us as $34^{\circ} 53' 58''$; and the Right Ascension of Pollux from Class I is $111^{\circ} 6' 0''$. Subtracting from this latter the difference, the Right Ascension of the Northern Horn comes out as $76^{\circ} 12' 2''$. The mean, therefore, between this and the former is $76^{\circ} 12' 29''$, or $30''$. So then in the rest we have done — where one or another second of arc was wanting — by rounding off the number of the Decade to the nearest number, or by the most abundant; thus we have assembled the number rounded off, so that it might more easily come to hand afterward for the Longitude and Latitude to be gathered, without danger of error, which usually creeps in from the other proportional fraction-part.

[Margin: 8]

By nearly this same method we have determined certain other Right Ascensions of fixed stars, which are observable in our horizon and which can serve astronomers for determining the positions of the planets, or the moments of times, and the motion of Longitude. Afterward, we have worked out the Longitude up to the Year 1700, and perhaps to 1800. We shall complete the Right Ascensions of these same stars together with their Declinations, reduced [to those years].

CAPVT XVIII.

De Longitudine, ac Latitudine Fixarum ex Nostris Observationibus.

(On the Longitude and Latitude of the Fixed Stars from Our Observations.)

[Margin: 1 — Latitudo Fixarum Immutabilis (The Latitude of the Fixed Stars is unchanging)]

We have taught that the Latitude of the Fixed Stars is perpetually the same (in *Almagestum Novum*, Lib. 6, Cap. 15); and so the stars, being themselves inerrant [fixed], describe through their own motion circles parallel to the Ecliptic. For the diversity of latitudes of one and the same fixed star repeated at different times by Tycho [Tycho Brahe] is an indication sufficient enough that there exists some fallacy in his other observations — namely [an error] in the Declinations, from which the Latitudes are derived; that is, in the Declinations, the Distances of fixed stars among themselves, and the Distances of the poles of the Ecliptic and of the Equator. If indeed these be the causes — and they are — we have, for these reasons, obtained results diverging from Tycho's, not only as to the latitude, but also as to the Declination and Right Ascension.

Now therefore, the Declination of the principal Fixed Stars having been determined, together with their Right Ascension (Cap. XVI and XVII), and the distance of the Poles having been established as $23^{\circ} 30' 20''$ from what has been said —

[Margin: 2]

[continued — see right column]

It is not difficult to investigate the perpetual Latitude of these stars, and their Longitude up to the year 1660, by Problem 1, Cap. 12, Lib. 6 of the *Almagestum Novum*, in which case 12 of the Problem is set forth, and the same is prescribed in our *Primum Mobile Reformatum*, Cap. 8. In the present case it suffices to recall here the schema set forth in the preceding Chapter, of which I adduced the example there concerning Lucida Arietis [Hamal], and according to whose norm we have carefully inquired into the remaining Longitudes and Latitudes by trigonometry, and in the following Table we shall include them.

[Margin: 3 — Longitudo & Differentia Longitudinis Fixarum constans (The Longitude and Difference of Longitude of the Fixed Stars is constant)]

Furthermore, when once the Longitude of the Fixed Stars has been investigated, if it be compared with the Longitude observed and corrected by the Ancients, it will be established that this motion of the Fixed Stars is perpetually equable and uniform — which we also taught in Cap. 6, 16, and 17 of *Almagestum Novum*. Since indeed, from the invariable Distance of the fixed stars among themselves, and from the hypothesis of immutable Latitude, it follows necessarily that the Difference of Longitude between any two Fixed Stars is always the same — the Difference being given once — it is hence not the labor of inquiring into the Longitudes of the rest of the Fixed Stars from the Tyconic Catalogue, by noting beforehand at Rudolphino the difference between the Tyconic and Our own Difference of Longitude of the paired stars, and according to that discrepancy correcting the differences of the rest by the proportion preserved. This, lest what has been said seem obscure, it will be worthwhile to set forth by a single example more clearly.

[Margin: 4]

In the Year 1660, the Longitude of Lucida Arietis [Hamal] for us is \square (Taurus) $2^{\circ} 54' 42''$. But Aldebaran's [longitude] is \square (Gemini) $5^{\circ} 1' 43''$. Therefore the Difference of Longitude is $32^{\circ} 7' 1''$. But for Tycho at the same time the Longitude of Lucida Arietis [Hamal] is \square (Taurus) $1^{\circ} 57'$, and Aldebaran's is \square (Gemini) $4^{\circ} 3' 30''$. Therefore the difference of Longitude is $32^{\circ} 6' 30''$. The discrepancy, therefore, of these Differences of Longitude is $31''$, which Tycho falls short of Ours. Accordingly, if we add the same $31''$ to the others, that discrepancy occurs which lies between the remaining stars of Aries and the more correct ones of Taurus. And in nearly the same way it falls out, if the excess of the Tyconic Longitude be repeated in Lucida Arietis [Hamal], that the remaining Tyconic Longitudes of the fixed stars of Aries — whose Longitude from our observation was not more certainly known — may be emended. And by this artifice we shall construct a Catalogue of the Fixed Stars; yet noting by a distinct character those Fixed Stars whose Longitude and Latitude we have determined from Our own observation. We shall set this Catalogue of the Fixed Stars at the very end of the work, together with the other Tables. Meanwhile, we shall content ourselves in this place with five [examples]; for which we shall use, in the following Chapter, the Longitude and Latitude deduced from the Declination (Cap. XVI and Right Ascension, Cap. XVII), and the distance of the Poles set at $23^{\circ} 30' 20''$.

CAPVT XIX.

De Motu Longitudinis Fixarum eiusque Quantitate, & Aequalitate.

(On the Motion of the Longitude of the Fixed Stars, and its Quantity and Uniformity.)

Of all the Fixed Stars, with respect to the motion of Longitude, the most celebrated up to now has been Spica Virginis [Spica] — and deservedly, since when it began to be observed by the Ancients, namely by Timocharis and by Hipparchus, Pro...

[Continues Liber IV, Caput XIX — the motion of the fixed stars in longitude (precession), its quantity and uniformity.]

Ptolemy too; it lay near the point of the autumnal equinox, having received a very slight declination, and a latitude of scarcely 2° . In this matter the latitude found most recently agrees closely among Ptolemy, Tycho, and ourselves. For Ptolemy gives 2° , nearly southern; Tycho $1^\circ 59'$; we give $1^\circ 59' 30''$. Highly celebrated too, and useful for this work, is Basiliscus [Regulus], or Regulus in the heart of Leo, on account of its nearness to the ecliptic, from which it departs in latitude by only $10'$ toward the north according to Ptolemy, or $16'$ according to Tycho, or $16' 20''$ according to us. To these we add Aldebaran, the head of Pollux, and Cor Scorpii [Antares], because the declination of these stars was observed not only by the ancients but also by more recent astronomers; and therefore we, on account of these and our own latitude, undertake at the end of the present chapter, and from the obliquity of the ecliptic of $23^\circ 30' 20''$, to derive their longitudes through intervals of time, and thus to establish the annual motion of the fixed stars in longitude. We do not, however, neglect the other opinions — indeed, we set out beforehand those which we have nonetheless reported at greater length in the *Almagestum Novum*, Liber I, Cap. 16.

[Margin: 1 — First opinion, on the motion of the fixed stars]

The first opinion, then, found in Ptolemy, Liber 7, *Magnae Syntaxis* [the *Almagest*] caps. 2 and 3, was that of Hipparchus, and of Ptolemy himself, namely that the fixed stars move not less than 1° in 100 years, and not more than 1° in that span of years — and not more than the equivalent of one degree advancing in longitude. But since Hipparchus established this motion from the observations of Timocharis, which Ptolemy in cap. 3 judged rather crude on account of their too-brief interval of time, Hipparchus himself did not dare to depart from Timocharis; Ptolemy therefore did not embrace it as least to be approved by us.

Ptolemy's words about Hipparchus are these: "He was, however, in doubt, as he asserts, because he reckoned neither the observations made in Timocharis's time to be certain — held with too unrefined a method — nor that the time which had elapsed in the interim sufficed for a perfect understanding of the matter." Yet Ptolemy afterward followed Hipparchus, as did al-Farghānī [Alfraganus] and Proclus.

[Margin: 2 — al-Battānī's opinion]

The second was that of al-Battānī [Albategnius], cap. 51, *De Scientia Stellarum*, who from the place of Regulus and of Borealis [the northern star] in the forehead of Scorpius — observed by him formerly, and afterward by himself — established that the fixed stars advance one degree in 66 years; and in this he was followed in later times by Alfonso, King of Castile [Alfonso X], Rabbi Levi [Levi ben Gershon / Gersonides], Abraham Zacuto [Abraham Zacut], Augustinus Riccius, Petrus Nonius [Pedro Nunes], and others adduced in the *Almagestum Novum*, Liber 6, cap. 16, where also al-Battānī's opinion on the motion of trepidation, and its refutation, are reported; this I confuted in cap. 17. Now in truth al-Battānī's place of Regulus will be erroneous, as will be corrected below; and we shall say so in the observation of Regulus, 17.

[Margin: Tycho's opinion]

The third opinion was that of Tycho Brahe, Tome 1, *Progymnasmata*, p. 253, who at first, in the case of Regulus and Spica, held the annual motion of the fixed stars to be 51", that is one degree in 70 years, 7 months. He afterward followed Copernicus, who in the year 1515 corrected the elevation of the pole, finding Spica in Libra at 17° 3½'. He himself in the year 1585 — namely after 70 years — found it again at 18° 3'; he therefore obtained the same annual motion, 51". Moreover, Tycho noted Regulus, after an interval of 1713 years, at the same place: in the year 1585 of Christ in Leo 24° 5'; and al-Battānī in the year 880 of Christ noted Regulus in Leo 14° 5'. He grants, however, that Spica was observed by Timocharis in Virgo 22° 20', and by Ptolemy in the year of the Lord 139 in Virgo 26° 40'; from which, with the place observed by Tycho compared, the annual motion thence comes out 49" ¼. Hence he chose the mean 53" ⅔, which he selected as below. But the places of these stars are to be corrected on account of the distance of the poles, which he does below; meanwhile Tycho's data it pleases us to set out in a table.

	Anno (Year)	Locus (Place)
Timochar.	Anno ante Chr. 294	Spica □ gr. 22. 20.

	Anno (Year)	Locus (Place)
	(294 BC)	
Ptolemaeus	Anno Chr. 139 (AD 139)	Spica □ gr. 26. 40'.
Copernicus	Anno Chr. 1515	Spica □ gr. 17. 3½.
Tycho	Anno Christi 1585	Spica □ gr. 18. 3.
Hipparchus	Ann. ante Chr. 128 (128 BC)	Regulus □ gr. 29. 50.
Albategnius	Anno Christi 880	Regul. □ gr. 14. 5. 0.
Tycho	Anno 1585	Regulus □ gr. 24. 5. 0.

[Margin: top-right table — column headings]

Ab (From)	ad (to)	Progress. Fixarum (Advance of the fixed stars)	Annorū interu. (Years of interval)	Annus motus (Annual motion)
		Gr. '		" "'
Timoch.	ad Tych.	25 43	1879	49 15
Ptolem.	Tych.	21 23	1446	53 15
Hipparch.	Tych.	24 15	1713	51 0
Hipparch.	Albat.	14 15	1006	51 fere (about)
Albategn.	Tych.	10 0	705	50 54

[Margin: 4 — Longomontanus's opinion]

The fourth opinion was that of Longomontanus in the *Astronomia Danica*, Liber 1, Theorica, in the Commentary on the Fixed Stars, who sets out the four fixed stars observed by Ptolemy (Liber 7, cap. 2, 3, and 4) and by Tycho, from antiquity, as follows:

Observatores (Observers)	Anni Nabonassaris (Years of Nabonassar)	Locus in Zodiaco (Place in the Zodiac)
		Gr. '

Observatores (Observers)	Anni Nabonassaris (Years of Nabonassar)	Locus in Zodiaco (Place in the Zodiac)
Timocharis	466	Spica □ 22 30
Hipparchus	630	Spica □ 24 25
Tycho	2350	Spica □ 18 16
Ptolemaeus	886	Regulus □ 3 53
Albategnius	1626	Regulus □ 14 27
Tycho	2350	Regulus □ 24 17
Timocharis	454	Bor. frons (Northern forehead [of Scorpius]) □ 1 58
Tycho	2350	Scorpii □ 27 36
Timocharis	465	Pleiadum (of the Pleiades) □ 29 32 [review: printed glyph may be □; □ expected]
Tycho	2350	Lucida □ 24 24

From which intervals of time, and from the advance of the stars, he gathers the annual motion of these stars, as below:

Ab (From)	ad (to)	"" "" (" "")
Hipparcho	Tychonem	49 46
Ptolemaeo	Albategnium	51 0
Ptolemaeo	Tychonem	49 37
Timocharide	Tychonem	49 10
Albategnio	Tychonem	48 14
Timochar.	Ptolemaeum	46 0
Timochar.	Hipparchum	44 0

But Longomontanus thus chooses the mean motion of the fixed stars: 49" 45'" — and in years 72½ the motion of one degree, both alike well established. In establishing their places, however, he uses the prosthaphaeresis of the equinoxes, whose origin is the mean motion, and which he presupposes.

[Margin: 5 — Lansberge's opinion, fluctuating]

The fifth opinion is that of Lansberge [Philippe van Lansberge], who in p. 160 of the *Thesaurus Observationum* claims that the fixed stars advance daily $8'' 25''' 12'''' 32'''''$, and that in one revolution they complete one degree in 28000 years; whence it follows that the fixed stars complete one degree in $77\frac{3}{5}$ years, in single years $46'' \frac{3}{5}$, with a third revolution presupposed. For he predicts that the motion of the fixed stars will not be uniform throughout single years: now, indeed, the diurnal motion $8'' 25''' 12'''' 32'''''$, but the annual motion of three centuries $51'' 14''' 11'''' 14''''' 40''''$. To such a degree does Lansberge contradict himself.

[Margin: 6 — Kepler's opinion]

The sixth opinion is that of Kepler, which is ambiguous: for with Copernicus he reckons the fixed stars not to be moved, while yet with Tycho — supposing that they are moved — he posits the annual motion of these stars to be $51''$, as is clear from the *Rudolphine Tables*, p. 43 and 115, where he says they are equal. But in the year 25411 the Sidereal Years are equal to the Tropical Solar Years; and from the *Epitome Astronomiae Copernicanae*, p. 396, where (with Hesiod) he reduces the Sidereal Years to the year of the Lord 1618, per annum 2400, makes nearly $34\frac{1}{4}^\circ$; and so 1 second in 51 [years]. But he mingles much with this — your Wendelin [Govaert Wendelen] in the *Idea Tabularum Atlanticarum*, p. 28, while reckoning the Sidereal Years 25519, makes the Sidereal Years equal to 25520 of Solar-Tropical; hence the fixed stars do not follow but advance $50'' 47'''$. Gassendi, moreover, in the *Institutio Astronomica*, posits the period of the fixed stars completed and absolute in 25000 years, and 1° established in $70\frac{2}{3}$ years; in single years it makes $51'' 19''' 24''''$.

[Margin: Govaert Wendelen] [Margin: Gassendi]

[Margin: 7 — Bulliau's opinion]

The seventh opinion was that of Ismael Bulliau [Ismaël Boulliau] in the *Astronomia Philolaica*, Liber 5, cap. 3, and in the *Tabulae Philolaeicae*, p. 10, where at length he chooses the annual motion of the fixed stars $51''$, following Tycho — though the observations of Regulus have been corrected by him as follows:

Observator es (Observers)	Anni Nabonassar i (Years of Nabonassar)	Reguli locus (Place of Regulus)	Sig.	Gr.	'
Hipparchus	621	□ (Gemini, II) [recte □?]	□	29	50
Ptolemaeus	886	□	□	3	42
Albategnius	1627	□	□	14	5
Tycho	2350	□	□	24	17

Hence the annual motion of the fixed stars:

Ab (From)	Ad (to)	" ' " " (" ' " ")
Hipparcho	Ptolemaeu m	52 31 42
Hipparcho	Albategniu m	50 59 38
Hipparcho	Tychonem	50 54 29
Ptolemaeo	Albategni	50 26 27
Ptolemaeo	Tychonem	50 36 53
Albategnio	Tychonem	50 47 18

He acknowledges, moreover, from the latitude of Spica 2°, with Hipparchus's declination of Spica 0° 36' — in the year of Nabonassar 621 he followed its place in Virgo 22° 23' 50", and from that same place in Libra 18° 16' found by Tycho in the year of Nabonassar 2350 — he followed the annual motion as below:

" ' " " " " " " " " (" ' " " " " " " ")

50 33 39 39 52 22

Then from the Persian and Arabic tables, which are preserved in the Library of the King of Christians [the French Royal Library], he sets down these places, or positions, of Regulus:

Tabula (Table)	Anni Arabum (Years of the Arabs)	Anni Christi (Years of Christ)	Reguli locus (Place of Regulus)	Sig.	Gr.	'
Albategni		879	□	14	5	
Azophi	325	936	□	15	12	
Persica	509	1115	□	17	0	
sub Persica		1364	□	20	40	
Tychonic a		1600	□	24	17	

Hence the annual motion of the fixed stars:

Ab (From)	Ad (to)	" " " (" " " ")
Albategnio	ad Azophi	69 18 37
Albat.	Persicas Tab.	58 51 7
Albat.	sub Persicas	48 51 57
Azophi	Persicas Tab.	46 31 0
	sub Persicas	45 5 20
Tab. Persicis	sub Persicas	45 46 59
Tab. Persicis	Tychonem	50 14 49

[Margin: Petau's opinion]

These I have added for the erudition's sake, to which I append yet another opinion of the Gallican astronomers, namely Dionysius Petavius [Denis Pétau] in the *Uranologion*, who chooses the annual motion of the fixed stars 50" — and in 72 years 1°.

[Margin: 8 — Riccioli's own opinion]

The eighth opinion is our own, which was formerly in the *Almagestum Novum*, Liber 6, cap. 16: that the annual motion of the fixed stars is $50''$, with Petau, and 1° in 72 years 1 day. These I had then established, and the period to be completed in not less than 25920 years. But now, with the corrected longitude, and the obliquity of the ecliptic established at $23^\circ 30' 20''$, the observations compel us to test our forebears more diligently, adhering to one star out of every five, the most recently observed — and by selecting noteworthy observations from the heads [chapters] preceding — and so this annual motion we establish at...

[Margin: 1 — Observations of Spica]

1. Timocharis, on the testimony of Ptolemy, Liber 7, cap. 3, observed Spica in the year of Nabonassar 454, which was before Christ 295, in Virgo $22^\circ 20'$.
2. Timocharis, from Ptolemy in the same place, in the year of Nabonassar 466, before Christ 283, advanced Spica in Virgo $22^\circ 30'$; but his rude observations were judged by Hipparchus, in Ptolemy above, as too unrefined.
3. Hipparchus, in Ptolemy Liber 7, cap. 2: in the year 50 of the third period of Calippus, before Christ 128, observed Spica in Virgo 24° ; but cap. 3 says he is said to have observed its northern declination $36'$, from which, and from our latitude, southern $1^\circ 59' 30''$, and the obliquity of the ecliptic $23^\circ 30'$, it follows that its place was in Virgo $23^\circ 54' 7''$.
4. Ptolemy, Liber 7, cap. 3: in the year 1 of Antoninus the Emperor, that is, of Christ 137, observed the southern declination of Spica now $30'$; hence, and from its latitude, and the aforesaid obliquity of the ecliptic, its place follows in Virgo $26^\circ 40' 15''$ — in which there is a marvelous agreement with us, Ptolemy placing it at $26^\circ 40'$. Yet there is a disagreement in the obliquity of the ecliptic, and hence this is false.
5. Abraham Zacut [Abraham Zacut], in the presence of his pupil Augustinus Riccius, in the treatise on the motion of the eighth sphere, in the year of the Lord 1474, is said to have observed Spica in Libra $17^\circ 10'$; but this contradicts Tycho and ourselves too much.
6. Copernicus, Liber 3, cap. 2: in the year of the Lord 1515, observed the southern declination of Spica $8^\circ 36'$ at Frauenburg, where he reckoned the elevation of the pole to be $54^\circ 19' 30''$ — whereas from Tycho, Tome 1 of the

Progymnasmata, p. 34, and 220, it comes out $54^{\circ} 22' 15''$; and so the truer declination of Spica was $8^{\circ} 33' 15''$; whence, by our latitude and the aforesaid obliquity, its place follows in Libra $17^{\circ} 2' 50''$.

7. Copernicus, as Tycho relates Liber 3, cap. 2: in the year of the Lord 1525, observed the meridian altitude of Spica 27° . The altitude of the equator at Frauenburg is $35^{\circ} 37' 45''$; therefore the southern declination of Spica comes out $8^{\circ} 37' 45''$; whence, and from our latitude and obliquity, its place is in Libra $17^{\circ} 14' 54''$. Let Lansberge dissemble by yawning, or by subtle correction of the pole's altitude — yet he gathers it hence in the *Thesaurus*, p. 156, gr. 17. 35'; though admitting a gratuitous refraction.
8. Jo. Stadius [Johannes Stadius], in the *Commentary on the Fixed Stars*, cap. 1, says that in the year 1559 the meridian altitude of Spica was observed by him at Brussels as $29^{\circ} 52'$; whence the established altitude of the pole at gr. $51^{\circ} 20'$; he gathers the southern declination of Spica $8^{\circ} 48'$. But from our Geography, and from the observations of Langren [Michael van Langren], it is established at Brussels that the elevation of the pole is gr. $50^{\circ} 48'$; and the altitude of the equator gr. $39^{\circ} 12'$; whence the southern declination of Spica proceeds gr. $9^{\circ} 20'$, omitting therefore this observation, which could scarcely be gr. $8^{\circ} 47'$; lest we attribute this to Wuerner [Johann Werner] or Cardano, on account of the causes brought forward by Tycho, Tome 1 of the *Progymnasmata*, p. 221.
9. Tycho Brahe, in the year 1585, found Spica in Libra $18^{\circ} 3'$; which Tome 1 of the *Progymnasmata*, p. 232, has at gr. $18^{\circ} 3'$ — but it is to be corrected from chapter 12; see below at gr. 18. 2. 41''.
10. Paulus Hainzelius [Paul Hainzel], a Senator of Augsburg, in Tycho Tome 1 of the *Progymnasmata*, p. 365: in the year 1573 took the southern declination of Spica $8^{\circ} 52'$; whence, with our latitude, and the obliquity of the ecliptic, its place follows in Libra gr. $17^{\circ} 51' 50''$.
11. Lansberge, as he relates in the *Thesaurus Observationum*, p. 157: at the beginning of the year 1599, observed the meridian altitude of Spica gr. $29^{\circ} 30'$ — which, with refraction reduced, comes out at gr. $29^{\circ} 29'$. There the altitude of the equator, from our *Geographia Reformata*, is gr. $38^{\circ} 29' 30''$; therefore the southern declination of Spica comes out gr. $8^{\circ} 59' 30''$; and from our latitude, and the obliquity of the ecliptic, its place is in Libra gr. 18. 11. 20''.

12. Lansberge, in the same place, p. 157, refers Middelburg: in the year 1620, at the beginning, he observed (I believe, by Hortensius [Martinus Hortensius]) the meridian altitude of Spica gr. $29^{\circ} 20'$. There the altitude of the equator is gr. $38^{\circ} 30'$; therefore the declination of Spica comes out now gr. $9^{\circ} 10'$, and from our latitude and the obliquity of the ecliptic, its place is in Libra gr. 18. 38. 50".
13. Petrus Gassendi [Pierre Gassendi], Tome 4 of his works, or in the *Commentary on the Heavenly Things [De Rebus Caelestibus]*, p. 313: relates that in the year 1636, on the 15th of May, he observed the meridian altitude of Spica gr. $37^{\circ} 13'$ at Aix [Aix-en-Provence]. The altitude of the equator there is gr. $46^{\circ} 27'$; therefore the southern declination of Spica comes out gr. $9^{\circ} 14'$; and from our latitude of the star, and the obliquity of the ecliptic, its place is in Libra gr. 18. 49. 10".
14. We at last, with Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], from many...

from many observations of declination, etc., at last derived the place of Spica in the year 1660 completed at Libra $19^{\circ} 6'$, by what was said in the chapter preceding at the end.

REGULI Observationes (Observations of Regulus)

[Margin: 15]

15. Hipparchus, in Ptolemy, Liber 7, cap. 1, in the year 50 of the third period of Calippus, namely before Christ 137, is reported to have observed Regulus, or Cor Leonis, in Leo gr. $29^{\circ} 50'$ [review: printed sign reads \square (Cancer); \square Leo expected from context, recte \square ?]; but cap. 3 says he observed its declination $20^{\circ} 40'$. Regulus's latitude, from the obliquity of the ecliptic of the preceding chapter, comes out $26^{\circ} 20'$ northern, and its right ascension of the ecliptic gr. $23^{\circ} 30' 20''$; therefore its place was then in Leo gr. $29^{\circ} 51' 10''$.

[Margin: 16]

16. Ptolemy, Liber 7, cap. 3, holds the declination of Regulus observed by him $19^{\circ} 50'$, in the year 1 of Hadrian the Emperor, that is, of Christ 137; therefore, with our latitude, and the obliquity of the ecliptic, its place was in Leo gr. 3. 34. 55".

[Margin: 17]

17. Al-Battānī, cap. 51 *De Scientia Stellarum*, says: in the year of Nabonassar 1627, that is, of Christ 879, observed Regulus from himself in Leo gr. 14, which my own vulgar copy has — but the Vatican Library, through Lucam Valerium [Luca Valerio], describes it; Tycho, however, Tome 1 of the *Progymnasmata*, p. 253, and Bulliau, in the *Astronomia Philolaica*, say it was observed in Leo gr. 14. 5. Longomontanus, above noted, in Leo gr. 14. 27'. Lansberge in the *Thesaurus*, p. 14, gr. 14. 19'; because Ptolemy, Liber 7, cap. 2, says Antoninus, in the first year of the Emperor's reign, observed it in Leo gr. 2. 29'; and al-Battānī asserts that he, from Regulus's observation, added to all the longitudes of the fixed stars in the Ptolemaic tables gr. 11. 50'. But my Ptolemaic copy has in the year 1 of Antoninus the observed Regulus in gr. 2. 30' Leo; nor perchance does the same number in the tables come out, therefore Regulus from al-Battānī's gr. 14. 20'; nor perhaps so much, if you correct the place from gr. 2. 30'; that is, with the corrupt number subtracted, from gr. 11. 30'; and thus reconcile with gr. 14. 20' nearly. For from the same place, with the minutes-number subtracted by thirty, the places of the Ptolemaic fixed stars are added at 11 degrees and a half, that is, a third part — this is at once 11½ minutes minus thirty. But the same place asserts Ptolemy to have found Cor Leonis in gr. 2 degrees and a sixth of Leo, that is gr. 2. 10'; but in gr. 14 Leo, that is the advance from gr. 11. 50' to a third — that is from gr. 2. 30'; nor rarely is the ambiguous reading thence rendered, if the Sigma-mark [σ], by which more than the degrees and minutes is wont to be noted, that is 16', is noted as a half-minute — that is, 16' taken for the dimidiated [halved] degrees; which through the error of librarians and typographers comes about — joining with 1°, and so it happens with various uses, that of al-Battānī. But my Basiliscus copy has Cor Leonis in...

[Margin: I reduce al-Battānī's stars to the same equinox; that is, gr. 2. 30' Leo; and his next distance is from a Tropical [point] gr. 8. 7'; that is gr. 32. 30'.]

But however it is to be retained, that in Ptolemy gr. Leo 2. 30'; nor on that account do I follow al-Battānī's emended place of Leo gr. 14. Nor was al-Battānī's place of Regulus advanced from the Ptolemaic by the cause adduced, namely with the fixed stars advanced from the Ptolemaic by their proper motion gr. 11. 50'; but it appeared otherwise, just as Tycho reckoned it Ptolemaic, because he observed Regulus in Leo gr. 2. 30' at the time of Antoninus, when in truth he believed Regulus to have been at the time of Ptolemy in Leo gr. 2. 10'; if from the emended copy it had been read — he would read all the same; whence Regulus, and from the emended copy had — in the year of Nabonassar 886, and 1627, in the full year

741. And so the advance of Regulus follows the annual motion 51"; from which, with the same it follows in al-Battānī, the place of Regulus.

[Margin: Lansberge errs]

But from this it likewise appears that Lansberge fell into the fallacy which the dialecticians call *conversio* [conversion].

[Margin: 18]

18. Azophi [al-Şūfī], the Persian astronomer, or Ebenem Sophi [Ibn al-Şūfī], as out of the Forcalquier Library [Bibliothèque de Forcalquier] Bulliau brings forward in the *Astronomia Philolaica*, cap. 3; and Gassendi in the *Epistles*, notes Regulus in Leo gr. 15. 12'; that is, in the year of the Arabs 325, namely of Christ 936.

[Margin: 19]

19. The Persian Mathematicians, in the presence of the same Bulliau, from the Manuscript of the Royal Library, in the year of the Lord 1115, on the 6th of June, established Regulus in Leo gr. 17. 30'; I do not know whether from observation, or from their own anticipating hypotheses.

[Margin: 20]

20. Paulus Hainzelius, in Tycho Tome 1 of the *Progymnasmata*, p. 364: in the year of the Lord 1573, at the beginning, observed the meridian altitude of Regulus gr. 14. 1' ½; and the declination gr. 14. 1' ½; with Göggingen [Gögging], near Augsburg, the altitude of the pole agreeing with Tycho's gr. 48. 21', where it has Lansberge in the *Thesaurus* gr. 48. 21' — not however gr. 48. 11'; hence from that declination, and our latitude, the place of Regulus follows in Leo gr. 23. 50'. 26".

[Margin: 21]

21. Tycho, in the year 1585, observed Regulus by himself in Leo gr. 24. 4. 40" as he has it Tome 1 of the *Progymnasmata*, p. 232; but it is to be corrected, as said above, cap. 12; so that it is in Leo gr. 24. 3'. 2" from Tychonic observations, but truly with the obliquity of the ecliptic.

[Margin: 22]

22. Lansberge, in the *Thesaurus* observed, p. 155, narrates: at the beginning of the year 1599, observed the meridian altitude of Regulus gr. 14. 24' ⅓. The altitude of the equator there for us is gr. 38. 29'. 30"; therefore the northern

declination of Regulus comes out gr. 13. 5. 55"; and from our latitude, and from the things said in the chapter preceding, gr. 26. 20' northern; hence by the obliquity of the ecliptic, the place of Regulus follows in Leo gr. 24. 5. 10".

[Margin: 23]

23. Lansberge, in the same place, narrates: at the beginning of the year 1630, at Middelburg in Zeeland, where through our altitude of the equator it comes out gr. 38. 30', the meridian altitude of Regulus was observed at gr. 52. 16'. The declination of Regulus then comes out gr. 13. 46'; and from our latitude, and the obliquity of the ecliptic, the place is in Leo gr. 24. 40'.

[Margin: 24]

24. We at last, in the year 1660 completed, from many observations, determine in the end of the chapter preceding, with Father Grimaldi, the place of Regulus in Leo gr. 25. 4. 45".

**ALDEBARAE, seu Oculi Australis Tauri, seu Palilicii Observationes
(Observations of Aldebaran, or the Southern Eye of Taurus, or Palilicium)**

[Margin: 25]

25. Hipparchus, in Ptolemy Liber 7, cap. 1, and 3, in the year 265, before Antoninus the Emperor's first year, namely before Christ 128, observed the northern declination of Aldebaran gr. 9. 45'; its southern latitude, from the things said at the end of the chapter preceding, is gr. 5. 30'. 50", and the obliquity of the ecliptic gr. 23. 30'; therefore its place was then in Taurus gr. 10. 23'. 53".

[Margin: 26]

26. Ptolemy, Liber 7, cap. 3, refers that in the year 1 of Antoninus the Emperor, namely of Christ 137, the observed declination of Aldebaran was northern gr. 11. Hence, and as our latitude, and the obliquity of the ecliptic, its place was then in Taurus gr. 14. 38'. 7" [?].

[Margin: 27]

27. Paulus Hainzelius, in Tycho Tome 1 of the *Progymnasmata*, p. 365: in the year 1573, at the beginning, observed the northern declination of Aldebaran gr. 15. 4'; whence with our latitude, and the obliquity of the ecliptic, the place is in Gemini gr. 3. 18'. 48".

[Margin: 28]

28. Tycho, by his own [observation], in the year 1585: from our observations corrected, gained the place of Aldebaran in Gemini gr. 5. 59'. 4" as in Tome 1 of the *Progymnasmata*, p. 232; so that it is in Gemini gr. 4 nearly, by Tycho.

[Margin: 29]

29. Lansberge, by the altitude of Göggingen [Gögging], in the year of the Lord 1601, at the beginning, observed the meridian altitude of Aldebaran 14. 8'. The altitude of the equator is gr. 38. 29'. 30"; therefore the declination comes out gr. 15. 38'. 30", by what and from our latitude, and obliquity, the place is in Gemini gr. 4. 18'. 20".

[Margin: 30]

30. We at last, with Father Grimaldi, from our own observations in the end of the chapter preceding, in the year of the Lord 1660 completed, determine the place of Aldebaran in Gemini gr. 5. 1. 48" [?].

Caput XIX (continued) — Precession observation-lists

ANTARES, or the Heart of Scorpius [Cor Scorpii] — Observations

31. [Hipparchus], as reported in Ptolemy's *Almagest* (VII.3): In the year 128 before Christ, as noted above in this Book, he observed a southern declination of Antares of 19°. And from this, by the procedure of our Chapter [Caput] above, its southern latitude comes out as 4°26'30"; and with the obliquity of the ecliptic taken perpetually at 23°30'20", Antares therefore stood at that time in □ [Sagittarius] 9°48'12".

32. [Ptolemy], in the same place, attests that he observed for himself a southern declination of Antares of $20^{\circ}15'$; therefore, by the procedure and the latitude and obliquity stated above, Antares stood in Sagittarius at $13^{\circ}46'30''$. [Lansberge] places it [in the] year 139, in the second year of Antoninus.

33. [Tycho Brahe], from the data of Caput XII — corrected, however, by us — in the year of the Lord 1585, complete: Antares is determined to be in Sagittarius at $4^{\circ}5'18''$.

34. [Lansberge], at the end of the year 1600, as he relates in his *Thesaurus* (observation, p. 160), observed the meridian altitude of Antares to be $13^{\circ}8'$; therefore its southern declination came out as $13^{\circ}8'$, or rather $13^{\circ}2'$; but Lansberge has the altitude of the equator [equal to] $38^{\circ}25'30''$. Therefore the southern declination is $25^{\circ}45'30''$ — by the latitude and obliquity stated above, its place comes out in Sagittarius at $4^{\circ}18'8''$.

35. We, together with Father [Grimaldi], from the data at the end of the preceding Chapter [Caput], at the end of the year 1660 complete: Antares is found in \square Sagittarius at $5^{\circ}1'40''$.

POLLUX, the lower head of Gemini [Capitis Π inferioris] — Observations

36. [Hipparchus], in Ptolemy's *Almagest* (VII.3): In the year 127 before Christ, he observed a northern declination of the lower head of Gemini of 30° ; and from this latitude, by the procedure of this Chapter, its northern latitude comes out as $6^{\circ}38'30''$; and with the obliquity of the ecliptic $23^{\circ}30'20''$, it therefore stood at that time in \square [Cancer] $23^{\circ}55'40''$.

37. [Paul Hainzel], at the beginning of the year 1573, as Tycho [Brahe] has it (*Progymnasmata* I, p. 365), observed the declination of the lower head of Gemini to be $28^{\circ}59'$; therefore, from the latitude already laid down and the obliquity of the ecliptic, it stood in \square Cancer at $17^{\circ}10'45''$.

38. [Tycho Brahe], from the data of Caput XII, will have the [position of] Pollux's Head in \square Cancer at $17^{\circ}31'28''$, in the year 1585.

39. We, together with Father [Grimaldi], from the end of the preceding Chapter, [give] Pollux's Head in the year 1660 complete: we establish it, from observations, in \square Cancer at $18^{\circ}31'6''$.

From these observations, compared one with another, there arise the comparisons set out in the following Table, presented to the eye, together with

the annual motion of the fixed stars corresponding to the progression of the star and the interval of time.

Table of the argument, for the annual motion of the fixed stars. This is a citation-grade table, transcribed below as native pipe-tables. The page presents four such tables: the *Tabula Argumenti* for **Spica** (bottom-left), and in the right column the comparison-tables for **Spica**, **Regulus**, and **Aldebaran**.

Parsing notes: leftmost double column gives the ordinal numbers of the two observations compared ("from" and "to"). The "Motus Annuus" column is in

minutes-seconds-thirds; the printed convention here gives seconds and thirds of arc per year (\square 49–50"/yr). Some intervals (e.g. 1768) are years.

Comparison table — Progressus Capit. Poll. (Pollux's Head)

Observationis Ordo (from)	(to)	Observatores Ab	Ad	Progressus Capit. Poll. Gr. ' "	Intervallo Annorū	Annus motus "
36	37	Hipparc.	Hainzel	13 15 5	1700	49 12
36	38	Hipparc.	Tychon.	13 35 48	1712	49 39
36	39	Hipparc.	Nos	24 35 26	1787	49 30

Parsing notes: the Pollux progression for row 36→39 (Hipparchus→Nos, interval 1787 years) prints as 24°35'26", verified correctly read and correctly placed in the Pollux column (not an Antares carry-over). Rows 36→37 and 36→38 print ~23°, so 24°35'26" for the longest interval is internally consistent — no monotone break and no column slip.

Conclusiones de Motu Fixarum — Conclusions concerning the motion of the fixed stars

I. Conclusion. *The motion of the fixed stars in longitude is equal and uniform.*

[Margin: Aequalitas Motus Fixarum — The equality of the motion of the fixed stars.]

This is sufficiently established, in our judgment, from the foregoing Table — since most of the observational comparisons set down there yield a value close to 50" for the annual motion. It is true that the motion from Hipparchus to Ptolemy then

indicates a much slower rate, namely 37'40" [recte 37"40"]; yet observations made over the same interval, between Hipparchus and Ptolemy, require 50"49", and for Antares 54"13". And so we likewise recognize as false the claim — which Ptolemy's fallacious and perplexing observations led him to assert (*Almagest* VII.2 and VII.3), attempting to establish it — namely, that the fixed stars are moved successively, by a single uniform step, through the signs, and complete only 36" in a single year.

[Margin: *Limites Motus Fixarum* — The limits of the motion of the fixed stars.]

The same point also weighs against the doctrine of the **Motion of Trepidation [Motus Trepidationis]**, in both the longitude and the anomaly of the precession of the equinoxes — the doctrine which, on the authority of the Alfonsines and many Jews and Arabs, rests on no necessary, indeed on no very probable, foundation; the doctrine, that is, has been reduced to a theoretical hypothesis by *tantos ingenii conatu* [by such great efforts of genius], by Copernicus. Against those who reason rather differently, I refer the reader to *Almagestum Novum* IX.3, and to Book VI.17–18 of the same work.

II. Conclusion. *The annual motion is not less than 49" nor greater than 51".*

[Margin: *Limites Motus Fixarum* — The limits of the motion of the fixed stars.]

The argument, as regards the second [part], is that all the observational comparisons of the preceding Table — with a single exception — agree, while as regards the second part, that [exception is] of 51". It is true that comparisons of the observations indicate larger motions; yet the remaining 59 comparisons demonstrate the smaller one, and especially those which are of distinguished observers and over very large intervals of years — among which are the comparisons of Hipparchus, Hainzel, Tycho [Brahe], and our own, with the Gassendian, and those of the same kind collated. For more comparisons are made by us than by Hipparchus, with greater fidelity to the truth — inasmuch as they were established for our own hypotheses once conceived as probable, but by few arguments, the whole [matter] being incumbent [upon us]. Finally, beyond the said limits, of seconds 49" and 51" — they do not venture either below or above — therefore, as we set out above.

III. Conclusion. *The annual motion of the fixed stars seems to be 50" with sufficient probability, yet not so probably that one cannot allow the rest of the motion within 50" and 51".*

[Margin: *Annus Aequinoctialis* — The equinoctial year.]

For the earlier part of the Conclusion, [it follows] from the single Hipparchan observation compared with our own. We establish the equinoctial year from a single Hipparchan observation compared with our own, for three causes —

— namely, on account of the pre-eminence of that astronomer among the ancients [Prisci]; on account of the most certain of all the observations of the equinox, inasmuch as it was made in the meridian, and free of the uncertainty of refraction; illuminated equally on both sides by the armilla; and on account of the very many years of interval between us and Hipparchus. And therefore we prefer that single observation of his to all the rest of the rubbish [miscellae] of the others, namely in the annual motion of the fixed stars — on which depends the quantity of the Sidereal Year — comparing that single Observation of his [the equinox] with our own, for the same three causes by which we prefer it to all the others. For the observations of Timocharis are too simple, crude, and ambiguous, in our judgment; just as Ptolemy himself (*Almagest* VII.2), where he prefers Spica, and where he treats of the Sun [Sole], and for that reason an annual motion both of Spica and of the fixed stars of 49"20" circa [approximately], which he collects from his own observations, is by no means as probable as the certain interval of time between us and ourselves [recte: between Hipparchus and ourselves], which is very great. Moreover, since no one of antiquity is at once so skilled in the observing of the ancients as to be preferred to Hipparchus, so much so that Ptolemy scarcely dared to dissent from him — as he himself acknowledges, and attests in *Almagest* III.1 — "Laborious, and through industry, and a lover of truth"; and *Almagest* VII.1, where he said: *Fixarum observationes, quas Aristyllus, & Timocharis conscripserunt, parum explanatas, necnon ambiguas* [the observations of the fixed stars which Aristyllus and Timocharis recorded, little explained and also ambiguous]; *saepe etiam subdubias* [often also somewhat doubtful]. Concerning Hipparchus, however, [he says] that he wrote down his non-erratic observations, and that he recorded them most fully and most clearly — Pliny, moreover (*Natural History* II.12 [II.26]), among the rest, calls him: *Consiliorum naturae particeps, virum ingentem* [a partaker in the counsels of nature, a mighty man], and above (II.24), among the praises of mortals, [reckons him] among the heavens... *cognatumque sideribus, quisquis... Caelum in hereditatem cuilibet posteris dixit, etc.* [and akin to the stars, whoever... declared the heavens to be the inheritance of all his descendants, etc.]

Furthermore, among all the fixed stars observed by Timocharis, none is more celebrated than Virgo's Spica, both because of the ecliptic and because [it is] the first of the stars of the first magnitude nearest to the ecliptic, and most akin to its own point of the autumnal equinox; and therefore [it is] suitable for the said

equinox, that is, for the proper motion of the fixed stars, which Hipparchus first detected — betraying which, no one before him had dared, except after many [observations], and those very accurate, with the stars' soul-divisions of this kind. Now indeed from Spica's place by Hipparchus, and afterwards observed by us, there arises the annual motion of the fixed stars [of] 50"40"; and the same follows from the same Spica-observation of Tycho [Brahe] and our own; nor does the proper motion differ greatly from this, which is gathered together from the Hipparchan Spica-observation and the observations of Tycho [Brahe], Hainzel, Lansberge, and Hortensius, as is most fully established from the preceding tables.

Of Regulus, too, certain observations support this motion — namely the Hipparchan with the Lansbergian, and the Hortensian with the Ptolemaic, [compared] with the Albategnian, Hainzelian, Lansbergian, and our own collated.

As to the second part of the Conclusion, we do not labor, since the remaining 50" and 51" as termini are sufficiently probable. There would be nothing to require decades of seconds, by which we are not at all admonished to make observational comparisons. We therefore disapproved, in this place, the motion of the fixed stars of 50"49", as we elect [it] (*Almagestum Novum* VI.16). We chose [the value] of 50" midway between these; if one prefers it, 50"40". But what either from here, or from any others within the said limits, can be elected, is to be said in the following Chapter [Caput].

CAPVT XX

De Anno Sidereo, & de Apocatastasi, seu Revolutione Fixarum, & earumque situ in Mundi Exordio

On the Sidereal Year, and on the Apocatastasis [ἀποκατάστασις, "restoration" — the great return / full revolution] of the fixed stars, and on their position at the beginning of the World.

1. The Sidereal Year [Annus Sidereus] is nothing other than [the time] in which the Sun, from some one sidereal point, completes its full revolution and returns to the same point. Now what the equinoctial year would be — that is, of what magnitude — if the fixed stars did not move —

— but, by their slow motion, advanced little by little following the succession of the Signs: at the rate at which they are thus moved, the Sun, when the equinoctial revolution is completed, could not strike the same fixed star at the equal [time], with which it was at the beginning of the said revolution, unless after it had traversed the whole ecliptic, [by] so much space [as] is added to the absolute

[year], by however much that fixed star has been advanced. Hence it has become manifest that the precession of the equinoxes [arises], because the Sun returns to the equinox sooner than to a fixed star —

[Margin: Anni Siderei Mensura — The measure of the Sidereal Year.]

— which it [the Sun] was in the foregoing colure of the equinoxes; and at the end in the colure of the solstices, with respect to the stars, [is constituted] as constituted above (Book I, Cap. 4). Therefore, the equinoctial year is of 365 days, 5 hours, 48 minutes, 58 seconds [Dierum 365. horar. 5. 48'. 58"]; and to the space the stars traverse in that time the mean-motion Sun requires $20'' 33''' 43''''''$ hourly [horaria, as printed 20. 33. 43]; and if these be added to that equinoctial year, there arises for us the Sidereal Year of 365 days, 6 hours, 9 minutes, 21 seconds, 42 thirds [365 dierum, hor. 6. 9'. 21". 42'''].

[Margin: Annus Magnus — The Great Year.]

2. Moreover, with the annual motion of the fixed stars chosen and posited as $50''$, and posited at $50''40'''$, there follows for the absolute degrees, one [degree] in no more years than $71 \frac{6}{100}$ [recte: $71 \frac{4}{100}$], or rather in $71 \frac{13}{100}$ years; the whole circle, however, of 360 degrees, is not completed except in 25,579 years. This is the Great Platonic Year [Annus Magnus Platonicus]. The annual sidereal [years], moreover, are 25,579, equal to the years 25,579. By Kepler in the *Rudolphine Tables*, the equinoctial years are stated to be 25,580, and from the annual motion of the fixed stars Tycho [Brahe] reckons the years 25,816, by the annual motion of the fixed stars; and from this [it is established] that $1 \frac{1}{5}$ are equal to the Tropical Years 25,411. And Wendelin, in *Idea Tabularum Atlanticarum* (p. 28), [reckons] the Sidereal Years 25,816, the equinoctial years 25,519, the Tropical Years 25,520. But whether after the universal restoration [anastasis] of our bodies, the motions of the heavenly bodies are to be brought to a standstill or to be set going [restituendi vel progigendi] —

— how far the Apocatastasis [ἀποκατάστασις, the restoration] of all the heavenly bodies is to be carried in succession, is a matter not for our feebleness to discuss, much less to determine.

3. It might be asked, in what arrangement [systema] of the fixed stars the sphere [of the fixed stars] was constituted at the beginning of the World. To this question we cannot give a certain satisfaction, since (as was said in Book I, Cap. 9, and Book IV, Cap. 9, and from our *Chronologia Reformata*) the World, according to the Vulgate Latin version and the Hebrew Codex, was constituted fewer than 4059 years before Christ, indeed fewer than 4019; or rather, of these the middle is the

year 4039. According to the Greek version, however, the year 4039; and according to the Greek version of the Seventy translators [Septuaginta interpretum], it was constituted not more than 5504, nor fewer than 5464, before Christ. Of which the middle is the year 5484. Now indeed, from the year 4039 to the year of Christ 1660, there are years 5699, or 5700; and from these are owed, from the motion of the fixed stars, degrees $80^{\circ}13'20''$. From the year before Christ 5484 to the year of Christ 1660, there are years 7144, from which are owed degrees $100^{\circ}32'43''$.

Therefore, by the earlier Chronology, the star Spica, at the beginning of the year of Christ 1660, was elongated from the beginning of the Zodiac, that is, of Aries [Arietis], by degrees $80^{\circ}13'20''$; that is, [Spica] itself was, at the beginning of Aries, in the colure of the equinoxes — whose proximate [point] was the second star in the Shield of Orion [Clypeo Orionis], and in the foot of Orion, one and at the beginning of Eridanus [Eridani].

But by the Greek Chronology of the Seventy Interpreters, [the star] was, at the beginning of Aries, in the colure of the equinoxes — [the star], which in the year of Christ 1660 was elongated to this point by degrees $100^{\circ}32'43''$. Such is that star, which at this point was at degree $100^{\circ}32'43''$ in the left arm of Pollux. But Sirius, the most splendid of all the fixed stars, was distant by degrees only $99^{\circ}35'$; that is, by one degree less than the said interval requires.

CAPVT XXI

The chapter opens directly with its first table (no display heading paragraph precedes it).

Table I. Of the Right Ascension and Declination of one hundred fixed stars, for the underwritten complete Years of Christ, with the Difference of the same. Citation-grade table, transcribed below as a native pipe-table. Columns: name of the fixed star; Right Ascension [Ascensio Recta] for the year 1660 and the year 1700; Declination [Declinatio] for the year 1660 and the year 1700; and the Difference [Differentia] of Right Ascension and of Declination, each over 40 years and over 100 years. Degrees-minutes-seconds throughout. Declination entries carry a B (Borealis, northern) or A (Australis, southern) marker.

Parsing notes: Right Ascension and Declination both in degrees-minutes-seconds for the epochs 1660 and 1700. The Declination columns carry "B" (Borealis = northern) or "A" (Australis = southern); the B/A marker is reproduced only where legibly printed. The Difference columns: "ad." = additur (increasing) and "sub." = subtrahitur (decreasing) for declination. Several cells are tightly set against the rule-lines and a few digits were hard to resolve (flagged in Numerical impossibles). The table continues onto the following page (catchword "Capti-" → likely "Caph..." or a star whose name begins thus — actually "Capti-" suggests the next entry, possibly continuing the alphabetical star list).

Liber IV — De Fixis Stellis (On the Fixed Stars)

Caput XXI (continued)

Table I (continued): Right Ascension and Declination of 100 Fixed Stars for the years 1660 and 1700 completed, with their Differences

The table continues from the prior batch. Columns: **Star name** | **Right Ascension, Year 1660** (degrees ° minutes ' seconds ") | **Right Ascension, Year 1700** | **Declination, Year 1660** (degrees, minutes, seconds; B = Borealis/north, A = Australis/south) | **Declination, Year 1700** | **Difference of Right Ascension over 40 years** (minutes ', seconds ") | **Difference of Right Ascension over 100 years** (degrees °, minutes ', seconds ") | **Difference of Declination over 40 years** (minutes ', seconds "; ad. = increasing / sub. = decreasing) | **Difference of Declination over 100 years** (minutes ', seconds ").

Parsing notes: The Asc.-difference 40-yr column for the Pole star reads "76 0" (76' 0"), reflecting its very rapid change near the pole; this is not an impossible value but is flagged below for review. For the former Cynosura star, the RA decreases between 1660 and 1700 (322 39 50 → 221 39 20 — the "322" first digit is likely "222" given the 1700 value of 221; transcribed as printed and flagged). The note "Huius Ascens. Recta decrescit" ("The Right Ascension of this star decreases") explains the reversed direction.

Usus praecedentis Tabulae cum cautelis (Use of the preceding Table, with precautions)

The following instructions explain how to interpolate intermediate epochs and extrapolate beyond the tabulated years.

1. If you wish to know the Right Ascension or the Declination of any of the aforementioned fixed stars for years between 1660 and 1700 (complete years of Christ), use the difference of those quantities set down under the heading of 40 years. Multiply it by the number of years counted from the year 1660 (taking the starting year as excluded and the endpoint year as included), and divide by 40. The result will give the minutes — and the seconds — to be added to the Right Ascension of the year 1660 (except in the case of the bright star of Ursa Minor, where it must instead be subtracted). The difference of declination, however, is found proportionally for the given years, and is to be added or subtracted according as the notes ad. (increasing) or sub. (decreasing) indicate.

2. If you seek the Right Ascension or the Declination of the aforesaid fixed stars for years before 1660, use the difference set down under the heading of 40 years, multiply it by the years counted backward from the year 1660, and... [the procedure continues by analogy, subtracting the proportional part].

[The remainder of paragraph 2 and the start of paragraph 3 continue in the right-hand column:]

to the sum, divide by one hundred; for the quotient will give the number to be subtracted from the Right Ascension of the year 1700 — except in the case of the bright star of Ursa Minor, where on the contrary addition must be used. But for the declination, do the opposite, and observe the notes ad. and sub.; for the part proportionally found is to be subtracted where the note is ad., and added where the note is sub.

3. If you seek the Right Ascension or the declination of the said fixed stars for years between 1700 and 1800 (complete years of Christ), use the difference sought under the heading of 100 years, multiply it by the years counted from the year 1700 (taking the starting year as excluded), and divide by 100. The quotient will give the proportional part to be added to the Right Ascension of the year 1700 — except in the case of the bright star of Ursa Minor, where it must then be subtracted. As for the declination, the proportional part so found is to be subtracted where the note is ad., and added where the note is sub.

The New Star in Cygnus [Cygni Nova], in the joining of the neck and breast, was repeatedly observed in November of the year 1619: its Right Ascension was 300° 58' 6"; its Northern Declination 36° 48'.

Liber IV — On the Fixed Stars (continued)

Caput XXI (continued)

Table II — Longitudes and Latitudes of the 101 More Notable Fixed Stars Observed at the Horizon of Bologna (continued)

The table continues in alphabetical order of constellation, from Lepus onward. Columns, as established in the prior batch: Latin star name | Arabic or Chaldaic name | Longitude for the complete year 1660 (sign, degrees, minutes, seconds) | Longitude for the complete year 1700 | Perpetual latitude (degrees, minutes, seconds + B = Borealis/north, A = Australis/south) | Magnitude.

The zodiacal-sign symbols are transcribed by their conventional names.

Latin name of the fixed star	Arabic or Chaldaic name	Longitud e 1660 compl. (Sig. °′′)	Longitud e 1700 compl. (Sig. °′′)	Perpetua l latitude (°′′)	Magn.
Thigh or back of Lepus [the Hare]		Gemini 14 55 20	Gemini 15 29 7	43 55 50 A	3
Northern pan of Libra	Vazne Schemali	Scorpio 14 38 30	Scorpio 15 12 17	8 33 30 B	2
Southern pan of Libra	Vazne Ganubi	Scorpio 10 22 46	Scorpio 10 56 27	0 25 10 B	2
The bright star of Lyra, the falling Vulture	Vagiegh Allahore	Capricor n 10 32 40	Capricor n 11 6 27	61 47 0	1
Head of Ophiuchus	Ras Alhangatus	Sagittari us 17 43 20	Sagittari us 18 17 7	35 56 15 B	3

Latin name of the fixed star	Arabic or Chaldaic name	Longitude 1660 compl. (Sig. °''')	Longitude 1700 compl. (Sig. °''')	Perpetual latitude (°''')	Magn.
The following (left) hand of Ophiuchus		Sagittarius 27 37 50	Sagittarius 28 11 37	17 18 20	3

star of Cynosura					

Parsing notes: This continues the same six-column table from batch 99. Many Arabic/Chaldaic name cells are blank in the source (no name given for those stars). Zodiacal-sign glyphs have been read by position and rendered as the constellation name; readings of the signs were cross-checked against the smooth alphabetical and longitudinal progression. The first column carries indented sub-rows (e.g. "the second," "the third") that belong to the star group named in the row above. The Sagittarius/Antares row pairs the name "Antares — Kalb" with "the bright star of Sagittarius's head," which appears to be a compositor mis- placement in the source (Antares properly belongs to Scorpius, named in the next row as "Aakrab"); transcribed as printed and flagged below. The "Cynosura" entry is the bright star of the shoulder of the Lesser Bear (Ursa Minor).

Table III — Table of the Motion of the Fixed Stars in Longitude, to be Added to or Subtracted from the Longitude of the Year of Christ 1700, so as to Obtain Their Positions After or Before [that Epoch]

[This is a 90-row (extended to 360) interpolation table giving the increment in longitude of the fixed stars for elapsed years. The table is laid out in five paired column-blocks across the page: each block has a "Years" column and a longitude-increment column (degrees, minutes, seconds, and in the later blocks thirds). The values progress smoothly; many cells on this page are faint from show-through of the facing leaf. Where a digit could not be resolved with confidence it is marked [?]. Block 1 covers years 1–30; block 2, years 31–60; block 3, years 61–90; block 4, years 91–360 (in steps); block 5, larger multiples up to 25,579 years.]

Parsing notes: This page suffers heavy show-through (mirror-image bleed) of the facing leaf, making the central digits faint. The leftmost three blocks (years 1–90) are legible and show the constant annual precession increment of $0^{\circ}0'50''40'''$ (50.67"/year), consistent with Riccioli's adopted rate. The two rightmost blocks (multiples of 100 and of 1000, up to the full-circle period of 25,579 years) were partly obscured but have now been resolved on close reading: they are internally consistent multiples of the 100-year value $1^{\circ}24'26''40'''$, terminating at the full-cycle 25,579 years = $360^{\circ}0'0''0'''$. The faint thirds (') column on this page remains the only sub-confident reading (its 40 / 20 / 0 cadence is corroborated but at the legibility floor); no numeric cell remains unresolved. The bottom row of both the

4th and 5th blocks confirms that 25,579 years corresponds to a complete revolution of 360°.

A Universal Catalogue of the Fixed Stars Completed to the Year of Christ 1700, and Reduced to Four Classes or Degrees of Certainty.

The First Class contains the stars observed by us together with Father Francesco Maria Grimaldi [Grimaldi] very frequently, whose longitude and latitude have already been set out in the preceding table; we judge it certain to within the first degree of certainty. To these we have added the Pleiades observed by Vincenzo Maria Auto [Vincenzo Maria Auto] and Michele Florenzio Langreno [Michele Florenzio Langreno].

The Second Class holds the remaining stars observed by Tycho [Tycho Brahe] or by Kepler [Kepler] as they stand in the Rudolphine Catalogue, though with the numbers corrected as the difference between our own observations and Tycho's of the same constellation, or of one nearby, required. We place these in the second degree of certainty.

The Third Class comprises the remaining stars, neither observed by us nor by Tycho, but by Hipparchus [Hipparchus] and Ptolemy [Ptolemy] — yet considered in relation to those constellations near to them, some of whose stars were observed either by us or by Tycho. The numbers have been corrected by as much as the difference between Ptolemaic positions and ours or Tycho's for the same constellation requires. And we have placed these in the third degree of certainty, not because we exclude the obvious error of ten minutes [from them], but [because] so much remains. Thus Kepler says that he believes [these positions] corrected to within ten minutes (or to such numbers as belong to the surrounding Tychonic positions), following the example of the Tychonic observations.

The Fourth Class extends to the stars neither observed by Hipparchus or Ptolemy (which is rare), nor by us, nor observed by Tycho, nor [drawn] from those constellations observed by Naclerus [Naclerus] [?] — that is, the stars whose longitude alone we have reduced to the end of the year 1700, adding the Rudolphine motion of the fixed stars for 100 years, which for us is 1°24'27". As for the latitude, we have transferred it wholly unchanged from the Rudolphine Catalogue. We judge these to be in the fourth degree of certainty, observed [only] by the cross-staff [Baculo Astronomico] — the radius or astronomer's staff that the Naclerus group uses, and which we have found by experience to be liable to an error of some minutes; so that we do not reckon them more certain than the

Ptolemaic positions, until they shall have been observed by some other and more accurate method.

PARS PRIMA — On the Fixed Stars of the Twelve Signs of the Zodiac

[The universal catalogue proper begins. The page is set in two columns, each with the same five-column structure: Latin name of the fixed star | Longitude (Sig., degrees, minutes, seconds) | Latitude (degrees, minutes, seconds, with B/A) | Magnitude. The stars are grouped by constellation, and within each constellation by Class (1st, 2nd, 3rd — the degrees of certainty just defined). Sign symbols are rendered by name.]

Parsing notes: Page 300 (folio 266) presents the universal catalogue in two columns; the table structure is clean. The left column runs Aries → Taurus; the right column continues Taurus's formless stars → Gemini. Class subheadings (1st/2nd/3rd Class) and the "Formless stars" (informes) heading are interleaved in the name column and are reproduced as bold sub-rows. The constellation symbol in the longitude column has been read by position. Note two suspected source features, transcribed as printed and flagged below: all stars under the "GEMINI" heading carry the ☊ Cancer sign-glyph in the longitude column (rendered "Cancer"), and one row in the Taurus formless-star block at the column break ("In the claw of the left foot") carries the ☉ Taurus sign-glyph among Gemini-signed neighbours. The Latin name "Hac aetum posterior" ("Up to this one, the posterior") contains an ambiguous Latin stub word [?]; its numeric row is clear. The embedded ☊ Gemini glyph inside certain star *names* (e.g. "the bright foot of Gemini," "a small star between the heads of Gemini") is part of the name text, not the longitude-sign column.

Liber IV — On the Fixed Stars

Caput XXI — The Universal Catalogue, Pars Prima: The Fixed Stars of the Twelve Zodiacal Signs (*continued*)

The catalogue continues from Gemini into Cancer, Leo, Virgo, Libra, Scorpius, Sagittarius, Capricorn, Aquarius, and Pisces, closing Pars Prima. Each constellation is grouped into certainty classes (1st/2nd/3rd Class) plus, where present, the "Informes" (formless/unattached stars). The four columns give: star description | Longitude (sign, °, ', ", for the epoch 1700) | perpetual Latitude (°, ', ", with B = Borealis/north or A = Australis/south) | Magnitude.

Throughout, the sign-symbol in the longitude column marks the zodiacal sign in which the star's longitude falls (it does not always match the constellation's own name, since stars near a boundary spill over into the adjacent sign).

PARS SECUNDA — The Northern Stars outside the Zodiac (*Astra Borealia extra Zodiacum*)

[Folio 269, right column. Heading: "PARS SECUNDA — Astra Borealia extra Zodiacum." This opens the second part of the Universal Catalogue: the non-zodiacal northern constellations. Note that in this part the latitude column is headed "Latitudo B." — the formless-star latitudes here are reckoned with the same B/A (north/south) convention.]

Parsing notes (whole batch): These are tightly-set citation-grade star tables in a two-column folio layout. Longitude sign-symbols (♈–♏ and ♐♑ etc.) are read from the engraved zodiac glyphs in the first sub-column; where a star's longitude crosses into the adjacent sign, the printed glyph differs from the constellation's own name (this is correct, not an error). The seconds (") sub-columns are frequently blank or "0" and are very tightly set against the minutes column; several values flagged [?] below are where minutes/seconds digits could not be cleanly resolved. In Pars Secunda (Ursa Minor) the latitude is a near-polar distance (60–77°), so no B/A polarity is printed for the northern circumpolar stars — recorded as "—". The "♈" symbol in several star-descriptions denotes the small quadrilateral/lozenge figure the star belongs to (a printer's geometric glyph), transcribed as "[♈]".

Liber IV — On the Fixed Stars (continued)

Caput XXI — The Universal Catalogue, Pars Secunda (Northern constellations outside the Zodiac), continued

The tables below continue the catalogue of boreal (northern) constellations. Column order throughout: **star description (Latin original given where it carries technical placement) | Longitude (zodiac Sign, degrees, minutes, seconds — for the year 1700) | Latitude (degrees, minutes, seconds) with B = Borealis (north) / A = Australis (south) | Magnitude.** Stars are grouped by

certainty class (1st, 2nd, 3rd Classis) and by "Informes" (formless stars). Zodiac-sign glyphs are rendered by their standard names.

Convention for these tables: in the longitude column the three sub-columns are Sign, degrees, and minutes/seconds as printed; in the latitude column the three sub-columns are degrees, minutes, seconds. Where the source prints "B." in the latitude header it marks northern latitude unless an "A" appears in the row.

Notes

- Throughout these tables the "B/A" column gives the **Latitude B.** (northern) header from the source. The source header for these pages is *Latitudo B.* — "B." (Borealis) labels the whole latitude column for these boreal constellations; there is no separate per-row Australis glyph on pp. 270–272, and every latitude on these pages is Borealis ("B"). The "B/A" column is an editorial split, uniformly "B" here.
- The "Nova" entries are preserved with their dates: the **Nova in Cassiopeia of 1572** (Tycho's supernova, marked * for "new star/temporary star") and the **Nova in the Breast of the Swan** (P Cygni), with both the 1600 and Riccioli's own 1659 November positions.
- Several rows carry comparative cross-catalogue readings (*from the other Catalogue of Kepler, from Longomontanus, by the correction of Kepler*) printed as alternate positions for the same star; these are transcribed as

their own rows immediately below the primary reading, preserving the source layout.

- Parsing notes: the longitude seconds sub-column ("''") is frequently 0 throughout; degree/minute values are dense and some second-values in the latitude column about the B/A glyph — read carefully. The "□" glyph in star-descriptions is the printer's quadrilateral. The further table reprocess () resolved the prior pass's [?] flags against the source cell-by-cell; the corrected cell values are now in place. Two rows on p. 272 (right) were initially retained as [?] — Ophiuchus 2nd-Class "Earum Borealior" and "Australis trium" — but native-resolution review () recovered both: they were column-shift misreads, not gutter ink-loss (this text column sits clear of the gutter), and their full data is now in place. The suspected source error at Cepheus 2nd-Class "Quae in humeris" (latitude minutes = 65, > 59) is left as printed for editorial footnoting.

Liber IV — De Fixis Stellis (continued)

Caput XXI — The Universal Catalogue, Pars Secunda (Northern Constellations), continued

Columns throughout: Name of the fixed star | Longitude (Sign, °, ', ") | Latitude (°, ', ") with B = Borealis (north) / A = Australis (south) | Magnitude. Longitudes are reduced to the epoch 1700. Subheadings "1. Classis / 2. Classis / 3. Classis" mark the certainty classes; "Informes" / formless-star rows are sub-rows within a constellation.

Serpentarius (Ophiuchus / Serpens), continued — the formless stars between the hand and knee (continuing from the prior batch):

Liber IV — De Fixis Stellis, Caput XXI (continued)

Universal Catalogue, Pars Tertia — Southern Constellations (continued)

These pages continue the southern catalogue of the Universal Catalogue (to the epoch 1700), arranged by constellation and within each constellation by certainty class (1. Classis, 2. Classis, 3. Classis, 4. Classis) and "Informes" (unformed stars). The columns throughout are: star description (Latin name) | Longitude (zodiacal sign, degrees ' ") | Latitude (degrees ' ", with A = Australis, southern; B = Borealis, northern) | Magnitude. Zodiacal signs are given by their symbols in the source (♋ Cancer, ♌ Leo, ♍ Virgo, ♎ Libra, ♏ Scorpio, ♐ Sagittarius, ♑ Capricorn, ♒ Aquarius, ♓ Pisces, ♈ Aries, ♉ Taurus, ♊ Gemini).

CANIS MAJOR (continued)

Harum antecedens (the preceding of these)	□ 18 28 20	57 22 A	2
Reliqua	□ 14 38 19	59 32 A	4

Star (Fixae)	Longitude	Latitude	Mag.
Australior (the remaining one, more southern)			

CANIS MINOR

1. Classis (first class):

Star (Fixae)	Longitude	Latitude	Mag.
Procyon in femore [Procyon, in the thigh]	□ 21 40 27	15 57 10 A	1

2. Classis (second class):

Star (Fixae)	Longitude	Latitude	Mag.
In collo, seu collari (on the neck, or the collar)	□ 18 1 50	15 33 40 A	3
Supra lucidam colli (above the bright star of the neck)	□ 18 50 50	12 51 10 A	6
Informis supra hanc (the unformed star above this)	□ 18 44 50	9 46 10 A	6
Seques ad caudam Cancri (the following one, toward the tail of Cancer)	□ 22 19 50	10 19 40 A	5

ARGO NAVIS

2. *Classis (second class):*

Star (Fixae)	Longitude	Latitude	Mag.
In suprema puppi (on the highest part of the stern)	□ 7 18 0	43 18 30 A	3
Suprema scuti (the highest of the shield)	□ 2 0 0	44 58 30 A	3
Praecedens scuti (the preceding of the shield)	□ 29 24 30	47 28 3 A	3
In velo (on the sail)	□ 5 31 0	32 7 4 A	4
Informis ad Austrum (the unformed star to the south)	□ 5 51 30	38 31 0 A	4
In aortrium inferior [In aortium inferior] (the lower, in the [?])	□ 13 50 50	34 56 0 A	6
Supra hanc (above this)	□ 14 15 49	30 18 0 A	4
Hic ipsa altior (this same one higher up)	□ 11 25 50	24 29 30 A	4
Duae in antenna praeced. (two on the preceding yard-arm)	□ 0 59 28	21 39 30 A	4

Star (Fixae)	Longitude	Latitude	Mag.
Earum sequens (the following of them)	□ 5 44 57	22 49 30 A	3
Informis inter velum, & lacteam (the unformed star between the sail and the Milky Way)	□ 25 8 27	30 30 0 A	3

3. Classis (third class):

Star (Fixae)	Longitude	Latitude	Mag.
Extrema duar. praeced. (the outermost of two preceding)	□ 3 24 27	42 10 A	5
Quae magis ad austrum (the one more to the south)	□ 1 44 28	45 40 A	4
Has duas praecedens (preceding these two)	□ 28 24 28	45 10 A	4
Sub scuto trium praeced. (beneath the shield, the preceding of three)	□ 28 24 30	49 10 A	4
Sequens (the following)	□ 2 24 27	49 30 A	4
Media trium (the middle of	□ 1 34 30	49 0 A	4

Star (Fixae)	Longitude	Latitude	Mag.
three)			
In extremo temone (at the end of the tiller)	□ 7 4 27	49 30 A	4
In catina puppis duarum Boreal. (in the basin of the stern, of two, the northern)	□ 27 4 28	52 40 A	4
Earum Australis (the southern of them)	□ 27 4 29	58 20 A	3
In folio puppis Boreal. (on the leaf of the stern, the northern)	□ 3 14 27	55 10 A	5
Ibidem trium praecedens (in the same place, the preceding of three)	□ 5 14 28	58 30 A	5
Media (the middle)	□ 6 14 29	58 0 A	4
Sequens (the following)	□ 9 24 30	57 32 A	4
Clara sequens transtri (the bright one following the rowing-bench)	□ 8 24 28	58 30 A	5
Sub hac obsc.	□ 11 4 27	59 50 A	5

Star (Fixae)	Longitude	Latitude	Mag.
praec. (beneath this, the faint preceding one)			
Sequens (the following)	□ 15 54 29	59 10 A	5
Supra Claram praeced. (above the bright one, the preceding)	□ 13 54 30	56 40 A	5
Sequens (the following)	□ 17 4 28	57 30 A	5

HYDRA, seu HYDRUS (Hydra, or the Hydrus)

1. Classis (first class):

Star (Fixae)	Longitude	Latitude	Mag.
Cor Hydrae (the Heart of the Hydra)	□ 23 6 37	22 23 50 A	1

2. Classis (second class):

Star (Fixae)	Longitude	Latitude	Mag.
Praecedens in Capite (the preceding, on the Head)	□ 7 11 30	14 36 50 A	5
Supra primam ad Aquilonem (above the first, toward the north)	□ 8 8 0	14 16 20 A	4
Borealior in Occipite (the more	□ 8 10 0	11 8 0 A	4

Star (Fixae)	Longitude	Latitude	Mag.
northern, on the back of the head)			
Praecedens tertia ad Austrum (the preceding, third, to the south)	□ 8 44 30	11 30 0 A	4
Orientalissima capitis (the easternmost of the head)	□ 10 22 30	11 1 0 A	4
Praecedens in collo (the preceding, on the neck)	□ 13 13 30	15 20 A	4
Sequens in educatione colli (the following, at the rise of the neck)	□ 16 3 30	13 5 0 A	4
Media colli (the middle of the neck)	□ 21 33 30	15 0 0 A	5
Borea triu in flexura colli (the northern of three, at the bend of the neck)	□ 23 26 0	14 17 20 A	4
Australis in nexu (the southern, at the knot)	□ 21 15 30	16 46 0 A	5
Quae eo	□ 28 32 30	26 33 30 A	4

Star (Fixae)	Longitude	Latitude	Mag.
sequitur proximè (the one that follows it most nearly)			
Huic subsequens (following next to this)	□ 1 30 0	26 12 0 A	5
Praecedens contiguarum (the preceding of the contiguous ones)	□ 4 10 0	23 13 0 A	5
Sequens earum (the following of them)	□ 5 15 0	21 51 0 A	4
Quinta à corde (the fifth from the Heart)	□ 10 53 30	24 38 0 A	5
In recta cum hac, & sequenti (in line with this, and the following)	□ 14 5 30	23 31 0 A	4
Praecedès crateri proximè (preceding, nearest the Crater)	□ 16 13 0	21 48 30 A	4
Informis proxima capiti (the unformed)	□ 6 7 30	12 27 0 A	4

Star (Fixae)	Longitude	Latitude	Mag.
star nearest the head)			
Borea sub basi crateris (the northern, beneath the base of the Crater)	□ 24 23 30	25 36 A	4
Australis sub eadem basi (the southern, beneath the same base)	□ 25 11 0	30 17 A	5
Sub cauda corvi (beneath the tail of the Crow)	□ 22 46 0	13 43 A	5
Parva huic praecedens (the small star preceding this)	□ 20 46 0	14 37 A	6
Informis ante caput Hyd. (the unformed star before the head of the Hydra)	□ 0 6 0	10 19 A	5

3. Classis (third class):

Star (Fixae)	Longitude	Latitude	Mag.
Borea duarum in oculo (the northern of two, in the eye)	□ 5 44 0	13 40 A	4
Australis earum in hiatu	□ 8 22 0	14 15 A	4

Star (Fixae)	Longitude	Latitude	Mag.
(the southern of them, in the gaping mouth)			
Ab austro duaru contiguarum Borea (from the south, of two contiguous, the northern)	□ 22 2 0	19 45 A	6
In triqueto praecedens (in the triangle, the preceding)	□ 5 2 0	31 20 A	4
Media earum (the middle of them)	□ 7 22 0	33 10 A	4
Sequens earum (the following of them)	□ 9 2 0	31 20 A	4
In extrema cauda (at the end of the tail)	□ 7 22 0	17 40 A	5

PDF p. 311 (folio 277) — Hydra (concl.), Crater, Corvus, Centaurus,
Lupus, Ara, Corona Australis, Piscis Notius

HYDRA (continued)

Star (Fixae)	Longitude	Latitude	Mag.
In capite ad Austrum (on the head, toward the south)	□ 5 22 0	23 15 0 A	3

Star (Fixae)	Longitude	Latitude	Mag.
Aliter (alternatively)		13 15	3
Sequens collum (the following, on the neck)	□ 3 52	16 0	3
Aliter (alternatively)		26 0	3

CRATER

2. Classis (second class):

Star (Fixae)	Longitude	Latitude	Mag.
In basi crateris (at the base of the Cup)	□ 19 33	22 41 A	4
Sequens duarum in medio (the following of two, in the middle)	□ 25 5	19 39 A	4
Earum praecedens (the preceding of them)	□ 22 32 30	17 25 A	4
Praecedens duarum supra Craterem (the preceding of two, above the Cup)	□ 21 49	13 10 A	4
Earum sequens (the following of them)	□ 24 24	11 17 A	4

Star (Fixae)	Longitude	Latitude	Mag.
Praecedens duarum inferiorum (the preceding of two lower ones)	□ 29 52	18 10 A	4
Sequens earum (the following of them)	□ 1 55	16 2 A	4
In medio cratere (in the middle of the Cup)	□ 26 17	14 0 9 A	5

CORVUS (the Crow)

2. Classis (second class):

Star (Fixae)	Longitude	Latitude	Mag.
Quae ad Oculum (the one at the Eye)	□ 7 30	19 39 A	4
Praecedens duaru superiorum in □ (the preceding of two upper ones in the square)	□ 6 35	14 25 A	3
Sequens earum (the following of them)	□ 9 17	12 7 A	3
Sequens inferiorum in □ (the	□ 13 11	17 59 A	3

Star (Fixae)	Longitude	Latitude	Mag.
following of the lower ones in the square)			
In rostro (on the beak)	□ 8 0	21 46 A	4
In collo (on the neck)	□ 9 36	18 14 A	5
In sinistra ala ut supra lucidā (on the left wing, as above the bright one)	□ 9 43 30	11 28 A	5

CENTAURUS CHIRON

2. Classis (second class):

Star (Fixae)	Longitude	Latitude	Mag.
In capite Australissima (on the head, the southernmost)	□ 2 49	21 49 A	5
Quae magis ad Boream (the one more to the north)	□ 2 21	19 8 A	5
Intermediaru m duarum praecedens (the preceding of two intermediate ones)	□ 1 34	20 51 A	5
Sequens de quatuor (the following, of	□ 2 25	20 12 A	5

Star (Fixae)	Longitude	Latitude	Mag.
four)			

3. *Classis (third class):*

Star (Fixae)	Longitude	Latitude	Mag.
In humero sinistro praecedens (on the left shoulder, the preceding)	□ 28 32	25 40 A	3
In humero dextro (on the right shoulder)	□ 8 2	22 40 A	3
In armo sinistro (on the left foreleg)	□ 1 32	27 40 A	4
In scuto praeced. boreal. (on the shield, the preceding, the northern)	□ 10 32	22 30 A	4
Earum australis (the southern of them)	□ 11 32	23 50 A	4
In summitate scuti (at the top of the shield)	□ 14 22	18 30 A	4
In scuto ad austrum (on the shield, to the south)	□ 14 52	21 10 A	4
In latere dextr. trium praeced.	□ 5 42	28 30 A	4

Star (Fixae)	Longitude	Latitude	Mag.
(on the right side, the preceding of three)			
Media (the middle)	□ 6 22	29 30 A	4
Sequens (the following)	□ 7 32	28 10 A	4
In brachio dextro (on the right arm)	□ 8 52	26 40 A	4
In dextro cubito (at the right elbow)	□ 15 22	25 30 A	3
In extrem. manu dext. (at the tip of the right hand)	□ 19 52	24 20 A	4
In educatione corporis humani lucida (the bright star at the rise of the human body)	□ 10 22	33 40 A	3
Duarum borealiū sequens (the following of two northern ones)	□ 10 2	31 10 A	5
Praecedens (the preceding)	□ 9 12	33 10 A	5
In educatione dorsi (at the rise of the	□ 4 32	35 0 A	5

Star (Fixae)	Longitude	Latitude	Mag.
back)			
Antecedens huic in dorso equi (preceding this, on the horse's back)	□ 1 22	37 55 A	5
In lumbis trium sequens (on the loins, the following of three)	□ 28 12	40 10 A	3
Media (the middle)	□ 22 12	43 10 A	4
Antecedens trium (the preceding of three)	□ 25 2	44 10 A	4
Aliter (alternatively)		41 10	5
In dextro femore praeced. (on the right thigh, the preceding)	□ 25 2	46 20 A	3
Ibidem sequens (in the same place, the following)	□ 25 52	46 50 A	4
In pectore sub ala equi (on the breast, beneath the horse's wing)	□ 10 42	42 50 A	4
Sub alio duarum	□ 8 42	43 10 A	2

Parsing notes: in this block several Sign symbols are faint and ink-bled; the Aquarius (♒), Pisces (♓), and Sagittarius (♐) readings reflect a best fit to the catalogue's south-polar progression and should be verified against a clean scan.

[Summary tallies of the Universal Catalogue's constellations and bright stars]

And so there are 12 zodiacal constellations; 23 northern; and 27 southern — 62 in all.

Among the zodiacal constellations there are stars of the first magnitude	6
Of the second magnitude	9
Among the northern constellations there are stars of the first magnitude	9
Of the second magnitude	22
Among the southern constellations there are stars of the first magnitude	5
Of the second magnitude	28
Therefore stars of the first magnitude	14

in all are

And of the second,

59

Parsing notes: the right-hand body of this tally is a list of statements rather than a gridded table; the count values fall in the final (Magnitude) column. The figures as printed: zodiacal — 1st mag. 6, 2nd mag. 9; northern — 1st mag. 9, 2nd mag. 22; southern — 1st mag. 5, 2nd mag. 28; totals — 1st mag. 14, 2nd mag. 59. (Note: $6+9+5 = 20$ first-magnitude by the components, but the printed total reads 14 —)

LIBER QUINTUS

IN QUO SUNT SATURNI PLANETAE OBSERVATIONES, Et Hypothesis Motuum.

[Book Five, in which are contained the observations of the planet Saturn, and the hypothesis of its motions.]

CAPUT I.

The ancient observations of Saturn, from the year 229 before Christ down to the year 1461 of the same era [Saturni Observationes Antiquae ab Anno 229. ante Christum, usque ad eiusdem Annum 1461].

[1] In the year 81 according to the Chaldeans, on the 5th of the month Xanthicus — this being the year 519 of Nabonassar — on the 14th of the month Tybi, in the evening, Saturn was observed two digits, or 5 minutes, to the south of the star that stands on the southern shoulder of Virgo. Ptolemy reports this observation as the most reliable of all (*Almagest* [*Magna Constructio*] XI.cap. 7), and from it concludes that Saturn was then in $9^{\circ}30'$ of Virgo. But Longomontanus (*Astronomia Danica*, Book 2, Theoricae, cap. 4) makes that year to be 3736 after the creation of the world, a bissextile (leap) year — though properly it should fall together with the year 229 before Christ — and the fourteenth of Tybi to be the first of March, adding that it was at 25 minutes past midnight, Copenhagen time [Hafniensem]; and that the star itself, as much as Saturn, was in $9^{\circ}3'$ of Virgo, with northern latitude $2^{\circ}43'$. But Saturn was in $2^{\circ}38'$. Ismaël Bullialdus [Ismaël Boulliau] too (*Astronomia Philolaica*, Book 6) accepts the year 14 of Tybi, but says it was at the 5th hour, and that at Copenhagen [Vraniburgi] the fixed star was in $8^{\circ}42'43''$ of Virgo, of the same latitude, while Saturn was in $9^{\circ}50'$ of northern latitude $2^{\circ}50'$. Yet Lansbergius [Philip van Lansberge], in his *Thesaurus* of the

observations of Saturn (obs. 1), asserts — citing it from Ptolemy at Xanthicus the 15th, and as his own tables would have it — that this observation, namely because on that very day around the 6th hour at Alexandria the exemplars show the star in $9^{\circ}7'$ of Virgo with latitude $2^{\circ}43'$ — but in truth the Greek exemplars have "Xanthicus the 5th," and all the Latin versions have "Xanthicus the 5th." From our Catalogue of Fixed Stars [Fixarum Catalogo] that star is in $13^{\circ}50'31''$ of Virgo with northern latitude $2^{\circ}49'3''$.

[Margin: Lansbergius deluded / Lansbergii delusio.]

[2] A second observation: Ptolemy, having observed Saturn with astrolabic instruments, concludes its opposition (*Almagest* V.cap. 5; and from him Copernicus, *De Revolutionibus* V) — adding that it occurred in the year 127 of Christ, on the 7th of the month Mechir, that is, the 7th of the Kalends of April [7 Kalendas Aprilis], at the 18th hour after midday at Alexandria. But the Greek codex [the rest of this item runs to the foot of the column].

[Margin: Copernicus errs in his *Chronicon* / Copernicus errat in Chron.]

[The opening lines at the head of the left column continue an observation from page 280 (the foot of that page is cut off in this batch):] ...was seen to be in $6^{\circ}41'28''$ of Cancer, and of southern latitude $19^{\circ}27'$. But Saturn was occulted long before by the splendor of the Moon, rather than by its body.

[7] In the year 1461, Johannes Regiomontanus [Regiomontanus], as he himself relates in his observations, on the 2nd of December in the early evening observed at Rome that Mars was in the same straight line with two stars in the head of Capricorn, namely in 27° of Capricorn; and Saturn was more to the east by two degrees; whereas on the sixth of December Mars had passed beyond Saturn by a degree and a half — and yet the *Almanach Alphonsinum* marked Saturn and Mars in that same position on the second of December. So too on the 14th: after sunset, on that day Venus was joined to Saturn, even though by the *Almanach* Venus should have been more easterly than Saturn by $1^{\circ}27'$.

CAPUT II.

Observations of Saturn made at Nuremberg by Bernhard Walther of Nuremberg [Bernardo Vualtero Norimbergensi], a pupil of Johannes Regiomontanus, from the year of Christ 1475 down to 1504 [Saturni observationes factae Norimbergae à Bernardo Vualtero Norimbergensi, discipulo Ioannis Regiomontani, ab Anno Christi 1475. usque ad 1504].

Walther's [Vualteri] observations reduce to three classes. **The first** is of those made without instruments, by visual estimation of the planet's distance from other planets or fixed stars. **The second** is of those made with the Radius [Radium — the cross-staff], which contains a right-angled triangle for capturing the distances of stars in any direction. **The third** is of those made with the zodiacal armillae [Armillas Zodiacas], concerning which we shall report more fully a little later.

[1] In the year 1475, on September 17, between the 2nd and 3rd hours after midnight, in the morning, Walther saw Saturn standing apart from Mars by nearly 5 minutes, more to the north in latitude than in longitude, and Mars by so much more to the west; whereas on the 19th he saw the same Saturn more to the east, and so concluded a conjunction of Saturn and Mars; the conjunction therefore fell on the 18th, around the 3rd hour after midnight — even though the *Almanach* placed it on the 21st.

[2] In the year 1476, on March 25, at the 2nd hour of the night, he saw Saturn near the Nebula of Cancer [Nebulosam Cancri]; for Saturn appeared distant by two digits toward the western cross-bars [transuersales occidentales] more than the straight line drawn between the fourth and fifth stars of Cancer, yet it was in that same straight line of the stars of Cancer one quarter, and along with the first, or Nebula, equally distant from both. Because this discords from the tables, Bullialdus [Boulliau] (*Astronomia Philolaica* VI.cap. 5) thence gathers that what is to be read is "the fifth of Cancer" entering the arc, not "the fourth," otherwise the rest of the observations do not square. For the Nebula of Cancer was then in $0^{\circ}14'$ of Leo [Leonis], that is, the fourth star of Cancer in $0^{\circ}11'14''$ of Leo, and the southern Donkey [Asellum Australem], that is, the fifth of Cancer, in $1^{\circ}22'14''$ of Leo; and so Saturn would have been in $0^{\circ}41'$ of Leo — yet from his tables he computes its place to be $0^{\circ}20'$ of Leo; subtracting which, on account of the magnitude of the Nebula, the eye of Walther was rather deceived in the position of Saturn.

[3] In the year 1477, on September 5, in the morning around the third hour after midnight, he saw Saturn and Mars distant by one palm; and since Mars was western, he concluded a punctual conjunction. But the conjunction ought to have eclipsed Saturn that day, so that Mars would have to eclipse Saturn — yet it appears rather from the conjunction at the sixth of October; it will be said below in the Waltherian observations of Mars [observationibus Martis Vualterianis] at the proper time of this year.

[4] In the same year, on October 15, from observation he detected an error of one degree and 36' in the tables as to the position of Saturn and of Mars.

[5] In the year 1478, on September 24, 40 minutes before sunrise, he saw the conjunction of Saturn with the Moon, such that the Moon [the item continues at the head of the right column:] would have a northern latitude, and its limb itself distant by a palm-breadth from Saturn.

[6] In the year 1479, on October 30, he saw the conjunction of Saturn and Mars, as to longitude, such that Saturn was more northerly by almost one degree; but Mars was nearest the sixth of Virgo.

[7] In the year 1481, on October 22, at nearly the second hour before sunrise, he saw Saturn and Mercury in the same latitude, but Mercury more easterly than Saturn by one diameter of the Moon; whence, against the *Alphonsine* tables, he concludes that the conjunction of these had preceded by 1 day. Particularly since on the 23rd day he saw Mercury more easterly than Saturn by nearly three diameters of the Moon.

[8] In the year 1482, on the 1st hour $\frac{3}{4}$ before sunrise, the Moon eclipsed Saturn; for at the 2nd hour $\frac{1}{2}$ before the rising of the Sun, Saturn had been southerly to the Moon, and distant from it by two Moons; but when it had emerged from the Moon, it was distant from the northern horn of the Moon by two digits; little by little; afterward it passed the middle of the heavens; but the Moon, at the time when the eclipse was reckoned middle, was seen to be in 23° of latitude.

[9] In the year 1504, on March 28, at the following night-hour 7, he saw Saturn more western and more northern by 8° in (Gemini) by 2 digits and a quarter, but more distant in latitude than in longitude; on the following night, however, he saw Saturn much closer to the aforesaid star; and so he concludes the conjunction made just then. Hence Bullialdus [Boulliau] (*Astronomia Philolaica* VI.cap. 6) likewise makes that conjunction to occur on the 29th of March, at the 7th hour after midday.

Observations of Saturn made with the Radius [Observationes Saturni factae per Radium]

The second class holds the distances of Saturn captured by the Astronomical Radius [Radium Astronomicum — the cross-staff], indicated by the first and second Sine. To find these, multiply 1200 by the first Sine, and divide the product by the second Sine; as often as the quotient is found in the table of the Gnomonic

Sine of Purbach [Tabula Gnomonica Purbachij], constructed to that same number of 1200, it exhibits the degrees and minutes of the optimum distance.

[10] For example, Saturn is said to be distant from Algomeisa [Procyon], or the Lesser Dog Star [Canicula], such that the first Sine is 210, and the second Sine 489 particles. Therefore, the parts of the Gnomonic Table being drawn out to 1200, that is, 252000; which divided by 489 yields 515½; this number being sought in the aforesaid Table under the column of the 500 parts, opposite the number 15 in the side at the left, and by the proportional part computed it exhibits 23°13'53". Therefore Saturn stood apart from Algomeisa [Procyon] by 23°13'53" — unless the parallax should occur to correct these distances somewhat, for the reason that the angle at the center of the Astronomical Radius is greater than the angle made at the bottom of the eye.

No.	Year M. D. H. M.	Dist. of h from the fixed stars [Dist. h à Fixis]	Sine 1	Sine 2

Parsing notes: this is a multi-line table — each numbered row groups two or three fixed-star comparison stars, each with its own pair of Sine values (rendered slash-separated within the cell). The "p.m." here abbreviates *post meridiem* reckoning of the night-hour; "noct." marks a night observation; "mane" marks the

early-morning reading. The table continues beyond this batch (catchword "Nou." / row beginning continues).

Caput II (continued)

Saturn's distance from the fixed stars (Walther's cross-staff observations, continued)

The following table continues Walther's Nuremberg cross-staff observations, each row giving the year and date, the comparison fixed star(s) from which Saturn's distance was measured, and the two Sine values (Sine 1, Sine 2) used in the reduction.

No.	Year — date — hour — min.	Saturn's distance from the fixed stars	Sine 1	Sine 2
17	1475 Nov. 12, 1 ^h 30' p.m.n., morning	Sixth of Leo	210	708
		Eighth of Leo	210	798
18	Nov. 19, 4 ^h before noon, morning	Fourth of Leo	170	901
		Sixth of Leo	210	695
		Eighth of Leo	210	784
19	Dec. 1, 3 ^h before noon, morning	Fourth of Leo	170	887
		Sixth of Leo	210	692
		Eighth of Leo	210	779½
20	Dec. 29, 3 ^h	Fourth of	180	869

No.	Year — date — hour — min.	Saturn's distance from the fixed stars	Sine 1	Sine 2
	0' p.m.n., morning	Leo

		first of Virgo		
32	1482 Jan. 19, 3 ^h before sunrise, carefully	Spica Virginis	90	512
		Twenty- first of Virgo	110	520

Parsing notes: the comparison-star column abbreviates each star by its numbered position within a constellation (e.g. "Sixth of Leo," "Eighth of Leo") with the Latin sign-glyph; "Quinta Cancri," "Cap. seq. Gemin.," "Septima Virg.," "Vigesima prima," etc. The two right-hand columns are headed *Sinus 1.* and *Sinus 2.* I have rendered fractional values ($\frac{1}{2}$) as printed. Row 21's "Cap. seq. IL" is partly abbreviated; the sign-glyph here appears to be Gemini ("Cap. seq. Gemin." as in row 22), read as the "following head[-star] of Gemini" [?].

33. The third class contains observations made through the zodiacal armillaries, that is, observations verified or corrected against Aldebaran, the Heart of Leo, or other stars; but in these the certainty extends only to within about 10 minutes — for Walther says, under the year 1503: "*On September 16, ten minutes are to be added on account of the motion of Aldebaran with respect to all the stars observed by me; likewise on October 13 and December 12.*" And on December 11 he says: "*I observed these things again with delay and with the utmost diligence. Yet I see that, when the instrument is taken with precision, one is not off by more than 10 minutes, or thereabouts.*" Again, under the year 1504, on January 16, he has this: "*Item: I have corrected once more the motions of Jupiter and Saturn, adding 10 minutes on account of the variation of Aldebaran's place from September 1 of the year 1503; this was done through the position of the Heart of Leo, and is wanting in the preceding observations.*" Nevertheless I have selected not a few of these, just as they stand in Walther.

[A second table: Saturn's mean and apparent longitude and latitude]

This table records the year, month, and day; the *Mediab. Casu* [the mean motion / mean place — *medium caelum* or mean reckoning, with degrees and sign]; Saturn's longitude (sign, degrees, minutes); and the latitude (degrees, A = austral/southern).

No.	Year — Mo. — Day	Mean place: Gr. — Sign	Saturn Long.: Sig. — G. — ’	Lat.: G. — ’

Parsing notes: column headers read *Ann. M. D.* (year, month, day), *Mediab. Casu* with sub-columns *Gr.* and *Sign.*, *Saturn. Longit.* with sub-columns *Sig. / G. / ’*, and *Latitudo* with sub-columns *G. / ’*. The longitude sign-glyph in the upper rows is Cancer (☐); I have carried it where legible and left it blank where the cell repeats

the glyph above. The latitude letters "A" (austral/southern) and "B" (boreal/northern) are transcribed as printed. Several day-entries are prefixed *mane* (morning), *noct. seq.* (the following night), or *n. s.* (= *nocte sequenti*); I have rendered these in the day column. Row 64's longitude degree "19½" and row 46's split entry are as printed.

CAPUT III

Saturn observations of Copernicus, Pitati, Ristori, and Lansberg, from the year 1514 to 1563

The reader is forewarned, from Rheticus's preface to the Ephemerides of the year 1551, that Copernicus had abundant Saturn observations of his own, and that in his computations he did not stray from the truth by more than 10 minutes. Moreover, he made no mention of refractions, and — as Tycho Brahe attests in Book 1, Chapter 5 of his *Progymnasmata* — he established the altitude of the pole at Frauenburg as fully three minutes too large. Hence the certainty in the following observations is no greater than these limits.

1. In the year 1514, on the sixth before the Kalends of May [April 26], at the 5th hour after midnight, Copernicus saw Saturn in a straight line with the second star of the front of Scorpio — that is, at an elongation of 209° from the first star of Aries. So he himself, in his Book 5, Chapter 9.

2. In the same year, on the third before the Nones of May [May 5], at the 1st hour 12' before midnight, Copernicus observed an opposition of Saturn made with the mean place of the Sun — that is, with Saturn simple [i.e. with the Sun at its mean place and Saturn] in [the following column on the next page]...

at degree 205° 24' from the first star of Aries. So Copernicus, Book 5, Chapter 6.

3. In the year 1520, on the third before the Ides of July [July 13], from an observation of Copernicus of the opposition of Saturn with the mean place of the Sun on that same day, at midday at Frauenburg (or Cracow), Saturn was found to occupy the 272nd degree 15' from the first star of Aries. So he himself, Book 5, Chapter 6.

4. In the year 1524, in the same month of February, Saturn, Jupiter, and Mars were found nearly conjoined in Pisces, 10°, concerning which Kepler writes in his book on the new star, Chapter 29.

5. In the year 1527, on the sixth before the Ides of October [October 10], at the 6th hour 24' after midnight, an opposition of Saturn with the mean place of the Sun

was made (Copernicus observing), with Saturn elongated 7 minutes from the horn of Aries. So Copernicus, Book 5, Chapter 6.

6. In the year 1536, Peter Pitati, from his observation, judged Saturn to have been in conjunction with Mars on May 22; but Julian Ristori of Prato, a Carmelite, Doctor of Sacred Theology and an excellent mathematician, the teacher of Junctinus [Giovanni Battista Junctinus / Giuntini], saw Saturn at about the 19th hour of March 19, at the 2nd hour of night, nearly hidden by Mars — so that the conjunction of these took place, as Junctinus reports in the preface to his *Tables*. And yet Stöffler, in his *Ephemerides* and in the Alphonsine Tables, had assigned that conjunction to May 25, with the planets in part conjoined.

7. In the year 1542, on the 5th before the Kalends of January [January 9 — *recte* the date as printed], at the 9th hour, the following night, a conjunction of Saturn and Mars in Pisces was observed by the aforesaid Ristori, as Junctinus reports above.

8. In the year 1563, on the 9th before the Kalends of September [August 24], at the 14th hour 30' after midday, at Orange, Junctinus observed a conjunction of Saturn and Jupiter — Jupiter being the more northern, as if cooperating — with Saturn the more southern, in Leo at degree 28°, as he himself relates in the preface to his *Tables*; and yet the Alphonsines had deferred this conjunction to September 25, in Leo, degree 4° 12'.

CAPUT IV

Tychonic observations of Saturn, in which the days are noted according to the Old Style of the calendar

1. In the year 1582, on August 21, at the 2nd hour after midnight at Uraniborg, there was an opposition of Saturn with the true place of the Sun in Pisces, 6°; but by Tycho's observation, at 7° 22½'. So Longomontanus in his *Astronomia Danica*, Book 2, Theoricae, Chapter 2.

2. In the year 1583, on September 3, the 1st hour, there was a true opposition of Saturn with the Sun in Pisces, 19° 50', by observation. But by Tycho's calculation, the Danish [Tables] give 19° 48'. So Longomontanus, above.

3. In the year 1584, on September 15, the 6th hour 30', there was a true [opposition] of Saturn with the Sun in Aries, 2° 34', by observation; but the Danish Tables [give] 2° 15'. So Longomontanus, above, from Tychonic observation.

4. In the year 1585, on September 28, the 1st hour 30', there was a true opposition of Saturn with the Sun in Aries, $15^{\circ} 39\frac{1}{2}'$, observing (Tycho); but by the Danish Tables, $15^{\circ} 39' 15''$. So Longomontanus, above.

5. In the year 1586, on October 12, the 11th hour, there was a true opposition of the Sun with Saturn in Aries, $29^{\circ} 2'$, Tycho observing; but by the Danish Tables at $29^{\circ} 4'$. So Longomontanus, above.

6. In the year 1586 [*recte* 1587 — see context], on January 19, at the 9th hour 45' after midday, an opposition was observed at Uraniborg of Saturn in Aries $26^{\circ} 8'$, with southern latitude $2^{\circ} 23'$; yet by Alphonsine reckoning that place falls at $18^{\circ} 8'$, with latitude $2^{\circ} 30'$. But Copernicus [gives] that place at $25^{\circ} 58'$, with latitude $2^{\circ} 32'$. Bullialdus uses this observation, in his Book 6, for the investigation of Saturn's apogee and the inclination of the orb and the places of Saturn's nodes. See the Epistle of Tycho, page 56.

7. In the same year, on January 14, the 5th hour 50' after midday, Tycho observed Saturn in Aries $26^{\circ} 21'$, with southern latitude $2^{\circ} 26'$. The Alphonsine [place] for it was $28^{\circ} 21\frac{1}{2}'$; but Copernicus [gives] it at $26^{\circ} 12'$ — and these [latitudes] at $2^{\circ} 30'$. So Tycho, where above.

8. In the same year, in the same month, on the 15th, at the 5th hour 45' after midday, Tycho observed Saturn in Aries $28^{\circ} 24'$, with southern latitude $2^{\circ} 25'$. The Alphonsine [place] was $28^{\circ} 24'$; but by Copernicus $27^{\circ} 36'$. So Longomontanus, longitude $26^{\circ} 15'$, with latitude $2^{\circ} 26'$.

9. Likewise in the year 1587, on October 26, the 9th hour after midday, there was a true opposition of the Sun with Saturn in Taurus $12^{\circ} 46'$, by Tycho's observation, than which Tycho's Tables [give $26^{\circ} 44'$ — read $12^{\circ} 44'$ as printed]. By which occasion is to be noted [a discrepancy], as Longomontanus says in Book 2, *Theoricae*, Chapter 1. The Danish Tables [were] taken in the *Thesaurus* of observations from the Tychonic Tables, gathering longitude $26^{\circ} 23'$ [?], with latitude $2^{\circ} 26'$. Likewise in the year 1587, on October 26, the 9th hour after midday, there was a true opposition of the Sun with Saturn in Taurus $12^{\circ} 46'$, by Tycho's observation. The Danish Tables were taken corrected, [yielding for] the longitude the mean of Saturn, 10 minutes, subtracted from the apogee; for it is to be added to Saturn's apogee at 3° , but to be subtracted at the eccentric's longitude, everywhere; one part adds, the other subtracts. [The compositor has duplicated this entry's opening; rendered as printed.]

10. In the year 1588, on November 8, the 10th hour 10' — there was a true opposition of the Sun with Saturn in Taurus 26° 44', Tycho observing; but by the Danish [Tables] at 26° 44'. So Longomontanus, above.
11. In the year 1589, on November 22, the 14th hour 30', there was a true opposition of the Sun with Saturn in Gemini 10° 53', Tycho observing; but by the Danish [Tables] at 10° 53'. So Longomontanus, above.
12. In the year 1590, on February 8, the 8th hour, in the evening, Tycho observed at Uraniborg Saturn in Gemini 7° 32'; but the autumn one [the opposition] at about an hour in degree 7° 38'. Longomontanus, Book 2, Theoricae, Chapter 5; and Bullialdus, Book 6, *Astronomia*, Chapter 2, & 3.
13. In the year 1590, on September 7, the 12th hour, Tycho observed Saturn in Gemini 28° 8', with southern latitude 1° 11'. So Bullialdus, Book 6, *Astronomia*, Chapter 2, & 3.
14. In the same year, on December 6, the 10th hour 20½' at midnight, there was a true opposition of the Sun with Saturn existing in Gemini 25° 10', as observed by Tycho. But by the Danish [Tables] at 25° 8¾'; so the Danish Tables. So Longomontanus, Book 2, Theoricae, Chapter 1.
15. In the year 1591, on March 17, the 7th hour 30½', in the evening, Saturn was observed at Uraniborg in Gemini 22° 24½'. Longomontanus, above, Chapter 3.
16. Again in the year 1591, on December 1, the 6th hour at midnight, there was a true opposition of the Sun with Saturn placed in Gemini 9° 24½', as Tycho observed. But by the Danish [Tables] at 9° 23½'; so the Danish Tables. Longomontanus, above, Chapter 2.
17. In the year 1595, on January 30, the 21st hour after midnight, there was a true opposition of the Sun with Saturn placed in Leo 21° 15½', by Tychonic observation. But by the Danish [Tables] at 21° 18½'; so the Danish Tables. So Longomontanus, above.
18. In the year 1600, on January 13, the 7th hour 30' after midnight, Tycho, at the citadel of Benátky near Prague, observed Saturn standing at distance from Venus at degree 5° 25'; but it was then with Saturn approaching the station, observing its meridian altitude at degree 18° 7', and its distance from Spica at degree 11° 12' 1"; and at a distance from the northern Lance [northern Pan of Libra] at degree 30° 41½'; thence Tycho concluded Saturn to have been on the preceding day, in Gemini, at degree 28° 18' 44", with northern latitude 2° 43'. But on the 3rd day,

just before [it stood] in Gemini at degree $28^{\circ} 30' 44''$, with northern latitude at degree $2^{\circ} 34'$. So Snellius in his Tychonic observations.

19. In the year 1600, on April 2, the 12th hour 21' after midnight, Tycho — in the citadel of Prague — observed Saturn's meridian altitude at degree $32^{\circ} 28' \frac{3}{4}$, and at the 12th hour 43', the distance of the same standing from the northern Lance at degree $19^{\circ} 14\frac{1}{2}'$. So Snellius, above.

20. In the same year, on April 9, the 11th hour $37\frac{1}{2}'$, Tycho there observed Saturn distant from Spica at degree $8^{\circ} 9\frac{1}{3}'$, & at the 11th hour 46', distant from the northern Lance at degree $19^{\circ} 45'$, & at the 12th hour the altitude of its meridian at degree $32^{\circ} 40'$.

21. In the year 1601, on July 6, the 9th hour 39' after midday, Tycho there observed Saturn distant from Arcturus at degree $32^{\circ} 1'$; & from the northern Lance at degree $11^{\circ} 42\frac{1}{2}'$. Hence the place of Saturn in Scorpio [is] at degree $3^{\circ} 50\frac{1}{2}'$; and its boreal latitude at degree $2^{\circ} 0\frac{1}{2}'$. But by our calculation (says Tycho, with Snellius above), it gives the longitude at degree $3^{\circ} 43' 23''$, & latitude at degree $3^{\circ} 19' 26''$. If anyone desires the reduction of the aforesaid observations made according to the Gregorian-calendar style, let him add 10 days to them, those after the year 1582.

The remaining observations of Tycho, or of Longomontanus, which we shall append below in Caput XI [of the] Catalogue, we have for the most part taken from page 56 of Tycho's Epistles....likewise from Longomontanus's *Astronomia Danica*, Book 2, Theoricae, Chapters 2, 12, & 13; and partly from a manuscript of Tycho's observations supplied by Father Albert Curtius of the Society of Jesus, which (since Caesar [the Emperor] had been put in charge of the edition of the Tychonic observations) he had most liberally transcribed, and which he most generously shared with me. From these I have selected only certain few, for the purpose of testing the agreement, or disagreement, of the Astronomical Tables.

CAPUT V

Saturn observations of Justus Byrgius [Jost Bürgi], from the Hessian observations of Snellius; and also of Lansberg, Hortensius, Gassendi, and Bullialdus, from the year 1592 to 1640

Bürgi observes Saturn at Cassel, according to the days of the Old Style

No.	Year	Month	Day	Hour, min., before or after noon	Saturn' s distanc e from the fixed stars: Gr. — Min.	(from which star)
1	1592	Octob.	14	4 before noon	27 — 23	from Regulus
					52 — 57	from Aldebar an
2	1593	Januar.	3	6: 30 after noon	48 — 46	from Pollux [cap. Pollucis = the head of Pollux]
					34 — 12	from the right shoulde r of Orion
3	1594	Januar.	2	8 after noon	21 — 52	from Pollux [head

No.	Year	Month	Day	Hour, min., before or after noon	Saturn's distanc e from the fixed stars: Gr. — Min.	(from which star)
						of Pollux]
					24 — 49½	from Sirius
4	1595	Novem b.	24	0	13 — 46	from Regulus
	[Here Bulliald us, Book 6, Chapter 2, line 1]			5 before noon	6 — 7	from the back of Leo ☐
				elicits the place of Saturn	9 — 57½	in Virgo ☐
5	1596	Maij	5	9 after noon	9 — 7	from Regulus
	[Here Bulliald us, above]			post merid.	13 — 8	from the back of Leo ☐
				elicits the place of Saturn	1 — 29	in Virgo ☐
6	1596	Maij	7	9 after	10 — 10	from

No.	Year	Month	Day	Hour, min., before or after noon	Saturn' s distanc e from the fixed stars: Gr. — Min.	(from which star)
				noon		the neck of Leo ☐
				post merid.	17 — 52	from the tail of Leo ☐
7	1597	Martij	27	8 after noon	11 — 35½	from Regulus
				post merid.	10 — 2½	from the tail of Leo ☐
8	1595	Februa rij	18	8 after noon	8 — 24	from the mane of Leo ☐ [this ought to be set under the year 1594]
				post mer.	4 — 32	from Regulus

Parsing notes: column headers read *Ann., Mens., Dies, Hor. Min. ant. vel post merid., Distantia Saturni à Fixis* (with sub-columns *Gr.* and *Min.*). The comparison-star is given in the rightmost cell of each distance-row (Regulus, Aldebaran, head

of Pollux, right shoulder of Orion, Sirius, back/neck/tail/mane of Leo, etc.). Rows 4 and 5 carry interpolated Bullialdus citations ("Hinc Bulliald. l.6.c.2.1 elicet loc. h ...") indicating where Bullialdus derives Saturn's place; I have set these as bracketed sub-rows. The note at row 8 — "*debut poni sub anno 1594*" ("this ought to be placed under the year 1594") — is transcribed as printed.

9. In the year 1593, on January 4, Old Style, at the 9th hour after midnight, Lansberg at Goes observed Saturn in Cancer at degree $23^{\circ} 12'$, with southern latitude degree $0^{\circ} 2'$. So he himself in the *Thesaurus* of observations, adding from his Tables the collected longitude at degree $23^{\circ} 12' 28''\frac{3}{4}$, and the latitude at 2 minutes.

10. In the year 1628, on June 23, Old Style, about the middle of the night, Saturn was seen at Gendt [Ghent] by Martin Hortensius conjoined with [a star], so far as the star permits. The star, which is somewhat to the south of the shoulder of Virgo, but Saturn was more southern by 25 scruples [minutes]. So Lansberg in his *Thesaurus*: he observes, adding that star to have been in Libra at degree $5^{\circ} 4'\frac{3}{4}$, with northern latitude at degree $2^{\circ} 50'$; but by his Tables he computes Libra at degree $5^{\circ} 3' 47''$, with latitude at degree $2^{\circ} 25'$.

11. In the year 1632, on July 19, Old Style, after midnight, Martin Hortensius saw Saturn more to the west, [farther] from the Moon than the diameter of the Moon a little more — for before, the Moon had hidden Saturn. So Lansberg, above.

12. In the year 1633, on May 28, New Style, Peter Gassendi, at Aix-en-Provence [Aquis Sextiis], judged the opposition of Saturn made with the Sun to have occurred; for on the 27th, in the evening, about the 8th hour, by means of the [cross-]staff [ope Radii], he observed Saturn distant from the middle of the front of Scorpio at degree $10^{\circ} 11\frac{1}{2}'$, & from Antares at degree $6^{\circ} 50'$; but on the 30th, in the evening, at the 9th hour, he saw the same distant from the middle of the front of Scorpio at degree $9^{\circ} 59'$, & from Antares indeed at degree $6^{\circ} 43'$. So he himself, in observations sent to Mr. Dominic Cassini, the public Professor of Astronomy at Bologna.

13. In the year 1634, Gassendi established the opposition of Saturn with the Sun on the 9th day of July. For on the 8th day, observing Saturn by the [cross-]staff, he found it distant from the left shoulder of Sagittarius at degree $19^{\circ} 33'$, & from the right thigh of Ophiuchus at degree $7^{\circ} 56'$; but on the 10th, in the evening, about the 9th hour, he saw it distant from Antares at degree $14^{\circ} 46\frac{1}{2}'$, & from the highest of the front of Scorpio at degree $20^{\circ} 2'$. So in observations sent to Cassini.

14. In the year 1635, Gassendi adjudged the opposition of Saturn with the Sun to the 21st day of June; for indeed on the 19th, in the evening, observing it himself through the [cross-]staff, Saturn was distant from the Eagle [Aquila] at degree $38^{\circ} 12\frac{3}{4}'$, & from the highest of the front of Scorpio at degree $31^{\circ} 31'$. On the 22nd day, a little after midday, he found that the tail of Leo stood higher at degree 25° [?]; it was distant from the highest of the front of Scorpio at degree $31^{\circ} 25'$. But Aquila's bright [star, Altair] [stood] at degree $28^{\circ} 27'$. Thus far he himself, [in observations sent] to Cassini.

[Margin / displayed note:] *If, among Gassendi's observations — which are now being printed at Lyon — there shall have been other observations pertinent here, and they shall have reached our hands, they are to be added, and here understood [as included].*

15. In the year 1640, on October 12, New Style, at the 8th hour and a few minutes after midday, Bullialdus observed Saturn on the Meridian, distant from a star of the fourth magnitude, which belongs to the loins and haunches of Aquarius, by 26 minutes. But Saturn was more boreal than that one vertically; so Bullialdus, Book 6, *Astronomia*, Chapter 3, subjoining the observation made through an optical tube [telescope], & that star to have been in Aquarius at degree $23^{\circ} 47'$, with southern latitude degree $23^{\circ} 55' 39''$, & latitude austral degree $1^{\circ} 35\frac{3}{4}'$ — so that Saturn was indeed in Aquarius at degree $23^{\circ} 55' 39''$, with southern latitude degree $24^{\circ} 0' 8''$. Hence Saturn's [place], by his own Tables, gives Aquarius at degree $24^{\circ} 0' 8''$, with latitude $1^{\circ} 36\frac{3}{4}'$; but the Rudolphine [Tables give] degree $24^{\circ} 5'$, with latitude degree $1^{\circ} 38'$.

16. In the year 1630, on June 19, Michael Florentius van Langren [Langrenus] of Brussels observing, & at the culmination [of] the degree of the Equator $241^{\circ} 5' 52''$, Saturn began to be hidden by the Moon, & from the moment when it emerged; the foot of Virgo — to which Tycho assigns the longitude Libra at degree $28^{\circ} 57'$, latitude at degree $2^{\circ} 57\frac{1}{2}'$, & likewise at degree 22° . That star of Virgo lay hidden under the dark boreal part of the Moon; the culminating degree of the Equator [being] $253^{\circ} 42'$.

CAPUT VI.

Observations of Saturn made near the perigee of the eccentric, in Majorca, by Don Vincenzo Mut [Vincenzio Muto], a man most skilled in astronomy; recorded on days of the New Style, all of them around the ninth hour after midday, and most generously communicated to us by letter — together with the place of Saturn as derived both from observation and from a fivefold calculation.

The following table gives, for each observation, the date, Saturn's distance from the fixed stars, the observed place of Saturn, and the differences of five sets of tables (Prutenic, Danish, Rudolphine, Lansberge's, and Boulliau's) from that observed place.

latitude. 046

Parsing notes: Row 1's distance description reads *à praecedenti summum pedem* □ ("from the preceding [star] to the topmost foot of Gemini"). Row 10 has two distance components (from Propus, 0°36', latitude 0°49'; and from the heel of following Gemini, 3°2'), with the table-differences attached to the second; transcribed across two sub-lines. Row 11 gives the distance from the preceding [star] in the foot of Gemini (0°7') with latitude 0°46'.

Continuation of the table (a separate panel below, for the year 1654, using a different set of comparison tables — Danish, Rudolphine, Lansberge, Almagest [i.e. *Almagestum Novum*], and *Novum* [Riccioli's "New" tables]):

#	Yea r	Mo nth	Da y	Ho ur Mi n. afte r mi dda y		Pla ce of Sat urn obs .	Da nic.	Ru dol.	Lan sb.	Al ma g.	No v.
				Sig.	G. M.

				lati tud e		1 28					
13		Feb rua r.	15	9 0	□	20 31	20 57	20 50	20 46	20 45	

Parsing notes: In the lower panel the column headers shift to *Danic. / Rodul. / Lansb. / Almag. / Nou.* with units "G. '" (degrees, minutes). Row 12's second sub-line gives the observed latitude (1°28'). The rightmost "Nov." column appears blank in both data rows.

The observations of this year 1654 were made with Saturn very nearly at acronychal rising [acronychal].

Earlier, in the year 1651, on the fifth day of June at the eighth hour, [Mut] had observed Saturn at the same latitude as a star which lies in the belly of the southern twin of Gemini, but more easterly by 5'; from which he concluded that on the fourth day of June there had been a partial conjunction of the two.

[15] The same [observer], in the year 1643 on September 23, had observed Saturn's meridian altitude to be $53^{\circ}38'$, Saturn then standing in a straight line with the Head of Algol [Cap. Algol] and the more northerly star following in the Horn of Aries.

[16] The same, in the year 1644 on September 30 at the ninth hour, observed Saturn more westerly by 5' than the star preceding [it] after the bend of the Three Fishes, and more northerly by $30''$.

CAPUT VII.

Observations: 2 of Tycho [Brahe], and 4 of the Fathers of the Society of Jesus at Oeniponte [Innsbruck], and 22 of the Marquis Cornelio Malvasia [Cornelio Malvasia], made at Modena [Mutina].

In the year 1582, on August 21 at hour 10, minute 2, Saturn was distant from the left shoulder of Aquarius $22^{\circ}29'$ — but at hour 10, minute 39, it was distant from the right shoulder of Aquarius $16^{\circ}5'$. At hour 11, minute $57\frac{1}{2}$ — or corrected, hour 12, minute $1\frac{1}{2}$ — it had a meridian altitude of $23^{\circ}23'$.

In the same year, on August 23 at hour 9, minute 57, Saturn was distant from the lower Horn [of Capricorn] $70^{\circ}39'36\frac{2}{3}''$; and at hour 10, minute $5\frac{1}{3}'$, [it was distant] from the left shoulder of Aquarius $22^{\circ}20'$.

Observations made at Oeniponte [Innsbruck] by members of our Society, and transmitted to me by Father Michael Staudacher of the Society of Jesus.

In the year 1636, on July 10, with Arcturus at an altitude of $39^{\circ}14'$ toward the west and Saturn at $18^{\circ}40'$ toward the east, Saturn itself was observed to be distant from the Head of Ophiuchus $41^{\circ}17\frac{1}{2}'$, and from the bright star of Aquila $32^{\circ}46\frac{3}{4}'$.

On the 13th of July, with Arcturus at an altitude of $44^{\circ}25'$ toward the west and Saturn at $16^{\circ}50'$ toward the east, Saturn was seen to be distant from the bright star of Aquila $32^{\circ}53\frac{1}{2}'$, and from the Heart of Scorpio $35^{\circ}39'$.

On the 23rd of July, with Aquila at an altitude of $17^{\circ}12'$ toward the east, Saturn was distant from the Head of Ophiuchus $40^{\circ}54\frac{4}{5}'$, and from the bright star of Aquila $33^{\circ}10'50''$.

Finally, on the 25th of July, with Aquila at an altitude of $34^{\circ}30'$ toward the east and Saturn at $18^{\circ}18'$, Saturn was observed to be distant from the Head of Ophiuchus $40^{\circ}51'50''$, and from the bright star of Aquila $33^{\circ}18'30''$.

Observations of the most illustrious Marquis Cornelio Malvasia, made at Modena.

These observations are extant in the *Ephemerides* of the same Marquis Cornelio, published at Modena in the year 1662, and most generously presented to me by the author himself, at fol. 187, where he states that he had observed for himself the altitude of the pole at Modena to be $44^{\circ}38'$ by the Pole Star — whereas when we observed it, we found it to be $44^{\circ}38'50''$ — and he supposes the longitude of Modena to be $34^{\circ}5'$, namely the one nearest to that which we determined in the *Geographia Reformata*, where we put it at $34^{\circ}6'30''$, as we have set down.

In the year 1662, the said Marquis, on May 30, around the second hour of [after?] noon, using a wooden sextant of six feet exhibiting individual minutes, and assisted by Don Geminiano Montanari [Geminiano Montanari], doctor of laws and a most skilled astronomer, observed Saturn to be distant from Spica $42^{\circ}17'$, and from the Heart of Scorpio $27^{\circ}46'$ — Saturn's altitude above the horizon being then $11^{\circ}57\frac{1}{2}'$. Antares [stood at] 10° , Spica at 35° , by which, ordered from Cassini's Table of Refractions (extant in the same volume, fol. 173), he found Saturn's refraction to be $3\frac{1}{2}'$, [that of] Antares $5^{\circ}42'$, [that of] Spica $1^{\circ}25'$. And whence proceed the corrected distances — of Saturn from Antares, $7^{\circ}43'$; and from Spica, $42^{\circ}16'45''$ — or in round numbers, just as before, $42^{\circ}17'$. Hence, taking the latitudes assumed from Tycho [Brahe] of Antares $4^{\circ}27'$ and of Spica $1^{\circ}59'$, and the difference of longitude of Spica in \square $19^{\circ}8'12''$, they collected by trigonometry the longitude of Saturn in \square $1^{\circ}13'8''$ and the northern latitude $2^{\circ}14'6''$. With Lansberge's calculation giving it as $4^{\circ}22'29''$, and this [Riccioli's?] as $2^{\circ}16'$.

By this method, both of observing and of calculating, he collects from the evening observations the longitudes, latitudes, and excesses written below, of Lansberge's Tables ascribed to them — using, however, the distances of Saturn from Spica, or from Antares, or from Arcturus.

Parsing notes: This is a single longitude/latitude/excess table for Saturn through June–July 1662 (the left column-block of the page continues into the right column-block, which I have merged here in date order). The "Lüsberg." column = Lansberge's Tables. The dotted Saturn symbol (♄) heads the "Observed" and "Lüsberg." sub-columns. The June rows run 3–16, then jump to 23, 24, 30; "Jul. D." begins July 1. Some seconds-columns are blank as printed. Row 14 in June is given (no row 13 printed in this block).

Moreover, on the 3rd day of July, from Saturn's distance from Spica and from the northern Pan [of Libra] — or from the middle of the neck of Ophiuchus, corrected, and deduced from the Tyconic stars — the same Marquis derived Saturn's longitude in Scorpio as $29^{\circ}9'8\frac{3}{4}'$ and its northern latitude as $2^{\circ}7'46'$; for since by means of the optical tube [telescope] the silvery grate [reticule?] with which Saturn is described in the same volume, fol. 196, was seen together with a small star — a certain fixed star distant from Saturn's eastern limb by an imperceptible interval, and therefore Saturn's apparent semidiameter neglected — he established that the same place is that of the fixed star, and so that of Saturn. And by the distances of the following days he could define Saturn's place as more certain from that same prominent fixed star. Hence, on the 4th day in the evening Saturn was found distant from that fixed star $1^{\circ}35'$, as much as the whole tube would take in, $41\frac{1}{2}'$; and so [Saturn was] in Scorpio $29^{\circ}6'30''$. Therefore by a similar method he will exhibit to us Saturn's longitudes and latitudes written below, but [these are] selected by me [i.e. Riccioli].

Parsing notes: Second longitude/latitude/excess table, for July–August 1662, headed "Day July ʰ". The "Excess." column shows the (growing) discrepancy of Lansberge's tables from observation.

This is a sample of the said observations, from which it is clear that Lansberge's tables at this time exceed the true place of Saturn by about 15 minutes; for we can establish here nothing more exact concerning the excess, the more so because the Illustrious Marquis Cornelio used the Tyconic stars, which require some small correction — as we showed in Book 4, [drawing] on Cassini's Refractions, about which we nevertheless raised some doubt, as indicated in Book 1, Chapter 1, [section] number 9.

But in the year 1663, the same most illustrious Marquis Pansano [Pansano?], from many days of observation and from distances taken with a very large sextant, with Saturn and Jupiter referred to the fixed stars, concludes that there was a Great Conjunction of Saturn, Jupiter, and Mars on October 16, at hour 7, minute 34, after midday, in Sagittarius $13^{\circ}2'46''$, and at northern latitude of Saturn $1^{\circ}16'$. We, however, [observed] it around that same time at 8 p.m. of the same day in $13^{\circ}3'$ [of Sagittarius]. ♃ at $6^{\circ}16'$. [Saturn ʰ and Jupiter ♃ then both in Sagittarius, at nearly the same latitude.]

CAPUT VIII.

Selected observations of Saturn, out of many, which Fathers Giovanni Battista Riccioli [Riccioli] and Francesco Maria Grimaldi [Grimaldi] carried out at Bologna in the College of St. Lucia, together with others helping from time to time, where there was need, fellow members of the Society of Jesus.

[1] In the year 1641, on the night following the 20th day of August, at the hour acquired from the fixed stars after midday $13^{\circ}59'$, Saturn's altitude above the western horizon was observed to be $13^{\circ}23'$.

[2] In the same year, on the 31st of August, the night following, at the hour after midnight $3^{\circ}25'37''$, Saturn's acronychal [acronychal] altitude above the horizon was seen to be $19^{\circ}35'$.

[3] In the same year, on October 14, the night following, [there was] a transit through the middle of the Heavens of Markab Pegasi [Markab of Pegasus], with Saturn numbered at perpendicular minute $8^{\circ}45'$; the meridian crossing [M.C.] of Saturn [followed], whose altitude was then seen to be $31^{\circ}6'$. It was estimated to be at hour after midday $10^{\circ}50'$, but the meridian [reading?] was incorrect.

[4] On the same day, of the same month, the night following, [there was] a transit of the star Fomahant [Fomalhaut], with Saturn's transit numbered; the lesser time was 4', [and] Saturn's meridian altitude was seen to be $34^{\circ}50'$.

[5] In the year 1642, on June 6, in the morning, with the altitude of the western bright star of Aquila toward the west $51^{\circ}15'$, the minutes of time being numbered up to Saturn's altitude of $25^{\circ}52'$ & $8'55''$; and on the 7th of June, in the morning, about one hour before sunrise, with the altitude of the bright star of Aquila toward the west obtained $52^{\circ}40'$, the minutes of time being numbered $3'22''$, by means of a perpendicular, immediately afterward Saturn's western altitude was captured at $22^{\circ}32'$.

[6] On June 16, 1642, in the morning, from the transit of Fomalhaut by the M.C. [meridian crossing], with Saturn's transit numbered along with it, the minutes were $6^{\circ}40'$ — after which Saturn's meridian altitude was observed to be $41^{\circ}57'$.

[7] In the same year, on September 13, the night following, Saturn's acronychal meridian altitude was seen to be $39^{\circ}59'$; after which, with Saturn's transit numbered, the perpendicular [reading] being $13'$ & for the seconds $45''$, the altitude of the bright star in the tail of Cetus was captured at $24^{\circ}56'$; and thence,

from the transit of the same star by the M.C. numbered, [the perpendicular reading was] 18'35".

[8] In the same year, on September 28, around the 3rd hour 5' of the night following, Saturn's distance from the bright star of Aries was captured by sextant at 19°34'30"; and the southerly Jaw [Mandibula] of Cetus, which is of the second magnitude, [was] at 43°46'.

[9] In the same year, on October 24, around the 2nd hour of the night, Saturn was seen to be distant from Fomalhaut 26°51'; and from the bright star in the tail of Cetus 20°2'; and likewise from Jupiter 10°31'.

[11] In the year 1643, on January 20, the night following, Saturn's altitude was seen [to be] from the west 31°23'; and its azimuth 39°40'; thence, the minutes having elapsed 4'40", the rising altitude of Aldebaran [was] 38°50'.

[12] In the year 1643, on June 28, in the morning, the western altitude of the bright star of Aquila was 46°2'; thence, the minutes of time being numbered, Saturn was nearest [to it]; Saturn's distance from the southern foot of Andromeda by sextant [was] 42°54'; thereafter, 4 minutes of time having elapsed, [Saturn] was distant from the bright star of Aries 28°1'30" — most exact.

[13] In the same year, on July 15, in the morning, the bright star's eastern altitude was 46°50'; the minutes having elapsed 32', Saturn's distance from the bright star of Aries by sextant was 27°43', & after 4 minutes of time it was distant from Aldebaran 35°7'; thence, 4 minutes of time having elapsed previously, & after another 4 minutes of time, it was distant from Jupiter, more easterly, by 15°50'.

[14] In the same year, on July 26, in the morning, with the altitude of the bright star of Aries captured at 59°10', perpendicular minute 6 having been numbered; afterward, Saturn's distance from the Sextans [Sextant constellation?] was captured at 27°43' from the same [star], thence after another 6 minutes of time it was seen distant from Aldebaran 56°58½'.

[15] In the same year, on July 30, in the morning, the rising altitude of the bright star of Aries having been taken at 58°27', & being distant 4 minutes [of time], Saturn was distant from the bright star of Aries 27°50'; & after 10 minutes of time it was distant from Aldebaran 57°2'; there was also then Saturn Retrograde, & nearest to the [quartile?] of the Sun.

[16] In the same year, on August 31, in the morning, with Aldebaran shining in the East at vertex 24°10'; after which, 10 minutes having been numbered, Saturn was distant from the same [star] 58°25'; thence after 2 minutes of time it was

distant from the Jaw of Cetus, the bright [star], $40^{\circ}2'$; but this was not verified, [being] therefore suspect; from which the sole [reliable] distance remained that of Aldebaran from Saturn in Aries $6^{\circ}12'$, [taken] nearest.

[17] In the year 1643, on September 27, the night following, Saturn was transiting by the M.C.; of which, the meridian altitude captured by double quadrant on both sides [was] $44^{\circ}48'$: of its rising altitude, however, the minutes being numbered $13^{\circ}47'$, there was observed the rising altitude of the bright star of Aries $62^{\circ}24'$.

[18] Item, in the year 1643, on December 22, under the second hour of the night following the fourth from sunset, [with] Saturn quartile to the Sun, [Saturn] near the head of Andromeda $29^{\circ}15'$, & [near] Markab Pegasi $25^{\circ}15'$.

[19] In the year 1644, on June 11, with the bright head of Aries' altitude seen at $20^{\circ}30'$, we obtain Saturn; but on the 13th [June], Saturn's distance seen from the bright star of Aries by sextant [was] $18^{\circ}53\frac{1}{2}'$; thence after 8 minutes of time Saturn's distance from the bright star of the belt of Andromeda was $29^{\circ}6\frac{1}{4}'$; and it was nearly Italic — & the refraction of the bright star [equal to that] of Aries, since Saturn was nearest to it; and so the distance scarcely needs correction.

[20] In the same year, and the same month, on the 9th day, there was observed Saturn's distance from the bright star of Aries $18^{\circ}54'$; & after 7 minutes of time-observed [there was] Saturn's distance from the bright foot of Andromeda $36^{\circ}9'$.

[21] In the year 1644, on July 11, the night following, at the Italic hour nearly sixth & a half, or with the bright star of Aquila toward the west at $60^{\circ}40'$, we observed Saturn distant from the bright star of Aries $17^{\circ}24\frac{1}{3}'$; & after 9 minutes [of time] it was distant from the bright foot of Andromeda $35^{\circ}13'$. The Sun itself at the rising of Andromeda's bright star was distant from the bright star of Aries $18^{\circ}48\frac{1}{3}'$; as often [as] observed at other times.

[22] In the same year, on the 22nd of July, in the morning at the civil hour 8, Saturn was seen distant from the bright star of Aries $17^{\circ}15'$; & [from] Aldebara [Aldebaran] $43^{\circ}56\frac{1}{3}'$.

[23] In the year 1644, on August 1, in the morning, with the bright star of Aries distant from the vertex $33^{\circ}15'$; prepared beforehand, the minutes [being] 2, Saturn was distant from Aldebaran $11^{\circ}1'$ — who [i.e. which observation] by another instrument's half-hour before was distant from Capella $60^{\circ}15'$.

[24] In the year 1644, on August 13, in the morning, in the most serene [sky], with Aldebara [Aldebaran] distant from the East toward the vertex $44^{\circ}53'$; Saturn was seen distant from Aldebara $44^{\circ}44'$; thence, distant Aldebara from the vertex

43°36'; Saturn distant from Aldebara 17°18' — hence soft, minimal distance from the preceding shoulder of Orion 56°4': but it was nearest to the quartile of the Sun.

[25] In the year 1644, on October 8, the night following, at the Italic hour 3, Saturn acronychal was likewise distant from the bright star of Aries 17°51', & at the southern foot of Andromeda 36°3'; & it was more westerly than both stars. But on the 9th [day], the Sun's meridian distance from the vertex was 29°8'40"; & on the night following the same day, at the civil hour 3½ Italic, Saturn

Saturn was distant from the bright star of Aries [Lucida Arietis = Hamal] by 19°54', and from the southern foot of Andromeda by 36°6'.

26. In the year 1644, on November 17, in the night following, I observed Saturn rising eastward, distant from the vertex by 63°56'; and 3 minutes farther Saturn was distant by 49°57'; afterward, Saturn was distant from the bright star of Aries [Hamal] by 3 minutes, and was 3 minutes distant from the [southern] foot of Andromeda.

27. In the year 1645, on July 26, in the morning, Saturn was distant from the bright star of Aries [Hamal] by 33°50' when reckoned at that time; 2 minutes after the observation Saturn was observed once, and again 2 minutes later it was distant from Capella by 48°16'½, and after 1 minute it was distant from Aldebaran by 30°59' — at which point it was nearest to its quadrature [□] with the Sun, whose distance from the Sun by the great quadrant was seen to be 25°19', but through the smaller quadrant 25°19'.

28. In the year 1646, on June 1, in the morning, after Saturn's conjunction [♄] with Mars, while the bright star of Aries [Hamal] was distant from the vertex by 61°36', Saturn was distant from Capella by 40°32'; while the bright star of Aries [Hamal] stood distant from the vertex by 62°46', Saturn stood distant from the bright star at Perseus's side [in latere Persei] by 14°31'.

29. In the year 1646, on August 10, with the bright star of Aries [Hamal] distant from the vertex toward the east by 39°40', Saturn was near its quadrature [□] with the Sun; it was distant from Capella by 18° precisely. And when the bright star of Aries [Hamal] stood distant from the vertex by 38°22', Saturn stood distant from Aldebaran by 17°26'; and Saturn itself was then at an altitude of about 31°.

30. In the year 1647, on February 2, in the night following, at the first civic hour 3¾, with the observations being most carefully repeated, Saturn was distant from

the bright star of Aries [Hamal] by $15^{\circ}3\frac{3}{4}$; but at the very minute of the observation it was distant from Aldebaran by $23^{\circ}27\frac{1}{2}$.

31. In the year 1647, on November 16, about the second hour of the morning, half an hour after sunset, Saturn was seen distant from Capella by $30^{\circ}48'$, and from the northern horn of Taurus [a cornu Boreali Tauri] by $10^{\circ}25\frac{1}{2}$, when the altitude of Saturn was $21^{\circ}50'$, and from the northern horn it was distant by $17^{\circ}16'$.

32. In the year 1647, on November 18, in the night following, at nearly the first Italian hour, Saturn, observed acronychal, was distant from Capella by $31^{\circ}7'$, and from the northern horn of Taurus its altitude was $26^{\circ}50'$; at the end of the observation Saturn's altitude was $24^{\circ}45'$, and Aldebaran was distant from the vertex toward the east by $55^{\circ}15'$.

33. In the year 1647, on November 25, in the following night, about the third Italian hour, we saw Saturn distant from Capella by $31^{\circ}17\frac{1}{2}$, and from the southern horn of Taurus [a cornu Austro Tauri] by $21^{\circ}16\frac{1}{2}$. These observations, to which this is subjoined, are 53 & 54, to be set down below.

34. In the year 1648, on December 2, with Saturn drawing near to the perigee of its epicycle [ad Perigeum Epicycli, accederet] and in opposition [\oslash] under the hour of the following night, Saturn was seen distant from Aldebaran toward the vertex by $40^{\circ}57'$. The observations made on that day, as is more often the case, gave Saturn distant from Aldebaran by $7^{\circ}40'$, and from Capella variously as the observations were repeated, by $24^{\circ}52\frac{1}{2}$.

35. In the year 1649, on July 27, in the morning, Saturn was at an altitude of 23° , distant from Capella by $25^{\circ}24\frac{1}{2}$, and from Aldebaran by $20^{\circ}56\frac{1}{2}$.

36. In the same year, on July 31, in the morning, Saturn was seen at an altitude of $27^{\circ}20'$, and then distant from Aldebaran by $21^{\circ}17'$, and from Capella by $25^{\circ}50\frac{1}{2}$.

37. In the year 1651, on that same day, January 1, about the third Italian hour, when Aldebaran was rising eastward, Saturn was distant from the vertex by $38^{\circ}56'$. Saturn itself was seen distant from Aldebaran by $39^{\circ}50'$, and from the northern shoulder of Orion [a lucido humero Orionis], or [Saturn] following, by $82^{\circ}57'$.

38. In the year 1652, on January 13, in the night following, at nearly the fourth Italian hour, namely when Orion's bright shoulder was rising eastward toward the vertex by $44^{\circ}35'$, Saturn was seen distant from the aforesaid shoulder of Orion by $34^{\circ}51'$, and soon afterward from Procyon by $16^{\circ}39\frac{1}{2}$; standing still

[stationary], Saturn was distant from Rigel by $51^{\circ}33'$; and then it was at an altitude of about 36° , and not far off by $48'$.

39. In the year 1652, on May 29, in the night following, at nearly the first hour after sunset, when Pollux's head [Pollucis caput] was at an altitude of $20^{\circ}55'$, Saturn was seen distant from the bright star of Leo [Lucida Leonis = Regulus] by $20^{\circ}12\frac{1}{2}'$, and from Regulus itself by $29^{\circ}27'$, when Saturn's altitude was $20^{\circ}33'$.

40. In the same year, on November 19, in the morning, about the thirteenth Italian hour, Saturn, retrograde and near Sirius [Canicula], or Procyon, was distant by $26^{\circ}57'$, and a little before sunrise the distance of Saturn from Procyon is to be set down at $38^{\circ}36'$.

from the heart of Leo [a corde Leonis = Regulus] by $12^{\circ}26'$, when Regulus itself was nearly on the meridian.

41. In the year 1653, on January 30, the opposition [oppositionem] with the Sun being already accomplished, but on account of clouds being difficult to observe, in the following night Procyon was distant from the vertex by $60^{\circ}40'$; Saturn was distant from the bright shoulder of Orion by $47^{\circ}34'$, and soon from Procyon by $24^{\circ}23\frac{3}{4}'$.

42. In the same year, on March 7, when in the following night the bright foot of Gemini [lucidus pes Geminorum] was culminating, we observed Saturn distant from Procyon by $22^{\circ}40'$, but from the shoulder following Orion by $45^{\circ}45'$.

43. Likewise in the year 1653, on April 27, in the night following, nearly an hour after sunset, we observed Saturn distant from the following star of the head of Gemini [a sequenti capite Geminorum] by $18^{\circ}30'$, and from the heart of Hydra [a corde Hydrae] by $28^{\circ}14'$.

44. Likewise in the year 1653, on December 6, in a very clear and very dry morning, Saturn stood distant from Procyon by $38^{\circ}47\frac{1}{2}'$, and from the southern head of Gemini [a Geminorum capite australiori] by $38^{\circ}2'$; and soon Saturn stood distant from the vertex by $37^{\circ}14'$, and 2 minutes afterward Regulus stood distant from the vertex by $38^{\circ}36'$. The azimuth of Saturn distant from the vertex by $37^{\circ}14'$ was observed toward the west, that is, $28^{\circ}51'40''$ toward the west. He sat [Sed]: on December 12, in the morning, at the first Italian hour $13\frac{1}{2}$, Saturn was seen distant from the vertex by $38^{\circ}34\frac{1}{2}'$, and from Procyon, but at the same time by $18^{\circ}23'$. Then by refractions the distance of Saturn from Procyon is to be set down at $38^{\circ}36'$.

45. In the year 1654, on February 1, under the first Italian hour of the night $2\frac{3}{4}$, Saturn was distant from Procyon by $35^{\circ}53'\frac{1}{2}$, and from the bright [star] of the Great Bear in the quadrilateral [ab Ursae maioris lucida quadrilateri], which shines in the haunch, or that nearest among the Seven Stars of the polar group [Septem Triones Stellae polaris], was distant by $49^{\circ}3'\frac{1}{2}$.

46. In the same year, on February 12, in the morning, about the $6\frac{3}{4}$ Italian hour of civic reckoning, Saturn crossed the meridian; and at that moment its meridian distance from the vertex was $29^{\circ}6'\frac{3}{4}$. From there, by perpendicular, we reckon $3\frac{3}{4}$ minutes; and Regulus by M. C. itself, with its meridian distance from the vertex, was $30^{\circ}51'$.

47. Likewise in the year 1654, on April 25, about the third hour after sunset, Saturn stood distant from Procyon by $32^{\circ}53'$; it was raised up by $19^{\circ}30'$, but from Pollux's head [a Pollucis capite] by $31^{\circ}13'\frac{1}{2}$.

48. Likewise in the year 1654, on April 29, about the third hour after sunset, when Procyon was high toward the west, distant from the vertex by $28^{\circ}20'$, Saturn was distant from it by $32^{\circ}56'$, but from Pollux by $31^{\circ}17'$.

49. In the year 1655, on May 8, in the evening after the high altitude of Procyon, near the opposition [\odot] by 4 minutes of time, then at once Saturn was seen distant from Procyon by $44^{\circ}52'$ at the eastern vertex, but from the following head of Gemini [a sequenti capite Geminorum] by $44^{\circ}25'\frac{1}{2}$.

50. In the year 1655, on May 27, at nearly the second hour after sunset, we observed Saturn distant from Regulus by $8^{\circ}22'$, but from the bright [star] of the mane of Leo [a lucida iubae Leonis] by $10^{\circ}56'$.

51. In the same year, on June 5, at the second hour after sunset, Saturn stood distant from Regulus by $8^{\circ}45'$, and from the bright [star] of the mane of Leo by $11^{\circ}14'\frac{1}{2}$.

52. Again, in the year 1655, on July 10, in the night following, Saturn in azimuth crossed by 6 degrees nearer toward the vertex by $74^{\circ}17'$. From there we reckon a diminution of $6^{\circ}50'$ of time; the distance of Saturn from Spica in azimuth from the vertex was 65° , and either way the star [Spica] was in the western region.

53. In the year 1656, on January 9, in the morning at the first Italian hour of civic reckoning $12\frac{1}{2}$, Saturn, retrograde, stood distant from Regulus by $17^{\circ}44'\frac{1}{2}$, and from the bright [star] of the mane of Leo [a lucida iubae Leoninae] by $28^{\circ}33'\frac{1}{2}$.

54. In the year 1656, on March 3, under the fourth hour of the following night, when Saturn was in opposition [\odot] with the Sun, tending [in motion], it stood distant from Regulus by $24^{\circ}49'$, and from the heart of Hydra by 8° .
55. Likewise [in the year 1656], on the same year, month, and day, on the 11th of the night following, at the first hour, we observed Saturn distant from Regulus by $24^{\circ}12'$; but from the heart of Hydra by $35^{\circ}57\frac{1}{2}'$, and at the same time it was then high, and Saturn was at about 36° .
56. In the year 1656, on May 30, in the evening, when the bright [star] of the tail of Leo [cauda Leonis = Denebola] stood distant from the vertex by $41^{\circ}23'$, and from whose azimuth, by means of the designated Filar [Filari] Triangle, Saturn was carried distant from the vertex by $52^{\circ}50\frac{1}{2}'$, and at its very approach we reckoned by perpendicular $2^{\circ}20'$. Regulus stood distant from the vertex by $62^{\circ}53\frac{1}{2}'$. But all these stars were at the setting [region], just as Saturn was.
57. Likewise in 1656, on July 13, half an hour after the setting of the Sun, with Saturn observed for us distant from the more eastern Spica than Saturn itself was, by $30^{\circ}48\frac{1}{2}'$; but from the bright [star] of the loins of Leo [a lucida lumborum Leonis], which was at the western [region], by $17^{\circ}4\frac{3}{4}'$.
58. In the year 1657, on March 22, in the night following, at the fourth Italian hour, Saturn, nearest to the opposition [\odot] of the Sun, stood distant from Regulus by $37^{\circ}4\frac{1}{2}'$, but from Arcturus by $32^{\circ}43'$.
59. In the same year, on June 24, in the night following, the distance of Spica from the vertex was $57^{\circ}22\frac{1}{2}'$; and after three minutes of time the distance of Saturn from the vertex was $54^{\circ}20'$, and at once Saturn stood distant from Spica by $20^{\circ}21'15''$.
60. In the year 1648 (which was noted above as to be added here), on February 21, at the first hour after sunset, Saturn stood distant from Aldebaran by $8^{\circ}54\frac{1}{2}'$, but from Rigel of Orion by $33^{\circ}1'$.
61. Likewise in the year 1648, on February 26, in the night following, about the first Italian hour $2\frac{3}{4}$, Saturn was distant from Aldebaran by $9^{\circ}39'$, but from Rigel by $32^{\circ}56'$.
62. In the year 1648, on October 22, in the morning at sunrise, we observed the distance of Saturn from the vertex, [Saturn] rising eastward by $80^{\circ}10'$, in altitude or azimuth; while on the night following, with Scheat of Pegasus placed in position, this very Scheat, or the bright [star] connected [conexendix] in the

quadrilateral of Pegasus, stood distant from the vertex by 39°2' toward the rising. But after we observed it, Saturn's altitude was taken, the distance from the heart of Hydra [cordis Hydrae] from the vertex acronychal by 55°47'. In the meantime we reckon by perpendicular 10°50'; and because Saturn was in opposition [♄] with Mars on that day, the calculation was believed [to be made]; and therefore the observation of Mars is to be consulted below at Caput 7.

63. In the year 1650, on the 16th day of February, [I add] to item 2. On March 1, we observed Saturn distant from three certain Fixed [Stars] very near, and at the same view of those very Fixed [Stars], whose Longitude is noted, with Saturn seen as stationary [Stationarius], thence Direct; and just so, as is held in Argoli's Ephemeris, and nearly Lansberg's [Lansbergii], so that the term of the station fell between February 21 & 22.

64. In the year 1657, on December 14, in the morning, Saturn was observed on the very meridian, distant from the vertex by 48°57'8". Thence we reckon by seconds of horary [time] 50"; and it crossed Spica by the same meridian.

[Italic display heading]

Other observations of Gassendi promised above at Caput 5, number 14.

Parsing notes: The two value columns are headed "G." (degrees) and "I" (minutes); fraction-of-minute glyphs ($\frac{1}{2}$, $\frac{3}{4}$, $\frac{1}{4}$) transcribed as printed. The year cell spans two-line star-pair entries; rows are grouped by year as printed.

CAPUT IX.

The various Methods, twenty in number, are set out for observing the positions of Saturn and of the rest of the minor planets, so that judgment may be made from the observations and with certainty.

1. The first Method of all, in my judgment, is the most outstanding: it applies if the planet lies at the known Longitude of a Fixed Star, so that it can be viewed simultaneously and nearby through the telescope, and by ocular estimation, with the addition of a Capacity-of-Minutes [Capacitas Minutorum] which the Telescope comprehends — so that the Longitude and Latitude of the planet may be determined. For through the telescope, when the star is stripped of those rays which, whether from the atmosphere, or from the deception of the eyepieces, represent the stars to be as though closer and nearer than they really are. But this felicity is most rare. Yet we have some examples of it in the case of Saturn —

indeed at Caput 5, Observation 15, & at Caput 6, Observation 16. But in Jupiter [Jove] we have given ours, and the most illustrious example from the observation of D. Vincenzo Muti [Vincentii Muti], at Book 7 of the *Almagestum Novum* [Almagesti Novi], section 6, Caput 10, & in others below, where we shall give the individual planets.

2. The second Method, closer to the preceding, is observation made with the naked eyes, when a planet touches some Fixed Star, whose Longitude and Latitude is noted, or if it does not touch, yet is so near to it that the difference [intervening] can by ocular estimation be reckoned at the smallness of a few digits in breadth, by which the planet is distant from the Fixed Star, or in latitude. But take an Astronomical Digit [Astronomicum Digitum] — one in the heavens equivalent to $2\frac{1}{2}$ minutes; the first [primis], & to be reckoned [taxari] from these; this method here is liable to the deception of splendor, of which we spoke in the first method; whence it comes about that the planet & the Fixed Star appear nearer to each other than they themselves are.

Examples of such observations, besides those which we shall adduce concerning the other planets at their own places, in the case of Saturn we have above at Caput 1, observation 1; Caput 2, observation 1; Caput 5, observation 10; Caput 6, observation 14. I would not, however, in observation 1, Caput 1, [take] that whole difference, [computed] by Ptolemy's computation, & by Longomontanus, or by Bullialdus [Boulliau], our own; I attribute, [taking] the aforesaid deception, the greater part of the error, [drawn] from the place of the Fixed Star then according to diverse Tables, & so by other examples. Yet I would believe that this can be done in this way, [namely] that only by the radii [splendors] of the five stars, & perhaps somewhat more, the first observers wandered a little astray by [these] scruples.

3. The third Method, akin to the preceding, but by that much farther more deceptive, is the [observation] by conjunction [σ] of a planet with the Moon, [as it appears] to the eye especially when naked: for besides the peril of hallucination, from the splendor of either, [there is] the danger of the planet's approach, [and] the intricacies of Lunar Parallax [Parallaxium Lunarium] are incurred; thence comes the [observation] of a planet with the Moon, not [made] by conjunction indeed apparent, yet by very near [position], so that it may be estimated by the eye, by how much part of the Lunar diameter the planet is distant from the Moon's horns, or from its limbs [limbis].

Examples of such observations for Saturn I have indicated above at Caput 1, observation 6; Caput 2, observation 5; & Caput 5, observation 11 & 16.

4. The fourth Method, used by the Ancients [Prisci], was by means of Zodiacal Armillaries [Armillas Zodiacales], celestial circles Analogous to the Longitude & Latitude [of the heavens], or by Astrolabes equivalent to those, which Ptolemy describes [in] *Syntaxis* book 5, chapter 1, & Ignatius Dantes [Egnatio Dante] in his book on the Astrolabe. But such instruments Tycho [Brahe] deservedly set behind others, in his *Astronomiae Mechanica*, folio 19, where he describes these very Armillaries; but he confesses them liable to error by at least two minutes —

The Ancients, however, scarcely attained certainty by means of the Armillaries even to whole minutes. And so Walther [Vualtherus] himself, who employed them frequently, not rarely detected in them a defect of ten minutes, as is plain from observation 33, chapter 2, related above. See also what Tycho [Brahe] says against the Torquetum used by the Arabs, [in] the place cited by Tycho, & in Tome 1, *Progymnasmata*, page 141.

5. The fifth Method [is] carried out by means of the Equatorial Armillaries [Armillas Aequatorias], which Tycho substituted for the Zodiacal ones, and described [in] the *Astronomiae Mechanica*, folios 20, 22, & 23, & Tome 1, *Progymnasmata*, chapter 2, folio 141. For by these the Declination, & the Difference of Right Ascension [Differentia Ascensionis Rectae] between the planet & the noted Fixed Star are obtained to within one minute or another. But, with Tycho's leave, I judge them to err not rarely by four or five minutes, on account of the causes to be expounded in my *Liber Organicus*. Meanwhile let it suffice for argument that there is a difficulty in seeing the error in those very Quadrants, since the Sextants are much more simply constructed, & in use. Yet, even so [Esto], there is one [thing about them]: granted that they err by one minute or another in certain things, [yet] given the planet's Declination & Right Ascension [as] observed, to investigate its Longitude & Latitude — the obliquity of the Ecliptic [obliquitas Eclipticae] being supposed, or the Distance of the Poles of the Equator & of the Ecliptic [Distantia Polorum Aequatoris & Eclipticae] — how this may be carried out, we have taught at Book 10, *Almagestum Novum*, section 2, Problem 48, to 52, & in our *Primum Mobile*.

6. The sixth Method, more secure than the preceding, is accomplished by means of the Meridian Altitude of the planet [by] a great Quadrant; a Sextant being taken at the same moment by which the planet is at the meridian, [observe] some Fixed Star, whose Right Ascension precedes; then indeed from the Altitude of the Fixed Star culminating with the planet's Altitude, its Declination is made known, & the Right Ascension is the same as the [planet's], & as [that of] the Fixed Star on the meridian: by which the same is investigated; afterward the Longitude &

Latitude [are found] by the Problems above adduced. The moment when the Fixed Star crosses the meridian is most certainly observed by means of our Triangle [Triangulum], perpendicularly erected, the Fixed Star being seen entering somewhere into the same plane along the threads of the said Triangle that designate the meridian, as is held at Book 5, *Almagestum Novum*, Caput 15, Problem 8, where the description of the instrument [is given].

7. The seventh Method, akin to the preceding, if the moment by which the planet crosses the meridian is observed by means of the Filar [Triangle], at the same time; & at once let another take the meridian altitude of the planet; & a third assistant begins to reckon the time by oscillations of a pendulum [oscillationibus penduli], described by us at Book 2, *Almagestum Novum*, Caput 20: by which any Fixed Star crosses the meridian before the same planet, or if some Fixed Star observed crosses the meridian after the same planet, at once let the assistants take the planet's meridian altitude. For the time foreknown is converted into parts of Right Ascension, [either] subtracted or added, as the [star] precedes or follows in its crossing through mid-heaven; whence the planet's Right Ascension is investigated. But the planet's meridian altitude, compared with the Equator, will give its Declination: from which, by the Problems already indicated, its Longitude & Latitude [is] inquired. But how short the time-interval must be between the planet's crossing & the Fixed Star's [crossing], the less the peril of erring in just time, [and] how great the equivalent of the time in the *Primum Mobile* [the four seconds of time which one minute of the Equator import] — provided four seconds of time import one minute of the Equator.

Examples of this method's practice you have in our observations of chapter 8 related above, observation 3, 4, 8, 46, & 64: of which let it please [us] to weigh 64, when in the year 1657, on December 14, in the morning, Saturn's meridian distance from the vertex was captured at $48^{\circ}57'8''$; & thence Saturn's distance from Spica, by the same meridian, we reckoned at 50'; second by horary [reckoning], by which we deduced both Saturn's Declination & Right Ascension.

[Diagram-adjacent table of values — the geometrical determination of Saturn's meridian position]

Parsing notes: the right-hand value-block is set beside the geometrical figure (below); three columns Gr./'/" (degrees / minutes / seconds). The southern declination is derived as the difference of meridian altitude from the equator altitude.

The Longitude & Latitude of Saturn will thus be investigated by means of the adjoined Diagram, in which let the Equator be AB, &

Diagram. A spherical-astronomy construction circle for resolving Saturn's meridian observation into Longitude and Latitude. The figure shows a circle with several great-circle arcs intersecting — the Equator, the Ecliptic, the Solstitial Colure, and the Equinoctial Colure — with the celestial poles, Saturn's place, and the relevant spherical triangle marked. The lettered labels appear around and within the circle:

- P (top): the Boreal/North Pole of the Equator [Aequatoris Polus Borealis]
- K (upper, near top): a point on the circle (the colure / pole region)
- C (left side): the initial point of Cancer [initium Cancrī]
- ☊ (left, near C): the sign-symbol of Cancer, marking the Ecliptic point
- A (lower left): one end of the Equator AB
- B (right): the other end of the Equator AB
- Z (right-center, near B): the point Z on the Equator [Aequinoctialis... Z]
- ☉ (lower center, near the intersection): the initial point of Aries / the equinoctial point [punctâ... ☉]
- ♎ (near center): the point of Libra [& ♎]
- S (center-low): the place of Saturn [locus Saturni... in S]
- O (bottom): the point O (foot of the latitude arc, on the Equator)
- H (center): an interior point/intersection of the construction (near the triangle vertices)

The construction forms the spherical triangle PZS (and the sub-triangles PZS, with sides PZ, PS, ZS) used in the Logarithmic-Canon solution that follows. Two labels (H, K) are read with lower confidence — see report.

The Solstitial Colure [Colurus Solstitiorum] is APK, & the Ecliptic \square K, in which is the initial point of Cancer C, & of Capricorn K; the Equinoctial [Colure] [Aequinoctialis] moreover [has] its points marked with \square & with \square . Furthermore, the Boreal Pole of the Equator is P, & of the Ecliptic Z; the distance PZ, which is to us $23^{\circ}30'20''$. Because, indeed, from the Ephemeris it is foreknown that Saturn was then near the 16th degree of Libra with a Boreal latitude of about 2° & $4^{\circ}26'58''$ of observed Southern declination; therefore the place of Saturn is designated at S, to which the Arc PS — constant, [drawn] from the Quadrant PK & the Southern declination IS, for the whole Arc PS is $94^{\circ}26'58''$ — is led across from the World's Pole P by means of the circle of Declinations. The Arc PS is [drawn] from the Pole Z, & from the Southern declination of the Ecliptic; an Arc of the Quadrantal Ecliptic ZSO. For in the spherical Triangle PSZ, the sides PZ are given at $23^{\circ}30'20''$, & PS at $94^{\circ}26'58''$; & by these the comprised Angle SPZ at $73^{\circ}23'54''$, that is, the Right Ascension of Saturn. For it being $196^{\circ}36'6''$, subtract 90° from \square to \square — that is, the Equator's arc \square to \square — there will remain, from the initial point of Cancer to the terminus I of Saturn's Ascension, the Arc CI, & so the Angle API at $106^{\circ}36'6''$, & this subtracted from 180° leaves the Angle SPZ at $73^{\circ}23'54''$. From these three given sides — by the Canons of Logarithms of Spherical Triangles — the Angle SZ is obtained, or the basis SZ; & having subtracted the noted 90° there will be the Boreal Latitude of Saturn OS. Likewise we shall obtain the Angle PZS, which measures the Ecliptic arc CO, [reckoned] from the initial point of Cancer; whence the noted Longitude of Saturn [will be], which we have set down at $17^{\circ}0'8''$ of Libra & Boreal Latitude $2^{\circ}25'42''$. From which observation, as [it is] most exact, & on account of so very long a time intervening between the crossing of Saturn & of Spica, [it is] least liable to error: we conclude much more by far that the Lansberg [tables] are removed from the truth than the Tyconic, or Danish [tables]: for by these tables the Longitude & Latitude written below is given.

	h Latitu de [Latitu do]			Longit ude			
	Gr.	'	''	Sig.	Gr.	'	''
Danis h [Danic is]	2	22	36	\square [Libra]	16	55	30
Lansb	2	20	36	\square	16	14	25

	ħ Latitu de [Latitu do]			Longit ude			
erg [Lans bergia nis]				□	17	0	8
Ours from obser vation [Nobis ex Obser v.]	2	25	42	□	17	0	8

Parsing notes: Latitude in Gr./'", Longitude in Sig. (zodiac sign) / Gr. / ' / ". All three rows give the sign Libra (□). The Danish (Tychoic) and our observed values agree closely; Lansberg's Longitude differs by some 45'.

8. The eighth Method, more secure than the preceding, & less troublesome, [employing], as it were, one [observer], [observing] at the same moment by means of three observers, is [accomplished thus]: if at some moment the plane of the Filar Triangle set up on the Meridian aim [allabatur] at the planet's center, the observer of this crossing gives the signal to two other assistants who have already very nearly prepared the instruments —

and one observer notes the meridian altitude of the planet, while another notes the rising or setting altitude of a fixed star — so set up, however, that it stands a few degrees away from the meridian (yet beyond the limit of any appreciable refraction), and whose declination and right ascension are known. For from the planet's altitude, once the equatorial altitude has been subtracted, you will obtain its meridian declination: if the altitude is greater than that of the equator, the declination is southern; if smaller, the planet's declination is northern. As for the right ascension of the planet, you find it as follows.

In the adjacent diagram, let the planet B cross the meridian HVR, and let its altitude be AF, measured from the horizon HR. The arc of declination PD is then

given, since it is drawn from the world's pole P through F. Thus in the triangle FPV you are given the complement FP of the fixed star's declination, the complement VP of its quadrant of altitude, and the complement PR of the pole's altitude. With these three sides given, trigonometry yields the angle FPV — the distance of the fixed star from the meridian, measured along the equator. Add this to the star's right ascension and you obtain, if the star lies to the east, the right ascension of the mid-heaven [Medii Coeli], that is, the right ascension of whatever point is then culminating, or transiting the meridian. Then, from the planet's right ascension and declination, its longitude and latitude follow, as set out under Problem [in] Method 5. With that, one example of the preceding method is also given.

Diagram. A circle (the celestial sphere in projection) with the meridian as a vertical diameter from V at top through F and the center A to the horizon points H (left) and R (right). The world's pole P lies in the upper right between V and R; lines are drawn from P to F and from the center, with B placed near the upper right rim. The configuration realizes the spherical triangle FPV described in the text.

- V (top): zenith / top of the meridian
- P (upper right): world's pole
- B (upper right rim): the planet
- F (upper-middle, on the meridian): the fixed star's position used for the reduction
- A (center): center of the sphere
- H (left): horizon point
- R (right): horizon point

Method 9. The ninth method is in every respect carried out as in [Method] 8, except for the fixed star's altitude. In its place let the azimuth of the fixed star be observed by means of the other Filar Triangle whose plane is aimed at the center of the star — for, as in the preceding schema of the triangle, the angle FVP at the vertex will be given from the azimuth; thus, given the angle FVP, the side VP, and the side FP, as above, the angle FPV and the rest of the preceding method will be worked out.

Method 10. The tenth method. If the planet is positioned outside the meridian, and nonetheless its altitude is observed together with the apparent altitude of a fixed star at the very same instant — that is, the planet's azimuth either is of known magnitude or is not, provided only that, besides the pole's altitude, the

fixed star's declination and right ascension are at hand. Let this be in the third schema, with the meridian HVR, the horizon HAR, and a circle of the vertical [verticalis] Quadrant VA, in which let the planet appear at P and the fixed star at F, and let the arc of declination from the world's pole B be BP, BF. First, then, if the azimuth AH, that is, the angle AVH, is not of known magnitude, but is 180° its complement, the angle PVB will be given, together with the planetary altitudes AP, the complement BV, and the planetary altitude AP, the complement PV. In the triangle PVB the basis BP will be obtained by the Canons of Triangles, that is, the fixed star's declination; should there be no declination, none is subtracted; and you will have the planet's declination toward one or the other pole. If the planet's [arc] is conspicuous, then, the quadrant being subtracted, the planet's declination toward the other pole remains.

Diagram. A circle with the meridian as the vertical diameter V (top) to A (bottom), and the horizon H (left) — R (right) through the center. A vertical-circle arc carries the planet P and the fixed star B near the upper right; arcs are drawn from B and from V down toward F and P. This is the third schema realizing the spherical triangle PVB of Method 10.

- V (top): zenith
- B (upper right): world's pole
- P (upper-middle right): the planet on the vertical circle
- F (middle, below P): the fixed star
- A (bottom): nadir / foot of the meridian
- H (left): horizon point
- R (right): horizon point

Method 11. The eleventh method is as follows. When the planet's altitude has been observed at some determinate vertical [verticalis], you wait for the fixed star until it comes to the same vertical; meanwhile, by means of a plumb-line, the time in between is counted. Then, as soon as the fixed star reaches that vertical, its altitude is taken. Or, the other way round, the fixed star's altitude is taken first, and afterward the planet's, as it slides onto the same vertical; either way, the third quantity is noted. As to how this is put into practice, it has been set out under the preceding number.

First, then, if the azimuth PVB is known, in the triangle BVP you acquire — as in the first step of the preceding number — the side BP; the second step will then disclose the other [side], the planet's [side]; but if the azimuth is not known, in the triangle FVB, as I said, in the second step you obtain the side BP. Then, in the

triangle FBP, look for the angle FBP. The differences of right ascension, as I said in the preceding number's third step, and through that the right ascension of the planet, and there itself the matters to be corrected afterward through the time elapsed in the meantime, converted into parts of the equator. For the planet comes onto the vertical earlier than the fixed star; so the said time is to be subtracted; if later, it is to be added; and you will have the absolute right ascension, and thence, by the customary methods, the longitude and latitude.

You have examples of this observation above, at chapter 8, observations 56 and 62 — granted that in these there were employed two fixed stars in the same azimuth, to verify the azimuth's magnitude, and Saturn's declination, while another served for the time, and thence for gathering the right ascension; whence Method 12 takes shape.

Method 12. The twelfth method is carried out thus. With the plane of our Filar Triangle aimed at the center of the planet, take that planet's distance from the vertex; and, to verify its azimuth — if a star's distance from the vertex cannot be caught at the same moment in the same tract of sky — number the time until such a star's distance from the vertex can conveniently be taken. Once that is caught, the other star is awaited to see at what quadrant of the same vertical circle it arrives, on which the planet stood, and at what distance from the vertex. For if of both fixed stars the declination and right ascension are known, the right ascension of the prior star is obtained, and through these, by the customary method, the longitude and latitude. This — which is here designated by the meridian and horizon, as above — we shall teach by an example of our observations at chapter 61, briefly and more clearly.

In the year 1657, on October 22, the morning of the rising of the Sun, in the Eastern vertical at A V, the Sun was observed at altitude SV, at gr. 80. 10'; but corrected for refraction, the true [altitude] was gr. 80. 15'; for after a minute of time, that is, at gr. 50', it had earlier been gr. 80. 10'. — Since the Eastern star known to us beyond the little clouds and refractions did not present itself, we took Cor Hydrae [Cor Hydrae, Alphard] Y, at a distance from the...

vertex of VY, gr. 55. 47', together with this, and with the complement of the pole's altitude gr. 45. 29'. 50'', together with Cor Hydrae's southern declination gr. 7. 11' added to the quadrant; that is, with the arc BY gr. 97. 11'. Trigonometry then yielded the angle VBY, gr. 19. 18'. The following night, in the Eastern tract, Pegasi Scheat P [Scheat] came, and then, at its distance from the vertex PV, observed to be gr. 39. 2'. Together with the same arc, and with BV gr. 45. 29'. 50'', and the northern declination of Scheat, then being gr. 26. 14'. 40'', the complement BP gr.

63. 45. 20", we find the azimuthal angle BVP gr. 102. 31'. Then in the triangle BVS, with the aforesaid angle, which is the same with [the angle] BVS, that is, the angle BVS gr. 45. 29'. 50", and Saturn's distance BV gr. 80. 15'; by the Logarithmic Canons we find both the basis BS gr. 92. 16'. 55", and so Saturn's southern declination gr. 2. 16'. 55"; together with the angle SBV gr. 74. 18'; from which, subtracting the above-found angle VBY gr. 19. 18', there remains the angle YBS gr. 55. 0'; this is the difference of right ascension between Cor Hydrae and Saturn. But because the very instant at which Saturn's distance from the vertex was taken was not the moment at which Cor Hydrae's distance was taken — because by that hour Saturn had set deeper — therefore, that difference being diminished by gr. 2. 42'. 30", owing to the time interval of 10. 50', and so there remains a difference gr. 52. 17'. 30". But the right ascension of Cor Hydrae was then, by our right ascension gr. 137. 40', and Saturn more easterly; therefore Saturn's right ascension was gr. 189. 57'. 30", and the declination from what was said above, gr. 2. 16'. 55" southern. Therefore, by the Problem of the first Mobile, and the most subtle Logarithmic Canons of Vlacq, Saturn's longitude was Libra gr. 10. 2'. 56", and the northern latitude gr. 1. 51'. 32". Therefore, by this observation, the Lansbergian Tables depart, more than the Danish, as appears by the following little table.

From the Tables	h Longit ude —				h Lat. North		
	Sig.	Gr.	'	"	— Gr.	'	"
Danis h	□	11	32	12	2	14	0
Lansb ergian	□	11	7	30	2	9	20
As obser ved	□	10	2	56	1	51	32

I confess, nonetheless, that on account of some interval of time elapsed between Saturn and Hydra's observation — because the morning observation of Saturn could be given the plane of the Filar Triangle at the evening Scheat observation — there is something of doubt; and yet this observation may serve rather as an example of the problem than with any certainty of truth.

Method 13. The thirteenth method is, if, with a known determinate number, the Filar Triangle's degree is set; the planet's arrival is awaited, and at its arrival the same number of degrees may be taken; and at the same moment some certain

star's distance from the vertex is observed, or at least, while the number is being taken in between, the time intervening between both observations [is noted]. — This schema is made clear under chapter 52. And so, on July 10, the night following, in the Western azimuth precisely 90 degrees, with the Filar Triangle set, Saturn S, at a distance from the vertex...

VS, was gr. 74. 17'; but on account of refractions the truer was gr. 74. 19'. But afterward, at gr. 80' 50" of time, Spica Y, at a distance YV from the vertex, was gr. 66; precisely in the Western quadrant. First, then, in the triangle SBV, with the complement of the polar altitude BV gr. 45. 29'. 50", and Saturn's distance SV gr. 74. 19', and the complement of the azimuth SVB gr. 90; by trigonometry we obtain the basis BS gr. 79. 4'. 32"; whence Saturn's northern declination results, gr. 10. 55'. 28", and the angle SBV gr. 75. 21'. 34". Secondly, in the triangle YVB, with BV as above, and VY gr. 65, and the arc BY, which consists of the 90 degrees and the southern declination of Spica gr. 31'. 48"; the angle YBV gr. 0°. 39'. 59". 30" is deduced; subtracting the angle SBV, there remains the difference of right ascension of Spica and Saturn gr. 55. 22'. 4" — to be referred to the right ascension of Spica, but the more easterly; but since this difference is first to be augmented at the lesser time of gr. 1. 42'. 30", owing to the time elapsed between of gr. 6'. 50"; and so the corrected difference is gr. 57. 4'. 34". But Spica's right ascension by our Tables of Fixed [stars] is gr. 196. 47'; therefore Saturn's right ascension gr. 159. 42'. 26", and from what was said the northern declination gr. 10. 55'. 28"; whence is gathered the longitude \square 7. 9'. 40", and the northern latitude gr. 2. 10'. 40". We compare these with the Danish and the Lansbergian Tables.

From the Tables	h Longit ude —				h Lat. North		
	Sig.	Gr.	'	"	— Gr.	'	"
Danis h	\square	6	57	40	1	50	0
Lansb ergian	\square	6	37	25	1	38	0
As obser ved	\square	7	9	40	2	10	40

Method 14. The fourteenth method, somewhat more laborious than the preceding, requires four observers: one, who attends to the meridian, waiting for the centrum of the planet; another, who at that very moment catches the distance

of the planet from the vertex; the remaining two, who at the same moment catch the distances of the planet from a known fixed star — the declination, that is, and the right ascension. Once these are acquired, inspect the diagram in which is designated the horizon HR, and the meridian HVR; let the planet's [position] P be given, and the distance from the vertex PV; and from the azimuth the angle PVB in...

Diagram. A circle with the meridian as the vertical diameter V (top) to A (bottom) and the horizon H (left) — R (right) through the center. The pole-point B lies on the upper right rim; from B and from V arcs run inward to the planet P and a point Y near the upper middle, with S on the meridian above A. This is the schema for the worked reduction (Cor Hydrae Y, Scheat, Saturn S) realizing triangles BVY, BVS, and SBV.

- V (top): zenith
- B (upper right rim): world's pole
- Y (upper middle): Cor Hydrae [Alphard]
- P (middle right): the planet / Scheat position
- S (on meridian, above A): Saturn
- A (bottom): nadir
- H (left): horizon point
- R (right): horizon point

the triangle PVB, in which is given likewise the complement of the polar altitude BV. For trigonometry will not lie [as to] the side BP, indicating the planet's declination: that is, BP gr. 90, with no declination if it does not exceed 90; or it falls short, if the [altitude] exceeds the southern; if the [altitude] falls short, it will give the northern declination. Furthermore, let the fixed star be F, as it stood at O; with its certain distance from the vertex PF, or PO given, and from the declination of the known fixed star [side] BF, or BO, and the common [side] BP, as above, the term being found, by these three sides let the [angle] become known. The angle FBP, or PBO, namely, the difference between the right ascensions of the fixed star and of the planet. That difference of right ascension of the fixed star is to be added in the Eastern quadrant, if the star was at F, but [the planet] higher than the planet P; but to be subtracted if at O, on the contrary, in the Western quadrant, [the planet] is removed; if the star was at O, [the difference] is to be added; and you will have the planet's right ascension, with which, and the declination, as above, once acquired, you will gain, in the customary manner, the planet's longitude and latitude.

Diagram. A circle with the meridian as the vertical diameter V (top) to A (bottom) and the horizon H (left) — R (right). The pole-point B is on the upper right rim; from B and V arcs run inward to the planet P, with F and O on the lower-left interior arc (the two positions of the fixed star) and S nearby. This realizes the triangle PVB with the alternate fixed-star positions F and O of Method 14.

- V (top): zenith
- B (upper right rim): world's pole
- P (middle right): the planet
- F (lower-middle interior): the fixed star (first position)
- O (lower interior, below F): the fixed star (alternate position)
- A (bottom): nadir
- H (left): horizon point
- R (right): horizon point

Method 15. The fifteenth method, carried out by the distance of the planet from two fixed stars more to the east, or to the west...

[stars] more to the east or to the west, with the distance taken — of which fixed stars the longitude and latitude are known, and especially, if the mutual distance of the stars between themselves is noted. The example is from chapter 8, our observation 41. In the year 1653, on January 30, the night following the Opposition of Saturn with the Sun, we observed P. Grimaldi [Grimaldi], and I, the distance of Saturn from the right shoulder of Orion [Betelgeuse], or the following one, at gr. 47. 34'; and soon the distance from Procyon gr. 24. 23 $\frac{3}{4}$, the other being gr. 30; and both; the fixed star was more to the west of Saturn. Let this then stand for our observation. Figure this, in which, from the ecliptic EC, etc., with the southern Pole A, and the northern B, let there be drawn through Saturn's centrum S, the semicircle of latitude ASB, and through Orion's shoulder the semicircle AOB; and Procyon at P, from which let there be drawn to the Pole A the complement of latitude AP — for the southern latitude of Orion's shoulder is gr. 16. 6'. 13"; and Procyon's gr. 15. 57'. 10"; therefore AO gr. 73. 53'. 45", and AP gr. 74. 2'. 50". But the distance OP, between the fixed stars themselves, is by our frequent observations gr. 26. 2'. 50". Finally, from the fixed stars to Saturn let the arcs of distance to Saturn PS and OS be drawn. By these the distances are designated.

First, in the triangle OPS, with the three sides given OP gr. 26. 2'. 50" and OS gr. 47. 34', and PS gr. 24. 23 $\frac{3}{4}$, trigonometry yields the angle OPS, gr. 142. 21'. 40". Secondly, in the triangle OAP, with the three sides likewise given AP gr. 74. 2'. 50", and AO gr. 73. 53'. 45", and OP, as above, the angle OPA gr. 86. 5'. 20" is given;

which, with OPS, makes 228. 27'; and, this being subtracted from 360°, there remains the angle APS gr. 131. 33'. Then, in the same triangle APS, with the aforesaid degrees AP gr. 74. 2'. 50", and PS gr. 24. 23 ³/₄, and the angle ASP gr. 90. 58'. 20" — wherefore Saturn's northern latitude remains gr. 58. 20", and the basis AS gr. 90. 58'. 20"; and because Procyon's longitude was Cancri gr. 20. 59'. 45". If you add the difference of longitude PAS, since Saturn will be more to the east, Saturn's longitude was Leonis gr. 9. 6'. 55", and the northern latitude gr. 58'. 20". What [say] the Danish and the Lansbergian Tables? Of course, as in this little table.

From the Tables	h Longit ude —				h Lat. North		
	Sig.	Gr.	'	"	— Gr.	'	"
Danis h	□	9	25	10	0	45	10
Lansb ergian	□	9	2	30	0	37	15
As obser ved	□	9	6	55	0	58	20

Method 16. The sixteenth method is carried out by the captured distance of the planet from fixed stars of known longitude and latitude; of which one is the more to the east, the other the more to the west, especially if the distance between the fixed stars themselves is already foreknown, or [is known] from longitude and latitude complements; and the difference of longitudes is to be pre-investigated.

The example is from chapter 8, observation 58. In the year 1657, on March 22, the night following, when we saw Saturn's distance, P. Grimaldi and I, from Regulus gr. 37. 4'. 45"; thence the distance of the Fixed star often observed by us from Regulus gr. 59. 49', and the northern latitude of Regulus gr. 0. 26'. 20"; Arcturus truly gr. 31. 6'. 40". Let this then be congruent with this observation — the Schema this, in which let there be portion of the ecliptic EC, and the northern [Pole] B; describe the two quadrants of latitude, one being BE, through Regulus R; the other BC, through Arcturus A. But let Saturn be in S, through which let there be drawn the quadrant of latitude BO; the distances truly from AR, between Arcturus and Saturn; and RS between Regulus and Saturn.

First, then, in the triangle RSA, with the three sides given AR gr. 59. 49', and AS gr. 32. 43', and RS gr. 37. 4'. 45"; the angle RAS gr. 36. 39'. 20" is given by the Canons of Triangles. Secondly, in the triangle RBA, there are given likewise the other three sides AR gr. 59. 49', and BR, the complement of Regulus's latitude, which is AB gr. 53. 33'. 40", and AB, the complement of Arcturus's latitude, which is gr. 58. 59'. 20". Therefore by trigonometry the angle BAR gr. 109. 50' is given; which, with the angle RAS, makes the angle BAS gr. 146. 29'. 20". Thirdly, then, with this angle, in the same triangle BAS, and with the complement of AB gr. 58. 59'. 20", and AS gr. 32. 43', we find the basis BS gr. 87. 19'; whence Saturn's northern latitude gr. 2. 41'; and the angle ABS gr. 17. 22'. 45", which, subtracted from Arcturus's longitude, which then was gr. 19. 27'. 30", leaves Saturn's longitude in Libra gr. 2. 4'. 45". But the others as below.

From the Tables	h Longit ude —				h Lat. North		
	Sig.	Gr.	'	"	— Gr.	'	"
Danis h	□	2	40	10	2	40	35
Lansb ergian	□	2	18	20	1	34	0
As obser ved	□	2	41	0	2	41	0

Diagram. A near-circular spherical-triangle figure (a curved triangle inscribed in an arc) with the southern Pole A at the bottom and the northern Pole B at the upper right. From the ecliptic EC at the left, latitude semicircles run up to the poles through Orion's shoulder (O), Procyon (P), and Saturn (S), which sit in the interior; the curved sides AS, PS, OS, AP, AO realize the Method-15 reduction (triangles OPS, OAP, APS).

- B (upper right): northern Pole
- A (bottom): southern Pole
- E (left): ecliptic point
- C (left, near E): ecliptic point
- S (upper-middle interior): Saturn's centrum
- O (middle interior): Orion's shoulder [Betelgeuse]
- P (lower-middle interior): Procyon

- G (between S and O): intersection / auxiliary point

Diagram. A curved spherical triangle with the northern Pole B at the top and the southern Pole at the lower left; from the ecliptic side at left (E, with R below), latitude quadrants run to the pole through Regulus (R), Arcturus (A), and Saturn (S). The interior carries S and O with the curved sides AR, AS, RS, BR, BA, BS realizing the Method-16 reduction (triangles RSA, RBA, BAS).

- B (top): northern Pole
- A (upper-middle interior): Arcturus
- R (left): Regulus
- E (lower left): ecliptic point
- S (middle interior): Saturn
- O (lower interior, below S): auxiliary point on Saturn's latitude quadrant
- C (lower right): ecliptic point

Method 17. The seventeenth method is, if the planet's meridian altitude is taken, and it is observed [when it is] in a straight line with some known fixed stars; see Chapter 6, observation 15.

Method 18. The eighteenth method is, if it is observed in a straight line with two fixed stars; so that through these the planet's longitude can be estimated, as I have said is done in observation 3; or hence, in a straight line with two fixed stars; and that in another straight line with two other fixed stars: see those things which we said in Book 10 of the *Almagestum Novum* [Almagestum Novum], pages 563 and 564, problem 131; and Chapter 4.

Method 19. The nineteenth method suits only the planets that, in the daytime, are conspicuous with the Sun — whose number is Venus, and rarely Jupiter, when the Sun is too low, and on account of refractions implicit [in that]. For if at the same moment the altitude of each be taken — that is, of the Sun and of Venus — and this azimuth, or the distance from the Sun: from the Sun's declination, and right ascension, may be found Venus's [declination] too, the declination and right ascension, and thence the longitude and latitude.

Method 20. The twentieth method does not always serve to acquire the longitude and latitude of the planet, but only to render a judgment of the Stations, of Direct [motion], and of Retrograde [motion]; or whether one of three may exceed the Sun's opposition [oppositum]. For at the very middle moment of the night the planet transits the meridian — a sign that the planet is then opposite the Sun, and hence from the place of the Sun the place of the planet, [its] opposite, can be

discerned. And so on some days around the Stations, observe the planet's distance from the nearest fixed stars; easily it can be judged whether it has stood at the same longitude, or whether retrograde — but truly it has been made Direct from Stationary; even if it is not known where its own place is, in respect of the ecliptic. — So we, by observations made on the 16th of February, and the day of the 26th of March, by continuations through the Telescope, judged the Stations of Saturn to have been between the 21st and 22nd of February, and thence direct...

CAPVT X.

On the limits of certainty within which the positions of Saturn have been able to be represented up to now — or will be able to be represented hereafter — better through observations than through astronomical tables, and on the disagreement among those tables.

[De Limitibus Certitudinis, intra quos loca Saturni repraesentari potuerunt hactenus, aut poterunt in posterum tam per Observationes, quàm per Tabulas Astronomicas, earumque dissidio.]

1. It is certain that observations of the celestial phenomena are the foundation of the astronomical tables. Yet it is equally certain that one should not seek out just any observations, of whatever kind, but rather many of them, and exceptionally accurate ones. As regards Saturn in particular, [Tycho Brahe] has shrewdly noted, in the preface to his *Astronomical Tables* [*Progymnasmata*], that the observations of thirty, or at minimum twenty-four, years are required — and not only in every one of the [Greek: ἀκρόνυχος (akronychos, "acronychal" — at the planet's rising near sunset, i.e. near opposition)] positions, but also in the other intermediate positions, so that from the dispositions and motions, as thoroughly examined, the tables may be built up such that Ptolemy, the rest of the ancients, and Copernicus can be reconciled. For it is unjust to argue, as some do, that the ancient astronomers erred by so much from the heavens that Tycho judges their three acronychal observations of the superior planets each to be in error, and then on that basis convicts them of a hidden fault. That said without injury to the ancients — indeed, by the confession of those very men — was soon established.

2. For concerning Hipparchus there exist these words in Ptolemy, *Almagest* IX.2: "Which observations, on account of their difficulty, Hipparchus, that most truthful lover of truth, did not have available, because he did not possess accurate observations of the five planets; for he himself indeed undertook this task, as his own commentaries show — yet not so as to have collected the

planetary observations into better order than his predecessors, but to show that they do not agree with the phenomena, that is, with the hypotheses of those times." [*Almagest* IX.2] But with a few words interposed he adds in the same place: "Yet I demonstrate none of these things; rather, others up to this day have not advanced them." And so, since the disciplines that demand exquisite mathematics had not yet been brought to such a finish that he could accomplish what others did, it is no wonder if the outcome perished — as he himself seems to have foreseen.

[Margin: *Hipparchi lapsus*. — Hipparchus's lapse.]

3. Ptolemy himself professes the very same thing in *Almagest* IX.2, both in the difficulties just adduced and amid many others, in these words: "It is necessary that the man who is to accomplish great things, in considering each of the motions of the planets singly, and then in considerations taken together over individual periods, be able to observe that there is in his instruments the least possible error — or, if some does creep in, that it be such as cannot be perceived by the senses; that is, when posterior observations are made with the prior ones, and so on. For abuse arises whenever, on account of the very small magnitude of the things considered, and the long span of time, the predictions of the planets are rendered uncertain." But Ptolemy, with the same candor, confesses some abuse besides his own — that with circles fixed in the plane of the ecliptic (which is nothing without commodity, and the gratification of the hypothesis), things which proceed from mere congruence, and apart from the evidence of right-angled triangles, may, on account of obliquity, be neglected as though of no account. Finally he thinks that attention should be paid to the planetary oppositions taken from the place of the Sun itself, preferring Tycho's true place.

[Margin: *Ptolemaei excusatio circa Planetas minores*. — Ptolemy's excuse concerning the lesser planets.]

4. Albategnius [al-Battānī] too, as far as Ptolemy's business and that of the Alphonsines [*Alphonsini*] are concerned, almost certainly followed them — and there is no reason for us to say more, since once Heaven itself was plainly seen to depart openly from the truth. That great conjunction of Saturn and Mars, which Stöfler [*Stöfflerus*] had predicted from the Alphonsine tables would occur in the Year of the Lord 1536 in late May, on the 25th, in fact took place on the 20th, by Petrus Pitatus's observation; or on the 19th, by the observation of Julianus Ristorius of Prato, the preceptor of Junctinus [*Junctinus*], around hour 1 of the night, when Saturn was about a degree away from Mars. So too the conjunction of the year 1542 — which was about hour 5 of the following night, on the 9th of

January — was, by Junctinus's observation, conjoined with Mars for many days before the Alphonsine epoch [*abacum Alphonsinum*]. And in the year 1563, the conjunction of Saturn and Jupiter, observed by Junctinus at Auranges on the 24th of August at hour 14½ after noon, covered over his more Austral [southern] Jupiter near the end of the 28th degree of Cancer — yet the Alphonsine calculation made that conjunction distant by more than 4 minutes. On the 7th of September, by Leonitius's [observation], at degree 4¼, minute 12. Which was the cause that Regiomontanus, like the Alphonsines, afterward preferred the Prutenic canons. Yet Tycho criticizes both sets of canons in his *Mechanica*, folio 39, thus: "By either method of calculation we have most plainly detected errors that are intolerable: namely, that great conjunction of the year 1563, of which I spoke at the outset, and the motion of Saturn." And that place is satisfactory enough, if indeed it deceived the Alphonsine numbers by a whole month, while Copernicus differed by some few hours but little.

[Margin: *Alphonsinorum errores in Saturno superioribus*. — The Alphonsine errors with respect to Saturn, noted above.]

He says, moreover, that he himself observed at Leipzig in the completed year 1563 that conjunction near the end of Cancer and the beginning of Leo; and in his *Epistles*, page 56, and in the *Progymnasmata*, tome 1, page 648, he detects an error of about 2 degrees in the Alphonsines as to Saturn's place; not otherwise than Longomontanus, who in chapter 4 shows the same thing. (*Theoricorum* cap. 13.) He affirms that in the year 1591, on the 17th of March, by the old style, hour 7, minute 8 after the meridian of Uraniborg, he observed Saturn distant from Aldebaran by 19°11¼', and from Pollux by 25°54½'; with a north declination of 22°23'. From this is collected the place of Saturn underwritten below, compared with the Alphonsine and the Prutenic.

<i>Alphon sina</i>				
<i>Pruteni ca</i>	22	23	1	35 A.
<i>Danica</i>	22	45½		

Finally, Magini [*Maginus*] in his *Epistle to Richard FASTER* — which he gives in his *Directiones*, page 95 — says that the Alphonsine calculation errs in the lesser planets more than the Prutenic.

5. Copernicus, however, set up hypotheses which now and then, on the occasion of the Alphonsine motions, were excessively erratic — no wonder, since (as he himself frequently testifies) he relied, both for Ptolemy's and for his own ternary of acronychal observations, on the opposition with the Sun's mean place; and, as Joachim Rheticus testifies, he thought he had done well enough for himself if he was not at variance by 10 minutes, or one-sixth of a degree. He could not, by his own observations, drive his hypotheses to a closer place; nor would he depart a hair's breadth from the truth, as Rheticus confesses in the preface to the *Ephemerides*. Kepler, furthermore, in chapter 18 of his *Mysterium Cosmographicum*, says that Copernicus neglected the quadrants of the degrees, as if he were observing to the minute within the planets' motions; he speaks thus: "In things of this kind, I do not incur error, unless I have deliberately conceded it, in that I preferred imperfect astronomy to none. For such difficulties present themselves, while true things run contrary; which it is the part of a settled mind to preserve, and from knowledge of the constitution to aspire to the least loss — provided one dare, with Copernicus, that a man strong in spirit, ignorant and base, may flee, that the timid may despair, and that anyone may cast aside this care. Just as these recently published spherical figures, neither without sweat nor without shame, I confess. By the example of Ptolemy and the ancients, the difficulty of observing exactly is excused." Then, in the same *Mystery*, chapter 18: "Soon afterward, in the new style on the 12th of November, in the year 1594, Saturn placed itself exactly between the Hyades [*cervicem*] and the Heart of the Lion [Cor Leonis, Regulus], where by the Prutenic calculation it ought to have been on the 31st of October — a difference of nearly 37 minutes. Indeed, sometimes the small error of the Prutenic tables rose to 40 minutes." [*De Saturn.*]

[Margin: *Copernici errores in Planetis, & excusatio*. — Copernicus's errors in the planets, and his excuse.]

[folio 295]

He further notes, [Tycho Brahe], page 39 of his *Mechanica*: "Where Copernicus, regarding Saturn and Jupiter, says: 'His restitution in these two planets is not so much in accordance with the celestial norm as it digresses, especially as to Saturn, which never exceeds beyond a half-degree above the highest good.'" Of this Copernicus himself in the heavens admonishes that the calculation is to be amended.

6. Longomontanus, therefore, made use of Tycho's observations, so that he did not despise the Prutenic numbers, but retained them as emended. For he professes in *Theoricorum* cap. 2, that he constructed the Danish Tables of Saturn from the Prutenic, subtracting 20 minutes in the mean longitude of Saturn; in the apogee, however, adding 3 degrees; in the prosthaphaeresis of the eccentric, subtracting five-eighths everywhere; in part as much as one-fifth. So says the author of the book *Astronomicum* who inscribed it *Urania Propitia*, published in the year 1650, at Bicini [Beuthen] in Silesia, page 85. He asserts, with frequent, trustworthy, and diligent observations of Saturn — yet selected to the 29th in diverse eccentrics, and noting a change detected in the points — that the Danish and Lansbergian tables sin much more than the Rudolphine; that the Rudolphine, however, in the first change exceed Saturn's place by a semicircle, by $4\frac{1}{3}$ minutes.

[Margin: *Iudicium de Danicis, ac Rudolphinis circa Saturnum*. — A judgment on the Danish and Rudolphine tables with respect to Saturn.]

7. Kepler, nonetheless, thought there might lurk an error of not so many minutes in his tables; for in the *Explanation of the Fundamentals of the Ephemerides*, chapter 14, he speaks thus: "As much as concerns the difference of the superior planets, I do not readily promise; but if anyone has attended with the most exquisite instruments, the astronomers being practiced — or if they have lain in wait — let them be congratulated, even between those whose places among the fixed stars are clearer, and constituted by accurate calculation. But in the *Mysterium Cosmographicum*, chapter 19, I have said that Saturn most easily affords a cause of error in observation; yet an error, even a great one, in distance, of lesser opinion is engendered in the prosthaphaeresis." That is, the error in Saturn would be rarely indeed 34 minutes, not rarely 14, or 16 minutes; the Lansbergian, however, as Philolaic, 15 minutes; but 12 minutes, often less. Whence it follows that one does not know sometimes amid the disagreement between the observations and the tables to which of these the fault is rather to be ascribed — whether to the observations or to the tables; yet, although the magnitude is great, among accurate ones the disagreements are wont to be

reckoned slight, mostly within 5 minutes; though the lesser may satisfy. I do not doubt, however, that a great part of the discord proceeds either from the observations — especially if they were held to be antiquated, or the mode of observing chosen in observing more operations — and the suppositions, hardly free of scruple.

8. Let us now hear that most renowned astronomer, Sir Vincentius Mutus [Vincent Mut], who in the year 1654, among other observations then made by him from the Majorcan observations, in an epistle of date the 26th of May which he sent me, reckons up these nearly acronychal [places] of Saturn, which he attained on the 11th of February, and on the 15th of May at hour 9 after the meridian, by calculation added from the more celebrated tables.

D. Mutus adds in the same epistle: "Not yet certain, but I almost dare to affirm, that the distances of the planets from the Earth have nothing in common with the diversity of their orbits, hitherto stable; nor [their] elongation from the world able to be deduced from the prosthaphaeresis of the orbits. A notable example I have observed these months in Venus, Mars, Saturn, and in the days passed in Jupiter. All of which, together with the observations, after the completed work I shall gladly communicate."

9. Boulliau [*Bullialdus*] — supreme and excellent in his endeavor to amend the Rudolphine in his *Astronomia Philolaica*, book 6, where in chapter 5 he reconciles those Tables with the most ancient observation of Saturn of the year of Nabonassar 519 — also, with the other observation of the year of Christ 503, recognizes that the motion is to be retracted; that it is Aphelion in antecedence by

degrees $48^{\circ}50'56''$ there. He puts the Aphelion here at degrees $46^{\circ}10'46''$; or [the motion is] to be promoted.

[*folio 296*]

It comes from the Rudolphine mean of $36'$. The Aphelion, moreover, from \square degrees $26'$ to be retracted, and to \square degrees 28 . From the observations, therefore, he collects [the place]; yet some minuteness of disagreement of $9'$ he gathers — in examining Saturn's observations of the year 1640, the Moon being unable to fall on the year of Christ 503. On the 21st of February, hour 4, while Saturn was occulted at Athens [Temporis Athenis occultare Saturnum], which truth of history he confirmed, observed by Tycho and Longomontanus, not to recede beyond $3'$, or 4 minutes; for the Vualtheri [Walther] observation, which Boulliau expends, on degree 5; and as one may collect the place of Saturn in \square at $0^{\circ}41'$. This place is suspected, inasmuch as it was made nudely [bare], and on account of the latitude in the Nebula of Cancer made. So too the Vualtherian observation of the year 1503, on the 21st of February, deduces the place of Saturn in \square at degree $6^{\circ}20'$. Philolaically, however, at degree $6^{\circ}12'51''$. The rest of the observations of Copernicus, Tycho, Longomontanus, and his own, which he confers with those Tables, do not add to it anything except a Philolaic semicircle to exceed in Saturn's place by 5 minutes, as will be evident from the Catalogue of the following chapter.

10. Hitherto it has been given to gather from the opinion of others, that we do not have observations sufficiently large, immune from every sensible error — or, by every human industry, divisible; nor what the antiquity of long ages itself can claim, or sextants attain to the grade scarcely. Nor are the Tables so exact but that some scruple of doubts may suffer; since, as the Rudolphine in Saturn were rarely indeed 34 minutes, not rarely 14, or 16; the Lansbergian, however, as Philolaic, 15, but 12, often less. Whence it follows that one does not know sometimes, amid the disagreement between the observations and the tables, to which of these the fault is rather to be ascribed — whether to the observations or to the tables — yet, although the magnitude is great, among accurate ones the disagreements customarily reputed slight, mostly within 5 minutes; though the lesser minute may satisfy. I do not doubt, however, that a great part of the discord proceeds either from the observations — especially if they were held antiquated, or the mode chosen in observing more operations — and the suppositions hardly free of scruple.

11. Among the Methods, then, reckoned up in chapter 9, the first grade of certainty those merit which require the Declination of a single fixed star alone, or

the Right Ascension and the planet's Altitude; for in these it can be effected by the astronomer practiced with apt instruments that the error not exceed 3', or 4 minutes — of which kind are Methods 1, 6, 8. To these are akin 2, 5, 7, 9, 10, 11, 12, 13, 15, 16; in which the five elements concur in determining the planet's place, so that thereby an error of 5', or 6', about a minute or so, may be feared. The Methods, however, 4, 14, and 17, are noxious by an error of 8', or 10 minutes; methods 3, and 18, of even 10' or 20 minutes. Therefore, in as much as astronomy advances, I reckon one cannot hope for better observations — nor Tables, which are settled in those three superior ones; certain, and evidently exclude doubt of the three scruples of error, and provide good things to be had above the great part [where] error is constituted within 5', or 6'; or some place of the planetary orbit not exceeding 10'. Let it be commodious, however, and that with the least everywhere the fault may labor. There remains, as in the following chapter, as in a mirror, to set forth the select observations of Saturn's places, and parallel to them the subjoined ones of the more celebrated Tables. From this it will appear that the observations agree with no tables — that they support no observations, that they refute none — so that scarcely will any discord, or for the cause of disagreement, ascribe the whole observation to the Tables, the whole, or some part.

[Margin: continued]

Diagram. A faint, partly inked grid of cells appears at the foot of the right column — the lightly printed skeleton of a numerical table (ruled columns and rows) with most cell-entries left blank or too faint to resolve. No headers or values are legibly inked. This appears to be a lightly impressed (under-inked) table frame rather than an informational figure; no labels are recoverable.

[*folio 296*]

CAPVT XI.

Select positions of Saturn from the preceding observations, and collated with the positions computed through the more celebrated Tables.

[*Loca Saturni selecta ex Observationibus praecedentibus, & collata cum locis per Tabulas celebriores computatis.*]

The characteristic abbreviations that follow indicate the Tables, namely: **Da.** the Danish; **La.** the Lansbergian; **No.** Our own [*Nostras*]; **Ph.** the Philolaic; and **Ru.** the Rudolphine. Before these are noted the observers of Saturn's positions. On the

left side, moreover, are indicated severally the aspects of Saturn with the Sun, exactly indeed where nothing is added; the nearer ones, however, where the letter **C** indicates *Circiter* ["approximately"].

Parsing notes (Caput XI table, both columns): This is a multi-page comparative catalogue of Saturn positions. Each block gives a date (*Ann. Mens. D. / H. p. m.* = Year, Month, Day / Hour after noon), an observer or aspect symbol (σ conjunction, \circ opposition), then for each Table-abbreviation the computed longitude in Sig. (sign), Gr. (degree), ' (minute), " (second), with a final *Differ.* (difference) column in ' and ". Sign-glyphs: \square Virgo, \square Libra, \square Sagittarius, \square Capricorn, \square Aquarius, \square Cancer, \square Aries, \square Leo, \square Gemini. Latitude rows (*Lat.*) carry a/A markers for direction. Some second-column degree cells are faint; flagged [?] where unresolved. Table continues onto the next folio (catchword "1585" at foot of right column points to the 1585 block continuing).

Table continues onto the next folio (the 1585-onward observation blocks continue beyond this batch's pages).

Liber V — On Saturn

Caput XI (continued)

Selected positions of Saturn from the preceding observations, compared with the positions computed by the more celebrated Tables

The comparison table continues from the previous batch. In each block: the first row gives the date (year, month, day) and, beneath it, the hour and fraction of an hour of observation, together with the aspect symbol where shown; the Obs. & Tab. column names either the observer/observation source (Tycho, Lansberge, Longomontanus, Hortensius, Bullialdus [Boulliau], "Nobis" = ours/Riccioli, "Mutuus"/"Mutus") or the comparison Table being computed (Pru. = Prutenic, La. = Lansbergian, Da. = Danish [Tychonic via Longomontanus], Ru./Rud. = Rudolphine, Ph./Phi. = Philolaic [Boulliau], No. = Nobis/ours). The h Loca column gives Saturn's longitude (zodiac sign, degrees, minutes, seconds) and, where flagged, its latitude (Lat., with a = australis/south, B = borealis/north). The Differ. column gives the difference (minutes, seconds) of each Table's computed place from the observed (Tychonic or Nobis) place.

[Margin: Tabularum recensio]

COROLLARIUM [Corollary]

From the preceding Table the following conclusion may be drawn. There exists no set of Canons of the more celebrated astronomers that the observations do not support in some cases, nor any that they do not contradict in others — depending on how the figures fall. Even so, more of the observations stand in favor of Our Tables [Boulliau/Riccioli "Nobis"]; next come the Philolaic [Boulliau], to which the Rudolphine [Kepler] and the Danish [Tychonic, via Longomontanus] come closest; and in third rank fall the Lansbergian and the Prutenic. To make plain by an actual count the number of times — and the cases — in which each set of Tables satisfies the observations within 5' or within 10', the figures are set out in the little table inscribed below.

This always allowing for a more accurate computation, in case some error has crept in here through us, as men are liable to do.

Liber V — De Saturno (continued)

CAPVT XII.

On the Hypothesis and Theory of the Motions of the Five Minor Planets — geometric as well as arithmetic — and, in particular, on Saturn.

In which is shown the progress Astronomy has made in this matter, and the deficiency still latent in it.

On this first occasion offered by Saturn, I shall here take up in common those points that are shared with the remaining four lesser planets, prefacing some Suppositions.

I. Supposition.

[Margin: The seven kinds of motion.]

In the five minor planets, seven kinds of motion have been observed up to now. (1) The first is the daily revolution from the same meridian back to the same one over a span of about 24 hours; this is called the **First Motion**, or **Common Motion**, from east toward west. (2) The second is the planet's own motion [*Motus Proprius*], or **Secondary Motion**, from west toward east, by which the planets seem to move contrary to the motion of the *primum mobile*. (3) The third is the motion of declination from the equator [*Motus Declinationis ab Aequatore*], inasmuch as it is performed not about the poles of the equator but about the poles of the ecliptic, the axis of which is described about the poles of the Zodiac. (4) The fourth is the motion of latitude [*Motus Latitudinis*], because the proper orbit of these planets is inclined to the plane of the ecliptic, and so cuts it in two nodes, beyond which it is established that they deviate in latitude from the ecliptic. (5) The fifth is the motion of altitude [*Motus Altitudinis*], by which at certain times they recede higher from the Sun and from the Earth more rapidly and more strongly, until, at the greatest distance, they stand at apogee [*Apsides*], or rather at the apogees [*Apogei*]; and thence, gradually descending, they approach the Earth and the Sun more rapidly and more strongly, until at the least distance they pass out at the perigees [*Perigei*]. (6) The sixth is the motion of the perigee [*Motus Perigaeus*] about its own bodily center [*centrum corporis*]. (7) The seventh is the motion of libration [*Motus Librationis*], which has only recently been detected by the telescope and is not yet sufficiently confirmed.

The remaining differences of motion do not constitute distinct kinds, but are diverse affections of the same motion, considered as to quantity and anomaly.

For it is in this respect that the planets are said to be **direct**, **stationary**, or **retrograde**; or, by a twofold anomaly, are moved by one — which they call the **first inequality** or **eccentric** [*Primam inaequalitatem, seu Excentricam*] — and bound up with another, which some call the **second inequality** or **epicycle** [*Secundam inaequalitatem, seu Epicyclum*], and others the **commutation** [*Commutationis*]. And the first inequality alone shows itself [*exhibens*] in the line of the apsides, passing through the centers of the Sun and of the Earth; for it happens that the true conjunctions and oppositions of the planets with the Sun, and likewise their true [oppositions] under the same point of the ecliptic or of the Zodiac, appear — whether from the Earth or whether viewed from the Sun. Beyond these cases, the second inequality intervenes, however diverse the position of the highest heaven [*coeli supremi*] under which the planets are viewed from the Sun.

II. Supposition.

[Margin: Fluidity of the heaven — a Planetary [hypothesis] [*Fluiditas Coeli Planetarij*].]

To explain the aforesaid motions of the bodies of the heavenly orbs, the solidity of the heavens — taken as the multiplicity of the orbs, as the ancients held, whether absolutely or as a merely bare hypothesis — is asserted, and is by Us (Almag. Nov. sect. 2.) refuted as not only contrary to fact, but, if not on self-evident grounds, then at least on grounds in the highest degree probable, and is more commonly rejected after Copernicus by the recent astronomers, as we have shown at length (Almag. Nov. sect. 1, cap. 2, qu. 2).

and more fully, sect. 2, cap. 7, in speaking of the heavens proper to the planets. For that the sphere of the fixed stars is solid is held more probably, and perhaps above this is granted yet another sphere — that of the *primum mobile*, by whose daily snatching-round [*raptu*] the whole sphere of the fixed stars, together with these [planetary heavens], is daily carried about: unless these motions be everywhere performed throughout the bodily mass of the fixed stars and planets, by the sole intelligences, namely of the Angels, driving them on.

III. Supposition.

Although nothing has been indicated by the Suppositions set out — neither concerning the [first] motion, nor concerning any celestial phenomenon — that could not be saved without manifest error, mathematically and absolutely, or [taken] explicitly — whether the **First Motion**, or **Common Motion**, be attributed to the stars themselves, or to the Earth — yet, when these things are examined by

physical experiments and by mathematical rules, it is physico-mathematically evident that the Earth is not moved with the daily motion, much less with the yearly motion; both parts of this proposition we have shown, with the whole effort of our talent and with as great an erudition gathered from every quarter as was possible, at length (Almag. Nov. sect. 3, cap. 3 & 4). For the present, however, it suffices the Reader that the last chapter of Book 1 of this volume be read attentively and without prejudice, which we most earnestly beg.

[Margin: 4]

These things being supposed, we shall now set out how far, and in what direction, Astronomy has advanced up to now. First, Astronomy, profiting beyond what it had hitherto attained, learned this line: that the line of the apsides passes through the centers of the Sun and of the Earth at the same time; and that consequently the planets are not driven about unequally [*inaequaliter*] from the centers of the Sun and of the Earth — as the old Astronomy supposed — but in truth, together with the Sun, exhibit oppositions and conjunctions, and the orbits of the planets, free from so many librations toward the poles; that with a simpler inclination to the ecliptic they display the varieties of latitude; but that all the aforesaid motions are performed freely in a fluid aether [*fluida aura Aetheris*], without that farrago of solid orbs which they had excogitated.

[Margin: 5]

Next it [Astronomy] profited in this: that, although it sub-detected that inequality which appears in the motion of the planets — not the whole Optical [inequality], nor merely the Apparent one, but real, since it is not the center of the Planetary Motion that is regarded — yet, as though [the planets] were regarded from their own proper orbit about a certain center, and were moved equably, uniformly, and self-consistently: which indeed agrees with those celestial bodies, as being nearly divine, as the Ethnics [pagans] used to say; so persuaded were the Astronomers, even down to Longomontanus inclusively, that they included it as an axiom: **that the celestial motions are equable**. And therefore, by some and by other Eccentric Circles, Epicycles, etc., they tried to explain the diverse motions of the planets — by which causes the motion that has its centers equable would seem to us on Earth to be unequal, just as we have explained, in agreement, by figures (Almag. Nov. sect. 2, cap. 2 & 3).

[Margin: But Kepler [was] the first of all.]

But Kepler was the first of all who observed that inequality to be partly **Optical** — as it appears to us Earth-dwellers — and partly **Physical** and **Real**: for in the orbit

of the planet there are two centers, of which at one is the center of the Earth, at the other the center of the planet's own orbit; about which center the planet is moved really unequally. For if the planet be supposed to be moved equably about the center of its orbit, and about the whole eccentricity — that is, by however much the orbit's center is distant from the Earth's center — then, from the base of the triangle measuring the angle of prosthaphaeresis, the **mean motion**, or **equable** [motion], can never be reduced to the **true** [motion], unless the line ascribed [to it] exactly satisfies the places of the planet exactly observed. But if the eccentricity be bisected, three points are set up in the line of the apsides: one is our Earth, the other the center of the planet's orbit, and the third in the middle, which is distant from the Earth by an interval equal to that by which the planet is distant from the center of the orbit; about which middle point the planet is moved equably: which arises far more justly from the equation compounded from the **Physical** [equation], whose basis is the distance of the orbit's center from the center of the Earth, and from the **Optical** [equation], whose basis is the distance of the orbit's center from the center of the Earth.

[Margin: 6]

But because the Ellipse has this property — that in its diameter there are three points equally distant, namely the center of the Ellipse, and from it on either side the two foci, or umbilici [*foci, seu vmbilici*], and that the points which coincide with the [reflected] radius—

—[the radius] reflected from the periphery, and that the physical power [*virtus physica*] is dispersed through it: therefore Kepler, by his own sagacity, perceived the Orbit of the planets to be not circular but **elliptical**, and the causes of the planetary motion to be physical. For from the Ellipse he renders the reason why the planet, at the extremities of its greater diameter, is there at aphelion and apogee, here at perihelion and perigee, and dispenses its motions according as they appear. He showed, however, the manner of constructing the **prosthaphaereses** in the Ellipse, and of investigating the **Aphelion**, or Apogee — but did not demonstrate it geometrically [*non demonstrauit Geometrica*]
[Margin:... [*deficit*]].

[Margin: 7]

Ismaël Boulliau [Bullialdus] succeeded Kepler, who not only (Astron. Philolaica cap. 13 & lib. 11) endeavored to demonstrate the motion of the planet, in such a way that it should describe an Ellipse through diverse circles upon the surface of a single cone — yet [a thing] soluble by equipollence into several circles — but

also taught the same by an exact method of the way of investigating the prosthaphaereses in the Ellipse, and the places of the aphelia: though indeed not so exact in subtlety [*subtilitate*], so that there remained for Sethus Wardus [Seth Ward] the place [task] to emend it, then for Boulliau to investigate the places of the aphelia more exactly in the Ellipse. But Count Pagan [the Comte de Pagan] showed the Elliptical figure rather felicitously, [the figure] in use for demonstrating the planetary motions; and the same [is] essayed by our most friendly Io. Dominicus Cassinus [Giovanni Domenico Cassini].

[Margin: 8]

Thus far recent Astronomy has progressed; but it still seems to me that it must profit yet, until we recognize that the motion of the planets is to be saved not from a part only, but as a whole; that it is to be made not equable, but uniformly non-uniform; that the heavenly bodies are not adorned [*decorem*] without reason, but most highly in agreement with the bounds set by God the supreme Maker: for those equalities which seem to us beautiful are themselves beautiful; but those inequalities are more beautiful, which constitute the regular harmony of the World by a regular [law], as I have set forth in many other examples (Opificio Dei). Furthermore, I consider that [the motion] is to be resolved not only into several circles through an Ellipse, but also through Eccentrics, and Copernican Epicycles, or Danish [ones], not rarely [*representing*] the observed places of the planet more exactly — which is an indication that we do not yet hold that genuine figure by which the measure of the planetary motions is defined.

[Margin: 9]

Moreover, I suppose that the aforesaid Authors, who by a single Ellipse expound the planet's motion, hold the Earth to be moved by the **First Motion** from east to west; otherwise the **First Motion** cannot be saved by a single Ellipse, by the fluidity of the Planetary heaven, of which [we treat] in Supposition 1. And just as the First Motion cannot be reconciled with the Second by a single Ellipse — and with the remaining [motions] enumerated in Supposition 1 — and since the Earth's being so moved is false from what was said in Supposition III: it remains, therefore, that it be expounded by the Astronomers in what way the aforesaid motions, without physical repugnance, are continually performed by a single planet.

[Margin: 9 (continued)]

Now indeed, if what was found by Kepler — too friendly to his own inventions — seemed absurd, then at last Astronomy will be recalled to that [view], so that we

recognize the Planets to describe a Conical surface from east to west toward others, and otherwise [toward others], by spirals as it were circular, now broader, now narrower, according as the five prior motions enumerated in Supposition 1 require; and easily not only will the First Motion be reconciled with the Second, but also at once with the remaining three; and at once the planets will appear: now stationary, direct, or retrograde, but in very fact perpetually carried about toward the west in their circumference, and then they will seem not to advance in the Zodiac, when they come to the same meridian at the same moment together with some one of the fixed stars, after [the interval] by which it was the previous day under the same meridian; **direct**, however, when they return more tardily to the same meridian than the same fixed star; but **retrograde**, when they revert thither more swiftly than the fixed star, with which they had been the previous day under the very same meridian.

[Margin: 10]

Nor indeed does it befit Astronomers to be of so confined a breast that they should not comprehend this spiral motion, because it cannot be drawn by a single simple figure; especially since, with a kind of [gypsum] string [*gypso*] turning about the surface of a cone [*conum*], the spiral motion is unrolled, and through any point a section can be made of such a vestige left on the conic surface — and that point [section], if not exactly Elliptical, yet very near, approaching the Elliptical — even though by this the orbit of the planet itself is not really moved.

[Margin: 11]

Finally, Astronomy ought to profit in the observing—

—of the places of the planets most exactly, by mutual conjunctions [*congressus*], or with the fixed stars by aid of the Telescope, or by appulse with the fixed stars to the meridian: so that all the places may be noted, and free from error of many minutes; then there will be by far a more certain measure from observation, whether of a single Ellipse, or of the figure described by spirals — equipollent to the Ellipse; and so, from a sounder foundation, Tables yet more certain are to be constructed for setting up the places of the planets. But, retaining meanwhile the Elliptical figure — whether really or whether equipollently — we lay down in Saturn these things that follow.

[Table — Saturn's mean motions and apogee/node motions. Three columns of motion-arc groups under a tabular rule. Headers read across: Sig. (signs) | G. (degrees) | I | II | III | IV | V (successive sexagesimal orders).]

Mean motion from □		Sig.	G.	I	II	III	IV	V
	Daily [<i>Diurnus</i>]	0	0	2	0	35	13	38
	Annual [<i>Annuus</i>]	0	12	13	34	17	54	32
Of the Apogee [<i>Apogei</i>]	Daily [<i>Diurnus</i>]	0	0	0	0	18	45	14
	Annual [<i>Annuus</i>]	0	0	1	54	5	12	10
Of the Nodes [<i>Nodi</i>] [Boul liau]	Daily [<i>Diurnus</i>]	0	0	0	0	4	15	36
	Annual [<i>Annuus</i>]	0	0	25	54	51	[?]	43

Parsing notes: The first column-block is the row-label group (apogee / node bracketed to their Diurnus/Annuus rows); the body labels "Apogei" and "Nodi

Bo[ulliau]" sit beside the Diurnus rows. The "♈" in the heading is the symbol for Aries. The IV-order entry of the Nodes-Annual row is partly obscured (read "51"); flagged. The leading "Diurnus/Annuus" pair without a row-label belongs to the mean motion itself.

Epoch of Christ, at noon of the last day of December, in the Meridian of Bologna [*Bonon.*].

[Table — radix (epoch) positions for Saturn.]

	Sig.	Gr.	I	II
Mean motion [<i>Motus medij</i>]	2	13	1	45
Apogee [<i>Apogei</i>]	7	5	15	25
Nodes ♁ [<i>Nodi</i>]	3	8	59	18

For the Geometric Figure of the Hypothesis.

The Ellipse having meanwhile been chosen — whose nearest traces the planet's daily motion designates, made toward the west through some [points], and through others as it were circular about the cone — let the measures written below be chosen.

Of such parts as the radius, or semidiameter, of the Solar Ellipse is 100000, its bisected eccentricity is 1740. Of such parts is the following.

[Table — Saturn's ellipse dimensions and distances. Two-column structure; the upper block gives semidiameters and eccentricity referred to "If the Radius of the Orbit ☉ be 100000."]

	If the Radius of the Orbit ☉ be 100000

Sun at Perigee, Saturn at Perihelio n [☉ <i>Perig.</i> ♁ <i>Perihelio</i>] in ☐	2	15	12
[same] in ♁	2	48	4

Parsing notes: The conjunction/opposition symbols are rendered by Riccioli with the planetary aspect glyphs (here transcribed ☉ for conjunction-with-Sun and ♁ for opposition); each latitude-case is paired across these two aspects. "in σ / in ∂" in the source are the aspect symbols; read as conjunction (☉) and opposition (♁) of Saturn with the Sun.

You have the figures described and explained (Almag. Nov. sect. 2 & 3) — but [read] in place of the Ellipse, the Circle [*Circulus*], and its use.

The right-hand column of p. 302 [recto text block, continuing the prose]:

re-read in this Volume Book One, and its Chapter XI with the Appendix; or read the Geometric Astronomy of Seth Ward [*Sethi Vuardi*], published at London in the year 1656, in which he teaches how to investigate, both by the circle and by the Ellipse, the inequality in the quality of the planets, the Nodes, the Inclinations, etc. — whether the eye be placed in the Sun, or in the Earth, or in some other [point] from which the Sun is seen. But in that work it requires Observations

somewhat too delicate, and bound to certain precise moments of time, which cannot be reduced to the nearest [value] with ease, and [it requires] subtlety; so that perhaps who would think it could be done — and the precepts of these, by occasion, not rarely, are sub-derived from clouds, or from elsewhere. If, however, the Astronomers should at length persevere in this study with patience [*longanimiter*], it can finally be brought about that such [Tables] may be made, or that, from so many observations obtained, and by the benefit of the Geometry demonstrated by Ward, they may perfect Astronomy. But it is always incumbent upon them [to reconcile] the daily motion of the *primum mobile* — which at the end we show cannot be attributed to the Earth — to reconcile [*conciliare*] it with the Sun, with the proper motion of the stars.

BOOK SIX

IN WHICH ARE THE OBSERVATIONS OF THE PLANET JUPITER, AND THE HYPOTHESIS OF ITS MOTIONS.

CHAPTER I.

Ancient Observations of Jupiter, from the Year 241 before Christ down to the Year 807 of the same era.

1. In the year 45 — according to Dionysius, on the 10th of the month Parthenon, that is, in the year 83 [of the Era of Nabonassar?] reckoned from the death of Alexander the Great, on the 17th of Epiphi, the next day being the 18th — at the first hour after midnight Jupiter approached the southern Donkey [the Aselli], which lies in the Nebula [Praesepe] of Cancer (Ptolemy, *Almagest* XI, ch. 3). Ptolemy judged that this star lay one degree to the east of Jupiter. Longomontanus (*Theoricae*, Book 2, ch. 7) and Boulliau [Bullialdus] (*Astronomia*, ch. 7) hold that this fell in the year 241 before Christ, and they place it [the observation] on the 3rd of September. The hour was 16, reckoned after noon at Uraniborg, when the star stood with Jupiter in Cancer at $7^{\circ}33'$, as Longomontanus has it — or, by Boulliau's calculation, at minus $6'$ — with southern latitude $25'$. But Lansberg, in his *Thesaurus* of observations, says that it was the year 507 of Nabonassar, the 17th of Epiphi, and the hour 17, [placing] the Asellus, that is, Jupiter, in latitude $10'$ south, and the longitude of Cancer at $7^{\circ}32'$ by the observation, but at $7^{\circ}54'$ by his own Tables. Truly it was the 3rd of September; nevertheless [Lansberg makes it?] fixed at Cancer $7^{\circ}11'$ with southern latitude $5^{\circ}30'$.

2. In the 17th year of the Emperor Hadrian, on the 1st day of Epiphi, at the first hour before the middle of the following night, Ptolemy at Alexandria gathered from his observation, made by the acronychal opposition, that it [the opposition] had occurred with the mean place of the Sun, Jupiter standing in Scorpio at $23^{\circ}11'$ (so he himself, *Almagest* XI, ch. 1, and also Copernicus, Book 5, ch. 10). That year was the year of Christ 133, and the 18th of May.

3. In the 21st year of Hadrian, on the 13th of Phaophi, at the second hour before the middle of the following night, Ptolemy, observing at Alexandria, judged it [an opposition] to have been made by the acronychal opposition of Jupiter, [occurring] with the mean place of the Sun, Jupiter standing in Pisces at $7^{\circ}54'$ (so he himself, *Almagest* XI, ch. 1, and Copernicus likewise). That was the year of Christ 136, and the 31st of August.

4. In the first year of the Emperor Antoninus, on the 20th of the month Athyr, the next day being the 21st, at the fifth hour after midnight, Jupiter stood opposite the mean place of the Sun in Aries at $14^{\circ}23'$, by observation and by Ptolemy's reasoning (*Almagest* XI, ch. 1); and indeed it is designated in Greek thus: ἀθὺρ κ̄ εἰς τὸν κα κ̄ [Greek: athyr 20, into the 21st — a date-formula, "Athyr the 20th, going into the 21st"]. That is, Athyr 20 going into the 21st. Copernicus erroneously placed the day at the 15th (Copernicus, Book 5, ch. 10). It was the year of Christ 137, and the 7th of October.

5. In the 2nd year of Antoninus, on the 26th of the month Messori, the next day being the 27th, at about the fifth equal hour after midnight, Ptolemy, observing at Alexandria, compared Jupiter with the bright [star] of the Hyades [Succula], and judged it to be in Aries $15^{\circ}45'$ (Geminus also reports it, Book 11, ch. 2). Lansberg, in his *Thesaurus* of observations, reports this same observation of Jupiter in the year 139 [of Christ?], July 20, hour 17, after noon at Alexandria, and [states] that Jupiter together with the splendid star of the Hyades stood in Gemini at $15^{\circ}36'$ (so Longomontanus, Book 2, ch. 7); and so it was indeed the year 139, the first of Antoninus 136 to 139, the 20th of July, the next day being the 21st, in the year 139.

6. In the year of Christ 508, that is, the year of Diocletian 225, on the 30th of the month Thoth — that is, the 28th of September — Jupiter was seen in the morning at Athens to be very close to the Heart of Leo [Cor Leonis, Regulus], three digits distant from it; this is the minutes $7\frac{1}{4}$, [measured] from the north toward the Boreal side. So Boulliau, Book 7, *Astronomy*, ch. 7, from a manuscript of the Library of the Most Christian King [the French royal library], adding that the Heart of Leo then stood in Leo at $8^{\circ}49'54''$. And in the same manuscript it is indicated that the conjunction of Jupiter and Mars was observed in the year of

Diocletian 214, the 6th of Pachon, coming in the 7th [year], at the second hour after midnight.

In the year of Christ 807, on the day before the Kalends of February [31 January], on the 17th day of the Moon, the star of Jupiter was seen to pass across, as it were, below the Moon, as is recorded in the *Annals of the Franks* and in the *Life of Charlemagne* [Charles the Great].

CHAPTER II.

Observations of Jupiter made by Johannes Regiomontanus and by Bernhard Walther, from the Year of Christ 1471 to 1504.

The First Class consists of observations made by visual estimation.

1. In the year 1471, March 15, Regiomontanus at Esztergom [Strigonium] saw Jupiter very nearly in a straight line between the brighter of the two stars in the middle of Virgo and a dimmer one near the eye, toward the side of Leo; and he distinguished it [its position] more obscurely as two-fifths of the interval between the said stars. On the 9th of August, at evening, he saw Jupiter and Venus at Nuremberg distant from each other by $1^{\circ}13'$; using his own [observing] Rods [Radii], let it be supposed. The Alphonsine reckoning would require it to be $4^{\circ}33'$.
2. In the year 1478, Bernhard Walther observed, both on the 22nd of August and on the 30th of September, that Jupiter [lay] in a straight line with the two eyes of Taurus, as if 3 [units] after midnight, and from the more westerly eye toward the west it was distant by half the interval of the eyes of Taurus.
3. In the year 1488, October 8, with [Jupiter] standing in M.C. [the meridian-crossing or mean conjunction?] at $13^{\circ}\frac{1}{2}$, it was observed by Walther in degree $13^{\circ}20'$ of Pisces, with southern latitude one degree. Boulliau (*Astronomy*, ch. 7) says that Jupiter was in degree $14^{\circ}16'$ of Pisces. If the place of Aldebaran is corrected, it was in Gemini at $2^{\circ}36'$; but this observation looks toward the armillaries, concerning which see below.
4. In the year 1497, February 15, in the morning at the 4th hour after midnight, the Moon and Mars and Jupiter were equally distant by a lunar diameter, says Walther; but this distance, for the half on the latitude side, [showed] Mars to be the more westerly and southerly of Jupiter, although by the *Almanac* their conjunction, which was still to come, had passed by.
5. In the year 1503, September 8, in the morning at the 4th hour after midnight, I saw, says Walther, Jupiter near a star, which is the eighth of Gemini, on the right

side of the preceding [star], and it had been almost in the same conjunction in longitude with that star; so that, if you imagine an arc drawn through the Pole of the Zodiac and the star, it would touch the western limb of Jupiter; but truly toward Jupiter's eastern part it [transgressed?] by the breadth of two digits beyond it. Moreover, the aforesaid star, distant from the Ecliptic of Ptolemy toward the north, [stood at] degree $2^{\circ}40'$; granted that by the armillaries it was observed by Walther to have scarcely any latitude. Lansberg, in his *Thesaurus*, gathers that Jupiter was in Cancer at degree $12^{\circ}2'$ from the Tables $11^{\circ}56'$, with southern latitude $6'$. But the aforesaid fixed star, which he says [is at] $12' - 11'$. The fixed star itself [Mihi Fixa] is at Gemini $11^{\circ}55'$, with northern latitude $56\frac{2}{3}$. But the fixed star [is at] Gemini 12° , latitude $15'$.

6. In the year 1503, October 6, I judged, says Walther, by ocular [estimate] the conjunction of Jupiter and Mars in longitude; but Mars was more northerly than Jupiter by one [digit], at about the rising of the Moon, before the rising of the Sun by two hours.

7. In the year 1504, February 9, Walther notes the conjunction of Jupiter with Mars; and on the 29th of April [he notes] the conjunction of Jupiter with the eighth of Gemini after noon, [Jupiter being] in longitude according to the half-degree, with Jupiter standing more northerly by half a degree; but Boulliau (Book 7, ch. 7) affirms that Walther, here as in the observation of the year 1503, September 8, was deceived in reading the catalog of Ptolemy, [confusing] the eighth of Gemini with another twelfth, which is in the left groin of the following Gemini; and that the time of that observation was Cancer $11^{\circ}33'$ with southern latitude at least $13'$; but from the Tables he gathers the place of Jupiter to be in Cancer at degree $12^{\circ}0'25''$.

[Margin / table: the right-hand column carries this observation table, headed by the source's running note.]

The Second Class contains only two observations made by the Rods [Radii], concerning whose use see the Saturnine observations of Walther, no. 10.

8. I have already mentioned the first observation. The other was made in the year 1478, August 24, in the morning, when the first interval of distance between Jupiter and the right eye of Taurus was 70 [units], and the second interval 811; but between Jupiter and the left eye of Taurus the first interval was 30, the second 942.

The Third Class is of Observations by the Zodiacal Armillaries, concerning whose uncertainty within 10 minutes see the observations of Walther on Saturn, no. 33, above.

Table of Jupiter's positions observed:

No.	Year/ Mon./ Day	☿ Place observe d (Sign)	Gr.	M.	Med. coeli Gr.	Sign
		Lat. B.	0	20		

Parsing notes: This is a four-part table — observation number, date (Year/Month/Day, "n.s." = new style, "manè" = morning, "p.m." = post meridiem), the observed place of Jupiter (☿) by sign/degree/minute (with latitude rows interleaved, "Lat. A." = northern/austral?, "Lat. B." = boreal/northern), and the *Medium coeli* (meridian) by degree and sign. Several rows in the central sign column read only the degree/minute, the sign being carried down from "Cancer" (Cancrī) above; I have bracketed [Cancer?] where the sign is implied by the column rather than freshly printed. Row 41's day is ink-faint ([?]). The latitude sub-rows ("Lat. A."/"Lat. B.") belong to the observation immediately above them. The "Med. coeli" entries mixing hour-values ("hor. 4 p.m.", "h. 2½ p.m.") for rows 11–12 are as printed.

Table of Jupiter's positions observed (continued, left column):

No.	Year/ Mon./ Day	☿ Place observe d (Sign)	Gr.	M.	Med. coeli Gr.	Sign
46	1504 Maij 9 n.s.	Cancer	13	18	4	Librae
47	Maij 18 n.s.	[Cancer]	15	2	19	Librae
48	Maij 23 n.s.	[Cancer]	15	53	26	Librae
49	Maij 24 n.s.	[Cancer]	16	0	1	Scorpij
		Lat. B.	0	20		
50	Maij 25 n.s.	[Cancer]	16	13	4	Scorpij
51	Maij 28 n.s.	[Cancer]	16	53	5	Scorpij
52	Maij 29 n.s.	[Cancer]	17	3	14	Scorpij

Parsing notes: Continuation of the Class-Three armillary table from folio 304. Same column layout. The sign "Cancer" is carried down from the foot of the previous page's column; I bracket [Cancer] where the printed cell shows only degree/minute. The right-hand column of this page (rows 1–3) belongs to a *different* comparison table (observed vs. Alphonsine vs. Copernican places), transcribed separately below.

CHAPTER III.

Copernican Observations of Jupiter, from the Year of Christ 1520 to 1530.

It must be noted that Copernicus reckons the longitudes of the planets from the first Fixed Star at the preceding horn of Aries, which in the year 1525 he places at a distance of $20^{\circ}40'$ from the Vernal Equinox; the longitude is thence derived in due order.

1. In the year 1520, on the 11th of the Kalends of March [19 February], in the morning, at hours 6 before noon, Copernicus by an instrument most diligently observed Jupiter [the distance of the intervals], to precede the first Star, which is in the forehead of Scorpio, the brighter one, whose place I have said to have been in the parts $224^{\circ}15'$ scruple [of arc] 9 — that is, with respect to the inerrant [fixed] sphere — and so the place of Jupiter was then in the parts $215^{\circ}9'$ of Scorpio at $16^{\circ}48'$ (Copernicus, Book 5, *De Revolutionibus*, ch. 14).
2. In the year of Christ 1520, the day before the Kalends of May [30 April], in the middle of the preceding night, Copernicus, as he himself asserts, diligently observed Jupiter acronychal in degree 200 [parts] of the Fixed Stars, scruple 18, that is, in Scorpio at $10^{\circ}57'$ (so he himself, Book 5, ch. 11).
3. In the year of Christ 1526, the 4th of the Kalends of December [28 November], at hours 3 [past?] the middle of the night, Copernicus observed Jupiter acronychal in the parts $47^{\circ}33''$ of the Fixed Stars, that is, in Gemini at $2^{\circ}36'$ (Copernicus, Book 5, ch. 11).
4. In the year of Christ 1529, on the Kalends of February [1 February], the night of the transit, at hours 19 from the middle of the night, Copernicus observed Jupiter acronychal in degree 113° of the Fixed Stars, scruple 44, that is, in Leo at $14^{\circ}28'$ (Copernicus, Book 5, ch. 11).

CHAPTER IV.

Observations of Jupiter by Tycho.

Tycho himself, in his *Letters to the Landgrave of Hesse* [Wilhelm IV of Hesse-Kassel], page 56, sets down the following observations of Jupiter made at Uraniborg [Vraniburg] in the year 1587, and noted in the Old Style, with the calculation drawn from the Alphonsine and Copernican Tables.

Comparison table — observed vs. Alphonsine vs. Copernican places of Jupiter:

No.	Hour H. : M. after mer.	Source	Longit. of Jupiter (Sign : Gr. : M.)	Latitude (Gr. : M.)
1	9 : 15	Observed	Cancer 7 : 52	0 : 9 B
		Alphonsine	7 : 55	0 : 6
		Copernican	7 : 32	0 : 32 A
2	14 : 8	Observed	Cancer 7 : 19	0 : 8 B
		Alphonsine	7 : 0	0 : 5 A
		Copernican	7 : 1	0 : 32 A
3	15 : 6 : 10	Observed	Cancer 7 : 15	0 : 8 B
		Alphonsine	7 : 1	0 : 5 A
		Copernican	6 : 56	0 : 32 A

Parsing notes: A three-row comparison table, each row giving the time after meridian (H : M, with row 3 carrying a third sub-figure), then three rows of values (Observed / Alphonsine / Copernican) for the longitude of Jupiter (sign Cancer + degree : minute) and the latitude (degree : minute, with "B" = Boreal/north and "A" = Austral/south). The sign "Cancer" is printed once per observation and applies to all three sub-rows.

Lansberg, in his *Thesaurus* of Observations of Jupiter, no. 4, examines the Tyconic observation of day 14, and gathers from his own Tables the place of Jupiter in Cancer at 7°19'59", with northern latitude 9'.

Longomontanus, in the *Astronomia Danica*, Book 2, *Theorica*, ch. 1, exhibits eight acronychal places of Jupiter from the Tychonic observation — to be sure, with the place of Jupiter supplied from the latest three by the Prutenic Tables, but corrected, by adding to the mean longitude $4^{\circ}\frac{2}{3}$, and to the apogee $40'$. The prosthaphaeresis, moreover, everywhere uses the twenty-fourth part, and these are of the kind [reckoned] in the Old Style of the [Julian] Calendar.

From the aforesaid acronychal [positions] Boulliau, Book 7, *Astronomia Philolaica*, uses observations of the years 1583, 1584, 1591, and 1596, in ch. 1 and 2, which you may consult.

There follow the latest Tychonic observations, made in the fortress of Benátky near Prague, in the year 1600 — or at Prague, in the house of Curtius, in the year 1601 — recorded by Snellius in the *Observations* published at Leiden of the Batavians [Lugduni Batavorum] in the year 1618.

12. In the year 1600, February 3, when the bright [star] of Hydra was distant from the meridian toward the south by about one degree, and the head of Hydra had crossed [the meridian] before about one hour of the meridian, Tycho observed Jupiter distant from the head of Pollux by degree $29^{\circ}51'\frac{2}{3}$, and corrected for refraction by $29^{\circ}52'\frac{3}{5}$; and from the bright [star] of the feet of Gemini by $44^{\circ}11'\frac{1}{2}$, but corrected by $44^{\circ}11'50''$.

13. In the year 1600, February 4, in the New Style, on the following night the meridian altitude of Jupiter was observed to be degree $56^{\circ}29'\frac{1}{3}$; immediately afterward the meridian altitude of the more southerly [star] in the head of Leo was taken, and was degree $65^{\circ}15'\frac{3}{5}$; and the following [stars] in the other foot of Leo were degree $65^{\circ}15'\frac{3}{5}$; and at that time Jupiter had withdrawn from the meridian, by as much as was the diameter of its own body.

14. In the year 1600, April 12, in the New Style, at hour 9, 46' after noon, Jupiter stood distant from the bright [star] of the feet of Gemini by degree $39^{\circ}0'\frac{1}{3}$; and at hour 9, minute 53', it was distant from Regulus by degree $12^{\circ}36'$.

15. In the year 1601, July 16, in the New Style, on the following night at hour 9, 40', Jupiter was high by degree $10^{\circ}40'$ and was seen to be distant from Arcturus by degree $41^{\circ}26'$; and at hour 9, 29', it was high by degree $9^{\circ}51'$ and distant from Saturn by degree $45^{\circ}18'$.

There follow the observations of Jupiter completed by Tycho from the year 1583 down to 1599 at Uraniborg, with the rest in Bohemia, which the Reverend Father Albert Curtius of the Society of Jesus selected from a manuscript of Tycho, and

transmitted to us, to be published by us among the Tyconic observations once entrusted to the Emperor [Caesar], noted in the Old Style.

Caput IV (continued) — Jupiter's Observations by Tycho

(continuation of Tycho's 1583–1599 series at Uraniborg and in Bohemia, Old Style)

The table continues the numbered observations begun in the prior batch.

Columns: item number; year, month, and day; H. M. p. mer. (hour and minute past the meridian); Long. ♃ observ. (Jupiter's observed longitude — zodiac sign, degrees, minutes); Lat. observ. (observed latitude — degrees, minutes, with the A/B marginal direction-flag where present).

Parsing notes: In the right-hand block (items 77–86) the printed "H. M." cells are blank in the source for items 77–80 (no time recorded for those four rows); the longitude column carries distinct degree-minute values, not a repetition of the H. M. column. The zodiac sign is given only at the head of each sign-group (♋ Cancer for items 77–78, ♌ Leo from item 79 onward). The A/B flags in the rightmost column mark the marginal direction-letters as printed.

After the Bologna printing of the Tyconic observations had already begun, Fr. Curtz sent me the specimen of the observation transcribed below, made in Bohemia in the year 1600:

(A second detailed table follows. Columns: item number; Month, Day [with explanatory note]; Distance from fixed stars [Distantia à Fixis]; Jupiter's [reading] in degrees, minutes [I], seconds [II].)

No.	Month, Day	Distance from fixed stars (à Fixis)	Jupiter Gr.	I	II
87	Ianuar. 6, with Jupiter high in the meridian , grad. 44. 6¾	from the heart of ♌ [Leo, i.e. Regulus]	27	57	40

No.	Month, Day	Distance from fixed stars (à Fixis)	Jupiter Gr.	I	II
		repeated twice	27	57	40
		corrected nonethel ess	27	55	40
		from Spica ☐ [Virgo]	26	16	0
		repeated	26	16	0
		corrected	26	14	0
88	Ianuar. 9	from the heart of ☐ [Leo]	28	0	40
		repeated twice	28	0	40
		corrected	27	48	40
		from Spica ☐ [Virgo]	26	19	0
		repeated twice	26	19	0
		corrected	26	17	0
	Jupiter's meridian altitude was 44		44	14	40

Note to item 88: Jupiter was in a straight line with Arcturus and with Vindemiatrix [☐ Virginis], and by nearly the diameter of its own body it inclined to the south of the line drawn through the heart of Leo, and a third of that.

No.	Month, Day	Distance from fixed stars (à Fixis)	Jupiter Gr.	I	II
89	Febr., on the last day of the following night	from the heart of Leo [Regulus]	24	2	0
		repeated	25	0	0
		repeated twice	23	59	0
		then [pone]	23	56	30
		corrected	23	56	0
		from Spica Virginis	30	17	30
		repeated	30	18	0
		repeated	30	19	0
		then [pone]	30	18	30
		corrected	30	16	0

On this observation, item 89, Riccioli notes: This discrepancy among the observations was caused by the unreliability of the instrument, by the excessive height of the pedestal, and by the mobility of the sextant suspended from it. But at that time Jupiter's meridian altitude was:

	Gr.	I	II
by the quadrant	46	2	20
by the sextant — better	46	5	0

No.	Month, Day	Distance from fixed stars	Jupiter Gr.	I	II
90	Mart. 3, h. 11.30'	Longitud e ♃: ♌ [Leo]	18	12	30
		Latitude, southern	1	33	30

Note to item 90: Since from the altitude of the Sun observed on the same day, which ought to have been 32. 5'. 14", it is gathered that the quadrant fell short of the true altitudes by 3' less than it should — these have been added to that altitude of Jupiter, and thus corrected.

On the same day [Jupiter] was distant:

	Distance from fixed stars	Gr.	I	II
from the heart of Leo [Regulus]	23		34	0
repeated	23		35	30
repeated	23		34	0
from Spica Virginis	30		42	30
repeated twice	30		42	0
♃ meridian altitude	46		9	50

(The second detailed table continues at the head of folio 307. Columns as before: Month, Day; Distance from fixed stars; Jupiter Gr., I, II.)

No.	Month, Day	Distance from fixed stars	Jupiter Gr.	I	II
91	Mart. 4, near oppositio n with ♃ ☉ ♁ [Jupiter– Sun oppositio n], with [Jupiter] ♁ from the heart [of Leo]		23	25	0
	repeated twice		23	25	30
	from the bright star in ♌ [Leo]		24	39	30
	repeated twice		24	40	0
	from the third in the wing of ♍ [Virgo]		17	0	0
	♃ meridian altitude, by quadrant		46	11	0
	from the eastern		46	13	0

No.	Month, Day	Distance from fixed stars	Jupiter Gr.	I	II
	horn [sextant orichalc.]				
	distant from Spica □ [Virgo]		30	49	30
	repeated twice		30	50	0
	≈ hour 11. 30'. Jupiter's longitude in □ [Leo]		17	47	30
	northern latitude		1	31	4

To this, on the 4th of March, [the following additional readings:]

	Distance from fixed stars	Gr.	I	II
Jupiter's declination		6	17	40
hence Jupiter's right ascension comes out		169	14	44
distance corrected from the third in the wing of □		16	58	20

Distance from fixed stars	Gr.	I	II
[Virgo]			
hence Jupiter's right ascension	169	13	50
Jupiter's distance from the bright star in the neck of ♌ [Leo], corrected	24	37	50
hence Jupiter's right ascension	169	14	17
Jupiter's distance from Spica ♍ [Virgo], corrected	169	15	37
right ascension everywher e limited [reconciled]	169	14	0
hence again Jupiter's longitude	17	38	30
northern latitude	1	30	50

[Margin / closing rubric:] **Thus far from Tycho's autograph** [Hactenus ex Authographo Tychonis].

CAPVT V.

Jupiter's Observations made at Kassel by Jost Bürgi [Iusto Byrgio], the instrument-maker of Landgrave [William IV] of Hesse, selected from Snel among the Hessian observations, together with the Keplerian and Longomontanian observations.

(A table follows. Columns: item number; year, month, day, hour, minute [Ann. Mens. D. H. M.], Old Style, past the meridian; Jupiter's distance from the fixed stars [Gr., M.]; the reference star.)

No.	Year, Month, Day, H., M. (Old Style, past mer.)	Distance Gr.	M.	from the star
1	1590 Dec. 5 13 18	4	2	from Spica
		8	20	from the northern arm [Lance Borea]
2	1591 Ian. 20 16 30	4	13½	from Spica

				Orió.]
8	— Oct. 1 13 11	13	5	from Aldebaran
		27	4½	from Capella
9	1595 Sept. 11 0 33	59½ [?]		from the third of Aries [tertia Arietis]
	(it had to be set down above)	33	9	from the shin of Pegasus [crure Pegasi]

Note following the table: Boulliau [Bullialdus], book 7, ch. 3, having used the observation of the year 1591, Jan. 29, gathers Jupiter's place to be \square [Scorpio] 17. 9'. 22", with northern latitude 1. 21'. 14"; but for the year 1597, Sept. 13, the place \square [Pisces] 16. 14'. 11", in \square [Scorpio] [the operative sign], with southern latitude 0. 35'. 29".

(Continuing in the right-hand column, three further numbered items close out the Longomontanus / Kepler material before Caput VI. These are observational prose, not tabulated.)

10. In the year 1593, Sept. 28, Old Style, at the 8th evening hour, Longomontanus, observing at Hven [Huena], found Jupiter high above the horizon by $33^{\circ} 59'$; and from the right knee of Ophiuchus [Ophiuchi] it was distant by $13^{\circ} 33'$. From the far tip of the tail of Capricorn it was distant by $33^{\circ} 59'$. Having removed the refraction, he deduced Jupiter's longitude as Capricorn $13^{\circ} 56'$, with southern latitude $0^{\circ} 25'$. So Longomontanus, *Theoricæ* lib. 2, ch. 6.

11. In the year 1604, Sept. 27, New Style, at Prague at the 8th hour after midday — or perhaps a little after — there occurred a conjunction of Saturn and Mars; but on the 10th day, in October, at the 1st hour before midday, from observations

before and after, there was a conjunction of Jupiter and Mars, as Kepler reports in his book *On the New Star in Serpentarius* [*De Stella Nova in Serpentario*], ch. 11.

12. In the year 1616, on March 10, Old Style, in the morning at the 4th hour, Longomontanus at Copenhagen [Hafniæ], using a sextant, observed Jupiter distant from the heart of Scorpio [Antares] by $23^{\circ} 46'$; and from the bright star of the Vulture [Vulturis, i.e. Altair] by $39^{\circ} 44\frac{1}{2}'$. Since [Jupiter's] altitude was 10° , having eliminated the refraction and parallax, he deduced Jupiter's place to be in Sagittarius $27^{\circ} 41'$, with northern latitude $0^{\circ} 24'$ — so he himself, *Theoricæ* lib. 2, ch. 6, & from Boulliau lib. 7, ch. 3, who uses this same observation.

13. The remaining observations of Longomontanus concerning Jupiter, acronychal, for the years 1607, 1610, and 1613, I have reported above with the Tyconic ones, nos. 9, 10, 11. See also what I noted above concerning Fr. Albert, no. 33, where Longomontanus reports (*Theoricorum* lib. 2, ch. 13) — saying that in the year 1591, on April 14, at the 11th hour of night, he observed Jupiter to be in Scorpio $14^{\circ} 16'$, with northern latitude $1^{\circ} 25\frac{1}{2}'$.

CAPVT VI.

Jupiter's Observations made by Pierre Gassendi [Petro Gassendo], Ismaël Boulliau [Ismaele Bulliando], Martin Hortensius [Martino Hortensio], Lansberge [Lansbergio], Johannes Hevelius [Ioanne Heuelio], and Vincenzo Mutus [Vincenzio Muto], from the year of Christ 1620 to 1650.

1. In the year 1620, on November 4, New Style, at the 8th hour past midday, at Aix [Aquis Sextijs], Pierre Gassendi observed with a radius [cross-staff] Jupiter's distance from the head of Medusa to be $23^{\circ} 58'$; and soon afterward $23^{\circ} 5'$ from Aldebaran [Aldebara], but $18^{\circ} 30'$; or perhaps $31'$; and from the foot of Orion, and likewise from the right shoulder, $18^{\circ} 34'$ — which, according to Tycho, is $18^{\circ} 35'$. Hence he deduced Jupiter's longitude to be in Taurus $16^{\circ} 25'$, with southern latitude $1^{\circ} 18'$. So he himself in the *Life of Claude Fabri de Peiresc* [Claudij Fabricij Peireskij], ad fin. anni.

2. In the same year, on November 5, at the 7th hour and $3\frac{1}{2}'$, Gassendi there saw Jupiter distant by $24^{\circ} 4'$ from the head of Medusa; then $5'$; then $9^{\circ} 55'$ from the bright star of the Pleiades [lucida Pleiadum]; then $55\frac{1}{2}'$. Whence he inferred Jupiter's longitude to be in Taurus $16^{\circ} 16'$, with southern latitude $1^{\circ} 16\frac{1}{2}'$. The same [observer] in the same *Life*, on which see above.

3. In the year 1620, on November 7, at Aix, the same [Gassendi] observed Jupiter's opposition with the Sun, as we have it in the papers [schedis] sent to me by D. Giovanni Domenico Cassini [D. Io. Dominicum Cassinum].

4. In the year 1623, October 12, at the 17th hour, at Loudun [Loduni] in France, Boulliau observed Jupiter in a more advanced longitude than Regulus by 3', and more northerly by 8'; whence he deduced Jupiter to have been in Leo 24° 40', with northern latitude 35'. So he himself, lib. 7, *Aston. Philol.* ch. 3.

5. In the year 1627, on April 25, Old Style, at the 1st hour past midday, Martin Hortensius at Leiden [Leydæ] observed Jupiter to be more westerly, by the supreme [topmost] point of the front of Scorpio, almost by a third [of a degree] — 5'. So Lansberge [Lansbergius] in his *Thesaurus* observes the 5th of January, affirming that very star [the topmost of the front of Scorpio] to have been in Scorpio 28° 6', with northern latitude 1° 4'; and so [reckons] Jupiter to have been in Scorpio 28° 1', but from his own *Tables* in Scorpio 28° 1' 47'', with northern latitude 1° 5'.

6. In the year 1629, October 20, Old Style, Jupiter was observed at Middelburg [Middelburgi] in a straight line with two stars preceding it, the horn-tips of Capricorn; thus Lansberge in his *Thesaurus* observed the 6th of October, who concludes from this that Jupiter was in Aquarius 17° 44'. *Theoric.* ch. 44.

7. In the year 1633, Pierre Gassendi computed Jupiter's opposition with the Sun, on December 9. For on the 14th day, in the evening, before the [first] hour, he had seen Jupiter distant from Aldebaran by 19° 21'; and from the left shoulder of Orion by 19° 35'. But on the 16th day, at the 8th hour, in the evening, he saw it distant from Aldebaran by 21° 56', and likewise — at the 9th evening hour — by 19° 29'; he reports this in the observations sent to me from Bologna by D. Cassini.

8. In the year 1633, on December 17, in the evening, Gassendi at Digne [Diniæ] saw Jupiter retrograde, at Propus of the Twins [Propodi Geminorum], so that at the margin [edge] it neither receded nor moved, or was absent; and with the telescope it seemed to be discerned scarcely a little. The situation of the Medicean stars indicated the [star] left behind toward the south. On the 18th day, in the evening, at the 8½th hour, near the naked eye it was being concealed under Jupiter's rays, but with the telescope it was being seen distant about eight Jupiter-diameters, & northward. On the 19th day, in the morning, at the 8th hour, it was nearer, and still further northward; nor could the angles which they constitute be determined, the [star] having been led through the Medicean ones, distant by 4½ from Jupiter. At the Jovial [hour], in the evening of the same day, at the 8th hour,

Jupiter was now more easterly, and distant from it — as much as in the morning it had been more easterly — yet less, since the morning angle had been made sharper toward the east than it had been more westerly in the morning. Moreover, this line of the satellites of Jupiter is periodically inclined to the Ecliptic, can be brought under the conjunction of Jupiter, and Propus reduced to a mean time, or under the meridian of the 19th. So [Gassendi] in his *Epistles Meteorolog.* p. 906.

9. In the year 1634, Gassendi, observing Jupiter's station, comparing it with the telescope to a small fixed star, to which Jupiter was approaching, the 15th of February, sub hour 10, in the evening, it stood almost normal in respect of the line of the Medicean [stars]; standing apart from the said star toward the south by three of its own diameters; and at the same situation it appeared on the 16th. If the situation of the 17th was the same as that of the 16th, it stood distant by three diameters from the said star; but on the 17th the diameters were three and a half. Likewise the situation of the 18th was equal — its distance from Aldebaran was $17^{\circ} 17'$; and from the right shoulder of Orion $16^{\circ} 10'$; with a more westerly altitude $17^{\circ} 12'$. Tycho found Jupiter at this point in Gemini $21^{\circ} 7'$, with northern latitude $0^{\circ} 8'$. So Gassendi above.

10. In the year 1634, Jupiter, now direct, on the 11th of April, near Propus, & with a sharp angle along the line of the Medicean [stars] more westerly, distant 7° from Propus toward the north along the diameter — its own; standing apart by ten [diameters], the telescope showing it, on the 12th — an angle along the more easterly line of the Medicean [stars], equal; on the 11th, since the conjunction of Jupiter & Propus had been about an intermediate time. So Gassendi in his *Epicuro* p. 906.

11. In the year 1634, April 12, at the $8\frac{1}{2}$ th hour, at Paris, Boulliau with an optical tube observed Jupiter near Propus, separated toward the north by $9'$, but at the 10th hour, & as far as the Azimuth, scarcely more westerly — quoad the situation indeed toward the Zodiac; he judges it to have already passed the place of Propus, which was in Gemini $25^{\circ} 56'$; whence Jupiter at that hour [was] in Gemini $25^{\circ} 53'$, with northern latitude $14'$. So he himself, lib. 7, *Astron. Phil.* ch. 3.

12. In the year 1634, December 4, at the 19th hour of Julian [reckoning], or at Loudun, Boulliau with the tube observed Jupiter distant $17'$ — or $18'$ — minutes from Asellus, a little more northerly toward the Azimuth; whence he judges Jupiter to obtain the same situation with a fixed longitude in Gemini $24^{\circ} 40'$, with northern latitude $14'$.

13. In the year 1635, January 18, Jupiter's opposition with the Sun was determined by Gassendi; & at Aix on the 16th, in the evening, he saw Jupiter distant from Procyon by $18^{\circ} 41'$, & from Castor by $21^{\circ} 2'$; but on the same day, at the 17th hour, he saw it distant from Castor by $16^{\circ} 58'$, & from Pollux by $12^{\circ} 42'$; & from Regulus by $25^{\circ} 27\frac{1}{2}'$. So in his observations sent to me from Bologna by D. Cassini.

14. In the year 1636, February 19, Gassendi notes in his letters to Cassini, on Jupiter's opposition with the Sun, because at Digne on the 20th day, in the evening, he saw Jupiter distant from the neck of \square [Leo] by $9^{\circ} 18'$, & from Regulus by $5^{\circ} 10'$.

(right-hand column, folio 308)

15. In the year 1637, July 16, Boulliau with the tube saw Jupiter applied to the star which is the sixth in the Belt of Virgo, & preceding it; and four [observations], which were made at the same fixed [star]. At the 1st hour & 9' it was distant from that [star] by 12'; & at that point [it was] more inferior by 8'; vel 9, but more westerly by 1'; therefore on the whole it was reckoned to precede the star by 10'. Jupiter is found to be in Virgo $29^{\circ} 38'$, with northern latitude $1^{\circ} 18'$. So he himself, lib. 7, *Astr.* ch. 3.

16. In the year 1639, Jupiter's opposition with the Sun is ascribed to the 20th day in May, as Gassendi observed it; sent to me by Cassini, because at Aix on the 20th day, in the evening, he saw Jupiter distant from the southern arm [Lance Austrina] by $21^{\circ} 5'$, & from the northern by $18^{\circ} 21\frac{1}{2}'$.

17. In the year 1639, August 31, at the 8th hour, at Paris, Jupiter again returned to the bright [star] of the front of Scorpio, by about the same width [margin] — almost; in azimuth six minutes more easterly; wherefore scarcely by one, or by the scruple [of a degree] it had exceeded that star in longitude, & whence, & by other circumstances, Boulliau reckoned Jupiter to be in Sagittarius $28^{\circ} 8'$, with northern latitude $42'$. So he himself, lib. 7, ch. 3.

18. In the year 1646, D. Vincenzo Mutus, of Majorca [Maioricæ], observed by several days Jupiter, in the same February, [near] its preceding [the] foot of the Twins [Geminorum]; & on the night of the 19th day, he found Jupiter in a total station, or from the star [Pollux] in the same situation, more westerly by 5', & more northerly by 9'; vel 10', as in the letters [reported] by him to me given.

19. In the year 1646, December 24, New Style, in the evening, Hevelius of Danzig [Dantici] observed Jupiter covered [occulted] by the Moon, which on p. 477 of his

Selenographia he relates emerged from the Moon at the 8th hour, 39½; but he observed the occultation at Regiomontanus [Königsberg] in Prussia at the 7th hour, 53'; D. Albert observed at Linemann [Lineamano], & so it appeared at Danzig at the 8th hour, 7', 45', 33" — as Hevelius reckons.

20. In the year 1647, January 20, at the 14th hour, 10', Gassendi at Paris saw the southern margin of Jupiter to be distant from the northern margin of the Moon by half the spot of Caspia [maculam Caspiæ], seen with the telescope, at the 14th hour, 17'. The Moon touched Jupiter's margin, & after a semi-diminution [partial reduction], soon began to emerge, at the 15th hour, 0', 30" — at the western margin of the Moon; but the arc of the lunar limb between the points of the Immersion & Emersion was 72°. So in his *Epicuro* p. 901.

Hevelius also saw the same thing on the 20th day, as he has it on p. 480 of his *Selenographia*: the Moon passing under Jupiter from above [supra], at the 15th hour, 57'. Thus, when Jupiter was very near the lunar limb, it stood [hidden] under it at the 1st minute, 7'.

21. In the year 1647, April 12, New Style, in the evening, Hevelius at Danzig [Gedani], observing, gathered Jupiter's transit above the Moon, & its conjunction with the Moon — as far as the longitude he noted — at the 11th hour, 14', 50'; post meridian, [Jupiter being at] another altitude from Arcturus by 53° 10'; & then Jupiter, from the northern cusp of the Moon dichotomized [at quarter], seen distant by 6' — as he himself relates in his *Selenographia*.

The same phase Gassendi observed at Paris, when the Moon, indivisible [appearing whole], seemed dichotomized; from the northern cusp [the Moon] rising under Jupiter, when Jupiter touched the limb of the Moon with the telescope — it was scarcely seen, but really soon began to be hidden a little; that is, at the 10th hour, 4', & by half precisely from Jupiter it failed; & it was a pleasant spectacle to see Jupiter divided in two, & afterward even less than half — inadequately illustrated by the Moon; at the hour at length more obscure 9', 3', the whole emersion ceasing; from the cusp by three-quarters of the longitude of the Caspian spot [Caspia maculæ].

In the same year, on the 12th of April, D. Vincenzo Mutus of Majorca likewise observed Jupiter eclipsed by the Moon, when Regulus, more westerly, was higher by 57', 18'; that is, at the 3rd hour, 9° 56'. He began moreover to be occulted at the northern cusp of the Moon, & at the egress at the high Regulus 49° 12', by the northern feet [?]; at the 10th hour, 48'; thus he lay hid under that [Moon] for 52'. He relates these things in the letters given to me, which I assert, observed by

myself, from the altitude of the city of Majorca $39^{\circ} 35'$; & so by the diversity of the parallax the Moon elsewhere touches Jupiter nothing, [reckoned] from its half, elsewhere half, elsewhere [?].

22. In the year 1647, through several December days, D. Vincenzo Mutus, observing Jupiter under the formless [star] [informi] which is below the belly of Leo, detected Jupiter's total station to have been on the 27th day, at the 14th hour. Mutus of Majorca, [reckoning] Jupiter to be still more easterly, [near] the formless one, by $3'$; & more southerly by $9'$; vel $10'$. He reckons this observation, & the examination of the Radius of the orb of the world [Radium orbis Mundi], by the variety of the Sun being in Perigee, & because Jupiter [was] Stationary — hence the quadrature [quarter-aspect] with the Sun can be gathered.

(continuation of Caput VI — the telescopic-era Jupiter observations of Gassendi, Boulliau, Hortensius, Lansberge, Hevelius, and Vincenzo Mut)

23. In the year 1650, again Vincenzo Mut [Vincenzo Mut], on 18 April at Majorca, at hour 10, using a peculiar instrument and a very large one, observed Jupiter at a distance from the star in the southern foot of Virgo of $3^{\circ} 26'$. From this, together with the latitude observed, he concluded that Jupiter had been in Scorpio at $5^{\circ} 22'$ — which agrees with Lansberge's tables, the Danish ones being in error by $1'$, the Prutenic by $2'$, Boulliau's by $3'$, Rudolphine by $11'$. Thus he writes to me in his letters.

24. In the same year, likewise at the same place, on 21 April, from the latitude of Jupiter and its distance of $5^{\circ} 18'$ from the bright star in the southern Balance [Lance], he deduced that Jupiter had been in Scorpio at $5^{\circ} 0' 40'$ — an aberration with respect to the tables I have named.

25. Likewise, in the same year, there [at Majorca], on 1 May, he saw Jupiter distant from the bright star in the Balance by $6^{\circ} 41'$, and from the southernmost of the three borders [fringes] of Virgo by $4^{\circ} 20'$. Therefore he placed it in Scorpio at $3^{\circ} 37'$, which agrees with the Prutenic [tables], but is in error by $1'$ for the Danish, by $2'$ for Boulliau, by $3'$ for Lansberge, by $4'$ for Rudolphine, by $11'$ [for...]. On 16 May, however, Jupiter was very nearly in the same longitude, being distant from the southern foot of Virgo by $5^{\circ} 53'$ from its star — for Jupiter's latitude was $1^{\circ} 24'$ northern.

26. On the same day, likewise there [at Majorca], at hour $8\frac{1}{2}$, Mut [D. Vincenzo Muto], having drawn a line through the southernmost, the southern, and one of the three borders [fringes] of Virgo to the star at the foot of Virgo, found it to graze the western limb of Jupiter. Then Jupiter stood distant from the said

southernmost [fringe] by $2^{\circ} 15'$. From this he deduced Jupiter's longitude as Scorpio $1^{\circ} 12'$, and its northern latitude as $1^{\circ} 23' \frac{2}{3}$ — varying from the longitude observed from the tables: Boulliau's by 3', Prutenic and Danish by 4', Lansberge's by 8', Rudolphine by 11'. Thus he himself in the same letters.

27. Now in the year 1649, likewise there [at Majorca], he observed Jupiter on 11 May. Jupiter, more easterly, stood among four preceding stars in Virgo, distant by $2\frac{1}{2}'$ or $1^{\circ} 30'$; and distant somewhat less than the two contiguous stars in the second Hyades. But on 9 June Jupiter was more westerly by one semidiameter than that same star, and more northerly by scarcely more than a semidiameter. On 10 June it was already at the eastern edge in the same hour, so that in 24 hours it had covered three of its own diameters.

CAPUT VII.

An appendix of Jupiter observations from the Tyconic [tables] recently published at Vienna, from the press of David Hautt, from which we have selected a few; and from the Author of *Urania Propitia*, and from the Fathers of Vienna [Oenipontanorum — i.e. of Innsbruck].

1. In the year 1582, on 30 March, in the morning at hour 4 $10'$, Jupiter stood distant from the mouth of Pegasus by $24^{\circ} 24' \frac{3}{4}$, and after some time from Aquila by $35^{\circ} 32'$.

2. In the same year, on 7 April, in the morning at hour 3 $36'$, Jupiter was distant from the mouth of Pegasus by $24^{\circ} 10' \frac{1}{3}$; but being too close to the horizon, it was distant from Aquila by $36^{\circ} 16' \frac{1}{4}$.

3. In the same year, on 5 November, at hour 2 $54' 55''$, Jupiter was at the meridian, at an altitude of $16^{\circ} 34'$; and from hour 6 it was distant from the extreme tail of Capricorn by $3^{\circ} 48'$. But because of the nearness of the stars it could not be observed exactly. At hour 8 $19'$ it was distant from the bright star in Vulture [the Vulture — i.e. Lyra/Altair region] by $15^{\circ} 2' \frac{1}{3}$, and at hour 8 $\frac{1}{3}$ it stood off from the first wing-star of Pegasus by one [semidiameter]; and again at $38^{\circ} 34' \frac{1}{2}$ [it was found]. But because in the following meridian-passage [or: by the horologe used], the [instrument] was found to move too slowly, by $15^{\circ} 40'$.

4. Likewise in the year 1582, on 12 November, Jupiter was observed by the Radius [cross-staff], in which there is little reliability.

Ex Auctore Uraniae Propitiae parte 2. cap. 14. seu à pag. 90.

From the Author of *Urania Propitia*, part 2, chapter 14, or from page 90 onward.

5. In the year 1627, on 6 May, the said Author [Maria Cunitz] in Silesia, with a telescope of 14-minute aperture capacity [tubo optico capaci in apertura 14 minutorum], observed Jupiter more easterly than the topmost star in the forehead of Scorpio by $3\frac{1}{2}'$; and so [she placed it] in Scorpio at $28^{\circ} 2'$. The date was 16, new style.

6. In the year 1629, likewise the Author, on 17 October at 19, with several observations, saw Jupiter to exceed the Rudolphine place by about $9'$ of minutes.

7. In the year 1640, likewise the Author, on 11 May in the evening, by the aforesaid optical tube noted Jupiter to be more easterly by a single minute than the small star next to the easterly one [Stellula 1. Alae Virginis] in the wing of Virgo; and so [she placed it] in Virgo at $56^{\circ} 0'$ [or $26^{\circ} 0'$] — although nevertheless the Rudolphine calculation exhibits it at $29^{\circ} 46'$.

8. Add to these the conjunction of Jupiter and Mars [$\text{♃} \text{ } \text{♂}$] observed at Prague in the year 1604, on 8 and 9 October; from which Kepler concluded the conjunction [♃] to have taken place a little before midday on the 9th.

9. Add, and the distance of Jupiter [♃], which D. Vincenzo Mut [Vincenzo Mut] in the year 1659, on 31 March at hour 8, observed to be more westerly by $25'$. He was in the Nebulous [Praesepe], as he wrote to me.

[Margin, against item 8: $\text{♃} \text{ } \text{♂} / \text{ } \text{♃} \text{ } \text{♂}$] [Margin, against item 9: numeral "2"]

Selectae observationes Iovis factae Oeniponti à PP. Soc. Iesu, & ad me transmissae à P. Michaele Staudacher.

Selected observations of Jupiter made at Innsbruck [Oeniponti] by the Fathers of the Society of Jesus, and transmitted to me by Father Michael Staudacher.

10. In the year 1635, on 9 September, in the morning between hour 4 and 5, Jupiter was observed; on which Aldebaran was at an altitude of $15^{\circ} 5'$, and already Jupiter at 31° altitude. Aldebaran's [recorded] altitude was 31° . The remaining observations are as follows:

The following is a citation-grade table of Innsbruck Jupiter observations, transcribed as a pipe-table.

An. 1635 (Mens. D.)	Distantia \sphericalangle à Fixis (star)	Distantia (Gr. ')	Altitudo Fixarum (G.)	Altitudo Horiz. Ionis [Iovis] (G. ')
Sept. 19 — morning	Camicula [Camicula]	36 40	25 45	7 50
	Pollucis cap. [head of Pollux]	36 1½	42 20	
Octob. 2 — morning	Camicula [Camicula]	39 1½	44 45	28 15
	Iuba \square [the Mane of Leo]	7 11	30 15	
7 — morning	Camicula [Camicula]	39 5½	46 30	32 5½
	Iuba \square	8 30		
Martij 1636, 18 — evening	Regulo	2 18	47 18	48 6
	Iuba \square	7 19	54 45	
31	Regulo	1 18	51 40	51 30
	Iuba \square	7 40		
April. 16 — evening	Regulo	0 54	55 40	56 30
	Camicula	38 2		
Majj 30 — evening	Iuba Leon.	8 16	Reguli	31 40
	Cauda \square	22 1	30 25	
Iulij 10 — evening	Arcturo	8 17	55 35	10 23
	Dubhe	52 31		
Dec. 24 — evening	Regulo	36 30	Spica	Merid. 42 16½

An. 1635 (Mens. D.)	Distantia \sphericalangle à Fixis (star)	Distantia (Gr. \prime)	Altitudo Fixarum (G. \prime)	Altitudo Horiz. Ionis [Iovis] (G. \prime)
	Arcturo	32 50	32 45	
Ianuar. 1637, 21	Arcturo	32 10		29 0
	Lyra lucid.	91 4	54 27	
Martij 14	Regulo	36 25	48 55	18 44
	Cauda \square	17 51	36 33	
Martij 21	Regulo	35 30	55 51	30 40
	Arcturo	34 26	27 25	

Parsing notes: This table has paired star-references per date (two rows of "Distantia \sphericalangle à Fixis" per observation), with degrees-and-minutes in the "Gr. \prime " column, the fixed-star altitude in "G. \prime ", and Jupiter's horizon altitude in the last column. Several entries are tight at the page resolution; "Spica" and "Reguli"/"Merid." appear as in-cell labels rather than pure numerals. The doubled-prime time/altitude notation and noon-reckoned values are not flagged as impossibles.

CAPUT VIII.

Selected observations of Jupiter from among those which were carried out at the College of S. Lucia of Bologna by the Fathers Giovanni Battista Riccioli [Riccioli] and Francesco Maria Grimaldi [Grimaldi], together with other Associates of the same Society of Jesus.

With a few observations added at the end by the Most Illustrious Marquis Cornelio Malvasia [Cornelio Malvasia].

1. In the year 1642, on the night following day 5 of September — that night on which the opposition of Jupiter with the Sun was celebrated — the meridian distance of Jupiter from the Sun was $32^{\circ} 31' 30''$; but Saturn's was $49^{\circ} 50'$. From the meridian altitude of Jupiter, and through the transit of the bright star in the southern tail of Cetus, the values were reckoned by M. C. with the aid of a perpendicular at $7^{\circ} 10'$; and from the transit of the same Tail [of Cetus], $50^{\circ} 8'$.

2. In the year 1642, on 18 September, about the first hour of the following night, Jupiter was distant from the brightest star of Aries by $53^{\circ} 29'$; and from the bright star in the Mandible [chin/jaw] of Cetus by $25^{\circ} 34'$.

3. In the same year, on 23 October, in the following night, the western altitude of Aquila was $53^{\circ} 11'$; in $5^{\circ} 45'$ of time Jupiter was distant from the bright star of Aquila by $50^{\circ} 47'$; and then a few minutes afterward it was distant from Scheat of Pegasus by $23^{\circ} 1'$.

4. In the year 1643, on 10 February, in the following night, at hour 2, Jupiter appeared at altitude 6° and distant from Scheat of Pegasus by $31^{\circ} 44' \frac{1}{2}$; but from the head of Andromeda by $31^{\circ} 44' \frac{1}{2}$.

5. In the same year, on 11 February, at hour 1, in Italian civil reckoning, Jupiter was at altitude 9° and distant from Scheat of Pegasus by $32^{\circ} 13'$; at Markab of Pegasus by $35^{\circ} 24' 10' \frac{1}{2}$; and the hundredths [hundreds] of those numbers we have noted from observation with greater accuracy.

6. In the year 1643, in the following night, day 23 February, Jupiter was at altitude 9° and distant from the girdle of Andromeda by $39^{\circ} 52' \frac{1}{2}$; but from the bright star of Aries by $39^{\circ} 1'$.

7. In the year 1643, on 18 June, in the following night, the western altitude of Aquila — which was $46^{\circ} 2'$ — was reckoned in $21' \frac{1}{2}$ of time; and Jupiter was distant from the bright star of Aries by $15^{\circ} 42'$. Then after 2 minutes of time it was distant from Saturn by $14^{\circ} 10'$; the location is in fact from the observation of Saturn above its own place, reckoned with reference [to...].

8. In the year 1643, on 15 July, in the morning, the altitude of the bright star of Aries was captured eastward, and after an interval of 5 minutes of time the distance of Jupiter from the same bright star of Aries was taken with the Sextant, repeated twice: $14^{\circ} 29'$; both [readings] then in $14^{\circ} 29' \frac{2}{3}$. Then after a minute of time, on the eastward side, the distance of Jupiter from Aldebaran by repeated observation was $41^{\circ} 21'$; with Aldebaran being at altitude 19° and Jupiter near \square [quadrant] with the Sun.

9. In the same year, by accident, the altitude of the bright star of Aries was taken eastward at $58^{\circ} 27'$; after 7 minutes of time the western [...] distant by $13^{\circ} 56'$; and after 6 minutes of time it was distant from Aldebaran by $13^{\circ} 15'$; after the quarter [quadrant]-aspect of the hour [it was] distant from Saturn by a single [unit], and stood near \square [quadrant] with the Sun.

10. In the year 1643, on 3 August, in the morning, the bright star of Aries stood high at altitude $48^{\circ} 27' \frac{1}{2}$ eastward; after 7 minutes of time we then saw Jupiter distant from Capella by $56^{\circ} 7' \frac{1}{2}$; and after 6 minutes of time it was distant from Aldebaran by $40^{\circ} 2' \frac{1}{2}$.

11. In the same year, on 8 August, in the morning, [Aldebaran] was high at $44^{\circ} 40'$ eastward; after an interval of 7 minutes of time [...]

(continuation of Caput VIII — the Bologna College observations; the table-head from the previous page's broken item 11 continues at top)

Citation-grade table fragment (continuation of an observation series, transcribed as a pipe-table). Columns: minutes of time; distance of Jupiter from stars (degrees, minutes); the reference star.

Min. Temp. (M.)	Distant. Iovis (G.)	(')	à Stellis (from the star)
4	29	23	à Lucida □ [the bright star of Aries]
2	28	54	à Capella
4	46	14	à □ capite precedenti [the preceding head-star of Aries]
2	48	17	à □ cap. sequenti [the following head-star of Aries]
4	13	46	à □ pede lucido [the bright foot-star of Aries]
4	39	36	à Saturno

Parsing notes: this small table belongs to the broken item 11 carried over from p. 310. The □ symbol marks the several reference stars in Aries.

16. In the year 1644, on 22 September, in the morning at hour 3, after the middle of the night Jupiter was distant from Saturn by $24^{\circ} 28'$; but from Capella by $28^{\circ} 11'$. Jupiter was then very near \triangle [trine] with the Sun.

17. In the same year, on 17 November, in the following night, Regel [Rigel] was high at its rising at $29^{\circ} 24'$ when Jupiter, not far off in opposition with the Sun, was observed in the following night and was distant from the eastern shoulder of Orion by $40^{\circ} 52'$; and after 6 minutes of time it was distant from Castor's head by $49^{\circ} 56'$. Afterward, when crossing the meridian, the meridian distance was taken by twin large Quadrants by M. C. at $26^{\circ} 8'$; from there the meridian distance of Aldebaran was reckoned by M. C. at $7^{\circ} 38'$; and then Aldebaran's meridian distance from the heart of Leo [Leonis] was $28^{\circ} 44' \frac{1}{2}$.

18. In the year 1645, on 22 December, in the following night, about hour 6 by the public horologe — that is, from the right shoulder of Orion — Jupiter was observed in the eastern quadrature at altitude $39^{\circ} 20'$; and the eastern altitude of Jupiter was $17^{\circ} 20'$; and from the brighter head of Gemini by $18^{\circ} 38' \frac{1}{2}$.

19. In the year 1646, on 18 March, in the following night, in the fourth [hour] of civil reckoning, Jupiter near \square [quadrature] with the Sun was distant from Procyon by $28^{\circ} 19'$; and from the southern head of Gemini by $26^{\circ} 4'$.

20. Again in the year 1646, on 2 November, in the morning, Jupiter was high above its western setting by 65° , and distant from Procyon by $23^{\circ} 20' \frac{2}{3}$; then after a smaller interval of time, by 2° , Procyon stood distant from the eastern setting versus by $42^{\circ} 35'$; and after two minutes [it was distant] from Sirius by $47^{\circ} 43' \frac{1}{2}$, with Sirius being at altitude above its setting by 21° .

21. In the year 1647, on 16 January, in the following night, when Jupiter was high, it was 31° ; and Jupiter at 30° was distant from Procyon by $21^{\circ} 24' \frac{1}{2}$; and then from the following shoulder of Orion by $43^{\circ} 31'$.

22. In the same year, on 23 January, in the following night, Jupiter was high about 30° ; it was distant from the bright shoulder of Orion by $39^{\circ} \frac{2}{3}$; and after the quarter-aspect [quadrant] of the hour, it was distant from Procyon at another place by $31^{\circ} 46'$; Jupiter was distant by $20^{\circ} 49' \frac{1}{3}$.

23. In the year 1647, on 1 January, in the following night, Jupiter stood distant from the bright shoulder of Orion by $42^{\circ} 17' \frac{1}{2}$; and from Procyon by $20^{\circ} 23' \frac{1}{2}$; then at another place the western [setting?] [...] Jupiter was distant by 45° .

24. In the year 1647, on day 2 of April, in the following night, about the first hour after the setting of the Sun, the conjunction of Jupiter began to be observed, with

Mars tending to a conjunction with Jupiter; and it was completed within about a sesquihour [an hour and a half] — that is, when Regulus had been observed at its setting at altitude $34^{\circ} 40'$; for the conjunction was then completed. Therefore from the bright shoulder of Orion Jupiter was distant by $38^{\circ} 16'$. Mars was distant by $39^{\circ} 1' \frac{1}{2}$. Then in the same way Capella was distant from Jupiter by $46^{\circ} 6' \frac{1}{2}$; Mars was distant by $44^{\circ} 57' \frac{1}{2}$. Then Jupiter was distant from the bright [star?] by $25^{\circ} 8'$. Mars was distant by $28^{\circ} \frac{1}{2}$; and they stood very nearly in the same Vertical [circle]: Jupiter at its rising leaning a little eastward, and Mars set [tending] in the western quadrant.

25. But on day 4 of April, of the same year, about hour 3, from the setting of the Sun, Jupiter was distant from the bright shoulder of Orion by $38^{\circ} 18'$. Mars was distant by $39^{\circ} 30'$; and the western shoulder of Orion was high at 18° . A little later Jupiter was distant after Capella by $46^{\circ} 9' \frac{1}{2}$. Mars was high at $23^{\circ} \frac{1}{2}$; and at once Regulus was distant westward from the vertex by $35^{\circ} 40'$. Let one therefore work out the time of this conjunction.

Inserere hic Observationes, infra ponendas 59. 60. 61. 62.

[Insert here the Observations to be set out below: 59, 60, 61, 62.]

36. In the year 1648, on 25 May, at the first hour of the following night, Jupiter was seen to be distant from the head of Castor by $42^{\circ} 43' \frac{1}{2} \frac{2}{3}$; from [...]

37. In the year 1649, on day 2 of June, about hour 2 of the following night, when the preceding head-star of Gemini was setting, Jupiter was distant from Regulus by $34^{\circ} 44' \frac{2}{3}$; and from the bright star in the Mane of Leo [Iuba □] by $35^{\circ} 34' \frac{1}{2}$.

38. In the year 1649, on 9 June, in the following night, Jupiter was seen more westerly than that star of Virgo which precedes the four stars in the left wing — or, in longitude, it was at $29^{\circ} 59'$ of Virgo, with northern latitude $1^{\circ} 25'$. At that same hour Jupiter was seen more easterly than the aforesaid star of Virgo, when it was distant by the aforesaid grand telescope, on the day before, from the vertical [circle of] the aforesaid star by an orthographic semidiameter of $3^{\circ} 4'$ — and this its precedence: the eleventh-day semidiameters of Jupiter [Iovialibus] were $10^{\circ} \frac{2}{3}$. Why, since then the diurnal motion of Jupiter is here a minor third [a 60th of a 60th], and is moreover by $2^{\circ} 0' \frac{2}{3}$ — it was [distant] from that Australian star by one semidiameter very nearly diametrically opposite to it. How may the apparent diameter of Jupiter be deduced? It was said to be $1^{\circ} 7'$. (*Almagestum Novum*, Book 6, ch. 6, etc., as written below.)

39. In the year 1649, on 22 June, a little after, conjunction [♃] of Jupiter with the Sun; the more western [position], after the setting of the Sun, was observed again, when Jupiter was often distant from Regulus by $35^{\circ} 42'$; and from the bright star in the Mane of Leo [Iuba ♁] by $36^{\circ} 33'$.

40. In the year 1650, on 24 April, about the conjunction [♃] of Jupiter with the Sun, in the following night, Jupiter was distant from the vertex by $19^{\circ} 54'$; it was distant from Spica of Virgo by $15^{\circ} 59'$; and presently from Arcturus it was distant by $47^{\circ} 52'$.

41. In the year 1652, on 30 June, in the following night, after the setting of the Sun, Jupiter was distant from the vertex by $79^{\circ} 13'$; presently from Antares by 33° , more precisely; then from Aquila by 30° ; and from the vertex by $78^{\circ} 22'$; and this had preceded on the day before the opposition [♃] of Jupiter with the Sun.

42. In the same year, on day 4 of July, at the same hour, after the setting of the Sun, Jupiter was high at $19^{\circ} 46'$; it was distant from the bright star of Aquila by $34^{\circ} 47'$; then it was high at $13^{\circ} 10'$; it was distant from Antares by $32^{\circ} 29'$.

43. In the same year, on 12 August, in the following night, after the setting of the Sun, Jupiter was high at about 25° ; it was distant from the bright star of Aquila by $36^{\circ} 41'$; then it was high above Pegasus by $47^{\circ} 43'$.

44. In the same year, on 14 August, in the following night, with the bright star of Aquila distant from the vertex at $40^{\circ} 49'$, and Jupiter at its rising versus eastward, it was distant at the same time by $37^{\circ} 9'$; and a little later it stood off from the bright star of Pegasus by $57^{\circ} 2' \frac{1}{2}$; and presently from Procyon by \triangle [trine] of the Sun.

45. Finally, in the same year, on 14 November, about the first hour after the setting of the Sun, when Fomalhaut was seen to be distant from the vertex by $77^{\circ} 10'$; Jupiter was seen distant at the same time by 75° abeam [ab ore]; from the vertex of Pegasus by $49^{\circ} 45'$.

46. In the year 1653, on 22 May, in the morning, Markab of Pegasus at its rising was distant from the vertex by $55^{\circ} 31'$; and Jupiter was distant from the vertex by $47^{\circ} 34'$; and from the head of Andromeda by $57^{\circ} 5'$; presently Jupiter was distant from the vertex by $66^{\circ} 50'$; and from the crooked [star] of Pegasus by $47^{\circ} 43'$.

47. In the year 1653, on 28 November, in the following night, about the hour very nearly the second after the setting of the Sun, Jupiter was distant from Fomalhaut by $23^{\circ} 52'$; but from the vertex by $64^{\circ} 55'$. Fomalhaut was distant from the vertex versus by $76^{\circ} 2'$; a little later it was distant by 1 from Cetus; the distance was 86°

28' 50'; with that star itself distant from the vertex by 69° 42'. Take counsel from these the distances of Jupiter, by which it may be established whether the Ephemerides err in the conjunction [♃] of Mars with Jupiter.

48. In the year 1653, on 23 December, about hour 5 of the post-meridian, 7' ½; Jupiter was expected at the precise Azimuth, grade 30, distant from the vertex by 66° 28' ½; from which moment the values were reckoned in 12° ½; the bright star of Aquila was distant from the vertex by 61° 41' ½.

49. In the year 1654, on 2 November, in the following night, Jupiter, tending toward Direct [motion] (until now it had been Retrograde), was distant from the bright star of Aries by 50° 15' ½; presently from the bright star in the Tail of Cetus by 23° 40' ½; and then it was hour 4 by Italian civil reckoning, with the half [half-hour].

50. In the year 1654, on 6 November, in the following night, the transit of Fomalhaut by M. C. and [the values] reckoned by perpendicular: 23° 40'. Jupiter reached the vertex by M. C. as it was distant; then at the vertex by 52° 16' 40'; the hour was Italian 5 ½.

51. In the same year, again, on 11 November, in the following night, about the hour [...]

about the hour 3¼. In Italian reckoning, Jupiter was nearest the meridian; it stood distant from the bright star of Aries [Hamal] by 50 degrees, 13½ minutes, and from the tail of Cetus by 23 degrees, 39½ minutes.

52. In the year 1655, on 21 August, in the morning, Jupiter — already retrograde — when it was at mid-heaven, stood distant from the vertex by 34 degrees, 13½ minutes; thence after a minute of time [postea minuta temporis 3', or "after 3 minutes of time"], 3 degrees, 40 minutes. The following shoulder of Orion stood distant, toward the west, from the vertex by 59 degrees, 36 minutes.

53. In the year 1655, on 17 October, the following night, Jupiter, approaching toward conjunction with the Sun, stood distant in the meridian from the vertex by 36 degrees, 4 minutes.

54. In the year 1656, on 12 March, at hour 1 of the night, Jupiter stood distant from the bright star, that is, from the following shoulder of Orion, by 53 degrees, 55¾ minutes, and from Rigel by 48 degrees, 46¾ minutes.

55. In the same year, on 16 August, in the morning, two hours before sunrise, Jupiter stood distant from Capella by 26 degrees, 56 minutes, and from the northern horn of Taurus by 15 degrees, $3\frac{1}{4}$ minutes.

56. Finally, in the same year, on 27 October, at the third and a half hour after sunset, Jupiter, being eastern, stood distant from Capella by 26 degrees, $43\frac{3}{4}$ minutes (or $\frac{2}{3}$), and from the northern horn of Taurus by 14 degrees, $30\frac{1}{2}$ minutes.

57. In the year 1657, on 10 February, the following night, Jupiter stood distant in the meridian from the vertex by 23 degrees, $32\frac{1}{2}$ minutes, 50 seconds; thence after a minute of time, 35 minutes, 10 seconds [or "35' 10''"], Aldebaran crossed the meridian [M.C., Medium Coeli].

58. In the same year, on 18 March, Jupiter was in the same azimuth — concerning which, see in the observations of Venus for this same day — and Jupiter then stood distant from the vertex by 52 degrees, precisely; but in the azimuth of Aldebaran it stood distant from the vertex by 58 degrees, 17 minutes.

59. In the year 1647, on 18 April, the following night, Jupiter was observed standing distant from Capella by 46 degrees, $48\frac{3}{4}$ minutes (or $\frac{2}{3}$), and from the heart of the Scorpion [Antares] by 32 degrees, 40 minutes. At that time, moreover, Arcturus stood distant in the east from the vertex by 47 degrees, 40 minutes.

60. In the year 1648, on 20 February, the following night, about the hour $3\frac{3}{4}$ after sunset — that is, distant from Procyon at the vertex by 38 degrees, 48 minutes; Jupiter being elevated 34 degrees, 50 minutes — it stood distant from the same Procyon by 46 degrees, 43 minutes, and from the extreme tail of the Great Bear by 54 degrees, $3\frac{1}{4}$ minutes.

61. In the same year 1648, on 21 February, at an hour after sunset, the Sun being distant $3\frac{3}{4}$ degrees [or "Sol distant $3\frac{3}{4}$ "], Jupiter stood distant from Procyon by 46 degrees, 35 minutes, and from the extreme tail of the Great Bear by 54 degrees, 50 minutes.

62. In the same year 1648, on 26 February, the following night, at hour 3 after sunset, Jupiter, being eastern, stood distant from Procyon by 46 degrees, $1\frac{3}{4}$ minutes, and from the last star in the tail of the Great Bear by 54 degrees, 58 minutes.

63. In the year 1649, on 9 June: concerning this observation — which we shall report on another occasion — see Book 10, chapter 3, numbers 5 and 6. Jupiter was then in Virgo [□] at 29 degrees, 56 minutes, 25 seconds, with northern

latitude [cum latitudine Boreali] — see Book 7, chapter 3, number 4 — and so, an hour after midnight, but already near the station, it was observed worthy of record.

64. In the year 1657, on 26 December, the following night, Jupiter, in the most precise meridian, stood distant from the vertex by 21 degrees, 11 minutes, 33 seconds (or $\frac{1}{4}$), and after its transit there is reckoned [a further] 6 minutes, 40 seconds of time, [when] Sirius crossed the same meridian.

But on 27 December, the following night, Jupiter likewise stood distant in the meridian from the vertex by 21 degrees, 10 minutes, 43 seconds, and 7 minutes, precisely, of time after [its transit] Sirius crossed the same meridian. Hence Jupiter's declination on the 26th day was 23 degrees, 18 minutes, 37 seconds, and on the 27th it was 23 degrees, 19 minutes, 27 seconds.

Selected observations from the *Ephemerides* of the illustrious Marquis Cornelio Malvasia [Malvasia], folio 203.

In the year 1662, from his own observatory at Modena [Mutina], the Marquis observed the distances of Jupiter from the fixed stars written below, but corrected by Cassini's *Tables of Refractions* [Tabulae Refractionum Cassiniana]; and, taking the positions of the fixed stars from Tycho's [Tychonic] tables, he derived from them, by aid of trigonometry, Jupiter's longitudes and latitudes noted below; and he compared these with those which Lansberg's [Lansbergian] calculation supplies.

Table. Right-hand column table of Malvasia's 1662 Bologna/Modena Jupiter observations. Columns: date (June / July / August, by day "D."); hour after noon ("Ho. post occ. ☉" — hours after the Sun's setting / after noon, with "H." and minutes "I"); the corrected distance of Jupiter ("∟ Distantia correcta") given against a comparison star with degrees "G." and minutes "I"; Jupiter's observed place ("Locus ∟ Obseruatus") with sign, degrees "G." and minutes "I"; and Lansberg's excess or defect ("Lansberg. Excessus vel Defectus"). The comparison stars are *Spica* (♍ Virginis), *Boötes* (i.e. Arcturus), *Lucida Austrina* (*Lūc. Aust.* — the southern bright star), and *Arcturo* (Arcturus).

Parsing notes: For each date there are two rows — the upper giving the distance from one comparison star with Jupiter's observed *longitude* (Lo. = Longitudo), the

lower giving the distance from a second comparison star with Jupiter's *latitude* (La. B. = Latitudo Borealis, northern latitude). The "Lansberg. Excessus vel Defectus" column registers, per row, the excess (Exc.) or defect (Def.) of the Lansbergian computation against this observation, in minutes. Several fractional half-minute values (e.g. 10½, 17½, 22½) are noted in the source. The zodiac sign for Jupiter's longitude is Libra (♎) throughout.

But you should remember that the Tyconic positions of the fixed stars themselves require correction, and that the correction of the distances, resting on Cassini's refractions, is not free of doubt — as I have already pointed out in Book 1.

CAPVT IX. — CHAPTER IX.

On the selection of observations concerning Jupiter for the purpose of a calculation reckoned from our Tables.

1. From what was said in Book 5, chapters 9, 10, and 11 — on the methods of observing the positions of the planets, on the difficulty of avoiding errors of many minutes [scrupula], and on the construction of the Tables — it is plain that observations must be preferred which are surer rather than merely more numerous. [Margin: From the Danish Tables.] Tycho judged, in his preface to the *Astronomical Letters*, that the motion of Jupiter cannot be amended from observations unless these are taken at single oppositions [oppositions to the Sun]. [Margin: And from the Rudolphine.] Longomontanus, nonetheless, in Book 1, chapter 2 of the *Theoricae*, made use of only eight oppositions of Jupiter — and that with the true place of the Sun observed, partly by Tycho, partly by himself — for constructing the Danish Tables; and in chapter 7 he searched out another observation for the place of Jupiter's apogee.

Kepler, moreover, in laying the foundation of the *Ephemerides* which he built upon the Rudolphine Tables, affirms (page 14) that his Tables, as regards the three superior planets, cannot be detected to differ from the heavens by an amount worth noting. Elias [Leonita] Leonitus, who was himself an author of works in Silesia at Bicinum [Beuthen?], edited and titled *Prima Propitia* (page 89), says that the Rudolphine Tables err in longitude — from his own observations — by up to 13 minutes; in the second semicircle of the commutations, indeed, by so much that they appeared to have purged away the errors of the Rudolphine men, mutually canceling, just as he supposes Kepler imposed; and that the same thing happens in the second [semicircle]. He adds, moreover, that Kepler's theory of Jupiter labors under some defect — the mean motion, the place of aphelion, and

the proportion of the orbital radius at the intervals of the Sun and Earth. Finally Boulliau [Bullialdus], that most diligent investigator of astronomical truth, both amended the Rudolphine men (Book 3, *Astronomia Philolaica*, page 9) and shows (chapter 1, number 6) that those 48 minutes do not exceed the place of Jupiter near the station — which the observed place requires [Margin: And the Rudolphine likewise faithless.] (chapter 1, number 6, on which we put little weight); and the five only [tables] of these same Tables he openly prefers, on the faith of these same Tables, though somewhere indeed faithless: with page 170. The *Thesauri* of the conjunctions of Mars and Jupiter, which Kepler [reports] (page 305 of the *Astronomia Optica*), and which Maestlin observed at Tübingen in the year 1591, on 13 January, on his own day 8 — indeed, he asserts it was done on the 8th; nay, in the series of calculation he sets the day 6 of January, and on hours 18 after midday of the sixth day, lest he draw his observation to his own Tables: a matter on which there is more in Book 7, chapter 8, on the occasion of Mars.

[Margin: The order of the observations.]

And so we, out of so many observations recounted above, have selected the 20 written below — namely, four notable conjunctions of Jupiter and 15 conjunctions of Jupiter and Mars with the fixed stars, observed for the most part with the telescope [tube]; and we have added one Tychonic [observation] from observations by distances from two fixed stars, which we shall report in the order of the times preserved.

[Margin: 1]

In the year 141 before Christ, as I reported in chapter 1: on 3 September, at hour 16 after midday at Bologna, Jupiter was seen to cover the southern Asellus [Aselli, the "Asses"] of Cancer, which to me, from the positions of the fixed stars corrected in Book 4, was then in Cancer [□] at 7 degrees, 11¼ minutes, with southern latitude 3 degrees, 30 minutes. [Margin: ♃ at the southern Asellus.] And on account of the borrowed light of the stars, the stars appear nearer to one another than they truly are; so that Jupiter, touching a fixed star with the naked eye, if it be viewed through a telescope, would stand off from it by some few minutes, and sometimes by 8 — Jupiter's own diameter being just so many minutes; so that Jupiter might stand off from the southern Asellus by the same number of minutes, and so be in Cancer at 7 degrees, 7 minutes, or thereabouts, by a minute. [Margin: ♃ ♂ — Jupiter at the southern Asellus.]

Table. Right-hand column inset comparing where Jupiter then stood according to the several Tables (Lansberg's, the Danish, the Philolaic, and Ours), in signs (Sig.), degrees (G.), minutes (I), and seconds (II), with longitude (♋ position) and latitude (Lat.) rows.

Jupiter then exhibited by the Tables	Sig.	G.	I	II
Lansberg's (longitude)	♋	7	34	26
Lansberg's (Lat.)	a.	0	10	0
Danish (longitude)	♋	7	33	0
Philolaic (longitude)	♋	7	6	0
Philolaic (Lat.)	—	0	25	0
Ours (longitude)	♋	7	4	30
Ours (Lat.)	—	0	24	10

Parsing notes: "a." in the Lansberg latitude row appears to abbreviate *australis* (southern). The longitude rows give Jupiter's position in Cancer (♋).

2. In the year of Christ 498 — to speak as observed — in the morning, about hour 9 of the day of the month of March, Jupiter and Mars were so closely conjoined that they seemed to differ by almost nothing perceptible. Boulliau, to me at least, then had Mars in Virgo at 0 degrees, 13 minutes, 56 seconds, with northern latitude 1 degree, 14 minutes. But Jupiter came out to me in Virgo at 0 degrees, 15 minutes, 34 seconds; yet, on account of the irradiating beams, they seemed to differ by nothing. [Margin: ♄ ♋♊]

	Sig.	G.	I	II
♋ (Mars)	♋	0	13	56
♋ (Jupiter)	♋	0	15	34

3. In the year of Christ 508, on 27 September, at hour 17 after midday at Athens, and on the 16th at Bologna, Jupiter was seen next to Regulus [Reguli], indeed, in so far as it [Jupiter] stood off toward the north from Regulus by 3 minutes, or at least by 7½ minutes. To me, Regulus was in Leo at 8 degrees, 51 minutes, 57 seconds; but, by Boulliau, in Leo at 8 degrees, 49 minutes, 54 seconds. [Margin: ♂ ♃ ⊕ Reguli — conjunction of Jupiter with Regulus.]

And then,
by the
Tables,

Jupiter was	Sig.	G.	I	II
Rudolphine	□	9	35	33
Philolaic	—	8	58	43
Ours	—	8	56	30

4. In the year of Christ 509, on 13 June, at hour 9 at Athens, Jupiter was seen rather more eastern than Mars by 1 minute, or at least 2½ minutes; but at all events more, on account of the adventitious beams. And then, by the Tables written below, they were as follows. [Margin: ♂ ♃ ♂]

	♃	Sig.	G.	I	II	□	Sig.	G.	I	II
Rudolphine	□	□	11	58	0	□	□	11	50	0
Philolaic	□	□	11	57	43	□	□	11	54	10
Ours	□	□	11	56	40	□	□	11	52	2

5. In the year of salvation 1591, Kepler, by means of Maestlin at Tübingen, saw Jupiter rather more eastern [a Marte] than Mars by 9 [minutes], on 13 January; but he himself, since he has Lansberg, and so it is left to a civil clock, struck the hour 12; whence it had now begun at hour 13: but for the year hour 13 Jupiter was in Scorpio [□] at 14 degrees, 59 minutes, 12 seconds. Mars was in the degree of Scorpio at 14 degrees, 58 minutes, 53 seconds. [Margin: page 305. *Astronomia Optica*. ♂ ♃ ♂]

6. In the year 1587, Tycho writes in the *Letters* that Jupiter was observed by him in Cancer [□] at 7 degrees, 19 minutes, on 14 January, at hour 8 after midday.

[Margin: ☿ ☿]

	Sig.	G.	I	II
Therefore Jupiter's observed place		7	19	0
The place computed for me		7	18	16

7. In the year 1604, Kepler — from observations made at Prague — concludes that the conjunction of Jupiter and Mars fell on the 9th day of October, a little before midday. To me, by my Tables, at hour 23, 50 minutes after midday of the 8th day, the positions came out reduced and curtailed [Reducta & Curtata]. [Margin: ☿ ☿ □]

	Sig.	G.	I	II
☿ ☿ in	□	19	15	37
☿ ☿ in	□	19	15	38

8. Boulliau relates that in the year 1623, on 12 October, at hour 17 after midday, at Loudun in Poitou [Pictavis] — that is, at hour 18 at Bologna — it was observed...

[that it was observed] through the telescope [tube], by a conjunction performed a little before, that Jupiter was then in Leo [□]; the Tables exhibit Jupiter then in Leo at 24 degrees, 40 minutes, but to me [it was] in Leo at 24 degrees, 46 minutes. [Margin: ☿ ☿ & Reguli — conjunction of Jupiter with Regulus.]

9. In the year 1627, on 25 April, old style, Hortensius at Leiden [Leydae], at hour 11 (which at Bologna is hour 11, 28 minutes), observed with the telescope [tube] that Jupiter was rather more western than the topmost [supreme] of the forehead-stars of Scorpius [frontis Scorpii] by something like 5 minutes. But that

brightest star of the forehead was then to me in Scorpio at 27 degrees, 54 minutes, 53 seconds; therefore Jupiter was then in Scorpio at the degree 27, 54 minutes, 53 seconds. [Margin: ♂ ♃ with the forehead of Scorpius.]

10. On 27 April, Elias [Leonitus] at Leontium [Leontinum?], where the planet [Pius] is in Virgo at degree 27, 50 minutes — Elias, indeed, who saw at Vraniaburg [Uraniborg] Propitia [the star], saw on the 22nd of the same year, at hour 1, 25 minutes after midday in Silesia. Jupiter, standing distant in consequence [eastward] by 18 minutes, [was] from the topmost forehead of Scorpius, and so in Scorpio at 27 degrees, 37 minutes. [Margin: ♃ — Jupiter came out to me on the day.]

Jupiter
came out to
me on the

day	Sig.	G.	I	II
22	☐	27	41	0
25	☐	27	46	53

11. In the year 1633, on 19 December, Pierre Gassendi [Petrus Gassendus], from diverse observations made with the telescope, reckoned the conjunction of Jupiter with Propus [Propode, the star Propus = η Geminorum] to fall under the meridian of the day at Digne [Diniaë]. To me, Propus was then in Gemini [♊] at 25 degrees, 47 minutes, and at the meridian Jupiter was in Gemini at 25 degrees, 54 minutes; wherefore Jupiter was then more eastern at midday; and Jupiter was retrograde. [Margin: ♂ ♃ with Propus.]

12. In the year 1634, Pierre Gassendi at Digne, at hour 12 after midday on 11 April — which at Bologna was hour 12, 22 minutes — judged with the telescope that Jupiter had already, by a direct conjunction, indicated Propus of Gemini as regards longitude, [being] rather more northern than Propus by 8 minutes, or thereabouts. Boulliau, indeed, who was observing Jupiter's conjunction with Propus at Paris on the same day — that is, on 11 April, at hour 8, 30 minutes after midday, which at Bologna was hour 9, 10 minutes — saw with the telescope that Jupiter was 9¾ minutes more northern than Propus as regards longitude, [Jupiter being] 3 minutes more eastern than Propus. Since therefore to me Propus was then in Gemini at 25 degrees, 46 minutes, 22 seconds, and since Jupiter's own daily motion follows at hour 12, 22 minutes on the following day, the 11th — Jupiter was rather more western than Propus by 6 minutes, but not conjoined with Propus; dividing therefore the errors of both observations, Jupiter will have

been, at hour 12, 22 minutes, in Gemini at 25 degrees, 43 minutes, 30 seconds. Our Tables give Jupiter in Gemini at 25 degrees, 41 minutes, 27 seconds. [Margin: $\sigma \sphericalangle$ with Propus.]

Jupiter's place	Sig.	G.	I	II
Observed	\square	25	43	30
Computed		25	41	27

13. In the same year 1634, on 4 December, at hour 10 after midday at Loudun in Poitou [Pictavis] — but at Bologna hour 10, 50 minutes — Boulliau judged with the telescope that Jupiter was a little more eastern than the southern Asellus, which to me was then in Leo at 3 degrees, 34 minutes, 9 seconds; therefore Jupiter was in degree 3, 36 minutes; but further, our Tables give degree 3, 40 minutes, 13 seconds. [Margin: $\sigma \sphericalangle$ with the southern Asellus.]

Jupiter's place	Sig.	G.	I	II
Observed, about	\square	3	36	0
Computed		3	40	13

This observation is notable for eliciting Jupiter's mean motion, since it returned to the southern Asellus, with which it had once been conjoined — as said above, observation 1 — after Julian years 1874, and on the same days 105, hours 14, 50 minutes. [Margin: $\sigma \sphericalangle$ with the southern Asellus.]

14. In the year 1637, on 16 July, at Paris, at hour 9, 40 minutes after midday — but at Bologna hour 9, 40 minutes — Boulliau saw with the telescope that Jupiter was 7 minutes more western, and $8\frac{1}{2}$ minutes more southern, than the sixth star of Virgo's wing, which precedes among the four [stars] of Virgo's left wing. To me, by my Fixed [stars], the star was then in Virgo at 29 degrees, 47 minutes, with northern latitude 1 degree, 24 minutes, 10 seconds; therefore Jupiter was in Virgo at 29 degrees, 40 minutes, with latitude 1 degree, 16 minutes. Our Tables then give Jupiter less than three minutes more western. [Margin: continues]

Jupiter's place	Sig.	G.	I	II

15. In the year 1639, on 31 August, the same Boulliau, at Paris, at hour 8 after midday — that is, at Bologna hour 8, 40 minutes — observed with the telescope...

by a conjunction performed a little before, [that] Jupiter's place in Leo, the Tables then exhibit Jupiter in Leo at 24 degrees, 46 minutes.

16. In the year 1646, on 19 February, the following night, Don Vincenzo Mutus of Maiorica [D. Vincentius Mutus Maioricae — Vincenzo Mutus] noted with the telescope that Jupiter was rather more eastern, by one minute or another, [than] the northern of the forehead-stars of Scorpius, which to me was then in Scorpio at 28 degrees, 5 minutes, 10 seconds. Therefore Jupiter was in Scorpio at 28 degrees, 6 minutes, or at least 7 minutes; but the Tables answer to the marvel, for me. [Margin: ♂ ♃ — with the forehead of Scorpius.]

Jupiter's place	Sig.	G.	I	II
Observed	☐	28	7	0
Computed		28	7	10

17. In the year 1649, on 11 May, at hour 1 of the first after midday — at hour 8 at Maiorica — Don Vincenzo Mutus, with the telescope [tube], saw Jupiter rather more eastern, by 1½ or 2 minutes, [than] the star preceding among the four of the left wing of Virgo; but Elias Leonitus saw in Silesia that this very star [stood] more eastern at almost the same moment of time, whence indeed it is notable, and accords with certainty. To me that star was then in Virgo at 29 degrees, 57 minutes, 10 seconds; therefore Jupiter was in Virgo at 29 degrees, 58 minutes, 40 seconds, and perhaps in Virgo at 29 degrees, 59 minutes. [Margin: ♂ ♃ with the wing.] What [say] the Tables?

Jupiter's place	Sig.	G.	I	II

Ours		0	0	50

18. In the same year 1649, on 9 June, when Jupiter had already gone direct, Father Francesco Maria Grimaldi [Grimaldi] and I, with the telescope, at hour 1 after sunset, plainly saw Jupiter so much more western than the preceding star among the four of the left wing of Virgo, by 4 minutes, that on the 10th we saw it [had become] more eastern by that same amount; or perhaps on the 10th day, at the same hour, it had become a little less eastern than it had been more western on the 9th, when we beheld Jupiter's conjunction made — as set forth in Book 9 of the *Almagestum Novum* [Almag. Novi], section 6, chapter 10. But that star was then in Virgo at 29 degrees, 57 minutes, 16 seconds. [Margin: ♂ ∽ Direct, with the wing.]

Jupiter's place	Sig.	G.	I	II
Observed	☐	29	57	16

Rudolphine		5	33	0
Philolaic		5	21	0
Ours		5	23	30

20. Likewise in the year 1650, the same Don Vincenzo Mutus of Majorca, on 24 May, at hour 8, 30 minutes after midday — which at Bologna...

at Bologna it was 9h7'. With the telescope he noted Jupiter in Scorpio at degree 1 and minute 12.

Comparison table (item 20, 1650 May 24, Mut at Majorca, reduced to Bologna):

☾ position	Sig.	G.	I	II
Observed	☾ (Scorpio)	1	12	—
Computed from the Tables: Lansbergian	☾	1	18	0
Danish	☾	1	21	30
Rudolphine	☾	1	16	0
Philolaic	☾	1	31	0
Ours	☾	1	15	0
(Ours)	☾	1	14	40

Parsing notes: the first computed line is headed "Comput. ex Tab." (computed from the tables), then the table-sigla Lansberg., Danic., Rudolph., Philolaic., Nostris run down the rows. The Prutenic row is given (☾ 1 18 0 appears against "Pruten."); the printed block lists "Pruten. — 1 18 0", "Lansberg. 1 21 30", "Danicis 1 16 0", "Rudolph. 1 31 0", "Philolaic. 1 15 0", "Nostris 1 14 40", with the observed value ☾ 1 12 at the head. The two-column degree/minute alignment is tight in the gutter; values transcribed as printed.

Since we have now applied to twenty observations as reliable and as carefully selected as these, we shall have given a not improbable demonstration of the excellence of our Tables. If any discrepancy remains in some of the observations, that could be accounted for without great difficulty. But it would be superfluous to heap up here, at the cost of more tedium, the other comparisons we have drawn between our Tables and observations made by others — and not without some weariness. And so, although we have also examined the eight acronychal positions [loca 8. Acronychia] which Longomontanus examined one by one, we nevertheless do not place as much trust in them as in the twenty and more we have used. The doubtful uncertainty of minutes could undermine their reliability, on account of the motion of the Sun assumed in the Tychonic Tables — which is false — and other quantities assumed in the Prutenic Tables for fixing the moment and the place of the true opposition with the Sun.

CAPVT X.

De Hypothesi Arithmetica, & Geometrica Motuum Iouis.

[On the Arithmetical and Geometrical Hypothesis of the Motions of Jupiter.]

The things to be selected are those we discussed in Book V, Chapter 12, inasmuch as they are common to the five lesser planets. The remaining matters proper to Jupiter are written out below.

Mean motions of ♃ [Motus ♃]:

Motion of ♃	Sig.	G.	I.	II.	III.	IV.	V.
Mean from ♈ (Aries)	0	0	4	59	15	58	33
—							
Diurnal							
Mean from ♈	1	0	20	32	11	9	7
—							
Annual							

Motion of α	Sig.	G.	I.	II.	III.	IV.	V.
Apogee — Diurnal	0	0	0	0	14	38	11
Apogee — Annual	0	0	0	1	29	2	15
Node ϑ — Diurnal	0	0	0	0	4	2	52
Node ϑ — Annual	0	0	0	0	24	37	28

Parsing notes: the "Apogei Annuus" and "Nodi ϑ Annuus" rows each carry a sixth/seventh sexagesimal place in the source (Sig.G.I.II.III.IV.V. columns); the Annual-apogee row reads "0 0 0 1 29 2 15 18" and the Annual-node row "0 0 0 0 24 37 28 0", which run one place beyond the column header count — transcribed verbatim as printed.

The epoch of the motions is set to the beginning of the Common Era of Christ, at the last meridian [i.e. midnight/noon] of the preceding December, on the meridian of Bologna [in Meridiano Bononiensi].

Right column (continuation of the mean-motion / hypothesis data):

α	Sig.	G.	I	II
Mean motion from \square (Aries)	5	29	49	45
Apogee [Apogei]	4	28	25	24
Node ϑ	2	27	40	25

For the geometrical hypotheses, see what was said in Book 7 of the *Almagestum Novum* [Almag. Noui], Section 2 and 3, and here in Book 5, Chapter 12, and at the end. But choosing for the present an ellipse, whose track [vestigia] near the apsides [conum, i.e. the cone of the apse-line] seems to mark out the diurnal motion of the planet through the several other (intermediate) parts — let there also be selected measures, written out below, in the parts of which the radius of the Orbit of the Solar Year [Radius Orbis Annui Solis], that is the greater semidiameter of the Sun [maior semidiameter Solaris], is.

Si Radius Orbis ☉ fit
[If the radius of the
Sun's orbit be]

Let the ellipse be [Ellipseos sit]	100000.	100000.
And the bisected solar eccentricity [Et bisecta Solis Excentricitas]	1740.	

Greater semidiameter of the
ellipse of ☾, or its
[Semidiameter maior Ellipsis ☾
seu eius à]

Mean distance from the Sun [Sole media distantia est]	522521
Lesser semidiameter of the ellipse [Semidiameter minor Ellipsis]	521794
Whole eccentricity from the Sun [Excentricitas tota à Sole]	50736
Bisected eccentricity [Excentricitas bisecta]	25368

Distances [Distantia]:

With ☾ at [Sole Apogeo & ♃]		from the Sun [à Sole] / from the Earth [à Terra]	
Sun at apogee & ☾ — Aphelion [Aphelio]	from the Sun	547889	
	from the Earth	649629	
Sun at apogee & ☾ — Perihelion [Perihelio]	from the Sun	497153	
	from the Earth	395413	
Sun at perigee & ☾ — Aphelion [Aphelio]	from the Sun	547889	
	from the Earth	646149	
Sun at perigee & ☾ — Perihelion [Perihelio]	from the Sun	497153	
	from the Earth	398893	
	Gr.	I	II
Inclination of the orbit to the Ecliptic [Inclinatio orbitæ ad Eclipticam]	1	42	20

Greatest variations of latitude [Varietas latitudinum maximarum]:

	Gr.	I	II
Sun at apogee & ☾ —	1	8	30
Aphelion, in ♋ (Cancer) [in ♋]			
Aphelion, in ♎ (Capricorn) [in ♎]	1	40	25
Sun at apogee & ☾ —	1	7	50
Perihelion, in ♋			
Perihelion, in ♎	1	42	50
Sun at perigee & ☽ —	1	9	20
Aphelion, in ♋			
Aphelion, in ♎	1	39	40
Sun at perigee & ☽ —	1	8	18
Perihelion, in ♋			
Perihelion, in ♎	1	41	55

Parsing notes: in the latitude block the "in ♋" / "in ♎" entries are paired under each Aphelio/Perihelio sub-bracket of "Sole Apogeo & ☾" and "Sole Perigeo & ☽". The zodiac sigla read ♋ (Cancer) and ♎ (Capricorn) in the source.

For the remaining distances, see in the 2nd Volume, Table 97 [Reliquas Distantias vide in 2. Volumine Tab. 97].

MARTIS PLANETÆ OBSERVATIONES

Et Hypothesis Motuum.

[BOOK SEVEN]

[IN WHICH ARE CONTAINED]

[THE OBSERVATIONS OF THE PLANET MARS,]

[And the Hypothesis of its Motions.]

CAPVT I.

Martis Obseruationes Antiquæ ab Anno ante Christum 357. vsq; ad Annum Christi 509.

[Ancient Observations of Mars from the year 357 before Christ down to the year 509 of Christ.]

1. Aristotle, in Book 2 of *On the Heavens* [*De Cælo*], Chapter 12, in the text numbered 60, reports as follows: "*For we saw the Moon, being half-full [dichotomam], approach the star of Mars [Stellam Martis] — which is the star observed in the front (face) of Scorpio [in fronte Scorpjij obscuram partem Lunæ] — and it [the star] went behind the dark part of the Moon, but came out again on the bright and shining side.*" From this observation Kepler gathers that this happened at the Moon's first quarter; but Aristotle, in his work *On Mars* [*de Marte*], Chapter 69, affirms that it could not have happened at any other time than the common epoch [vulgarem Epocham] of April 4, in the evening, the Sun being in Aries 10, Mars with the Moon in Taurus 3, of Leo's year [Leonis annum], 357 before Christ — when Aristotle was 21 years old and was a hearer of Eudoxus.

2. In the year 13, according to Dionysius, on December 20, in the consulship of Capricorn [Capricornius? — i.e. dated by the archon], in the third year from the death of Alexander, in the 476th year of Nabonassar, on the 21st day, in the morning [manè], the star of Mars seemed to be incumbent on the northern front of Scorpio [Boreali frontis Scorpij], which then was in Scorpio at gr. 2, 15. So Ptolemy, in Book 10, Chapter 9. Hence Lansbergius, in his *Thesaurus* of observation 1 of Mars, supposing the highest (star) in the front of Scorpio [supremam in fronte Scorpij], Mars to be in Scorpio at gr. 1, 42, 12, with northern latitude gr. 1, 13; and he commends his own Tables as exhibiting Mars in Scorpio at gr. 0, 53, 12, and at latitude gr. 1, 13. Bullialdus [Boulliau], however, in Book 8, Chapter 13, says it was at gr. 1, 17, after the meridian, as Rudolphinus [the Rudolphine] gathers. Fixing this same time, he holds the observation of Mars to have been in Scorpio at gr. 0, 34, and Mars in Scorpio at gr. 2, 33, 41. Kepler, indeed, in *On Mars*, Chapter 69, says that in the year before Christ 272, on January 18, in the morning, and (so Chapter 70) confesses that his own calculation differs from the observation by half — that the first observation in Scorpio was that Mars was more to the west by gr. 1, 31, 28; and therefore he thinks Ptolemy erred in Scorpio, using the first place in Scorpio for the fifth, because the observer called it "more northern in the front of Scorpio" [Borealiorem frontis Scorpij]. Of these stars, the fifth was elongated from Regulus by gr. 94, 46, 3; from which Regulus Mars was elongated by gr. 94, 49, or gr. 51, 3 — so Bullialdus, Book 8, Chapter 13. But Longomontanus, in Book 2, *Theoric.*, Chapter 10, contends that the first ought to be retained.

3. In the year 15 of Adrian [Hadrian], Ptolemy obtained from his observation that Mars was in opposition to the mean place of the Sun on day 26, Tybi, the morning following, hour 1, equally after midnight, when Mars was in gr. 21 of Gemini. So Ptolemy himself, Book 10, Chapter 7; and from him Copernicus, Book 5, Chapter 15. But Kepler, in *On Mars*, Chapter 69, calls this observation into doubt on suspicion of an error in the time, in the refractions, in the places of the fixed stars, and for the gr. 21 of Gemini he holds it should at least be gr. 21, 30; or rather gr. 21, 4. It was the year 135 of Christ, and day 14, December.

4. In the year 19 of Adrian [Hadrian], Ptolemy observed an opposition of Mars with the mean place of the Sun on the following day 7, at hour 3 before midnight, in Aquarius [♒] at gr. 28, 50. So he himself, Book 10, Chapter 7, and from him Copernicus, Book 5, Chapter 15. Kepler, nevertheless, in *On Mars*, Chapter 69, says it was in Leo [♌] at gr. 29, 29, or 31. It was the year 138 of Christ, and day 21, February.

5. In the year 2 of the Emperor Antoninus, on the day of Epiphi 12, the following day 13, hour 1, equally before midnight, Mars was seen in opposition to the mean place of the Sun, existing in Sagittarius [Sagittarij] at gr. 2, 34. So Ptolemy observed it, Book 10, Chapter 7; and from him Copernicus, Book 5, Chapter 15. Kepler, in *On Mars*, Chapter 69, says Mars was in Sagittarius [Sagittarij] at gr. 1, 36, or rather gr. 0. It was the year 139 of Christ, day 27, May, the 28th.

6. In the same year 2 of Antoninus, on Epiphi the following 15, the 16th, hour 3, equally before midnight, the sky was clear, Mars in Libra [Libræ] at gr. 20, and the Sun, according to the mean motion, existing at gr. 5, 17 of Gemini [Geminorum]. So Ptolemy observed Mars by comparison with Spica in Virgo [Spicam □] at gr. 1, 36. But Lansbergius, in his *Thesaurus* of observation 2, says Mars was in the year of Christ 139, May 30, hour 9, after the meridian, in Sagittarius [□] at gr. 1, 34, 38. But Kepler, in *On Mars*, Chapter 70, gathers from his own Tables that Mars was in Sagittarius [□] at gr. 1, 43, adding the instruments of Ptolemy —

— Ptolemy's [instruments] to admit an error of 10 minutes; and in truth it was day 30 of May, the following day 31.

7. In the year 498 of Christ, as Bullialdus [Boulliau] reports in Book 8, *Astron.*, Chapter 13, and from a manuscript of the Royal Library of Paris [Bibliothecæ Regiæ Parisinæ] an unnamed observer says: "*I saw, after the setting of the Sun, under Diocletian 214, on Pachon day 6, in the seventh hour of the night, Mars conjoined with Jupiter, in such a way that there was no interval and it [Mars] hid it [Jupiter].*" Bullialdus adds that it was the year 498 of Christ, day 1, hour 9; and then from his own Tables that Jupiter was with Mars in Virgo [Virginis] at gr. 13, 57, with northern latitude gr. 1, 13.

8. In the year 509 of Christ, as Bullialdus relates in Book 8, Chapter 13, in the same Royal manuscript this observation lies: "*In the year 225 of Diocletian, on Payni 19, after the setting of the Sun, the star of Mars touched the star of Jupiter, in such a way that they were seen to be at the same distance in the preceding part, but in the south by a digit [in Austrum vero digitis 2]*" — as much as the canonical numbers, and the *Magna Syntaxis* [Almagest], show, that the two planets were seen at the same distance in the same part, day 21, the said month — on which day they were seen very close to one another mutually. Bullialdus adds that, in that year 509 of Christ, on June 13, hour 9, after the meridian, at Uraniborg [Vraniburgi], Jupiter was, by his own Tables, in Leo [Leonis] at gr. 11, 57, 43. Mars, however, from the Rudolphine [Tables], was in Leo [□] at gr. 11, 50, 50 — though it ought to have

been in gr. 11, 55. He adds Mars [♂] with Regulus in the year 508, September 27, in the morning.

CAPVT II.

Martis Obseruationes ex Opusculo obseruationum Io. Regiomontani.

[Observations of Mars from the Little Work of Observations of Johannes Regiomontanus.]

1. In the year of Christ 1461, on December 2, at the beginning of the night, Johannes Regiomontanus [Regiomontanus], at Rome, saw Mars in a straight line with two stars of the head of Capricorn [capitis Capricorni], distant between themselves by gr. 2, and distant from Mars by the same amount, that is gr. 2 — which stars Alphonsine calculation [Alphonsinus calculus] placed as conjoined. On December 5 he saw them conjoined, but on account of intervening clouds could not note the hour. At the beginning of the sixth night he saw that Mars had already passed Saturn by gr. 1, $\frac{1}{2}$, because the distance between them was about subsesquialterate [subsesquialtera] of the distance of the two stars of the head of Capricorn. Hence Lansbergius, in his *Thesaurus* of observation 3, attests its reliability with his own Tables, as far as the observation of December 2.

2. In the year 1461, on December 14, at the beginning of the night, Regiomontanus saw Mars conjoined, as to longitude, in a more lucid (star) in the tail of Capricorn [cauda Capricorni], than he said it then was in Aquarius [♊] at gr. 14, 29. Alphonsine calculation places Mars in ♊ at gr. 17, 20; he doubts whether it was from the place of the Fixed star.

3. In the year 1462, on September 15, in the morning at hour 10, the same (observer) saw Mars almost in a straight line with Leo's seventh and eighth (stars), and distant toward the north by an eighth, that is, the heart of Leo [corde Leonis] across one diameter of the Sun. Bullialdus, Book 8, Chapter 13, says the seventh star of Leo was indeed astral, three in the neck [collo], of the third magnitude, in Leo [♌] at gr. 20, 21, 41, with longitude, and northern latitude gr. 4, 51; the eighth at gr. 4, 51, that is the heart of Leo [Cor Leonis], to have been in ♌ at gr. 22, 18, 41, with longitude, and northern latitude gr. 26, minutes; and therefore, although the Tables exhibit gr. 1, 17; and therefore he holds Mars to have differed from Regulus toward the north by gr. 51, and to have been in ♌ at gr. 21, 58. See the rest in Bullialdus.

4. In the same year 1462, on September 19, he saw in one straight line Regulus, Mars, and Venus, in such a way that, with Regulus more Austral [Australior],

Venus was, and Mars more Boreal [Borealiior], the distance of Mars from Regulus being sesquiquarter [sesquiquarta] of the distance of Venus from the same.

5. In the year 1462, on October 16, in the morning at hour 11, Mars, says Regiomontanus, was not yet conjoined with the twenty-fourth star of Leo, just as among themselves, and the distance of Mars was estimated equal to four diameters of Venus; and it happened that Mars was more Southern [meridionalior] than that star — I conjecture it to be the twenty-fifth (star) of Leo. On day 17, October, in the morning at hour 11, he saw Mars already —

Right column, page 317 (items 6–11, top right):

— having passed the said star, and from that distant by a space of sesquialterate to yesterday's distance; and Mars was more meridional [meridionalior].

6. In the year 1464, December 11, hour 13, after the setting of the Sun, Regiomontanus at Rome saw Mars in a straight line with the 22nd and 23rd stars of Virgo [Virginis], but Mars was more Boreal [Borealiior], by gr. 23, and at the same distance, by double — and from the said distance the Alphonsine calculation differs in latitude by very nearly gr. 2.

7. In the year 1465, June 19, about the beginning of the night, Regiomontanus saw Mars as if in a straight line with the first and second of Sagittarius [Sagittarij], a little more Boreal [Borealiorem], and distant from the first and second by a sesquialterate interval.

8. In the year 1468, April 26, in the beginning of the night, on the same day he saw Mars pass a little over the straight line, in which it had been Jupiter, and the tail of the Lesser Bear [cauda Vrsæ minoris], and because Jupiter was in the beginning of Cancer [principio Cancrī], besides their other earlier conjunction, and on the 29th. On April 1st he saw Jupiter, Mars, and the sixth (star) of the third of Gemini [Geminorum] in a straight line with the Boreal head of Gemini [Boreali capite Geminorum]; yet Mars was more profound [profundior] than Jupiter, and more Boreal [Borealiior], at a distance, in such a way that from Jupiter [♃] there might be just over a quarter the distance between itself and that thirteenth star.

9. In the year 1471, July 26, in the morning at hour 2, after midnight, at Nuremberg [Norimbergæ] Regiomontanus saw Mars in a straight line with the eyes of Taurus [oculis Tauri], and a little more eastern [orientaliorem] than that straight line, by gr. 3, about minutes, and distant from the obscure eye of Taurus [obscuriore oculo Tauri], by as much as those eyes are distant between themselves, by gr. 10, and the fourth part of (a gr.) of Taurus.

10. In the same year (1471), September 9, at Nuremberg, Regiomontanus, with the radius standing at the distance of Mars from the right shoulder of Orion [humero dextro Orionis], obtained the first bosom [Sinum primum] 210, and the second 674; but for the distance from the head of Castor [capite Castoris] (he obtained) the first bosom 210, and the second bosom 662.

11. In the year 1474, on the 7th of March, Regiomontanus at Nuremberg saw Mars more eastern [orientaliozem] than the Boreal ass [Asino Boreali] by a diameter of the Moon, it seemed; and it was approaching that star, but was already beginning to direct (its course) [dirigi, i.e. become direct].

CAPVT III.

Martis Obseruationes Norimbergæ habitæ à Bernardo Vualthero ab anno 1475. Christi ad 1504.

[Observations of Mars made at Nuremberg by Bernhard Walther from the year 1475 of Christ to 1504.]

Prima Classis est obseruationum oculari æstimatione peractarum.

[The First Class is of observations carried out by ocular estimation.]

1. In the year 1475, September 17, in the morning between the third (hour) and the fourth, after midnight, Mars and Saturn [♂ & ♄] were distant from one another by very nearly five minutes, as to longitude — though more probably to be conjoined, as to latitude, from which Walther [Vualtherus] judges them to be conjoined, without doubt, on the 18th; and in truth on the 19th, Mars [stood] in eastern aspect to Saturn — by how much Saturn's aspect [vsus] had appeared the day before the 17th. Let this Almanac of conjunctions stand, this differing to day 21.

2. In the year 1477, September 5, in the morning at hour nearly the third, after midnight, Walther saw Saturn with Mars [♄ cum ♂], more western [occidentaliori], distant by one palm [palmum], in the same latitude; whence it concurs that on the day of the said eclipse of Saturn [Saturnum] from Mars, Lansbergius indeed of observation 4 dares to say (pro 5). On September 6, October, because however little (it was) by his own Tables, he found that conjunction. At Walther's, however, the *Quinta Septembris* [the Fifth of September] stands, just as Snellius [Snellius] (has) in the observations of Walther [Vualtherianis], nevertheless in truth Walther subjoins on the 15th, in the

morning, to have observed Mars more eastern [orientaliozem] than Saturn at gr. 2, 47; but it is to be seen whether it was Retrograde [Retrogradus].

Caput III (continued)

Mars Observations made at Nuremberg by Bernhard Walther, from the year 1475 to 1504 — First Class, by ocular estimation (continued)

3. In the year 1478, on March 16, in the morning at the 2nd hour after midnight, he saw Mars together with the sixth star of Virgo, which lies midway between the other three stars on the left, in nearly the same longitude but more southerly by a little over half a degree.
4. In the year 1479, on October 5, [Mars] was in conjunction according to longitude with Saturn, and Saturn was nearly half a degree more northerly. Mars was very close to the sixth star of Virgo. Lansberge, in his *Thesaurus*, reduces this to the 4th morning hour from his own tables, placing Saturn in Virgo at 27 deg. 4 min., with northern latitude 2 deg. 1 min., and Mars in Virgo at 27 deg. 56 min., with latitude 1 deg. 12 min.
5. In the same year, on November 7, he saw Mars more than a full degree more southerly than the seventh star of Virgo, but so close in conjunction with respect to longitude that Boulliau, in Book 8, Chapter 13, says it was in conjunction with Mars in Libra at 1 deg. 51 min., and the northern latitude of the star at 2 deg. 56 min.
6. In the year 1482, on November 28, at the 1st hour of the night, or nearly so, Walther says, the Moon eclipsed [occulted] Mars.
7. In the year 1486, on September 7, in the morning at the 4th hour after midnight, he saw Mars between the two horns of Taurus, in the same straight line with them, more southerly with respect to the southern horn by two lunar diameters.
8. In the year 1488, on October 3, he saw Mars and the two heads of Gemini [Castor and Pollux] in one straight line, more easterly than the following [eastern] head of Gemini by nearly twice the distance separating the two heads.
9. In the year 1490, on September 18, he saw Mars a little more southerly than the nebulous [object] of Cancer [Praesepe], in the morning at the 4th hour after midnight; and the same Mars, after midnight, he saw to be by then more easterly, indeed a little more so than on the preceding day at about

the same intermediate time — hence its conjunction with the nebulous [object] had occurred at the intermediate time.

10. In the same year, on September 21, in the morning at the 3rd hour after midnight, he saw Mars distant from the fifth part [star] of Cancer by a quarter of a lunar diameter, and distant by a palm along a line drawn through the fourth part of Cancer, and by a fifth [part] through the fifth.
11. In the year 1491, on January 6, he observed the beginning of the retrograde motion of Mars in one straight line with the twenty-second and twenty-third stars of Leo.
12. In the same year, on March 13, in the morning at the 2nd and a half hour after midnight, Mars was seen in one straight line with the sixth and eighth stars of Leo, distant from the eighth by two-fifths of the interval between the sixth and the eighth.
13. In the year 1492, on September 27, in the morning at the 5th hour, or nearly so, after midnight, Mars was nearly in a straight line with the sixth and seventh [stars of Leo], and more southerly — being midway between the sixth and seventh, but Mars more westerly than that line.
14. In the year 1495, on March 25, Mars was more easterly than the seventh [star] of Virgo, a little more than a lunar diameter, in nearly the same latitude; on the 27th it was more easterly by four lunar diameters; and on the 29th more westerly than the seventh [star] of Virgo by a lunar diameter.
15. In the year 1497, on February 15, in the morning at the 4th hour after midnight, Mars was distant from Jupiter by a lunar diameter, yet such that it looked like half this distance to the eye on account of the latitude; and Mars was more easterly and more southerly than Jupiter.
16. In the year 1504, on March 27, Mars was seen also by armillaries in Cancer at 17 deg. 45 min., Aldebaran being placed at 2 deg. 45 min. of Gemini. Hence Boulliau, in Book 8, *Astron.*, Chapter 13, says that Mars was in Cancer at 17 deg. 48 and three-quarters min., because Aldebaran was at that time more advanced [easterly], in Gemini at 2 deg. 48 and two-thirds min.

The Second Class contains observations made with the cross-staff [Radius] — Sinus 1 and Sinus 2 — concerning the use of which see the Saturn observations of Walther, number 10.

[The following large table on this page continues the First Class observations, numbered 17–50, giving for each the date, the distance from fixed stars, and the two cross-staff sines.]

Table — First Class observations 17–50. Columns: No. | Year, Month, Day, Hour | Distance from fixed stars | Sinus 1 (Sinus prim.) | Sinus 2 (Sinus secund.).

No.	Year Mon. D. H.	Distance from fixed stars	Sinus 1	Sinus 2
17	1475 Sept. 1 3 / after midnight	from the prec. [star] of Gemini	210	772
18	Sept. 3 3 / p. m. n.	from the foll. [star] of Gemini	180	950
		from the prec. [star] of Gemini	210	725½
19	Sept. 4 3 / p. m. n.	from the prec. [star] of Gemini	210	623
		likewise from Algomisa [Procyon]	210	705
		from the prec. [star] of Gemini	210	960
20	Sept. 5 2½ / p. m. n.	likewise from Algomisa	210	614½
		from the foll. [star]	210	685

48	Aug. 20 3 / morn. p. m. n.	Aldebaran	70	587
		northern horn of	100	559

No.	Year Mon. D. H.	Distance from fixed stars	Sinus 1	Sinus 2
		Taurus		
49	Aug. 26 4 / morn. p. m. n.	Aldebaran	70	580
		northern horn of Taurus	100	571
50	Aug. 31 4 / morn. p. m. n.	Aldebaran	120	535
		northern horn of Taurus	60	547

Parsing notes: The "Hour" column entries carry sub-rows distinguished by "p. m. n." (post mediam noctem, after midnight), "p. merid." (post meridiem, after noon), and "noct." (of the night); these are reproduced as part of the date/hour cell. The "sub 3" at item 25 is read "below 3" (i.e. shortly before 3). Item 42's left cell reads "Sic fuerat die sexta" ("Thus it had been on the sixth day"). The two Sinus columns are unitless cross-staff readings (the *Radius* scale), not degrees; values above 1000 (1127, 1046½, 1010) are legitimate Sinus-secundus entries, not errors. Several rows are sub-rows of a single dated observation (two or more reference-star bearings sharing one date); the date and number columns are blank on the sub-rows.

Caput III (conclusion) — Third Class, by zodiacal armillaries

The Third Class holds observations made with zodiacal armillaries, whose uncertainty extends to about 10 minutes — see Walther's Saturn observations above at number 33. For this reason we select only a few of them, and only those for which Walther assigns the hour; for the rest, dismissing them, he notes the meridian altitude [mediation] of the heavens [in place] of the hour, by expressing the altitude.

Table — Third Class armillary observations 51–56. Columns: No. | Year, Month, Day, Hour, Min. | Place of observation (Sign, Degree).

No.	Year Mon. D. H. M.	Place of obs. (Sign Gr.)
51	1489 April 5 8 0 p. merid.	Cancer 29 0
52	1503 Aug. 26 3 0 morn. p. m. n.	Gemini 23 59
53	Sept. 16 2 30 p. m. n. / northern latitude	Cancer 5 15 / 0 15
54	Sept. 19 2 30 p. m. n. / northern latitude	Cancer 6 45 / 0 15
55	Oct. 13 4 morn. p. m. n. / northern latitude	Cancer 17 0 / 0 30
56	1504 Jan. 3 3 morn. p. m. n.	Cancer 10 45

CAPVT IV.

Copernican Mars Observations.

1. In the year of Christ 1512, on the Calends of January [January 1], at the 6th hour before noon, in the morning, Copernicus at Frombork [Fruenburg] saw Mars [at] a quarter degree distant from the bright first claw [star] of the Claws [of Scorpio/Libra], or rather more southerly, but deflected toward the summer-solstitial rising — which was an indication that Mars had begun to retrograde from that separation in longitude by 7 and a half min., and as to northern latitude by 12 min. (*Copernicus*, Book 5, Chapter 19). For he supposes that elongated star of the first [part] of Aries to be at 191 deg. 20 min., with latitude 40 min. northerly, and hence the place of Mars in the first part [of Aries] at 191 deg. 28 min., with northern latitude 51 min.; and hence Mars to have been in Scorpio at 1 deg. 53 min., according to his hypothesis of the first [star] of Aries.
2. In the year of Christ 1512, on the 9th of June at the 1st hour after midnight, Copernicus at Frombork, from his own observation, says he found Mars retrograde [*acronychal* — at opposition] in the 235th part [degree] of the ecliptic, [counted from a scruple of] 33 — this is in Sagittarius at 15 deg. 58 min. — and the Sun in opposition existing in the 55th part 33, this is in Gemini at 15 deg. 58 min. (*Copernicus*, Book 5, Chapter 16).

3. In the year of Christ 1518, on the day before the Ides of December [December 12], at the 8th hour after noon, Mars appeared retrograde [acronychal] to Copernicus at Frombork, and at opposition, in the 63rd part 2, this is in Gemini at 3 deg. 2 min., from the first star of Aries (*Copernicus*, Book 5, Chapter 16).
4. In the year of Christ 1523, on the eighth of the Calends of March [February 22], at the 7th hour before noon, Copernicus observing at Frombork, Mars was seen in the 133rd part, scruple [min.] 20, from the first star of Aries — namely in Leo at 24 deg. [from the first star of Aries] (*Copernicus*, Book 5, Chapter 16).

CAPVT V.

Tychonic Mars Observations, from the Year of Christ 1580 up to 1601, noted in the Old Style, [made] at Uraniborg unless otherwise added, [and] made for hours after noon.

Tycho himself, in his *Letters to the Landgrave of Hesse [Epistolae ad Landgravium Hassiae]*, page 56, places these three of the year 1587, [in] January, made with Alphonsine and Copernican calculation.

Table — Three 1587 January Mars positions. Columns: No. | January (Day, Hour, Min.) | Longitude of Mars (Sign, Deg., Min.) | Latitude (Deg., Min.) | source note.

No.	January D. H. M.	Long. Mart. (Sig. G. M.)	Latitude (G. M.)	Note
1	9 17 15	Libra 3 5	3 4 B	observed
			[north]	
		Libra 0 43	2 48	Alphonsine
2	14 16 40	Libra 2	2 50	Copernican
		Libra 1 25	2 12 B	observed
		Libra 4 56	2 57	Alphonsine
3	15 15 50	Libra 1 25	2 59	Copernican
		Libra 4 2	3 13 B	observed
		Libra 1 32	2 58	Alphonsine
		Libra 5 3	1	Copernican

Parsing notes: Each numbered observation gives three rows — the observed Mars longitude, then the longitude computed from the Alphonsine tables, then from the Copernican. The sign for all entries here is Libra (♎); it is printed only on the first sub-row of each group and carries down implicitly to the Alphonsine/Copernican sub-rows (which give degree-minute only). Latitude "B" = Borea (northern). The lone latitude "1" in item 3's Copernican sub-row is a minutes-only entry with the degree truncated; transcribed as printed (suspected dropped field).

There follow the acronychal [opposition] places of Mars from Tycho's observation, as to the apparent place — but as to the true place, with the place of Mars added as computed from the restored tables [Solar tables], then from Longomontano, Book 2, *Theoricorum*; then from Kepler reduced [in his work] *On Mars*, Chapter 15; finally, as to the opposition with the mean motion of the Sun, in *On Mars*, Chapter 8.

Table — Mars oppositions From Longomontanus (Ex Longomontano).

Columns: No. | Year | Month, Day, Hour, Min. | Observed longitude (Sign, Deg., Min., Sec.) | Computed longitude (Sign, Deg., Min., Sec.).

No.	Year	Mon. D. H. M.	Longit. obs. (Sig. G. M. S.)	Long. supp. (G. M. S.)
4	1580	Nov. 18 1 30	Gemini 6 27 30	6 27 30
5	1582	Dec. 28 4 0	Cancer 16 54 30	16 55 30
6	1585	Jan. 30 19 14	Leo 21 35 10	21 37 0
7	1587	Mar. 6 7 20	Virgo 25 42 0	25 42 10
8	1589	Apr. 14 36 0	Libra 4 23 0	4 16 30
9	1591	June 8 7 45	Sagittarius 26 42 0	26 45 30
10	1593	Aug. 25 17 30	Aquarius 12 15 0	12 14 45
11	1595	Oct. 31 0 40	Aries 17 30 40	17 29 10

No.	Year	Mon. D. H. M.	Longit. obs. (Sig. G. M. S.)	Long. supp. (G. M. S.)
12	1597	Dec. 13 16 0	Taurus 2 27 0	2 26 0
13	1600	Jan. 18 14 0	Leo 8 37 0	8 37 10

Table — Mars oppositions From Kepler, Chapter 15, *On Mars* (Ex Keplero cap. 15. Martis). Columns: No. | Year | Month, Day, Hour, Min. | Observed longitude (Sign, Deg., Min., Sec.) | Observed latitude (Deg., Min.).

No.	Year	Mon. D. H. M.	Longit. obs. (Sig. G. M. S.)	Latit. obs. (G. M.)
4	1580	Nov. 18 1 31	Gemini 6 28 35	1 40 B [north]
5	1582	Dec. 28 3 58	Gemini 16 55 30	4 38 B
6	1585	Jan. 30 19 14	Cancer 21 36 10	4 32 B
7	1587	Mar. 6 7 23	Virgo 25 43 0	3 41 B
8	1589	Apr. 14 36 0	Libra 4 23 0	1 12½ B
9	1591	June 8 7 43	Sagittarius 26 43 0	0 A [south]
10	1593	Aug. 25 17 27	Aquarius 12 13 40	6 A
11	1595	Oct. 31 0 39	Aries 17 31 40	6 8 A
12	1597	Dec. 13 15 54	Taurus 2 28 0	3 33 B
13	1600	Jan. 18 14 2	Leo 8 38 0	4 30½ B

Table — Mean oppositions from Kepler, *On Mars*, Chapter 8 (Opposit. mediae ex Keplero Marte c. 8.). Columns: No. | Year | Month, Day, Hour, Min. | Observed longitude (Sign, Deg., Min., Sec.) | Computed longitude (Sign, Deg., Min., Sec.).

No.	Year	Mon. D. H. M.	Long. obs. (Sig. G. M. S.)	Long. supp. (G. M. S.)
4	1580	Nov. 17 9 40	Gemini 6 46 10	6 50 40
5	1582	Dec. 28 12 16	Gemini 16 46 10	16 51 26
6	1585	Jan. 31 19 35	Cancer 21 36 10	21 9 41
7	1587	Mar. 7 17 22	Virgo 25 10 20	25 4 50
8	1589	Apr. 15 13 34	Scorpio 3 58 10	3 54 33
9	1591	June 8 16 25	Sagittarius 26 32 0	26 40 23
10	1593	Aug. 24 2 13	Pisces 12 43 45	12 34 36
11	1595	Oct. 29 21 24	Aries 17 56 15	17 57 14
12	1597	Dec. 13 13 32	Taurus 2 28 0	2 32 20
13	1600	Jan. 19 9 40	Leo 8 18 0	8 19 57

Parsing notes: The three Tyconic-opposition tables share the same numbering (4–13) and the same set of opposition events, each giving a different reduction (Longomontanus's computed longitude; Kepler ch. 15 observed longitude + latitude; Kepler ch. 8 mean opposition). The mean-opposition table (ch. 8) reckons longitude against the Sun's place [Lóg. ☉], so a few of its zodiac signs differ from the corresponding rows of the Longomontanus/Kepler-15 tables. Zodiac-sign glyphs read from the symbols: Gemini ♊, Cancer ♋, Leo ♌, Virgo ♍, Libra ♎, Scorpio ♏, Sagittarius ♐, Aquarius ♑, Pisces ♒, Aries ♈, Taurus ♉. Latitude "B" = Borea (north), "A" = Australis (south). The 1589 entry's date "Apr. 14 36 0" carries an hour-figure of 36 (>24); it appears identically in the Longomontanus and Kepler-15 rows, a shared typesetting carry, transcribed as printed. The 1585 mean-opposition supputatum "21 9 41" breaks the close observed/computed agreement of the other rows; transcribed as printed (suspected compositor error).

There follow other places of Mars deduced from Tycho's observation and calculation, as they appear in Kepler's *On Mars* — which we shall indicate by the letter K — or in the Tyconic observations sent to us by Father Alberto Curzio [Albert Curtz], of the Society of Jesus, which we shall indicate by the letter C.

Table — Tyconic Mars observations, items 14–66 (left column). Columns: No. | Year | Month, Day, Hour, Min. | Mars observed longitude (Sign, Deg., Min., Sec.) | Observed latitude (Deg., Min.) | Kepler chapters [Capita Kepl.].

124		April. 9 9 20	Taurus 3 30 47	2 33 0	Snell.

Parsing notes: Both columns share the format Year / Month-Day-Hour-Min / Mars longitude (sign glyph + deg-min-sec) / latitude (deg-min-sec, B = north / A = south) / "Capita Kepl." source-key column (the chapter of Kepler's *On Mars* — letter K — and/or Curtz's manuscript — letter C; one entry, item 124, cites Snell [Snellius]). Several month/year cells span multiple numbered rows in the source; the value is repeated or left blank where the source leaves it implicit. The sign glyph is printed only on the first row of each new-sign group and carries down implicitly; sub-rows with no fresh sign continue within the same sign (a layout feature, not illegibility). Zodiac-sign glyphs are read from the printed symbols. Where a row gives only a partial date (e.g. items 75–78, "19", "21", a bare day number), the month carries over from the row above per the source's columnar layout. Item 120 is a blank/spacer row in the printed table (the row-number is printed in the stub with no data). Two latitude-seconds cells remain illegible (ink-bled): item 66 ("11 47 [?]" — the degree "11" is also anomalously large for Mars's latitude and

may be a column-slip or mis-set) and item 97 ("7 9 [?] A"); both degrees-minutes are legible, only the seconds glyph is lost.

There are now coming to light the remaining Tychonic observations, edited at Vienna and reviewed by Lucius Barrettus [Lucio Barretto] — understand [this to be] Father Alberto Curzio [Albert Curtz] of our Society, who wished to conceal his name under this anagram, the care of which the Emperor Ferdinand entrusted to him. While all these are being published, take this specimen meanwhile, for the year 1582.

Liber VII — De Martis (continued)

Caput V (continued): Tychonic Mars Observations — the 1582 specimen

[The page opens with the continuation of the detailed Tychonic specimen table for the year 1582 (folio 321, left column). The columns are: the date (year/month/day, hour, minute); the distance of Mars [Distant. □] in degrees and minutes; and the reference star [à Fixis] from which the distance was measured.]

Year / Month — D · H · M	Dist. □ Gr.	Dist. □ M.	From the fixed star [à Fixis]
1582			
Nov. 23 — 8 50 (twice) [bis]	22	32	from the Knee of Castor [à Genu Castoris]
— 9 7 (thrice) [ter]	39	53½	from the Northern Horn of the Bull [à Cornu Bor. Tauri]
25 — 8 27	22	21½	from the Knee of Castor
— 8 50 (thrice) [ter]	39	43	from the Northern Horn of the Bull
Dec. 3 — 8 50 (twice,	21	7½	from the Knee of Castor

Year / Month — D · H · M	Dist. □ Gr.	Dist. □ M.	From the fixed star [à Fixis]
quarter) [o quarter]			
— 7 52 (thrice) [ter]	52	0	from the Eye of the Bull [ab Oculo Tauri]
— 8 19 (thrice) [ter]	38	27½	from the Northern Horn of the Bull
17 — 8 0	6	49½	from the head of Castor [à cap. Castoris]
— 8 ¼	44	41	from the bright star of Aldebaran [ab Aldebara]

Parsing notes: several time-entries carry the abbreviations *bis* ("twice"), *ter* ("thrice"), *quarter* and *o quarter* — these mark repeated readings or fractional minutes in the source; transcribed as printed. The row-bracketed numbers in the left margin of the source (325, 326, 327, 128, 129, 130, 131) are observation-item numbers; item "128" is printed thus (Arabic, in the running observation count). Item-number "128" sits at the row "17 — 8 0 ... 6 49½".

[Margin note within the table region:] Item 128.

It is to be noted that Mars was at almost exactly the same longitude as the head of Castor [caput Castoris], and at nearly the opposite [point of] its Epicyclic Apogee [in Auge fere Epicycli], conjoined with the Sun [cum ☉].

Year / Month — D · H · M	Dist. □ Gr.	Dist. □ M.	From the fixed star [à Fixis]
Dec. 27 — 6 51 (twice) [bis]	16	43½	from the head of Castor [à cap. Castoris]
— 7 8	36	42½	from the heart of Leo [à corde]

Year / Month — D · H · M	Dist. □ Gr.	Dist. □ M.	From the fixed star [à Fixis]
— 7 18 (twice) [bis]	36	43	Leonis] from the heart of Leo
29 — 11 6 (twice) [bis]	29	53½	from the Northern Horn of the Bull [à cornu Bor. Tauri]
— 19 6	6	16	from the head of Castor
30 — 8 10 (thrice) [ter]	19	15½	from the lower foot of Erichthonius [ab infer. ped. Ericht.]
— 8 18	35	27½	from the upper foot of Erichthonius [à super. ped. Ericht.]

Parsing notes: "Erichthonius" = Auriga (the Charioteer); the source abbreviates *Ericht*. The marginal item-numbers 129, 130, 131 attach to these rows.

Now we pass from the first Tychonic observations to the last, made in Bohemia — partly at the castle of Benatky near Prague [in arce Benatica prope Pragam], partly in a house in Prague itself — which Snel [Snellius] published at Leiden in the year 1618, together with the Hassiac [observations] and others taken from Curtz [Curtii]; and he reduced them to the days of the New Calendar.

[Item 132] In the year 1600, on January 1, New Style, in the night preceding, the meridian altitude of Mars as observed by Tycho [Brahe] was 58° 54'. And the longitude [of Mars] was 55° 6'. Hence, two hours afterward, [Mars stood] 27¾° distant from the Pole-star [à Pollucis capite], while Jupiter likewise was 29° 45' distant. But Jupiter itself was at 33° 35' ½.

[Item 133] On the fifth of January [Jan. 5], in the night, one hour before the meridian-transit of Mars, Mars stood distant from the Pole-star [Pollux] by $29^{\circ} 3'$; and soon, from the tail of Leo [à cauda Leonis], $30^{\circ} 13'$. It then crossed the meridian at an altitude of $59^{\circ} 12'$.

[Item 134] In the same year, on March 10, p.m., on the meridian, Mars stood distant from the bright star of Aries [à lucida Arietis] by $86^{\circ} 33' \frac{1}{3}$, and from Aldebaran by $55^{\circ} 47' \frac{1}{3}$; therefore, as Snel infers, the longitude of Mars was $29^{\circ} 14' 56''$ of Cancer [Cancri grad. 29], and its latitude $5^{\circ} 30' 51''$.

[Item 135] And on April 11, at hour $9^{\circ} 37'$, p.m., Mars stood distant from the bright star of the foot [of Gemini, à lucida pedis Geminæ] by $32^{\circ} 50'$; and after 14' of time, it stood distant from Regulus by $19^{\circ} 20' \frac{1}{3}$.

[Item 136] In the year 1601, October 10, in the morning, at hour $3^{\circ} 30'$, Mars stood distant from the head of Pollux [à Pollucis capite] by $25^{\circ} 0' 10''$, and from Procyon by $27^{\circ} 44' \frac{1}{3}$; and from Regulus by $12^{\circ} 2' \frac{1}{3}$.

[Item 137] And on October 11, in the morning, at hour $3^{\circ} 30'$, Mars stood distant from the head of Pollux by $25^{\circ} 33' 50''$; from Procyon by $28^{\circ} 12'$; and from Regulus by $11^{\circ} 23'$.

This was the last observation of Tycho [Brahe]; for he took to his bed [decubuit], being seized by a retention of urine, on October 13, and died on October 24.

Furthermore, besides Kepler and Longomontanus, those authors who make use of the aforesaid acronychal [opposition] observations and others are listed above [supra recensiti sunt]: Boulliau [Bullialdus], Book 1, *Astronomia* [*Astronomia Philolaica*], chapter 11, and to the end throughout; and Longomontanus [Lansbergius?], passim, in [his] observations of the years 1587 (January 15 and 1589), April 15 and 1591 (May 13), and 1595 (October 17, or rather 27).

CAPVT VI.

Mars Observations made by Jost Bürgi [Iusto Byrgio], Longomontanus, Kepler, Fabricius, and Gellius Sascridus, from the Year 1590 to 1613.

The observations made by Jost Bürgi [Byrgius] at Kassel [Casselis], and noted on the days of the Old Style [stylus vetus], at hours after midday [post meridiem], in the keeping of Snel [apud Snellium], among the Hassiac [observations] —

[The table at the head of the right-hand column of folio 321 lists the Bürgi/Kassel and related observations. Columns: year/month, day · hour · minute; distance of Mars [Martis dist.] in degrees, minutes, seconds; reference star [à Fixis]. The marginal item-numbers run 1–11.]

#	Year — Month · D · H · M	Mars dist. G.	M.	S.	From the fixed star [à Fixis]

	—	28	53	30	from Capella
11	1597 Sept. 28 — 14 0	14	26	0	from Procyon [à Procyone]
	—	22	26	30	from Procyon

Parsing notes: the right-hand table's running header reads "Ann. Mens. D · H · M ·
— Martis dist. G · M · S · — à Fixis." Item-numbers 1–11 are in the source's
marginal column. The entry at item 3 ("Jun. 8") appears to belong with the
following sub-rows; alignment preserved as printed.

[Item 12] In the year 1590, January 9, Old Style, Michael Mästlin [Michaël
Mæstlinus] and Johannes Kepler [Io. Keplerus], at Tübingen, saw the whole disk

of Mars by an eclipse: the color of Mars was fiery [ignis], and they argued [from this] that Mars was inferior [to the Sun]. Kepler, in his *Astronomia Optica* [*Astronomiae Pars Optica*], page 305, and likewise Lansberg [Lansbergius] at Thelaur [Thelauro], among these observations, however, places the day as the eighth [octauam], and the morning [mane] from his own conjecture [ex tuo figmento] — though in the calculation he sets the day as the sixth, at hour 18. Goët. [Goëtensis?] therefore, as if the observation had been made on day 7 — at any rate, since this table does not exhibit the conjunction of Mars with Jupiter [Iove], 18 hours after midday of [Tübingen? wait — see below] — [Margin: *duplex dies* ("a double dating")]. Goët., on the sixth day, supposes the place [of Mars] to be in [Scorpius]: place of Mars 13° 52', with latitude north [Borea] 1° 8'. The place of Mars [is reckoned] in Scorpius at 13° 11' ½, with latitude north 8° 18'; or [from a] vicious [reading] of Kepler's numbers, or [from] vicious tables of Lansberg. Maginus [Maginus], in his *Ephemerides* derived from the Prutenic [Tables], notes the same conjunction for the 9th, at hour 15° 41', after the meridian of Venice [Venetiis].

[Margin: *Lansbergius / duplex dies* — "Lansberg / a double dating."]

[Item 13] In the year 1591, June 8, Old Style, Gellius Sascridus [Gellius Sascridus], a disciple of Tycho [Brahe], observing at Padua [Patauii], concluded by [the position of] Mars, opposing his own master, that Mars at its mid-position [Medio ☽ wait] — [reads:] *Medio S. ☐ loco factam fuisse hor. 16. 25'*. — that [the observation] was made at the place [loco] in the middle, at hour 16° 25' after the meridian, when Mars was at 26° 40' ½ of Sagittarius [Sagittarii]. Kepler, *In Ad arte* [*In Astronomia Nova*], chapter 8.

[Item 14] In the year 1597, December 19, Old Style, David Fabricius [David Fabricius] in East Friesland [Frisia], at hour 12° 10', observed Mars in Cancer [in Cancri] at 3° 40' ½, with latitude north 5° 23'. Kepler, *In Marte*, chapter 15.

[Item 15] In the year 1602, February 16, Old Style, David Fabricius in East Friesland [Frisia Orientali], at hour 3 in the morning [matutina], observed Mars distant in the preceding [moment? *in præcedentia*] from the bright Southern wing of Virgo [clara Australis alæ Virginis] by 20° 18', and from the tail of Leo [à cauda Leonis] by 8° 17'; from which he gathers [colligit] Mars to have been in Virgo at 21° 21' ½. Kepler, *In Marte*, chapter 15, who collects [calculates] Mars to have been in the wing [ala] of Virgo at 14° 19', or [taking] Leo with the tail, in [grade] 14° 31' 36" at midday [meridie]; but with the latitude included, Mars was [at] 21° 21' ½, [as] purgans Sextantem [correcting the Sextant], so that Fabricius's [stated] distances exhibit somewhat greater values.

[Item 16] In the year 1602, Longomontanus [Longomontanus], Book 2, *Theoricæ [Astronomia Danica]*, chapter 8, gathers from his own observations the opposition of Mars with the Sun, [finding] indeed the place of the Sun to have been at 20° [Pisces?], Old Style, hour 14° 15'; at Copenhagen [Hafniæ], in Virgo at 12° 16', although his own Tables give 12° 24'.

[Item 17] In the year 1602, February 18, Old Style, at Prague [Pragæ], with the help of Matthias Seiffard [Matthias Seiffardo], a pupil of Tycho [Brahe], with Tychonic instruments, in the evening at hour 10° 30' after the meridian,

Liber VII — De Martis (folio 322 = PDF p. 356)

[Continuation of item 17 from the foot of the prior page:] — Mars's distance was observed from the middle of the tail of the Greater Bear [à media cauda Ursæ maioris] as 52° 22'; but because [the distance] lay between [the stars] of Leo and Procyon [inter cor Leonis & Procyona], the Sextant exhibited 37° 22' 20", whereas it ought to have been 37° 19' 40". [Kepler] therefore reckons the Sextant in excess [abundare] by 2° 14' ¾; and so he sets the distance of Mars from the middle of the tail of the Greater Bear, corrected, to have been 52° 19' ¾. Thus, [reckoning] between Mars and Regulus [Regulum], he puts [Mars] at 19° 47' ¾; and between Mars and the bright star of Virgo [clara Virginis] at 21° 1' 20"; he puts [Mars] at 21° 17' ¾; and from this wondrous agreement [mira consensu] he establishes the place of Mars in Virgo at 13° 19' 6". Kepler, *In Marte*, chapter 15.

[Item 18] In the year 1602, on the same night, February 18, hour 12° 40', at Prague [Pragæ], Kepler observed the meridian altitude of Mars to be 50° 1'; in whatever way [or: of which] he had the tail of Leo at 30° 15'. He deduced the place of Mars in Virgo to be 13° 19' 30", with latitude north 4° 7' 55"; and thence he recognized the future opposition of Mars with the Sun for the 20th of February, hour 14° 13' p.m., the Sun obtaining [a place] in Virgo of 12° 27' 35", with north latitude 4° 10'. Kepler, *In Marte*, chapters 15, 18, 52.

[Item 19] In the year 1604, February 27, New Style, Kepler, at night between the days of Jupiter and Venus [inter diem Iovis & Veneris — i.e. between Thursday and Friday], while a curtain [Cortus] darkened the sky [cœlum mediaret], observed Mars distant from Spica [à Spica] by 9° 44', and from the Northern Balance [à Lance Borea] by 17° 41'; but using the same instrument, he afterward exhibited the same [distance of Mars] from Arcturus [ab Arcturo] as 51° 57'; with which, since they agree with the data given by Tycho, [the distances stand at] 51° 1' 45". Therefore he corrected the aforesaid distances, ordering them thus: from

Spica $9^{\circ} 48' 45''$ — $17^{\circ} 45' 45''$ — $29^{\circ} 17' 43''$. Moreover, he took the meridian altitude of Mars [at] $32^{\circ} 4'$, and of Spica at $30^{\circ} 50'$; and from the difference of these, beneath the altitude of the Pole [sub altitudine Poli] at 32° , he ascertained the altitude of Spica to be properly [debuisset esse] $30^{\circ} 52'$; and that of Mars $32^{\circ} 6'$. He doubts, however, whether by some iron Rule [Regula ferrea] and weight [pondere], the impetus, loosened [from] the pulleys [solutis trochleæ], shook the pinnacle [pinnacida — sight-vane] by an example [or: in the manner described]. Kepler, *In Marte*, chapter 11.

[Item 20] In the year 1604, April 8, New Style, Kepler, together with Johannes Schuler [Ioannem Schulero], observing in the evening, [found] the distance between Arcturus and Spica [inter Arcturum & Spicam] to be $33^{\circ} 4'$, which ought to have been $33^{\circ} 1' \frac{1}{3}$, or $4\frac{1}{2}'$; whence, [taking] the corrected distances, he acquired the distance of Mars from Arcturus as $29^{\circ} 41' \frac{1}{3}$, and from the heart of Leo [à corde Leonis] as $54^{\circ} 8' \frac{1}{3}$; and although one might doubt that he sometimes took Mars for Spica, he nevertheless gathers the opposition with the Sun [veram oppositionem] to have been made on the 28th [of] March, Old Style, at hour $16^{\circ} 23'$ after midday. Mars [was] in Libra at $18^{\circ} 37' 50''$, with latitude north $4^{\circ} 26'$. Kepler, *In Marte*, chapter 15.

[Item 21] In the year 1604, September 27, New Style, at Prague [Pragæ], hour 8, [the observation] was made of the conjunction of Mars with Saturn [Saturno]; and on the 29th, October, hour 1 before the meridian [the observation] was made of the conjunction of Mars with Jupiter [Iove]. Kepler, [in his] *De nova Stella Serpentarii* [*De Stella Nova in Pede Serpentarii*], chapter 11.

CAPVT VII.

Mars Observations made by Pierre Gassendi [Petro Gassendo], Martin Hortensius [Martino Hortensio], Michael Florentius [Michaele Florentio], and Vincentio Mutus [Vincentio Muto], from the Year 1617; likewise by the Fathers of the Society [PP. Soc.] of Jesus at Ingolstadt [Ingolstadii] and at Innsbruck [Oeniponti].

[Item 1] In the year 1621, for the opposition of Mars with the Sun noted in the Ephemerides on the 6th [of] May, Gassendi [Gassendus] at Aix [Aquis Sextiis], with the Astronomical Radius [Radio Astronomico], on the 3rd of May, in the

evening at hour 10, observed Mars distant from the Northern Balance [à Lance Borea] by 8° 19', and from the Southern [Balance, ab Australi] by 5° 17'. The Balances [Lances], moreover, [stand] from each other [inter se] by 9° 12'; so that as far as the latitude and longitude [it] follows the Tychonic [reckoning], as Tycho has it, [namely] 9° 8'. Again, on the same [day], hour 8, he saw Mars distant from the Northern Balance by 8° 18'; and on the 8th [of May], hour 9, in the evening, he saw [Mars] distant from the Northern Balance by 8° 28', and from the Southern [Balance] by 3° 35'. Thus Gassendi —

gives [these as] Mars's distance from the middle of the tail of the Greater Bear [à media cauda Ursæ maioris] as 52° 22'; but because [the distance] lay between [the stars] of Leo and Procyon [inter cor Leonis & Procyona], the Sextant exhibited 37° 22' 20", whereas it ought to have been 37° 19' 40"; therefore he reckons the Sextant to exceed by 2° 14' ¾, [and] he collects the distance of Mars from the middle of the tail of the Greater Bear, corrected, to have been 52° 19' ¾.

Parsing notes: the right column at the top of folio 322 repeats verbatim the corrected-Sextant passage from item 17/the prior page; this appears to be a compositor's reprise of the same Kepler-Sextant calculation. Transcribed as printed.

[Item 2] In the year 1623, June 26, hour 13, after midday [post merid.], Gassendi [found], from the distance of Mars at Digne [Diniæ], from the left shoulder of Sagittarius [ab humero sinistro Sagittarii], at 6° 53'; and at 13° 3' from the Northern part of the arc of Sagittarius [à Boreali parte arcus Sagittarii], deduced the longitude of Mars [to be] in Capricorn [Capricorni] at 13° 21' ½, and the Southern latitude [latitudinem Australem] 6° 37' ½; as is to be had in the observations of Gassendi himself, in his writings, in which are contained also the underwritten [subscriptas] longitudes and latitudes observed from the same.

[The boxed table embedded in the left column of folio 322 follows. Running header: "Anno 1623. — Longit. Martis (Sig · G · M ·) — Latit. Austr. (G · M ·)." Columns: month, day, hour; longitude of Mars (sign, degrees, minutes); Southern latitude (degrees, minutes). Marginal item-numbers 3–20.]

#	Month — D · H	Long. Mars			Lat. Austr.	
		Sig.	G.	M.	G.	M.
3	Jun. 28 — 13	♋ Cancer	12	52	6	31

19	9 — 10	—	5	38	5	35
20	10 — 10	—	5	41	5	34

Parsing notes: the zodiac-sign column repeats ☐ (Cancer) at the head and is left blank (ditto) on intervening rows in the source; carried as "—". The latitude is consistently Southern (Austr.) and slowly decreasing then turning — note item 17 onward the longitude reverses (5° 34' → 5° 35' → 5° 37'...), consistent with Mars near its station/retrograde turning point; this is a real motion feature, not a transcription error.

[Item 21] In the year 1632, February 5, Michael Florentius Langren [Michaël Florentius Langrenus], Cosmographer to the Catholic King [Regis Catholici] at Madrid [Matriti], saw Mars occulted by the Moon [occultari à Luna] near the middle of the eastern limb [orientalis limbi], culminating at the equator

[culminante Æquatoris] at grade 178° 38'; and emerging from the western limb [ex limbo occidentali], culminating at grade 193° 35', [a quantity] scarcely [latius] sub —

[Item 22] — the Moon was less [than] 57¾' of one hour. The same conjunction of Mars [in its] acronychal [position] with the Moon, the Moon being full [plena], Hortensius [Hortensius] at Leiden [Leydæ] observed [as] made, and Gassendi [Gassendus] at Paris [Parisiis], hour 15° 18' after the meridian; which [observation] Hortensius [recorded] in his *Dissertation* [*Dissertatio*], and conjoined to the Tables of Lansberg [Tabulis Lansbergii]; and Lansberg himself, at Thelaur [Thelauuro], among the observations of Mars, supposing the place of Mars [at] the predicted moment to have been in Leo [Leonis] at 16° 24' 37", with latitude north 4° 33' 42"; the Moon's true place, moreover, in Leo at 16° 42' 31", the [Moon] seen [at] 16° 26' 26", with true latitude 4° 58' 33"; the [Moon] seen, moreover, at 4° 16' 19"; whereto he adds that through the Tube [Telescope, Tubo] Mars was seen less than one digit [vno digito] more Northern than the Northern limb [Boreaiorem limbo] of the Moon [Lunæ Septentrionali]; and the center of the Moon was seen to be higher toward the West [versus occasum] by 58° 51'.

[Margin: *Gassendus in Epicuro* — "Gassendi, in his *Epicurus*."]]

[Item 23] Gassendi [Gassendus], moreover, in his *Epicurus* [*Animadversiones in Diogenem Laertium / De vita ... Epicuri*], page 900, says that, observing himself at Paris, in the year 1632, February 6, hour 2, minute 3, [reckoned] after midnight [post mediam noctem], he saw the Moon high [alta] toward the West at grade 44° 15'; and that, at the highest part [supremo margine], the [Moon] subtly subentered [Mars], and somewhat [tum] departed [deseruisse] at hour 3° 33'; [its] inclined part [parte marginis inclinata] toward the North [versus Boream]; and although Mars was much earlier seen with the naked eye [oculo nudo] than [the moment when] Mars was occulted by the Moon, nevertheless through the Telescope [Telescopio] it was seen [the Moon's] whole [body] immersed; although for some little portion left [behind] in the middle of the occultation [in media occultatione relictam], as if not the whole [of Mars] were then immersed.

[Item 24] In the year 1634, the Ephemerides note the opposition of Mars with the Sun on the 12th [of] March; therefore Gassendi at Digne [Diniæ], on the 8th [of] March, in the evening, [saw] the other [body — Mars?] distant from Regulus [à Regulo] by 26° 41'; and from the heart of the Hydra [à corde Hydræ] by 27° 57'; and from the tail of Leo [à cauda Leonis] by 23° 56'; and from the tail of Leo [à cauda Leonis] by [again] —. The remaining days were cloudy [nubes], and on the 15th [of March] in the evening, [with] Regulus high [alto Regulo] at grade 44, he

saw Mars distant from Regulus by $23^{\circ} 56'$; and from the tail of Leo by $8^{\circ} 44'$. Thus also Cassini [Cassinum].

[Item 25] In the year 1634, June 18, [in the] night, following, Gassendi at Aix [Aquis Sextiis], with the naked eye [nudo oculo], estimated the last star [vltimam Stellam] of the four [stars] of the left [Southern? sinistræ] wing of Virgo [alæ Virginis] to be touched [tectam] by Mars — although [his] companion Lynceus [Socius ipsius Lynceus] saw, at the very beginning of night, how much [quantum] with the naked eye Mars [stood] from that distance, how greatly [quanta penè] the semidiameter of Mars seemed to lie before it [videbatur]; but Gassendi, with the Telescope, saw [Mars] to be distant from the star [by] nearly seven [proximè septem] diameters of Mars.

Liber VII — De Martis (folio 323 = PDF p. 357)

[Continuation of item 25 from the foot of the prior page:] — Then, at hour $11^{\circ} 19'$, Mars and the star were at the same vertical [in eodem perpendiculo], the former lower, the latter higher, with a distance of four diameters [diametrorum quatuor]. Finally, at hour $12^{\circ} 34'$, Mars was seen higher [altus] at the same longitude with the star, distant [from it] by no more than three diameters of Mars. In his *Epicurus* [*Epicuro*], page 902, understand [this of] the outermost [star] of the left wing [alæ sinistræ], as I shall say in chapter 8.

[Item 26] In the year 1636, Gassendi at Aix [Aquis Sextiis], March 17, in the evening, [with] Castor high [alto Castore] at $54^{\circ} 15'$, with the Radius [Radio] saw Mars distant from Arcturus [ab Arcturo] by $30^{\circ} 29'$, and from Spica [à Spica] by $22^{\circ} 15'$; but on the 18th [of March], [with] Spica high at $29^{\circ} 45'$, saw Mars distant from Arcturus by $30^{\circ} 23'$, and from Spica by $9^{\circ} 19'$. Thus [reported] to Cassini.

[Item 27] In the year 1642, August 15, with Michael Florentius [Michaele Florentio] observing at Brussels [Bruxellis], the Moon occulted Mars [Luna occultauit Martem], [the Moon] culminating at the equator [Æquatoris] at grade $300^{\circ} 33'$, [Mars] culminating at the equator at grade $308^{\circ} 54' 11''$. So [it stands] in his writings [in suis litteris].

[Item 28] In the year 1645, D[on] Vincentio Mutus [Vincentius Mutus] at Majorca [Maioricæ], on the 13th [of] February, hour 8, saw Mars [to be], by three little [intervals], more Westerly [minutis occidentaliorem], and by $33'$ more Northerly [Borealiorem] than the second star preceding [secundâ Stellâ præcedente] among the informal [stars] of Erichthonius [informes Erichtonii]; on the 18th [of] February, hour 8, an hour after sunset [post occasum Solis], he saw Mars distant

— as to longitude — by less [than] 2' from the star which is below and inferior [infra ad ortum inform] [to] Erichthonius, and more Northerly by 21 scruples [scrupulis]. So [it stands] in his own writings to me [in suis ad me litteris].

[Item 29] In the same year, likewise there [ibidem], April 6, hour 7, he saw Mars distant toward the East [Orientem versus], a little more [paulò plus] than half a [diameter] of the Moon from the star [à media Luna à Stella] which is in the upper thigh of Gemini [in femore superiori Geminorum]. The same [stands] in [his] writings to me [in litteris ad me].

[Item 30] In the same year likewise, 1645, hour 8, after midday, D[on] Vincentio Mutus at Majorca saw Mars at almost the same longitude with the extreme [star] of the Northern foot [extrema pedis Borealis] of Cancer, but more Northerly by about 24 scruples; finally, on the 15th [of] May, hour 8, Mars stood distant by about 3 scruples [from the same], but it was more Northerly by about 5 scruples. The same [stands] in his writings to me.

[Item 31] In the year 1649, June 13, hour 9, D[on] Vincentio Mutus at Majorca saw Mars more Southerly [australiorem], yet by about 13 scruples more Westerly [occidentaliorem] than the star which is at the extremity of the left wing of Virgo [in extremo Alæ sinistræ Virginis]; on the 24th, [in the] morning, hour 9, [Mars was] more Easterly [orientalior] than [on] the 23rd; and on that previous day [die præterita] it had been more Westerly [occidentaliior], so that, with Mars conjoined [conjuncto] with the said star, the star was [there] about the twentieth hour [circa horam vigesimam] after midday of day 23. Thus from Mutus's writings given to me [ex Muti litteris ad me datis].

[Right-column heading, folio 323:] The Fathers of Our Society [PP. Soc. Iesu] at Innsbruck [Oeniponti], indeed, as testified by the same Father Michael Staudacher [P. Michael Staudacher], observed the distances written below [infrascriptas].

[Note: the parallel left-column heading reads:] At Ingolstadt [Ingolstadii], moreover, the Fathers of Our Society [Patres Societatis Nostræ], as Father Michael Staudacher [P. Michael Staudacher] wrote to me, observed these distances of Mars.

Ingolstadt table (left column, folio 323)

Month — D · H (Vesp.)	from Spica □ Gr.	I (min.)	from Arcturus Gr.	I (min.)
Anno 1617				
May 25 — 9½	44	30	51	42
31 — 9½	41	56	49	12
Jun. 14 — 10½	35	14	45	12
19 — 10	32	45	43	30
29 — 10	27	24	40	0
Jul. 11 — 9½	20	48	36	27
14 — 9½	19	6	35	40
16 — 9½	17	50	35	10
16 — 9½	12	10	33	4
30 — 9	9	40	32	10
Aug. 6 — 8½	5	26	31	25
7 — 8½	4 (from Antares [ab Antare])	36	31	20
10 — 8½	48	32	31 (from Arcturus [ab Arcturo])	8
13 — 8½	46	39	31	5

Parsing notes: two rows are flagged in the source as measured from a different reference star (row "Aug. 7" gives the Spica-column distance "from Antares [ab Antare]"; row "Aug. 10" gives the Arcturus-column distance "from Arcturus" — an internal label change). The row "16 — 9½ ... 12 10 ... 33 4" repeats the day "16" of July; transcribed as printed (likely a third reading on the same date, or a compositor's repeat — flagged). The day-column entries are abbreviated; carried as printed.

10	Rigel [Rigel]	51	4½		(occid.)	15	25
	Aldeb aran [Aldeb ara]	38	18½	45	58		(occid.)

Parsing notes: this is a multi-section three-year table (1635/1636/1637) with running sub-headers that switch between rising altitude [Altitudo Ortiva], setting altitude [Altit. Occ.], and a final "Occid." block. Each observation occupies a two-row pair: the upper row a distance from one reference star, the lower row a distance from a second star, the right-hand altitude columns belonging to the pair. The altitude cells are sparsely filled in the source and several read only "occid." (i.e. setting) or "oriuu." (rising) as a position-marker rather than a number; these are transcribed as "(occid.)" / "(oriuu.?)" where no numeral is given. Several peripheral altitude numerals are faint near the gutter — flagged with "(?)" where uncertain. The final two rows give "Mar. 14" then "10" (out of date-order in the source) — transcribed as printed. The whole 1635–1637 multi-section table is dense and gutter-adjacent for the faint altitude columns.

Liber VII — De Martis (continued)

CAPVT VIII.

Selected observations of Mars, drawn from a larger number carried out at Bologna in the College of Santa Lucia by Fr. [Giovanni Battista] Riccioli and Francesco Maria Grimaldi of the Society of Jesus.

To these are appended the observations of the most illustrious Marquis Cornelio Malvasia.

1. In the year 1642, on 12 October, in the morning about one hour before sunrise, Mars stood $38^{\circ}24'$ from Regulus and $19^{\circ}44'$ from Aldebaran — repeated, just as the practice was in these and the following observations, by means of a large sextant.
2. In the same year, on 21 October, in the morning, by Italian civil reckoning, Mars stood from the bright star of Aries [Hamal] 15° , precisely, and from Regulus $40^{\circ}28\frac{3}{4}'$.
3. In the year 1642, on 16 July, in the morning at hour $7\frac{1}{2}$, Italian time, Mars stood from the bright star of Aries $17^{\circ}27'$, and from the tail of Cetus [Deneb Kaitos] $28^{\circ}31'$.
4. In the year 1642, on 21 August, in the morning, at the forty-first minute after the bright star of Aries had crossed the meridian, Mars stood from the bright star of Aries [via M.C., i.e. by the meridian crossing] $15^{\circ}37'$; and after 5 minutes of time it stood 44° from the following shoulder of Orion [Betelgeuse].
5. In the year 1642, on 23 August, in the morning at hour $9\frac{1}{2}$, civil [time], Mars stood from Aldebaran $24^{\circ}51'$; and after 2 minutes of time it stood from Rigel $41^{\circ}2'$.
6. In the year 1642, on 25 August, as the bright star of Aries crossed [the meridian] via M.C., 48 minutes being counted off, by the aid of a perpendicular Mars crossed the meridian, and its altitude was then taken at the tail of Capricorn [Deneb Algedi] $57^{\circ}58'$.
7. In the year 1642, on 28 August, in the morning, as the bright star of Aries crossed via M.C., we numbered $51^{\circ}10''$; after which Mars passed across via M.C. at $58^{\circ}18'$.
8. In the year 1642, in September, on the night following, about the fourth hour of the night, Mars stood from Capella $38^{\circ}20'$, and from Aldebaran $17^{\circ}50'$.

Here ought to be inserted in order the two earlier observations.

9. In the year 1642, on the night following the 31st day of October, after the bright star of Aries had crossed via M.C., we numbered 40 minutes and 12

seconds, with the sky tending [to clear], or Acronychal [setting just opposite the Sun]; then Mars stood at 16° . Thereafter, after 3 minutes of time, Mars stood from Aldebaran $26^\circ 12'$, and after 3 minutes of time from Regulus $42^\circ 26'$.

10. In the year 1643, on 5 January, on the night following, after the crossing of the bright star of Aries via M.C., we numbered $34^\circ 36''$; and then Mars had passed across the meridian, and its altitude was then observed at $60^\circ 58\frac{1}{4}$.
11. In the same year, on 11 February, on the night following, at hour 3, civil [time], Mars stood from the bright star of Aries $22^\circ 19\frac{1}{4}$; and the southern Andromeda [γ Andromedae?] was looked for at $20^\circ 19'$ — Mars then standing with the Sun.
12. In the year 1643, on 3 May, at hour one after sunset, Mars stood from Procyon $21^\circ 5\frac{3}{4}$, and from Capella $30^\circ 10\frac{3}{4}$.
13. In the year 1643, on 11 July, on the night following, at hour 1, Italian civil [time], Mars stood from Saturn, the more westerly, $30^\circ 33\frac{3}{4}$; and after 10 minutes of time it stood from the southern foot of Andromeda $19^\circ 14\frac{3}{4}$, being itself now 19° high, the sky vaporous [hazy] from below. [?]
14. In the year 1644, on 6 August, the night following, Mars stood from the bright star of Aries [continues at top of next column] ...

[Margin (left): drop-initial "A" beginning observation 1.]

[bottom of left column continues into right column]

[Mars stood] from rising toward the east $30^\circ 42'$; thence, 6 minutes being counted, in the Florisonian [reckoning] the seventh [hour] with the half striking [i.e. 6:30], Mars stood from the bright star of Aries $27^\circ 14'$; $\frac{3}{4}$ after 2 minutes [of time] from Capella $30^\circ 23\frac{1}{2}$. [?]

15. Likewise in the year 1644, in September, on the 9th, with Sirius high at 18° , or in one hour before sunrise, Mars stood from Aldebaran $13^\circ 24'$; and from the bright star of Aries [Hamal] $45^\circ 48'$. It was approaching: Sun and Mars [in conjunction].
16. In the year 1644, on 17 November, the night following, the distance of Regulus from the eastern vertex was $63^\circ 56'$; whence, 9 minutes of time being counted, Mars stood from Rigel of Orion $39^\circ 52'$; after which, 3 minutes again, Mars stood from Aldebaran $31^\circ 25\frac{3}{4}$.

17. In the year 1645, on 22 March, the night following, when there impended a [quadrature] of Mars with the Sun, Mars was observed standing from Procyon $25^{\circ}19'$, and from the bright side of Cetus [Menkar?] $31^{\circ}51\frac{1}{2}'$; and then the altitude of Sirius was seen to be $7^{\circ}33'$.

18. In the year 1646, on 23 June, in the morning, after a [quadrature?] of Mars with [the Sun], the distances of these planets from the bright star of Aries [Hamal] subscribed below were taken from the eastern vertex, to Saturn; the distances of these planets being as written below:

Bright star of Aries [Hamal], dist. from vertex		Distance of planets from fixed stars	
Degr.	Min.		G.
63	56	Saturn from Capella	40
63	44	Mars from Capella	39
62	46	Saturn, from the more eastern side of [the lat. of?] Perseus	34
60	52	Mars from the more eastern side	32
60	0	Mars from Saturn	1

Parsing notes: The five-column header runs "Luc. □ dist. à vertice" (bright star of Aries, distance from vertex) over the Grad./Min. pair, and "Distant. Planetar. à Fixis" (distance of the planets from the fixed stars) over the G./M. pair. The "lat. Perf." abbreviation in row 3 is read as "lateris Persei" (the side of Perseus) but is uncertain. [?]

Here is to be inserted the following observation, 22, 23, and 24.

19. In the year 1647, on 2 April, on the night following, at hour 1 nearly one [hour] after sunset, the observation was begun, and finished about the

[evening] hour, with one [hour] elapsed, since the observation of these planets was made. On 24 April [?], indeed, observe our [observation], because then Jupiter was celebrated [in conjunction], and Mars [stood] at $34^{\circ}34'$. [?] The reading of this entry is degraded; the relations among the bracketed values are uncertain.

20. In the year 1649, on 20 February, on the night following, about hour $2\frac{1}{2}$, by nights, Mars stood from the heart of Hydra [Alphard] 35° , and from Procyon $49^{\circ}\frac{1}{2}$.
21. On the 26th day of the same month, Mars on the night following was scarcely sensibly more eastern than the Moon with respect to the same Vertical; it was seen to stand from the vertex $69^{\circ}2\frac{3}{4}$, the center of the Moon being $68^{\circ}12'$; and after one minute of time the distance of Mars from the Regulus-Vertical [?] stood at $59^{\circ}4\frac{3}{4}$; when, at the same node, the eastern Regulus [?] stood from the vertex $52^{\circ}10'$, then Mars stood from the vertex 62° ab [62° from]; from the heart of Hydra [Alphard] $30^{\circ}11\frac{3}{4}$; and from Procyon $49^{\circ}40'$. [?]
22. In the year 1647, on 16 January, the night following, Mars was high at 30° from Procyon; high also at 31° , it stood from Regulus $25^{\circ}15\frac{3}{4}$; and soon from Rigel of Orion it was high at $46^{\circ}18\frac{3}{4}$.
23. In the same year, on 23 January, the night following, from Procyon at $31^{\circ}20'$, Mars was high about 33° . It stood from the bright [shoulder] of Orion $44^{\circ}4'$; and after 12 minutes of time it stood from Procyon 49° . [?]
24. In the same year, likewise, on 26 January, the night following, Mars stood from the bright shoulder of Orion $43^{\circ}4'$; and from Procyon $23^{\circ}12'$; it was then high, Mars, near 48° . From Procyon indeed 42° .
25. In the year 1649, on 2 June, with [the quadrature] now elapsed, [a conjunction of] Mars with the Sun [impending]: on the night following, about one and a half Italian hours, when the bright [star] of Leo [Regulus] stood from the vertex 50° , Mars stood from Regulus $16^{\circ}52\frac{3}{4}$; and from the bright [star] of Leo [Regulus] $18^{\circ}48'$.
26. In the year 1652, on 19 November, in the morning, when the bright [shoulder?] of Leo was 19° from the vertex, the times were reckoned by a perpendicular; and after 6 minutes Mars stood from Arcturus, the more eastern, $33^{\circ}50'$. Thereafter, after another 4 minutes, Mars stood from the more western heart of Hydra [Alphard] $45^{\circ}13'$.

27. In the year 1653, on 2 February, in the morning, with the bright [star] of Aquila [Altair] $69^{\circ}40'$ from the vertex, Mars stood from Spica, the more western, $24^{\circ}1\frac{3}{4}$; and soon from the eastern head of Ophiuchus [Rasalhague] more, when Mars was $46^{\circ}49'$. [?]

28. In the year 1653, on 15 May, on the night following, at hour $1\frac{1}{2}$, after sunset, Mars at its rising was observed to stand from the vertex ... [continues] 77° . [?]

[from the vertex] $77^{\circ}38'$; and from the bright [star] of Corona [Alphecca] 48° ; and soon, nearly 1° , Mars standing from the vertex $77^{\circ}6'$ it stood from Spica $36^{\circ}48'$.

29. On the night following, that is, on 16 May, with Mars now impending [in opposition] with the Sun, when it was about one hour after sunset, Mars was observed standing from the vertex $77^{\circ}4'$; and from the head of Ophiuchus $76^{\circ}24'$; and from Spica of Virgo $56^{\circ}16'$. [?]

30. In the year 1653, on 19 June, the night following, at the second hour after sunset, when Antares appeared high at $19^{\circ}45'$, Mars too was seen [high] at $25^{\circ}37'$; it was seen to stand from Antares $17^{\circ}53\frac{3}{4}$; and from the head of Ophiuchus $47^{\circ}35'$; it tended, moreover, toward Direction [direct motion], being retrograde.

31. In the year 1653, on 22 June, the night following, when Antares appeared high at $18^{\circ}10'$, Mars [high] at $26^{\circ}13'$, or one hour after sunset, it was seen to stand from Antares 18° , precisely; and from the head of Ophiuchus $47^{\circ}40'$.

32. Likewise in the year 1653, on 24 June, one hour after sunset, Mars was high, visibly, at $26^{\circ}14'$; it stood from the head of Ophiuchus $47^{\circ}42'$; and soon from the heart of Scorpio [Antares] $17^{\circ}58'$; with Antares itself standing $19^{\circ}12'$ high.

33. In the year 1653, on 28 November, when Mars with Jupiter was being celebrated [in conjunction], on the night following, Fomalhaut was seen to stand from the vertex $76^{\circ}2'$; Mars was seen [high] nearly at the second [hour], and stood from Fomalhaut 25° ; and a little after from the southern tail of Cetus [Deneb Kaitos] $47^{\circ}37\frac{1}{2}$; and the southern tail of Cetus stood from the vertex $69^{\circ}42'$; Mars, moreover, at 65° .

34. In the year 1653, on 23 December, the night following, the bright [star] of Aquila [Altair] stood from the vertex $61^{\circ}41\frac{3}{4}$; and therefore one hour after the meridian, 5 minutes 20 seconds being counted, Mars came through the

western Azimuth of 25 degrees, where it had been expected; and then the distance of Mars from the vertex stood at $59^{\circ}58'$. [?]

35. In the year 1653, on 16 March, the night following, Mars was expected at the western Azimuth of 85 degrees, and at it the vertex stood $66^{\circ}41\frac{3}{4}$; thence, after 5 minutes of time, Mars stood from Regulus, the more western, $58^{\circ}32'$.
36. In the year 1655, on 16 July, the night following, Mars appeared nearly as great as Jupiter; it came to the meridian, and was then seen to stand from the vertex $70^{\circ}54\frac{3}{4}$; thence, after 7 minutes 40 seconds, the head of Andromeda was seen toward the east; Mars stood from the vertex $45^{\circ}3'$. [?]
37. On 22 July (for indeed on the 20th the cloudy two-day spell had hindered the begun observation of the [opposition] of Mars with the Sun), the night following, after the crossing of the bright [star] of Aquila via M.C., the times were reckoned at $31'10''$, after which Mars came to the meridian, in which standing the distance of Mars from the vertex stood at $71^{\circ}22\frac{3}{4}$.
38. In the year 1655, on 21 August, the night following, Mars was expected at the western Azimuth of 20 degrees, [and] stood at it from the vertex $74^{\circ}31\frac{3}{4}$; and after a quarter of an hour, precisely, or 15 minutes, by a perpendicular the head of Andromeda was numbered; and Mars stood more westerly from the vertex $64^{\circ}21'$. [?]
39. In the same year, on 23 August, the night following, after 9 minutes of time, the crossing of the bright [star] of Aquila via M.C., Mars too crossed the meridian, and then stood from the vertex $71^{\circ}43\frac{3}{4}$.
40. In the year 1656, on 11 March, at the second hour of the night following, Mars was observed to stand from Aldebaran indeed at $20^{\circ}17\frac{1}{4}$, and from Regulus at $40^{\circ}35'$. [?]
41. In the year 1656, on 29 April, about three quarters of the first hour of the night following, the distance of Mars, more westerly, from the vertex was taken at $79^{\circ}55\frac{3}{4}$, in it [i.e. at that vertical and azimuth]; whereto, reaching the head of Pollux, or of the following Gemini, [it] stood from the vertex $67^{\circ}37\frac{3}{4}$; and after three minutes of time being elapsed, the more western Procyon stood from the vertex $55^{\circ}20\frac{3}{4}$. [?]
42. In the year 1657, on 21 October, in place of Mars, also of Saturn, [a quadrature] preceding, of which the discussion is on Saturn's observation

55: there was observed on the night following the eastern distance of Mars from the vertex $65^{\circ}41'10''$; designated for the Azimuth of the Vertical Triangle [Triangulum?], straightway; the times being numbered, and after 5 minutes, secondly, after 25 minutes, the [distance] of the bright [star] of Aries was taken, standing from the vertex toward its rising $62^{\circ}8'$. [?]

[bottom of right column on p.359 continues]

43. In the year 1657, on 12 November, with our observations begun, Mars being nearest to retrogradation, and on the night following, after the crossing of the southern bright [star] in the tail of Cetus through the middle of the Sky [meridian], the times were numbered at $9^{\circ}4\frac{1}{2}''$; before [the time] when Mars itself was seen at the middle of the Sky, [Mars] stood from the vertex $36^{\circ}1\frac{1}{2}'$. [?]
44. On the 14th day indeed, after the crossing of the bright [star] in the southern tail of Cetus, the times being numbered at $9^{\circ}4\frac{1}{2}''$, Mars crossed the middle of the Sky; and its distance from the vertex stood at $41^{\circ}26'10''$.
45. On the 15th day, moreover, on the night following, after the crossing of the southern bright [star] in the tail of Cetus, the times being numbered at $9^{\circ}40''$, when Mars crossed the middle of the Sky, and its distance from the vertex was taken at $41^{\circ}21'20''$; whence it is inferred that Mars had been below the Sky at the time of Station [stationary point]. [?]
46. In the same year, on 17 November (for on the 16th there had been cloudy weather), after the crossing of the bright [star] in the tail of Cetus, and [its] more southern position in the tail of Cetus, up to the crossing of Mars via M.C., the times were numbered at $9^{\circ}13''$; and then the distance of Mars from the vertex stood at $41^{\circ}10'20''$. [?]
47. In the same year, on 4 December, the night following, after the crossing of [the star] through the middle of the bright Sky, and of the more southern [star] in the tail of Cetus, the times were numbered at $22'45''$; and then Mars, in the middle of the Sky, its distance stood from the vertex at $39^{\circ}5'24''$. [?]
48. In the year 1660, on 28 May, Fr. Vincenzo Mut of Majorca observed Mars with the Sun [in conjunction] near the breast of Cancer, and from the little stars [stellulis] standing around Praesepe — but to none of the more notable, nor stars listed in the Tyconic Catalogue; nor in our [catalogue];

the nearest distance was beyond 7 minutes, from Praesepe, moreover, the distances of those standing about [it] roughly 5.

Observations made at the Astronomical Observatory of Modena by the most illustrious Marquis Cornelio Malvasia, and set forth in his Ephemerides, fol. 215.

[Table — Mars positions from Modena, 1662, distance from fixed stars (corrected), with place of the observed star (sign, degree, minute) and Lansberg's deflection (Lasberg. deflectit). Reproduced as printed:]

Parsing notes: This is a difficult eight-column table from Malvasia's *Ephemerides*. The first column pairs a "day H.ab.Occas." (day above, hours-from-sunset below); each dated observation spans two physical rows (one per comparison-star pair), so the day, the longitude/latitude block, and the deflection are written once against the pair. The "Distant. ♃ ♄ à Fixis correcta" block (A. = star [Astrum], G. = degrees, ' = minutes) gives the corrected distance of Mars from a named reference star (Regulus, the bright star of Leo [Iuba], Spica □, Arcturus). The "Locus □ Observatus" block gives ecliptic Longitude (Lo., with zodiac sign) and Latitude (La.) of Mars; some rows note "B." (boreal/northern latitude). The final column "Lasberg. deflexit" gives the deflection (in minutes) of Lansberge's tables from observation. The large degree values (53–57) sit in the degrees (G.) sub-column — angular distance from the comparison star — not in minutes/seconds, so they are legitimate; no impossibles. The two lower stacked digits of the "H. ab Occas." column in the first two observations (May 30 and June 3) are gutter-compressed; on the recovery tile they read 30 and 12, confirming the table values.

But it should be remembered that the fixed stars were seen by the Tychonic [positions], which themselves need correction, according to what was said in Book 4; and the Cassinian refractions of the fixed stars, by which the said distances are corrected, were declared by us, in Book 1, to be recalled into doubt.

CAPVT IX.

On the Astronomical Tables, to be tested against the selected observations made concerning Mars.

[Margin (left): *Longomontani opinio*. — Longomontanus's opinion.] [Margin (left): *Et Kepleri eum laudè ipsius*. — And Kepler's [opinion], to his [Longomontanus's] own praise.] [Margin (left): *Errores an[tiqui] eiq. or. in* □ [?]. — The errors in the ancient [hypotheses] in Mars [abbreviation partly uncertain].]

1. Having now set forth, with the causes of selecting from among so many observations, the most certain — as I have already touched on in Book 5, Chapters 9 and 10, and in Book 6, Chapter 9 — and since indeed Tycho [Brahe], in the Preface to his *Astronomical Letters*, requires the observations of 24 years for Mars to be set opposite to the Sun in the several signs of the Zodiac Acronychally [at opposition]: Longomontanus, nevertheless, in Book 2 of his *Theorica*, Chapter 8, brings forward only 14 oppositions of Mars to the Sun, taken from Kepler's *Commentaries on Mars*, denying yet, in Chapter 9, that the foundation of Mars's eccentricity has been established. Kepler, moreover, in his exposition of the Ephemerides constructed from the Rudolphine Tables, page 14, professes for himself that he had departed in nothing in Mars from his own *Commentaries*, and that the Great One [Magnum] [?] had most faithfully represented the motions of Mars in the *Commentaries* limited to those days. And truly, for the most part in this matter, Astronomy must be in Kepler's debt. For there was once a time, by Pliny's testimony (Book 2, Chapter 17), when the planet Mars was reckoned unobservable, and its errors in the ancient Hypotheses could not be known, to such a degree that Maestlin, in his Preface, admitted to the Ephemeris of the year 1577 an error of two degrees in narrowness; nay, it stood out from the autumnal observations of the year 1625 by nearly five degrees of excess. Kepler, with truer Hypotheses thought out, and using the Tychonic observations excellently, compelled the errors of this planet within a very few minutes — to such a degree that, as Elias de Leonibus asserts in his *Urania*, proper part 2, Chapter 15, the least that needs to be changed in the Rudolphine [Tables] is what is confirmed by the example of

the conjunction of Jupiter and Mars in the year 1591, of which we spoke above in Book 5, Chapter 9, and shall speak again below.

2. Lansberg [Philip van Lansberge], furthermore, among these same observations of Mars, brings forward those which he sets forth from his *Thesaurus* — the conjunction, namely, which he himself indicates of Jupiter with Mars, which Maestlin observed in January (*Astron. Opt.*, page 305) [affirms? from Maestlin], and saying nothing of Mané [the morning?] for himself: Lansberge, of his own addition, makes it [the conjunction to be] in the morning, and says — citing Kepler — that he [Kepler] writes for the 9th, [though] he himself for the 8th day; nor does this fit in the series of calculation, where he places only [the conjunction] for January, the 6th day, and hour 18, that he might wrest the observation to his own Tables, or trumped up [the figure], or [altered] other things at will, that he might appear to wave about Elias de Leonibus or Boulliau [as authorities]. Bullialdus indeed, in his *Astronomia Philolaica*, proper part 2, Chapter 15, [and] Ioannes Phocylides [Johannes Phocylides Holwarda], and Boulliau — who indeed examined the Rudolphine hypotheses with far more profound and prudent scrutiny.

[Margin (left): *Lansbergij dolus duplex*. — Lansberge's twofold deceit.]

Now then, in proof of the Astronomical Tables, we select these 10 Acronychal Oppositions of Mars with the true place of the Sun — those by which Kepler especially, in his *Commentaries on Mars*, built up the Martian Hypothesis: we add, besides, four notable conjunctions of Mars with Jupiter, and one with Saturn, and six with the most certain fixed stars, and laboring under the very least suspicion of error.

10. The Acronychal places of Mars at Opposition, compared with the true place of the Sun observed by Tycho [Brahe], from Kepler's Commentary together with the computation from the Tables.

[Table — ten Acronychal oppositions of Mars: Tycho's observation ("Observ."), the Danish [Tychonic] value ("Danicis"), and our value ("Nostris"), each given as Sign / Degree / Minute / Second. Reproduced as printed:]

Parsing notes: Each numbered opposition has three rows — "Observ." (Tycho's observed place), "Danicis" (the Danish/Tychonic computed value), and "Nostris" (Riccioli's own). The zodiac signs in the "Sign" column are engraved glyphs, now resolved in sequence: ♊ Gemini (1), ♋ Cancer (2), ♌ Leo (3), ♍ Virgo (4), ♏ Scorpio (5), ♐ Sagittarius (6), ♑ Capricorn (7), ♉ Taurus (8), ♋ Cancer (9), ♌ Leo (10). All minute (') and second (") values are ≤ 59 ; all degree (G.) values ≤ 30 within a single sign. The Observ./Danicis/Nostris triplets are mutually consistent (differing only by arc-minutes/seconds), as expected for the same opposition computed three ways; no numerical impossibles.

The portion of our Tables which differs from the observed Mars and the Tychonic place of the Sun [is] to be ascribed to false [reckoning]:

[Margin (right): ♋ *à fronte Scorpj.* — Mars from the front [forehead] of Scorpio.]

11. In the year 272 before Christ, on 17 January, at hour 17 p.m. [post meridiem], Mars was seen to lie upon the most northern [star] of the forehead of Scorpio — which star Ptolemy, from the things said here in Chapter 1, [and] Longomontanus (Book 2 of his *Theorica*, Chapter 10) and Lansberge (in his *Thesaurus*) contend to have been a bright [star] of the second magnitude — Mars observed. But better do Kepler and Bullialdus (Book 8) teach it to have been the most northern in the front [of Scorpio]...

(Continuation of Liber VII, Caput IX — the Mars table-comparison, item 11.)

of Scorpio, which is the fifth and of fourth magnitude — unless perhaps the proper motion of Mars was carrying it toward the bright star of the forehead of Scorpio. The conjunction of Mars with this star [Regulus of Scorpio — i.e. the bright frontal star] cannot be established for the years 508 and 509, which must shortly be discussed. Therefore Mars, in the years 508 and 509, was at most a little to the west, which our Tables exhibit with astonishing agreement; for:

		Sig.	G.	I	II
Mars:	Observed	□	2	39	ω
place	Computed	□	2	38	54

[The "ω" in the seconds column of the observed line marks an unstated/illegible value; the computed value is 54".]

12. In the year 498 of Christ, on the 1st of May, at about the 9th hour, Jupiter and Mars appeared so conjoined that they seemed almost not to be distant from one another, although by reason of the spreading of their rays they were perhaps a little apart [?]. I have drawn the places of the planets, both from our Tables, in Book 6, Cap. 9; and they are:

	Sig.	G.	I	II
Place ♃	□	0	15	34
Place □	□	0	13	56

13. In the year 509 of Christ, on the 13th of June, at about the 2nd hour, Mars appeared more to the west of Jupiter by one digit, or 2½ [minutes?]; and it was probably more on account of the dispersal of their rays. But in Book 6, Cap. 9, I derived the places of both planets from our Tables, namely:

	Sig.	G.	I	II
Place ♃	□	11	56	40
Place □	□	11	52	2

14. In the year 1490 of Christ, on September 18, at the 4th hour, Mars was seen by Bernard Walther [Bernhard Walther] joined to the Nebula of Cancer [Praesepe], which then was at □ grade 0.11.3. Our Tables, however, give Mars at □ grade 0.16.30; whence I ascribe part of the discrepancy to an error of Walther's eyesight.

15. In the year 1591 of Christ, on January 9, while Maestlinus [Michael Maestlin] and Kepler were observing at night, they saw Jupiter reddened by Mars, as Kepler reports in his *Astronomia* [*Astronomia Nova*], Opt. page 305. For my part, as I have said, in Book 6, Cap. 9, at the 9th hour 15 minutes after midday of the 8th day, the planets were thus:

	Sig.	G.	I	II
Place ♃	□	14	59	12
Place □	□	14	58	53

Hence at the 13th hour 1 minute 30 seconds they were exactly conjoined.

16. In the year 1604 of Christ, on September 27 of the new style, at Prague at about the 8th hour, Mars was seen joined to Saturn, as closely as possible in longitude. To me, however, Saturn was then at □ grade 9.58.58, while Mars was at □ grade 9.59.30; therefore I should believe that the conjunction occurred a little before the one celebrated.

17. In the same year 1604, on October 9, near the meridian, there occurred a conjunction of Jupiter and Mars, as Kepler deduced from observations made at Prague. To me, however, as I have said in Book 6, Cap. 9, at the 23rd hour 50 minutes after midday of the 8th day, the planets stood thus, reduced to the Ecliptic and corrected [for curtation]:

	Sig.	G.	I	II
Place ♃	□	19	15	37
Place □	□	19	15	36

18. In the year 1634, on June 8, at the 12th hour 34 minutes — at Aquae Sextiae [Aix-en-Provence], that is, at Bologna at the 13th hour — Gassendi [Pierre Gassendi] estimated by telescope that Mars was in the same longitude as the last star, or the extreme star of the southern wing of Virgo, which then to me was at □ grade 21.59.38.

19. In the year 1645, on February 18, at the 7th hour, Vincenzo Mutus [Vincenzo Muti] estimated by telescope that Mars was two minutes to the west of a faint star, which is in my Catalogue at □ grade 24.41.33. Mars to me was at □ grade 24.41.20. Hour at Bologna 7.37. Therefore it had previously obtained that distance.

		Sig.	G.	I	II
Mars:	Observed	□	21	59	38
place	Computed	□	22	3	19

[Margin: Fixed star [Fixa] ☿ ☿ ☿ in form (?) — three Mars symbols and "I-formis", i.e. "of the form of fixed stars."]

20. In the same year 1645, on May 15, the same Mutus, likewise there, at about the 8th hour 30 minutes, estimated Mars to be 2 minutes to the west, more easterly toward the north, in the quadrilateral of Cancer, which then was at ☿ grade 0.30.6; and yet Mars in my Tables comes out at ☿ grade 0.30.31. Again here we differ by 2 minutes.

[Margin: ☿ ☿ ☿ eū ☿ symbols for Mars, Leo, "with" (cum), and the quadrate/square aspect.]

21. In the year 1649, on June 25, from his own observations Mutus reckoned Mars at the 20th hour 5 minutes, joined with the extreme of the other wing ☿, which then was at ☿ grade 22.13.10; and Mars at ☿ grade 22.16.30.

CAPVT X.

De Hypothesi Arithmetica, et Geometrica Motuum Martis.

(Caput X. On the Arithmetical and Geometrical Hypothesis of the Motions of Mars.)

1. I have treated in Book 5, Cap. 12, of those matters that are common to the five minor [i.e. non-luminary] planets, besides those which I have treated more fully in Book 7 of the *Almagestum Novum*, Sect. 2 and 3. But those things which are proper to Mars are these:

LIBER OCTAVVS

IN QVO SVNT VENERIS PLANETAE OBSERVATIONES, ET Hypothesis Motuum.

(BOOK EIGHT, in which are the Observations of the Planet Venus, and the Hypothesis of its Motions.)

CAPVT I.

Veneris Observationes Antiquae ab Anno ante Christum 272. usq; ad Annum Christi 510.

(Caput I. The Ancient Observations of Venus from the year 272 before Christ down to the year 510 of Christ.)

1. In the year 13 $\frac{1}{3}$ of Ptolemy Philadelphus [Ptolemy II Philadelphus], on the 17th of the month Messori — or on the following 18th — at the 12th hour, at Alexandria, Timocharis saw Venus obscuring [occluding], exactly, the star set opposite the Praewindematrix [Provindematrix — i.e. προτρυνητήρ, the star ϵ Virginis]. Ptolemy, Book 10 of the *Almagest* [*Magna Constructio*], Cap. 4, adding that the star is at the extremity of the southern wing of Virgo; and that it was 52 [years] from the death of Alexander, and 476 of [the era of] Nabonassar. Copernicus, Book 5, Cap. 23, supposes the star to have been the one preceding the four that are in the left wing of Virgo. Longomontanus, Book 2 of his *Theorica* [*Theoricae*], Cap. 19, says it was the year 272 before Christ; and on the eleventh of October, at Alexandria, at the 18th hour. And Lansberge [Philip Lansberge], in the *Thesaurus* of observations, computes Venus at Virgo gr. 3.21' with latitude gr. 1.20'. But he places Venus at gr. 3.22 $\frac{1}{3}$ ' of Virgo, with latitude Boreal [North] gr. 1.22'. Boulliau [Ismaël Boulliau], finally, Book 9 of his *Astronomia* [*Astronomia Philolaica*], Cap. 6, says the star, with which Venus was [in conjunction], was at Virgo gr. 2.47 $\frac{1}{3}$ ', with latitude North; and Venus he places at gr. 1.10' of Virgo. And he says that Venus, according to Copernicus and the Rudolphine [Tables], was in Virgo at gr. 1.10'; nor does she render the star inconspicuous [occult it] by her own body, but rather by the expansion of her rays. To me the year was 272 before Christ, and the day 11 of October.

2. In the year 2 of the Emperor Adrian [Hadrian], on the 21st of the month Athyr — or on the following 22nd — Theon of Alexandria observed Venus in her greatest digression [elongation] from the Sun, distant from the summit of the southern wing of Virgo by as little as the longitude of the digression — or by as much as the diameter of Venus herself appeared to be; and Venus was North by one unit [unam]. Ptolemy, Book 10, Cap. 1, from which he gathers that Venus was in Virgo gr. 0.20', and her greatest distance from the mean place of the Sun gr. 47.32'. But Copernicus, Book 5, Cap. 23, says he does not know from which exemplar he has the year 4 of Adrian, and 119 of Christ; on the fourth of the Ides of October, since it was the year 2 of Adrian and 117 of Christ; and the day, the 13th of October.

3. In the year 13 of Adrian, on the day of [the month] Epiphi 2 — or the following 3 — Theon of Alexandria observed Venus preceding [the Sun] in the morning, in greatest digression, by a longitude of gr. 1.24', drawn through the preceding of the three [stars] of the head of Aries, and through the extreme [star] in the rear leg of Aries — so, however, that she was twice as far distant from the prior [star] as from the posterior. Ptolemy, Book 10, Cap. 2, who says Venus was in Aries gr. 10.36', with southern latitude gr. 1.30', and distant gr. 44.48'; from the mean place of the Sun in Taurus gr. 25.24'. Copernicus, however, Book 5, Cap. 20, says it was the year 129 of Christ. Calend. [the Calends of] June, or May 19; just as Longomontanus, Book 2, Cap. 19, adding to the hour gr. 16.10'. To Alexandria [Lansberge?], inasmuch as from his Tables he places Venus at gr. 10.57' of Aries, and her digression at gr. 45.4'; and the mean place of the Sun in Taurus gr. 25.53'. To us also, the year 129 — its day the 18th of May.

4. In the year 16 of Adrian, on [the day] Pharmuti 21 — the following 22 — Theon observed Venus in the evening in greatest digression, preceding the middle of the Pleiades only, by as much as the longitude of the Pleiades, but a little more to the south. Ptolemy, Book 10, Cap. 1, who from this says Venus was in Taurus gr. 3.30', and the mean place of the Sun in Taurus gr. 14.15'; with greatest digression of Venus gr. 47.15'. Copernicus, Book 5, Cap. 20, says it was the year 132 of Christ, on the eighth of the Ides of March [octavo Idus Martij], at the 1st hour of the night. Longomontanus, however, Book 2, Cap. 19, says it was at hour 7.15' after midday. To Alexandria [Lansberge], but from his Tables he places the mean place of the Sun in Pisces gr. 14.49'. Venus in Taurus gr. 1.39'; and his digression gr. 45.50'. To us it was the year 134; inasmuch as it was a bissextile [leap] year.

5. In the year 18 of Adrian, on [the day] Pharmuti, coming up — the 22 — Ptolemy observed Venus in the morning, most distant from the Sun, in Capricorn, while there was a middle [mean] in Aquarius gr. 15.50', and the greatest digression gr. 43.35'. Ptolemy, Book 10, Cap. 5, adding it was the year 134 of Christ. Copernicus, Book 5, Cap. 22, adding it was the year 134.

Liber VIII — De Venere (continued)

Caput I (conclusion) — Ancient Venus Observations

12. On the Calends of March [1 March], at dawn — but in fact on the seventeenth, in the early morning of the following 18 February [recte: see anomaly (a)], in the year 134.

6. In the year 134, on the Egyptian day Mechir 9 [seq. 10], in the evening, Ptolemy [Ptolemy] at Alexandria observed Venus in Aquarius at $19^{\circ}36'$, with a greatest digression of $47^{\circ}32'$, reckoned from the mean place of the Sun in Capricorn at $2^{\circ}4'$ (*Almagest* X.1 and X.2; Copernicus [Copernicus], *De Revolutionibus* V.5 and V.20, adding that the year was 134 of Christ, on the eighth before the Calends of January [25 December]; Longomontanus [Longomontanus] likewise, II.19, adding the hour). At Alexandria Venus was indeed in Aquarius at $19^{\circ}36'$, but the Sun was in Capricorn at $2^{\circ}36'$, and so the digression of Venus comes to 47° , and in fact it was 25 December.

7. Again in Hadrian's year 11, on Tybi 2 [seq. 3], Ptolemy observed Venus in the evening at its greatest distance from the visible Sun, in Capricorn at $12^{\circ}50'$, and distant $47^{\circ}20'$ from the mean place of the Sun in Aquarius at $0^{\circ}23'30''$ (*Almagest* X.2; Copernicus, *De Revolutionibus* V.5 and V.20, adding that the year was 136 of Christ, on the 5 before the Calends of January [28 December]; but Longomontanus, II.19, gives November 18, hour 5; the Sun in Scorpio at $26^{\circ}9'$, and Venus's digression at $46^{\circ}55'$). That day was in fact 18 November, in the year 136.

8. Again in year 1 of Antoninus the Emperor [Antoninus Pius], on Tybi 29 [seq. 30], Ptolemy observed Venus in the morning by means of an astrolabe, with respect to Spica [Spica], in Capricorn at $6^{\circ}30'$, with an equal distance of $47^{\circ}15'$ p. mid-night, the Sun obtaining by mean motion $22^{\circ}9'$ of Sagittarius (*Almagest* X.2; but Longomontanus, II.19, in that year of Christ 138, December 15, hour 15, minute 10; at Copenhagen [Hafniæ] he puts Venus in Scorpio at $7^{\circ}15'$, the Sun's middle in Sagittarius at $22^{\circ}43'$; but Lansberge [Lansberge] puts Venus in Sagittarius at $6^{\circ}31'$ Scorpio [?]). That day was in fact 15 December.

9. Again in year 4 of Antoninus, on Pharmuti 4 [seq. 5], Ptolemy observed Venus in the evening at its greatest digression in Aries at $13^{\circ}50'$, the Sun's middle in Aquarius at $25^{\circ}30'$, with a digression of $48^{\circ}20'$ (*Almagest* X.4; but Copernicus, *De Revolutionibus* V.5 and V.22, saying that it was the year of Christ 140, on the 12 before the Calends of April [21 March] [recte: see anomaly]; Longomontanus, II.19, the day after [seq.] 18 February).

10. Again in year 4 of Antoninus, on Thoth 11 [seq. 12], Ptolemy observed Venus near the greatest morning digression in Gemini at $18^{\circ}30'$, distant $47^{\circ}15'$ from the Sun's middle (*Almagest* X.3 and Copernicus, *De Revolutionibus* V.5 and V.22, assigning it to the year of Christ 142, on the 3 before the Calends of August [30 July]; but Longomontanus, II.19, puts it in the year 140, July 29, hour 16, minute 12, and Venus in Gemini at $19^{\circ}1'$, with a digression of $47^{\circ}11'$, reckoned from the

Sun's mean place at Leo $6^{\circ}12'$). It was in fact the year 140, on the following 29 July.

11. In the year of Christ 510, as Boulliau [Boulliau] reports, IX.6, [Venus was observed]; in a manuscript of the Royal Library it stands thus: *In the year 216 of Diocletian, the star of Venus was seen preceding Jupiter, in the star of the Sagittarius's bow [the star "Stella"], by 20 digits on day 18 [die 18.]; it appeared to follow by 10 digits, but in latitude there was no difference at all; it appeared that, by an exact calculation according to the Ephemerides, these two planets, conjoined nearly at the thirtieth degree of the month, though distant by a long interval of time, appeared as one alone.* Hence Boulliau, from the Tables of Ptolemy, gathers that the conjunction of Jupiter with Venus had occurred between days 27 and 28 Mechir, that is, between 20 and 21 August, hour 7 after midday; at Uraniborg [Vraniburgi], from his Tables he gathers the place of Jupiter in Virgo at $19^{\circ}1\frac{3}{4}'$, with northern latitude $1^{\circ}9\frac{3}{4}'$; but the place of Venus in Virgo at $18^{\circ}53\frac{1}{4}'$; and so Venus then stood distant from Jupiter in preceding direction by 8 digits, that is, 50 scruples [minutes], or at most 40 [scruples], by diurnal motion they ought to be scruples. He corrects, therefore, the Rudolphine [Tables] [Rudolphine Tables], so that Venus may be in Virgo at $18^{\circ}23'$, and the conjunction of Jupiter, and of Venus, was around the noon of day 28 Mechir, that is, 22 August.

CAPUT II

Venus Observations made by Johann Regiomontanus [Regiomontanus]

1. In the year of Christ 1461, on December 14, after sunset, Regiomontanus at Rome saw Venus immediately conjoined with Saturn, and more southerly by two Suns [solar diameters], or by no degree at all; so that, by the Alphonsine numbers [Alphonsine Tables], the longitude of Venus was greater than that of Saturn by $1^{\circ}36'$.

2. In the year 1462, on January 10, at Rome, after the beginning of night, he saw Venus conjoined with the star of the twenty-third magnitude [?] of Aquarius — which is at the beginning of the [water-]pouring — but Venus was reckoned more easterly by $45'$.

In the same year, on September 19, the same man at Rome, at hour 11 of night, saw in one straight line Venus, Mars, and Regulus [Regulus]; so that, as Venus was more southerly, Mars was more northerly, and the distance of Mars from Regulus was one and a half times the distance of Venus from Regulus.

4. In the year 1462, on October 21, Regiomontanus at Viterbo in the morning, at hour 12½ of night, saw Venus more westerly than the sixth [star] of Virgo by 16' minutes, but conjoined as to longitude with the waning Moon, yet much less northerly than the Moon.

5. In the same year, and month, the same man at Viterbo, on the 25th, in the morning, saw Venus conjoined as to longitude with the seventh [star] of Virgo, but more southerly by about one degree.

6. In the year 1472, on August 19, in the evening, Venus stood distant from Jupiter [Iove] by 5°, minute 13 [5°13'], as he found it by the radius [cross-staff]; but according to the Alphonsine [Tables] they were distant in longitude by 4°33'.

CAPUT III

Venus Observations selected from those made by Bernard Walther [Walther] of Nuremberg

The first class comprises observations made by ocular estimation.

1. In the year 1478, on August 11, in the morning, at about hour 3½ a.m. [post midnight], Walther saw Venus distant almost mid-way between the two stars of Gemini's head, but a little more toward the southerly capella [κ?] of the head, in nearly the same line with these stars; but on the following day, the 12th, at the same hour Venus, seen at so great a distance toward the east as on the day before, was more easterly.

2. In the year 1486, on September 20, in the morning at hour 5 p.m. [recte a.m.] of night, Venus appeared conjoined with Regulus by one Moon [lunar diameter], in the same latitude; but on the 21st, it was seen more easterly by three Moons.

In the same year, on September 24, between hour 10 and 11 before noon, [Venus was seen] conjoined with the Moon, but more northerly than the Moon's limb by half the Moon's diameter [semidiameter].

4. In the year 1489, on March 6, around sunset, with the zodiacal armillae [armillas Zodiacales] she saw Venus in Aries at 27°13' from the circle of the ecliptic; but from the circle of latitude she saw her in Aries at 25°30'. On the same day, and at the 7th [hour], at nearly the same instant, she saw Venus from the circle of latitude in Aries at 28°15'; this discrepancy she recognized to arise from refraction. See, in connection with this, the learned old man's discourse, and the manner of correcting the observations by the perpendicular [plumb-line].

5. In the year 1494, on September 19, in the morning, at hour 5 p.m. n. [of night], Venus was seen conjoined with Regulus, but more westerly than Regulus by about 10 minutes, and equally more southerly. But Lansberge in his *Thesaurus* observed it [recte: computed it]: from his tables he computes Regulus in Leo at $23^{\circ}19'$, with northern latitude $31'$, and Venus in Leo at $23^{\circ}20'$, with northern latitude $13'$.

6. In the year 1502, on September 19, in the morning, after the middle of night, he saw Venus conjoined with Regulus by the Moon's semidiameter, and judged the latitude of both to be the same.

The second class comprises observations made by the radius [cross-staff] through the sines; concerning the use of which, see in Walther's [observations] no. 10. And so that you may have a specimen of the errors of the radius, note that Aldebaran [Aldebaran], and the northern horn of Taurus, do not differ from one another by Tycho's sextants and ours by more than $16^{\circ}45'$, whereas the radius of Walther would have exhibited their distance as $16^{\circ}52'$, or $50'$.

No.	Year	M·D	Distance of Venus from Star	Sin. prim.	Sin. sec.

Parsing notes: Columns are Year / Month·Day·Hour; "Med·Cal." (mean catalogue place) giving zodiacal Sign + degree, with northern latitude [latit. Bor.] on its own sub-line where present; and "Longitude of Venus as seen" [Lōgit. □ visa] giving Sign + degree + minute. Sign glyphs read: □ Taurus, □ Gemini, □ Cancer, □ Aquarius, □ Pisces, □ Aries. Row 38 longitude minutes value flagged [?] (ink-faint). For rows 39–43 the two right-hand columns each carry a degree value above a latitude/minute value; transcribed slash-separated.

CAPUT IV

Copernicus's Observation of Venus

In the year of Christ 1529, on the fourth before the Ides of March [12 March], at hour 1 after sunset, Copernicus at Frauenburg [Fruemburgi] saw the Moon, which on its dark part began to occult Venus according to its middle distance from both [horns]; the horn lasted, the occultation for one hour; whence around the middle [of the interval], between the first and second hour, Copernicus reckoned that the conjunction of Venus with the Moon had occurred (*De Revolutionibus* V, ch. 23, where he adds that he saw Venus in the early evening, and around the contact of both). But Lansberge in his *Thesaurus* gathers the place of the Moon, seen, in Taurus at $7^{\circ}7'30''$; and the latitude of Venus, seen, was minute 34'; of Venus 39' [recte: see anomaly (b)].

CAPUT V

Tycho's Observations of Venus from the Year 1582 to 1601

First we select the observations of the year 1582, from those recently published at Vienna by Lucius Barretus [Lucius Barretus] — that is, [an anagram] of [Albert Curtz, *Astronomia*], by way of anagram — and by the letters of our [colleagues], as Albert Curtz [Curtius] of the Society of Jesus has taught us; with the azimuths left aside, which we make least of.

No.	Year/ Day·Hour·Min [Ann. D.H.M., 1582]	Venus from Fixed Stars [Veneris à Fixis Stellis]	Distance Gr.·M.
1	Febr. 15 — 7 43	from the extreme tail of Pisces [□] 9 0 bis	4 0 from Aldebaran
2	17 — 8 57	from the head of Aries 8 50 bis	10 20 from Aldebaran
3	22 — 8 3	from Aldebaran	34 42½

No.	Year/ Day·Hour·Min [Ann. D.H.M., 1582]	Venus from Fixed Stars [Veneris à Fixis Stellis]	Distance Gr·M.
		8 31 bis	from the head of Aries
4	24 — 6 10	from Aldebaran	32 52½
		6 45	from the head of Aries
5	26 — 7 6 bis	from Aldebaran	30 59
		8 53	from the head of Aries
6	27 — 6 25 bis	from Aldebaran	30 6
		6 42 ter	from the head of Aries
		2 48	Meridian Altitude [Altitudo Merid.]
7	28 — 8 36 ter	from Aldebaran	29 5
		8 55 ter	from the head of Aries
8	Martij 5 — 7 2	from Aldebaran	24 48
		8 5 bis	from the heel of Gemini [calce pedis ♊]

Parsing notes: The header columns are Year/Day·Hour·Minute (the year 1582 spans the column), the reference star [Veneris à Fixis Stellis], and the angular distance in degrees·minutes. "bis," "ter" mark second/third readings at adjacent times on the same day. Star glyph ♊ = Pisces, ♊ = Gemini.

No.	Day·Hour·Min [1582]	Venus from Fixed Stars	Distance Gr.·M.
9	Martij 9 — 7 6	from Aldebaran 7 35	21 38¼ from the heel of Gemini [calce pedis □]
10	14 — 9 17 bis	from Aldebaran 9 33 bis	18 0½ from the heel of Gemini [□]
11	15 — 8 26 ½	from the bright [star] of the Pleiades [lucid. Pleiad.] 8 37	4 41 from the heel of Gemini [□]
12	16 — 7 43	from the heel of Gemini [□] 8 7	39 31½ from the middle of Cassiopeia's chair [Media cath. Cassiop.]
13	20 — 7 26 bis	from Aldebaran 7 55 bis	14 40 from the head of Pollux [cap. Pollucis]
14	21 — 8 2	from the head of Pollux 8 58	52 29½ from the northern horn of Taurus [cornu Bor. Tauri]

No.	Day·Hour·Min [1582]	Venus from Fixed Stars	Distance Gr·M.
		9 37	from the bright [star] of the Pleiades [lucida Pleiadum]
15	26 — 7 47	from the head of Pollux 8 21	49 51 from the northern horn of Taurus

In the second place we shall put the observations of Venus which Tycho exhibits in *Progymnasmata*, volume 1, [to show] how, from the right ascension of Venus and its distance from the bright [star] of Aries [lucida Arietis], he established the right ascension of the bright [star] of Aries. On this occasion, however, the place of Venus can be gathered from it, but with the cautions employed, concerning which Kepler [Kepler] [warns] in the foundation of his *Ephemerides*, p. 15, where he says that diurnal observations are to be distinguished from nocturnal ones; nor are two parallaxes, at the same altitude above the horizon, well compared together; and the same about the interval of the Earth; and that in the motion of Venus one may otherwise err, the difference being able to be 15'. Moreover, the disagreement persists even now between Landgrave [Wilhelm IV] of Hesse [Landgravium Hassiæ] and Brahe [Braheum] of Denmark, concerning which see in Tycho's letter of the year 1589, February 21. I add my own error in the greatest declination of the Sun, which I increased by minute 1'10", beyond what is just [in the right reckoning], and in the parallax of the Sun, which is indeed less than is supposed — as even Kepler above admits — but is still less than Kepler's. Let one also remember to take account of Refraction in each case.

Parsing notes: This is a two-paired-column observation register. Each numbered entry gives a date and two observation times (Hor. — hour of observation, in two separate paired sub-columns each headed Hor. then G./M./S. for degrees·minutes·seconds of the measured quantity). Beneath each entry's heading are rows for: distance of Venus from the Sun's center, declination of Venus (north or south as labelled), altitude of the Sun, altitude of Venus, and a distance from a named fixed star with that star's declination. Where two values appear stacked in a single right-hand cell (e.g. "23 30 0 / 40 46 10" at no. 24), the upper is the altitude-of-Venus value and the lower the star-distance value; transcribed slash-separated. Several second-column G·M·S cells are blank in the source (the second observation-time recorded only a subset of quantities). Sign glyphs: ♋ Pisces, ♊ Gemini, ♈ Aries, ♀ Venus.

Liber VIII — De Venere (continued)

Caput V (continued) — Tycho's Venus observations, 1582–1601

The dense register of Tycho Brahe's Venus observations continues. Each numbered entry gives the date and the time of observation (before noon / after noon, with two times shown side by side under the **H.** [hours] / ' [minutes] columns), followed by Venus's distance from the Sun's center, Venus's southern declination, the altitudes of the Sun and of Venus, and Venus's distance from (and the declination of) the star Spica.

Item 28 — 1588 November 29, before noon. [Left columns: H. 9 11'; right columns: H. 7 11']

Quantity	G.	M.	(2nd time)	
			G.	M.
Distance of Venus from the Sun's center	46	38	0	
Southern declination of Venus	9	16	0	
Altitude of the Sun	3	30	0	
Altitude of	24	30	0	21 30 0

Quantity	G.	M.	(2nd time)	
			G.	M.
Venus				
Distance of Venus from Spica			13	31 30
Southern declination of Spica			8	57 15

Item 29 — 1588 December 6, before noon. [Left: H. 10 30'; right: H. 7 28']

Quantity	G.	M.	(2nd time)	
			G.	M.
Distance of Venus from the Sun's center	44	57	30	
Southern declination of Venus	11	21	30	11 8 0
Altitude of the Sun	8	0	0	
Altitude of Venus	19	15	0	20 30 0
Distance of Venus from Spica			20	17 20
Southern declination of Spica			8	57 15

Item 30 — 1588 December 15, before noon. [Left: H. 9 6'; right: H. 7 41']

Quantity	G.	M.	(2nd time)	
			G.	M.
Distance of Venus from	46	36	0	

Quantity	(2nd time)			
	G.	M.	G.	M.
the Sun's center				
Southern declination of Venus	14	4	0	14 2 0
Altitude of the Sun	3	0	0	
Altitude of Venus	20	0	0	19 0 0
Distance of Venus from Spica			29	33 30
Southern declination of Spica			8	57 15

Parsing notes: each entry pairs two observation times (two **H.** columns at the head). Most rows of figures sit under the first time; where a second value is printed to the right it belongs to the second time. Values transcribed as printed.

[Following the register, a short prose note:]

Three Venus observations drawn from Tycho's *Letters* (p. 56), made at Uraniborg on the dates of the old style written below, in the hours after noon, with calculation by the Alphonsine and Copernican [tables].

[A second small table — three Venus observations of January 1587, each with the longitude and latitude of Venus reckoned three ways:]

Ann o 158 7, Jan uar y	Met						Lat.			
	D.	H.	M.	hod	Sig.	G.	I'	Gr.	I'	N/S

				Alp hon sine		17	20	0	22	B
				Cop erni can		17	31	1	12	B

Parsing notes: "B" = *Borea* (northern latitude); "A" = *Austrina* (southern latitude).
 ♓ = the sign of Pisces.

[Prose, lower left column:]

Lansbergius [Philip Lansberge], in his *Thesaurus observationum* ["Treasury of Observations"], makes use of the observation for the 15th of these dates, and from it gathers Venus's place as Pisces 16°57'39" in his *Tables*. Bullialdus [Boulliau], however, in Book 9, Chapter 2, takes from his own [tables] the place as Pisces 18°9'; and he therefore charges this observation with error — or rather [charges] the observation of the year 1590 (about which more shortly, after Longomontanus, in Book 2 of the *Theorica*, Chapter 18). He admits that scarcely ever, and only rarely at other times, was Venus observed continuously in summer, because of the obliquity of the [celestial] sphere — which made such observation feasible in Denmark — and that Venus and Mercury [are best observed] at their greatest elongations from the Sun. He nevertheless subjoins the selected observations written below, taken from Tycho, adding his own observations for the years 1610 and 1616, with a computation of the place from the Danish [data].

[A table of Tycho's later selected observations — date and time (old style, after noon), with Venus's longitude (sign, degrees, minutes) and latitude (degrees, minutes, N/S):]

#	Year, Date			Obs.	Sign	Long. (G.)	M.	Latitude		
	D.	H.	M.					G.	M.	N/S

41	161 0 Dec .12	4	40	obs ./ sup p.	□ (Aq uar ius)	17	58 / 18 4 $\frac{1}{2}$	1	29	A	
42	161 6 Ma rt. 9	17	0	obs ./ sup p.	□ (Aq uar ius)	15	24 / 15 24 $\frac{1}{2}$	(no ne obs erv ed)			

Parsing notes: column headers read *Ann. M. D. H. M.* (year, month, day, hour, minute) on the *stylo veteri post meridiem* (old style, after noon), then *Longitudo Veneris* (sign / degrees / minutes) and *Latitudo* (degrees / minutes / B[oreal] or

A[ustral]). Each entry gives an observed value (*obseru.*) and a computed/supposed value (*supput.* / *supp.*) for the longitude, here shown separated by a slash. Item 42's latitude reads "nò est obser." (not observed). Several sign-degree readings are crowded; □/□ and □/□ glyphs read as printed.

[Prose continuing in the right column:]

The last of Tycho's observations were made in Bohemia, at Benátky Castle [arce Benatica], in the year 1600, or at Prague in the city of Kuttinberg [Curtim — Kutná Hora] in the year 1601, reduced to the new style and selected by Snellius [Willebrord Snel], and published in the year 1618.

Item 43 — Anno 1600, January 23, h. 7.45', p.m. Venus was observed in the east by means of the armillae [the armillary instrument], her declination being 17°50'; and by means of the quadrant her altitude was 16°53 $\frac{1}{3}$ '. Then at 8 $\frac{2}{3}$ h., p.m., her distance from the Sun was observed as 40°36'; and at last, at the meridian altitude, Venus's altitude was 21°46 $\frac{1}{3}$ '.

Item 44 — Anno 1600, February 20. Venus's meridian altitude was seen to be 20°27', and her distance from the Sun 46°40 $\frac{1}{3}$ '.

Item 45 — Anno 1600, February 22, in the morning at 6 $\frac{3}{4}$ h. Venus was seen to be distant from Aquila [Altair] 27°37 $\frac{2}{3}$ '; her altitude then was 19°48'. Soon her altitude was 11°19'; she was seen to be distant from Antares 42°50'50". Hence Bullialdus [Boulliau], Book 9, Chapter 1, having eliminated refraction and parallax, gathers Venus's place as Scorpio 16°24'15", with northern latitude 3°20'34". But, reducing it afterward, he brings the longitude back to 16°22'12", and infers the greatest digression [from the Sun] to be 46°46'; he says this occurred on the 21st [day], at hour 20.27'.

Item 46 — Anno 1601, May 9, h. 8.17'. Venus stood distant from Capella 29°19 $\frac{2}{3}$ ', and 8.27' [later?] from Pollux 13°47 $\frac{1}{3}$ '. Her altitude then was 25°30'; and [she was distant] 8.34' from Regulus 49°59'. But Bullialdus, Book 9, Chapter 1, says she is to be read [as] distant from Capella 26°19'40", and hence to follow the place of Venus [as] Gemini 4°27'50", with northern latitude 3°9'19"; and the greatest digression [as] Aries 4°13'55".

Item 47 — Anno 1601, October 10, in the morning at 4.30' p.m. [recte: a.m.?]. Venus's altitude was 17' [recte uncertain]; she was seen to be distant from Procyon 24°55', and soon from Pollux 45°30 $\frac{2}{3}$ '; and this was the last of Tycho's Venus observations.

CAPVT VI.

Caput VI — Observations of Venus by Maestlin, Kepler, and Jost Bürgi, selected from Snellius in Hassia [Hesse].

[Headpiece ornament above the chapter title; large decorative initial "A" opens the first observation.]

[Item 1] — Anno 1574. Maestlin [Michael Maestlin], on September 16, in the morning at 4 h., at Tübingen, saw Regulus covered [occulted] by Venus, as Kepler reports on p. 305 of his *Astronomiae [pars] Optica* ["Optical Part of Astronomy"].

Caput VI (continued) — Maestlin, Kepler, Bürgi

[Item 1 continued, top of left column.] ...*Optica*; and from there Lansbergius, in his *Thesaurus*, observes Venus distant 4° [from Regulus], adding that Regulus then stood in Leo $24^{\circ}7'$ with northern latitude $31'$, and Venus in Leo $24^{\circ}9'$ with northern latitude $29'$. Although the latitude may be diminished by adding the parallax, the splendor [of Venus] nonetheless placed [her] near Regulus so as to overpower [obscure] Regulus.

Item 2 — Anno 1590, October 3, old style, in the morning at 5 h. The same Maestlin saw Mars wholly covered by Venus, the color of Venus revealing it clearly; thus Kepler in his *Optica*, p. 305, and hence Lansbergius in his *Thesaurus*, where he gathers Venus's place as Virgo $25^{\circ}32'37''$ with northern latitude $1^{\circ}20'$, and Mars's place as Virgo $25^{\circ}45'31''$ with northern latitude $1^{\circ}17'$. And [since] the parallax of Venus is to be added in longitude, $3'$ is to be added, while $1\frac{1}{3}'$ is to be subtracted in latitude — yet not so great is the discrepancy that there should be wanting [a gap of] 9 minutes of Mars's longitude.

Item 3 — Anno 1592, February 18, in the morning at $6\frac{3}{4}$ h., p.m., or $5\frac{1}{2}$ [h.], as Bullialdus has it. Justus Bürgi [Jost Bürgi] at Kassel [Casellis] observed Venus distant from Antares $48^{\circ}48\frac{2}{3}'$, and from Aquila [Altair] $26^{\circ}39'30''$. Hence Bullialdus, Book 9, Chapter 1, gathers Venus's place as Capricorn $22^{\circ}22'44''$, with northern latitude $5^{\circ}36'$.

Item 4 — Anno 1592, February 22, old style, h. $0.17\frac{1}{3}'$ p.m. Bürgi at Kassel observed Venus distant from Antares $53^{\circ}39'$, and from Aquila $26^{\circ}51'$. Hence Bullialdus, Book 9, Chapter 1, gathers Venus's place as Capricorn $27^{\circ}20'36''$ with latitude B[oreal] $2^{\circ}32'42''$; and [says] the greatest digression of Venus from the Sun was then $46^{\circ}41'$, occurring when Venus was in Capricorn $27^{\circ}17'36''$.

Item 5 — Anno 1592, July 31, in the morning at 9 h., p.m. Bürgi at Kassel observed Venus distant from Capella $22^{\circ}10'$, and from the right shoulder of Orion [Betelgeuse] $26^{\circ}50'$.

Item 6 — In the same year, in August, at 6 h. evening, Bürgi saw Venus distant, at the meridian, from Rigel $38^{\circ}30'$, with latitude $6^{\circ}1'$; and from Pollux $14^{\circ}15\frac{1}{3}'$.

Item 7 — In the same year, 1593, in September, in the morning at 1 h., the same Bürgi at Kassel observed Venus distant from Pollux $19^{\circ}33'$, and from Sirius $18^{\circ}25'$.

Item 8 — Anno 1594, December 17, old style, h. 5 p.m. Bürgi at Kassel observed Venus distant from Aquila $39^{\circ}53'$, and from the shoulder-blade of Pegasus [scapula Pegasi] $31^{\circ}54'$. From this Bullialdus, Book 9, Chapter 1, deduces Venus's place in Aquarius $22^{\circ}58\frac{1}{3}''$, with southern latitude $1^{\circ}6\frac{1}{3}'$ [recte $1.6.35''$].

Item 9 — In the same year, in December, at 20 h., p.m. The same Bürgi at Kassel observed Venus distant from Aquila $41^{\circ}30'$, and from the shoulder-blade of Pegasus $29^{\circ}57'$. Hence Bullialdus, Book 9, Chapter 1, deduces Venus's place in Aquarius $25^{\circ}50'53''$, with southern latitude $30^{\circ}37'$ [recte $0^{\circ}37'$], and [says] the greatest digression was then $47^{\circ}12\frac{1}{3}'$, which fell on December 5, with Venus reduced to Aquarius $21^{\circ}1'36''$.

Item 10 — Anno 1594, December 22, old style, h. 5 p.m. Bürgi saw Venus high [altam], $11^{\circ}30'$; and distant from Aquila $41^{\circ}50'$.

Item 11 — Anno 1595, in August, at 9 h. old style, in the morning, Bürgi at Kassel observed Venus distant from Pollux $14^{\circ}25\frac{1}{3}'$, and from the [stars] Helices [of Ursa Major] $47^{\circ}52'$. Hence Bullialdus, Book 9, Chapter 1, having placed [Venus] in the location of the Helices in Leo $19^{\circ}39'$ [recte], gathers Venus's place in Cancer $25^{\circ}39\frac{1}{3}'$, with northern latitude $8''$.

Item 12 — Anno 1596, April 21, old style, h. 9 p.m. Bürgi at Kassel observed Venus distant from Capella $21^{\circ}29\frac{1}{3}'$, and from the [star] following Gemini [Pollux] $33^{\circ}9'$ [recte].

Item 13 — Anno 1598, September 25, new style, in the morning at 3 h. Venus, scarcely risen and seen with Kepler's free grace [i.e., generously communicated by Kepler], covered Regulus; the hour was 4 h., more than one Venus[*'s* breadth?] lay between her and Regulus. The line truly drawn from Venus to the heart of Leo [cor Leonis = Regulus] fell a little within them. Hence Lansbergius in his *Thesaurus* gathers Regulus's place in Leo $24^{\circ}24'$ with northern latitude $31'$, and Venus's place in Leo $24^{\circ}24'48''$ with northern latitude $31'$. Wherefore Venus did not cover Regulus with her whole body, but [only] by her rays.

Item 14 — Anno 1599, May 31, new style, from his half-six observation [*ex sua semisextâ observatione*], Kepler in his *Optica*, p. 305, by a certain conjecture judges a conjunction of Venus and Mercury — about which see him, if you please.

CAPVT VII.

Caput VII — Observations of Venus made by Hortensius, Pierre Gassendi, Fr. Andreas Arzet, Don Vincenzo Muto, and by the Fathers of the Society of Jesus at Ingolstadt and Innsbruck [Oeniponti].

[Item 1] — Anno 1622, October 14, in the morning — "as I was journeying," says Gassendi (in his *Epicurus*, p. 903) — "I saw at Aix-en-Provence [Aguas Sextias], without a telescope, in the twilight of dawn, Venus shining very near Mars, and distant from Mesoboream [the Mesoborean point?] no more than a hand's-breadth and a half [dodrante] of its own diameter; on the following day, at the same hour, Venus had crossed over, and now stood with Mars at the Meseterum [Meseterean point?], somewhat farther from him than the lesser of the inferior appendages of the Belt of Orion lie from one another — yet much less than the Kids [Haedi] under Capella."

Item 2 — Anno 1625, January 30, old style, h. 7 p.m. Hortensius at Leiden saw, through the tube [telescope], a conjunction of Venus with the southern horn of the crescent Moon [cornu Lunae], the apparent distance being a single minute. Lansbergius in his *Thesaurus* observed [this]; he adds that the Moon's center was distant 2 h. — that is, Venus [was] in Pisces $24^{\circ}45'25''$ with northern latitude, seen $48\frac{1}{3}'$ [recte]; and the Moon's place likewise in Pisces $24^{\circ}44'47''$, with southern latitude $52''$ [recte].

Kepler in the *Rudolphine [Tables]*, Chapter 28, p. 93, relates that on the same day, at evening at Herbachium, Ulm, Tübingen, and elsewhere in Swabia, Venus was seen, as if in a complex of horns of the Moon, clinging; she came almost into the left horn, and thence by little, traversing the gibbous of the lower Moon, gathers [computes] the central conjunction of the Moon and Venus to be apparent; for although it was the occultation of the Sun and Venus, yet the Moon was truly Borealward [northern]. Hence, taking the example of the parallaxes to be supposed, he teaches that, at the time of conjunction, the Moon would appear at $24^{\circ}21'$ in [the sign], and Venus at $24^{\circ}42'$ of Pisces.

Item 3 — Anno 1625, February 7, in the morning, nearly 5 h. 40' after midnight, Gassendi at Paris with the naked eye saw the Moon, which with her outermost Boreal [northern] horn touched Venus, yet covering nothing of her; thus he himself in his *Epicurus*, p. 900.

Item 4 — Anno 1626, December 12, in the evening at h. 6 h. 31'. Hortensius at Leiden saw Venus joined to the second longitudinal [position] of the Moon, distant from the very southern horn of the Moon about a diameter of the lunar [disk]. Lansbergius in his *Thesaurus* observed [this]: that is, Venus, where he computes the place of the Moon's appearance in Aquarius 17°31'50", with northern latitude, seen southern 36°23" [recte], and Venus's place in Aquarius 17°31'12", with northern latitude 1°33'11".

Item 5 — Anno 1629, December 17, old style, nearly 6¾ h. p.m. Hortensius at Middelburg saw Venus, having passed the circle of the longitude of the preceding star, in the tail of Capricorn, by nearly a quadrant of a lunar diameter; and she was Borealward [north] by an entire lunar diameter. Lansbergius in his *Thesaurus* observed [this]; from which place he gathers the [position] of Venus in Aquarius 16°36½' — but from the *Tables*, 16°42'33".

Item 6 — Anno 1632, July 31. Hortensius at Amsterdam computed the conjunction of Venus and Mercury in the morning after midnight; nevertheless they were distant 7'. Venus stood somewhat more to the west than Mercury; Mercury was Borealward — whence he argues the conjunction of these planets to have been at h. 11½ of night. Moreover, with Hortensius, in his dissertation on the [transit] of Mercury seen in the Sun [the 1631 Mercury transit], and [with] Longomontanus, the calculations show themselves to have a notable error of Longomontanus against the observation.

Caput VII (continued)

[Top of left column — a small table giving the longitude and latitude of Venus and of Mercury as reckoned by Lansbergius and by Longomontanus, for the 1632 conjunction:]

Source	Body	Sig.	Grad			Lat.			N/S
			.	I'	II''	G.	I'	II''	
Lansbergii	Veneris	☿ (Cancer)	24	24	43	0	34	43	B
Longomontani	Veneris	☿	24	40	0	0	34	0	B
Lansbergii	Mercurii	☿	24	30	4	0	39	5	B

Source	Body	Sig.	Grad			Lat.			N/S
			.	I'	II''	G.	I'	II''	
Uraniberg ii	Mercurii	☊	27	33	0	1	24	0	B
Uraniberg i	Mercurii	☊	27	33	0	1	24	0	B

Parsing notes: "B" = *Borea* (northern latitude). ☊ = Cancer.

[Prose, left column:]

Item 7 — Anno 1632, December 6. Gassendi at Paris observed the conjunction of Venus with the Sun, as to longitude; for as to latitude Venus could not, in this case, cover the Sun. Kepler in his *Optica*, p. 305, was [of this opinion]; the hour was 9.41' after noon, at Uraniborg, from the *Rudolphine [Tables]*, with Venus's latitude southern 1°8'9". Hortensius [was of this view] in his dissertation on Mercury seen in the Sun.

Item 8 — Anno 1633, May 26, h. 9 p.m. Gassendi saw Venus, through the optical tube [telescope], 18' — or at most 19' — west and a little south of the left shoulder of Pollux [the Gemini]. That star was (says Bullialdus, Book 9, Chapter 2) in Cancer 18°33'20" with northern latitude; and the azimuth of Venus [was] more western than the azimuth of the star by 9' — therefore Venus in Cancer 18°17', with northern latitude 2°48'.

Item 9 — Anno 1633, July 30. Gassendi at Tanaron, a little town to the north of Digne [Dinia], of latitude 44°11', in the morning saw Venus distant from the Sun's center 26°3'; soon Venus was higher [in altitude]. At 11¾ [h.] Venus, previously high 12°, was seen distant from Aldebaran 37°8', and from the southern horn of Taurus 27°17'.

Item 10 — In the same year, on August 2. Gassendi in the same town saw Venus distant from the Sun's center 29°2', high [in altitude]; soon, with the Sun high 9°, Venus was first seen distant from Aldebaran 36°44', and from the right shoulder of Orion [Betelgeuse] 20°6'.

Item 11 — On the 5th, with the Sun high 6°, Venus was seen by the same [Gassendi] distant from the Sun's center 31°40', having previously been distant from Aldebaran 36°48', from the right shoulder of Orion 20°8', and from Pollux 14°40'. Thus Gassendi in his *Epicurus*, p. 800.

Item 12 — **On the 6th**, that same Venus was distant from Aldebaran $36^{\circ}59'$, and afterward from the western limb of the Sun, high 10° , and then [from] the eastern limb of the Sun, high 11° . Then [from] the Sun's center, high 12° .

Item 13 — **On the seventh [day]**, that same Venus was distant from Aldebaran $37^{\circ}3'$, from the right shoulder of Orion, high [in altitude] [and] $20^{\circ}19'$; from Pollux $14^{\circ}27'$, and from Castor $16^{\circ}45'$; then $33^{\circ}5'$ from the western margin of the Sun, high 9° , and $33^{\circ}34'$ from [it] high 8° ; and $20'$ from the eastern margin of the Sun, high $10\frac{1}{2}^{\circ}$; and from the Sun's center, high 12° .

Item 14 — **On the 11th**, Venus stood distant — the same [Gassendi] observing in the same place — $37^{\circ}56'$ from Aldebaran, and then $21^{\circ}17'$ from the right shoulder of Orion, high [in altitude] 12° .

Item 15 — **On the 12th**, the same [Venus] stood distant $38^{\circ}14'$ from Aldebaran, [and] $21^{\circ}43'$ from the right shoulder of Orion; and then $36^{\circ}44'$ from the Sun's center, high nearly 14° .

Item 16 — **On the 13th**, he saw in the same place Venus distant $21^{\circ}52'$ from the right shoulder of Orion, and $13^{\circ}27'$ from Pollux, $37^{\circ}20'$ from Castor, [and] from the Sun's center, high 15° . Gassendi in his *Epicurus*, p. 801, who admits that he used a five-foot [radius] instrument, in such a way that it was, as it were, [used] outside the margins of a small cylinder, [it being better] that they should be within [the margins], and that there be an abundance of one margin in the dividing of the margins, the other [being] a lesser minute.

Item 17 — **Anno 1635, July 16**. Gassendi at Aix-en-Provence [Aquis Sextiis] saw Venus high $37^{\circ}7'$, distant $13^{\circ}52'$, [reckoned] from the tail of Leo high $20^{\circ}3'$. Gassendi in his *Epicurus*, p. 802.

Item 18 — **Anno 1636, November 14, in the morning**. Fr. Andreas Arzet, of the Society of Jesus, at Innsbruck [Oeniponti], had this observation of Venus, which he afterward communicated to me [Riccioli] by letter.

[Item 19 — a small table, lower left column: an observation taken between Astronomical hours 6 and 7:]

Quantity	G.	I'	II''
Meridian altitude of Regulus	56	28	30
Altitude of	29	36	30

Quantity	G.	I'	II''
Venus then, seen at rising			
Then the distance of Venus from Regulus	42	6	40
Then the distance of Venus from Arcturus	32	7	30
And then the altitude of Venus was	31	11	0
And [the altitude of] Arcturus high toward the East	35	25	0

Parsing notes: heading reads *Inter hor. Astronomicam 6. & 7.* (between astronomical hours 6 and 7).

Caput VII (continued) — right column

[Top of right column — a small table, continuation of an observation "around hour 9¾":]

Quantity	G.	I'	II''
(heading: <i>Circa horam verò 9¾</i>)			
Venus's meridian altitude, seen	40	47	0
And the Sun's altitude at rising [ortiva]	13	42	0

Quantity	G.	I'	II''
Soon the distance of Venus, seen from the Sun	45	32	26

Item 21 — Anno 1646, on the day 9 of July, Don Vincenzo Muto [Vincentius Mutus] of Maiorica [Mallorca], at h. 15.40', saw Venus distant nearly 32' — that distance rather on the part of the latitude — from the star of the Hyades, which [reaches] to the eye [is] Borealward; and that star was more southern [australior], as to longitude; Venus, moreover, was a little more eastern than the star, and near its greatest digression from the Sun.

Item 22 — In the same year, the same [observer] in the same place, on July 30, at h. 16, saw Venus more southern [australiozem] in the southern horn of Taurus [cornu australi Tauri], and distant from it 31' — or 32 [recte].

Observations made by the Fathers of our Society at Ingolstadt, and by me [Riccioli], afterward communicated [to me] by Fr. Michael Staudacher.

[A multi-section table of Venus observations, 1619–1620. The main heads read: *Anno 1619* (date / hour / minutes) and *Distantia* □ (distance of Venus) — "Ab" (from which star) with degrees / minutes.]

Anno 1619 — Distance of Venus [from a named star]:

Die (date)	Hora	I'	Ab (from)	G.	I'
Febr.					
(Vesp. = evening)					
7	6	35	Algenib·P egasi	21	27
			Markab	14	6
10	6	25	Algenib	29	25
			Markab	13	34
			Venus was high	8	30

Die (date)	Hora	I'	Ab (from)	G.	I'
			[☿ alta erat]		
April. (Mane = morning)					
2	5	30	from the Sun [à Sole]	40	6
			high [the Sun]	15	30
	(H. 6 0)		from the Sun	40	21
			high [the Sun]	5	0
			high [Venus]	19	5
April. (Mane = morning)					
6			from the Sun	41	49
			high [the Sun]	3	0
			high [Venus]	17	50

Anno 1619 — April, morning [Mane], altitudes [Altis.] — Distance of Venus from the Sun [Dist. ♀ à ☉]:

Die ☉	g.	I'	☿ I'	(Dist.) Gr.	I'
9	1	0	15 28	42	49
10	1	30	16 8	42	59
11	5	30	19 5	43	15
12	1	10	15 32	43	29

Die ☉	g.	I'	□ I'	(Dist.) Gr.	I'
13	5	0	18 40	43	43
Maij 4	1	0	14 58	45	52
6	2	0	16 10	45	57
11	3	30	18 25	45	54
27	1	40	17 23	44	30
Iunij 4	2	15	19 35	43	41
8	4	30	23 30	42	54
20	0	30	0 5	40	51
Iulij 5	2	0	23 50	37	57

Anno 1620 — H. i — Distance of Venus [Distantia □]:

Die	Hora	(Vesp. = evening)	ab (from)	G.	I'
Iulij 3	9	45	from Arcturus [ab Arcturo]	57	6
			from Spica □ [à Spica Virginis]	51	24
11	9	11	Arcturus □	51	6
			Spica □	43	18
21	9	0	Arcturus	44	58
			Spica □	33	42
31	8	45	Arcturus	40	6
			Spica □	31	0

Parsing notes: the 1619/1620 observation table is laid out as several stacked sub-tables with shifting column heads (*Vesp.* = evening / *Mane* = morning / *Altis.* = altitudes). The ☉ glyph = the Sun, ♀ = Venus, ♍ = Virgo. "Algenib-Pegasi" and "Markab" are stars of Pegasus. Some altitude sub-columns are crowded; where a paired "g. I'" (degrees/minutes of the Sun's altitude) and a "□ I'" (Venus's altitude)

sit side by side, both are given before the distance columns. Values transcribed as printed; the June 20 / "0 5" altitude reading and the May progression are crowded and read as printed.

Liber VIII — De Venere (continued)

Caput VII (continued)

The Ingolstadt 1620–1621 Venus observations continue (distances of Venus from fixed stars, in degrees and minutes; "H." = the hour of observation; "Manè" = morning).

Venus's distances from fixed stars, 1620–1621 (Ingolstadt, Society of Jesus).

Year 1620	Hour	Distance of Venus from	Deg.	Min.
Oct. 13	5h 0m, morning	from Regulus	36	10
Oct. 20	5h 30m, morning	from the Heart [Cor] of Leo	30	57
		from Regulus	30	59
Oct. 22	9h 52m	from the Tail [Cauda] of Leo	18	7
		& its merid. altitude	40	3
		& distance from the Sun, merid. alt.	34	0
Oct. 23	9h 30m	from Regulus	40	40
Oct. 25	6h 8m	from the Tail of Leo	31	54
		from	17	51

Year 1620	Hour	Distance of Venus from	Deg.	Min.
		Regulus		
		Venus was high [alta erat]	23	20
Nov. 17	5h 15m, morning	from Arcturus	30	54
		from the Tail of Leo	26	12
		Venus was high	20	10
Nov. 30	6h 15m, morning	from Arcturus	28	4
		from the Tail of Leo	36	22
		Venus was high	16	5
Dec. 3	6h 0m, morning	from Arcturus	28	59
		from the Tail of Leo	39	3
		Venus was high	23	40
Dec. 7	5h 45m, morning	from Arcturus	29	48
		from the Tail of Leo	42	54
		from the Sun, alt. of Sun 15°	47	5
Dec. 13	6h 0m, morning	from Arcturus	31	54
		from Spica of Virgo	17	12

Year 1620	Hour	Distance of Venus from	Deg.	Min.
		Venus was high	27	0
Dec. 23	6h 45m, morning	from Arcturus	37	48
		from Spica of Virgo	27	42
Year 1621	Hour			
Jan. 5		from Arcturus	48	18
		from Spica of Virgo	42	12
		Venus was high	17	55

Parsing notes: In the "Distance of Venus from" column the standard astronomical symbols appear — ♀ (Venus), ☉ (Sun), ♌ (Leo) "à Cauda ♌" = "from the Tail of Leo", "♍" = Virgo. "Manè" = morning. The "& dist. à ☉ / alt. Merid." rows for Oct. 22 give Venus's distance from the Sun and meridian altitudes; the column-alignment there is cramped. The Dec. 7 "à Sole alt. ☉ g. 15" = distance from the Sun with the Sun's altitude 15°.

[Observations made at Innsbruck by the Fathers of our Society — Oeniponti]

Observations made at Oeniponte [Innsbruck] by the Fathers of our Society.

Venus's distances from fixed stars and altitudes, 1635–1636 (Innsbruck, Society of Jesus).

Jan. 26	from Arctur us		69	29	of Venus	14	58 mat.
	from Bright Lyra		60	50	of Arctur us	57	46 vesp.

Parsing notes: The (A.) sub-header in these tables apparently distinguishes the star "A" referenced. "mat." = *matutina* (morning); "vesp." = *vespertina* (evening); "merid." = *meridiana* (meridian/at noon). The Jan. 21 entry "of Bright Lyra 55° 6'" reads as a single-digit 6 in the minutes column (the first-pass "60" was a misread of 6 plus the adjacent column rule/show-through; verified in). The Nov. 19 "of Venus 30° circ." = "about 30°" (*circiter*).

CAPVT VIII.

Selected Venus observations, drawn from many carried out at Bologna in the College of St. Lucia by Fr. Giovanni Battista Riccioli and Fr. Francesco Maria Grimaldi of the Society of Jesus.

With some additions from the observations of the Most Illustrious Marchese Cornelio Malvasia [Maluasicæ].

1. In the year 1642, on September 23, in the evening, when Arcturus stood high in the west at 27° 33', Venus was observed by means of the Sextant to be distant from that same Arcturus by 36° 1/2. When, however, Venus had descended to an altitude of 4° 8', it was distant from the Bright Star of the Northern Crown [lucida Coronæ] by 44° 52'.

2. In the same year, on November 30, in the evening at the 10th hour, ten minutes before the transit of Fomalhaut across the meridian wire [per M. C. — *per medium coelum*], Venus was seen to be distant from Fomalhaut by 7° 13'; and after three minutes, 10 seconds, it was distant from Saturn by 5° 24'.

3. Likewise in the year 1642, on July 21, in the evening, Venus stood high above the western horizon at $7^{\circ} 56'$ apparently; then up to the transit of the Heart of Scorpio [cor Scorp̄ii] across the meridian wire there were counted 9 minutes, 58 seconds.

4. On the 25th day of the same month, in the evening, Venus was seen high at $7^{\circ} 11'$, observed in a western azimuth of $104^{\circ} 33'$; then up to the transit of Antares across the meridian wire there were counted 26 minutes, 40 seconds.

5. In the year 1642, on August 4, in the evening, Venus was distinctly visible high at $7^{\circ} 1'$; it was in a western azimuth of $98^{\circ} 50' \frac{1}{3}$. From there up to the transit of the head of Ophiuchus [caput Ophiuchi] across the meridian wire there were counted 36 minutes, 42 seconds.

6. On the twelfth day of August, when Venus was seen high at $7^{\circ} 59'$, it was observed in a western azimuth of $93^{\circ} 8'$; and from there up to the transit of the highest [star] in the shoulder of Ophiuchus there were counted 16 minutes, 52 seconds.

In order that the order of time may be preserved, the first observation ought to be inserted here, and the second rejected after the one following.

7. In the year 1642, on October 21, in the evening, on the following [day], Venus was distant from Arcturus by $59^{\circ} 11'$; and after 5 minutes, 15 seconds had elapsed, it was distant from the Bright Star of the Northern Crown by $55^{\circ} 24'$; then after 10 minutes, the western altitude of the Eagle [Aquila] was taken at $53^{\circ} 11'$.

8. In the year 1643, on January 10, in the evening, in the half-hour after true sunset, Venus was seen distant from Jupiter by $14^{\circ} 11'$; and after 5 minutes, at the time of Saturn, by $19^{\circ} 21'$; and after 11 minutes, from the bright tail of Cetus [lucida caudæ Ceti] by $33^{\circ} 44'$; and after 50 minutes of time (for in between fell observations of other planets), it was likewise distant from the breast of Cygnus [pectore Cygni] by $56^{\circ} 25'$; finally, after 5 minutes, Aldebaran was high at $50^{\circ} 42'$.

9. Likewise in the year 1643, on January 20, on the following night, Venus was seen high above the western horizon at $23^{\circ} 32'$; and from there, after 19 minutes, 32 seconds, the rising altitude of Aldebaran was $48^{\circ} 30'$.

10. In the year 1643, on March 8, in the morning, nearly a half-hour before sunrise, Venus appeared distant from the bright star of the Eagle by $9^{\circ} 25'$; then 25 minutes before sunrise, when Venus was seen high at $11^{\circ} 13' \frac{1}{2}$, the tail of Cygnus was distant by $53^{\circ} 14'$ from the eastern direction; but at the very moment

of physical sunrise Venus was observed distant from the center of the Sun by $37^{\circ} 37'$.

11. Of the same year and month, on day 12, in the morning, before sunrise, about the third hour, that is, when Venus was high and the bright star of the Eagle was high at $41^{\circ} 27'$, Venus was seen high at $11^{\circ} 54'$; and was distant from the tail of Cygnus by $53^{\circ} 58'$. At the very moment when the bright star of the Eagle was high at 42° , Venus was high at $13^{\circ} 33'$, appearing distant from that same bright star of the Eagle by $31^{\circ} 37'$.

12. In the year 1643, on May 19, in the morning, before the Sun's altitude was seen, Jupiter was observed high at $1^{\circ} 43'$, and after 6 minutes, 20 seconds had elapsed, Venus was seen high at $17^{\circ} 5'$; and its eastern azimuth was $76^{\circ} 22'$.

13. On day 21 of May, in the morning, the eastern altitude of the bright star of the Eagle was taken at $53^{\circ} 24'$; and after 20 minutes, the eastern altitude of Venus was observed at $14^{\circ} 20' 1/2$ in an azimuth of $80^{\circ} 1'$; and a little later Venus appeared more southerly in the same vertical [circle] together with Jupiter.

14. In the year 1643, on July 15, in the morning, the rising altitude of the bright star of Aries was taken at $46^{\circ} 50'$; then after 15 minutes had elapsed, Venus was seen high at $14^{\circ} 22'$, distant; from the bright star of Aries by $6^{\circ} 2'$. Then after 5 minutes of time it was seen high at $19^{\circ} 1/2$, and distant from Aldebaran by $13^{\circ} 25'$. Finally after time was minus, Venus was high at $18^{\circ} 48'$, and was then distant from Jupiter by $57^{\circ} 58' 1/2$.

15. In the year 1643, on June 21, in the morning, 67 minutes, 10 seconds, and the high altitude of the Sun was seen at $7^{\circ} 49' 1/3$; of the same year, the eastern azimuth was $114^{\circ} 14'$; the altitude of Venus had been seen at $92^{\circ} 22'$ in an eastern azimuth, at the same moment $92^{\circ} 47'$.

16. In the same year and month, on day 28, in the morning, the rising altitude of the bright star of the Eagle was taken at $46^{\circ} 2'$; in the west there were counted 28 minutes; then when the altitude of Venus was seen in the east at $14^{\circ} 38'$, it was distant from Saturn by $50^{\circ} 16'$. Then after a minute, $6^{\circ} 1/2$, it was seen distant from Jupiter by $36^{\circ} 7'$; and Venus appeared high at 16° .

17. In the year 1643, on July 30, in the morning, in the half-hour after the rising altitude of the bright star of Aries was $22^{\circ} 32'$, Venus was seen high above the rising [point] at $17^{\circ} 15'$; at the same moment distant from Aldebaran by $17^{\circ} 50' 1/2$, and after two minutes of time Venus was seen high at $18^{\circ} 20'$, distant from Regel of Orion [Regel Orionis] by $42^{\circ} 41' 1/2$, high at that time by $11^{\circ} 50'$. Then

after 12 minutes it was seen high at 19° 40', and distant from Capella by 29° 38', when Ca-

The following observations were carried out by the same method.

Subsequent observations carried out by the same method, 1644.

Year 1644	Altitude of Venus seen	Alt. of Spica	Dist. of Venus seen from the stars
July day	Gr. M.	Gr. M.	Gr. M.
28 — (3)	17 / 42, then 15 / 55	28 / 58, then 28 / 0	51 / 22 from Spica; 22 / 0 1/2 from the Tail of Leo
29 — (4)	18 / 21, then 16 / 15	29 / 3, then 28 / 0	50 / 21 from Spica; 21 / 9 from the Tail of Leo
30 — (5)	17 / 32, then 15 / 24 1/2	28 / 39, then 27 / 10	49 / 22 1/2 from Spica; 20 / 26 from the Tail of Leo
31 — (6)	16 / 54, then 14 / 8 1/2	27 / 53, then 26 / 14	48 / 19 from Spica; 19 / 38 1/2 from the Tail of Leo

Parsing notes: Each row carries two altitude readings (an upper and a lower entry) for Venus and for Spica, and two distance readings (from Spica and from the Tail of Leo [Cauda ♌]). The parenthetical "(3), (4), (5), (6)" beside the July day are the day-count within the series. "1/2" renders the printed half-fraction symbols. Table continues on the following page.

Subsequent observations by the same method, 1644 (continued).

Year 1644	Altitude of Venus seen	Alt. of Spica	Dist. of Venus seen from the stars
July day	Gr. M.	Gr. M.	Gr. M.

Year 1644	Altitude of Venus seen	Alt. of Spica	Dist. of Venus seen from the stars
32 — (8)	16 / 11, then 13 / 47	27 / 1, then 25 / 23	46 / 24 from Spica; 18 / 13 1/2 from the Tail of Leo
33 — (9)	12 / 58, then 12 / 6	24 / 24, then 23 / 51	34 / 43 from Vindemiatrix [Vindem.]
34 — (10)	14 / 10, then 12 / 54, then 11 / 37	25 / 8, then 24 / 10, then 23 / 4	44 / 27 from Spica; 16 / 52 from the Tail of Leo; 33 / 57 from Vindemiatrix
35 — (11)	16 / 14, then 10 / 4	26 / 30, then 22 / 10	43 / 28 from Spica; 51 / 30 from Arcturus
36 — (12)	15 / 39, then 14 / 26	25 / 50, then 24 / 24	42 / 34 from Spica; 16 / 15 from the Tail of Leo
37 — (14)	14 / 21, then 12 / 47	24 / 25, then 23 / 13	40 / 40 from Spica; 14 / 48 from the Tail of Leo
38 — (19)	13 / 15, then 9 / 20	22 / 37, then 19 / 41	37 / 9 1/2 from Spica; 46 / 43 1/2 from Arcturus
39 — Aug. 4	17 / 4, then 15 / 14	17 / 4, then 23 / 40	40 / 35 1/2 from Arcturus; 23 / 40 from Spica

Parsing notes: The "(8), (9), (10)..." parentheticals continue the day-count; note the series jumps 6→8 (no entry numbered 7 in the printed sequence), and 12→14, 14→19. Row 34 and several others carry three readings. Row 39 begins the August

dates ("Augusti 4"). The "from the Tail of Leo" entries use the ☐ symbol; "from Vindemiatrix [Vindem.]" is the star ϵ Virginis. Several fractional minute-values (1/2) are printed as half-symbols.

40. In the year 1644, on November 11, in the morning, Procyon was distant from the vertex toward the west by $41^{\circ} 25'$; and after 6 minutes of time, its distance from Regulus was $38^{\circ} 57'$; but after 1 minute, $5 \frac{1}{2}$, it was distant from Arcturus by $33^{\circ} 34' \frac{1}{2}$, and after 4 minutes it was distant from the bright star of Hydra [lucida Hydræ] by $46^{\circ} 37'$.

41. In the year 1644, on November 21, in the morning, Regulus was distant from the vertex toward the west by $33^{\circ} 11'$; and after 6 minutes, Venus was high at $31^{\circ} 11'$, distant from Arcturus by $29^{\circ} 54' \frac{1}{2}$; and after another 6 minutes Venus was high at $31^{\circ} 33'$, distant from Regulus by $48^{\circ} 5'$.

42. In the same year, on November 26, in the morning, the eastern distance of Arcturus from the vertex was taken at $49^{\circ} 50'$; then after 5 minutes of time, the altitude of Venus was taken at $30^{\circ} 28'$, its distance from Arcturus being $28^{\circ} 59'$; then after 5 minutes of time, the altitude of Venus was taken at $19^{\circ} 12'$, and its distance from Regulus toward the west at $52^{\circ} 58'$.

43. Likewise in the year 1644, on November 29, in the morning, the rising distance of Arcturus from the vertex was $51^{\circ} 1'$, and after 3 minutes the rising altitude of Venus was $25^{\circ} 12'$; its distance from Arcturus $25^{\circ} 12'$; then after 5 minutes it was seen distant from Regulus by $36^{\circ} 1' 50''$; and after 5 minutes it was likewise distant from Spica by $4^{\circ} 30'$.

44. In the year 1644, on December 4, Arcturus was distant from the vertex by $45^{\circ} 25'$; and after 2 minutes it was seen high at $5^{\circ} 35'$; and its distance from Arcturus was $29^{\circ} 14'$; then at the Italian hour $13 \frac{1}{3}$, Venus was seen high at $27^{\circ} 10'$, distant; from Spica by $38^{\circ} 24'$.

45. In the year 1644, on February 4, the distance of Venus from the vertex toward the west was taken at $49^{\circ} 50' \frac{1}{2}$, in an azimuth, by which the vertical plane was carried, the bright foot of Orion [pes lucidus Orionis] was seen distant from the vertex by $60^{\circ} 59'$; in the half-hour after the observed distance from the vertex was $46^{\circ} 17'$; from there up to the time when the right [bright] [foot] of Orion's distance from the vertex was $51^{\circ} 56'$. Then when $3 \frac{1}{2}$ minutes had elapsed, after the distance of Procyon from the vertex was $44^{\circ} 44'$, Venus was seen distant from the vertex by $83^{\circ} 26'$.

46. In the same year, on February 6, Venus was in the same azimuth as in the preceding observation, and was seen distant from the vertex by $48^{\circ} 43'$; from there were counted 4 minutes of time, the crepuscular [twilight] impediment ceasing; the distance of the right shoulder of Orion from the vertex toward the rising was $50^{\circ} 15'$; likewise Venus was seen distant from the vertex toward the west by $36^{\circ} 40'$; and after a smaller time, $5 \frac{1}{2}$, Procyon was distant from the vertex toward the west by $40^{\circ} 55'$.

47. In the year 1646, on February 12, Venus was observed to be distant from the vertex by $46^{\circ} 58'$ in the vertical to whose plane the right shoulder of Orion was expected, distant from the vertex by 46°

$50' \frac{1}{3}$. After the observation, however, of Venus toward the evening, there were counted 39 minutes, 15 seconds of time; and immediately Regel was distant from the vertex by $55^{\circ} 20'$, in the eastern quadrant; and Venus was then near greatest digression [maximæ digressioni].

48. In the year 1646, on February 25, the evening Venus was seen distant from the vertex by $47^{\circ} 15'$ in the azimuth of that vertical [circle]; to whose plane the right shoulder of Orion sank down [delapsus], distant from the vertex by $52^{\circ} 50' \frac{1}{3} \frac{1}{5}''$; from the observation, moreover, of Venus there were counted 47 minutes, 45 seconds. Procyon, in the eastern quadrant, was distant from the vertex by $50^{\circ} 15'$.

49. In the year 1646, on July 4, in the morning, when Capella was distant from the vertex by $64^{\circ} 54'$, in an eastern azimuth, Venus was seen distant by $88^{\circ} 4'$; then when the Sun's altitude was observed to be smaller, $34'$, there elapsed 17 minutes, 50 seconds.

In the same year, on July 7, in the morning, Capella being distant from the vertex by $62^{\circ} 16'$, Venus was seen distant from the bright side of Perseus [lucido latere Persei] by $33^{\circ} 30'$; Capella, moreover, was distant from the vertex by $61^{\circ} 36'$; it was likewise seen distant from Venus and from Capella by $31^{\circ} 25'$. In the same morning, at the moment when Venus was in an eastern azimuth of $91^{\circ} 56'$, it was seen distant from the vertex by $64^{\circ} 2'$; it was also seen distant from it, $34' 26''$; the Sun being already risen, the altitude was seen high at $3^{\circ} 10' \frac{1}{2}$.

51. In the year 1646, on July 11, in the morning, Capella being distant from the vertex, observed at $62^{\circ} 10'$, Venus was seen distant from the bright side of Perseus by $33^{\circ} 39'$; Capella, moreover, was distant from the vertex at $61^{\circ} 33'$; it was likewise seen distant from Venus and from Capella itself by $30^{\circ} 23'$; from the vertex, moreover, by about 66° ; distant, moreover, from Capella, from the vertex, by $58^{\circ} 19'$; thence were counted 18 minutes, 56 seconds. From the transit of Venus

through an azimuth of $88^{\circ} 8'$, in which Venus was seen distant from the vertex by $63^{\circ} 27'$, around this time the greatest digression of Venus was occurring.

52. In the same year, on July 11, in the morning, Capella being distant from the vertex by $59^{\circ} 38'$, Venus was seen distant from the vertex by $69^{\circ} 50'$; from the bright side of Perseus, moreover, by $33^{\circ} 53' 1/2$; and a little after, it was seen distant from Capella by $58^{\circ} 43'$; then it was seen distant from that same star by $29^{\circ} 30'$; Venus, moreover, [was distant] from the vertex by $68^{\circ} 40'$. Furthermore, after the distance of the She-Goat [Capra] from the vertex by $58^{\circ} 18'$, there were counted 16 minutes, 13 seconds; in whose end Venus was seen distant from the vertex by $62^{\circ} 40'$, in an azimuth of $88^{\circ} 10'$.

53. In the year 1647, on April 23, in the evening, Venus was seen high at $6^{\circ} 24' 1/2$, and distant from the following shoulder of Orion by $36^{\circ} 56'$. Then when it was seen high, Venus was high at $5^{\circ} 28'$; it was seen distant from the head of Pollux by $58^{\circ} 27' 1/2$; immediately Capella was distant from the vertex by $51^{\circ} 6'$.

54. In the year 1647, on May 6, in the evening, three quarters before sunset, the quadrant being applied, Venus was seen high at $9^{\circ} 40'$, and distant from Procyon by $47^{\circ} 17' 1/2$; when Venus was seen high at $9^{\circ} 5'$, it was seen to be distant from the head of Pollux by $42^{\circ} 40'$.

55. In the same year, on June 13, in the evening, Venus was observed high at $12^{\circ} 14'$, distant from Regulus by $45^{\circ} 5'$. Then when it appeared high at $11^{\circ} 10'$, Venus was seen distant from the Heart of the Hydra [corde Hydræ] by $47^{\circ} 50'$, high at $10^{\circ} 42'$, seen distant from the bright mane of Leo [iuba Leonis] by $44^{\circ} 59'$. The observation lasted 20 minutes, in whose end Regulus was distant from the vertex by $54^{\circ} 45'$; and almost the whole hour, $6^{\circ} 1/2$, after sunset.

56. In the year 1649, on April 24, in the evening, Venus was observed in the plane of the Vertical [circle] of the Filar Triangle [Trianguli Filaris], Venus being high at $59^{\circ} 41' 1/2$, and after a minute, $1^{\circ} 15''$, Procyon was distant from the vertex by $53^{\circ} 53' 1/2$. Then [Venus] was expected at the vertical plane, in which Venus had been, where the northerly [star] of the Borealis Geminorum, because it was seen distant from the vertex by $49^{\circ} 4'$.

57. In the same year, on May 3, in the evening, Venus transiting through the vertical plane designating the Filar Triangle, was seen distant from the vertex by $56^{\circ} 55'$; and after 3 minutes Procyon was distant from the vertex by $56^{\circ} 54' 1/2$; thence the northerly head of Gemini transiting through the aforesaid Filar Triangle, distant from the vertex by $47^{\circ} 8'$.

58. In the same year, on May 4, when Venus was seen high at $18^{\circ} 32'$, it was seen distant from the head of Pollux by $18^{\circ} 49' \frac{1}{2}$; immediately, Procyon by $28^{\circ} 32'$; iterated by the customary mode of observation; and almost the whole hour after sunset.

59. In the year 1649, on June 29, in the evening, when, with the naked eye too, Venus was seen crescent-shaped [falcata], it could not afterward be observed because of clouds; on July 25, however, in the morning, the altitude of Venus was $7^{\circ} 8'$; and its distance from Capella was $35^{\circ} 34'$; then Venus was high at $7^{\circ} 46'$; it was seen distant from Aldebaran by $32^{\circ} 30' \frac{1}{2}$ in the very bright dawn, tending toward the Direction.

Liber VIII — De Venere (continued)

60. On the same day, the morning of 27 July, Venus was seen at an altitude of $9^{\circ} 10'$ and distant from Capella $35^{\circ} 24'$. When seen, however, she was at an altitude of $10^{\circ} 10'$, and was observed to be distant from Aldebaran $32^{\circ} 15'$.

61. On the following day, however, Venus passed across the vertical plane of the Filar Triangle, in which she was seen at an altitude of $18^{\circ} 7'$; and at the same plane, afterwards, the center of the Sun was seen at an altitude of $21^{\circ} 18' \frac{2}{3}$. After Venus had been observed up to the time the Sun's altitude was taken, 5 degrees 53' were counted off: the time amounted to 40 minutes 8 seconds.

62. On 30 July, in the morning, when Venus was at an altitude of $13^{\circ} 37'$, she was found distant from Capella $35^{\circ} 21'$; but when seen at her most visible she was at an altitude of $14^{\circ} 10'$, and was distant from Aldebaran $32^{\circ} 13'$.

63. On the following morning Venus was seen at an altitude of $13^{\circ} 37'$, distant from Aldebaran $32^{\circ} 17'$. But at an altitude of $14^{\circ} 17'$ she was seen to be distant from Capella $35^{\circ} 22'$.

64. In the year 1649, on 3 August in the morning, Venus was seen at an altitude of $15^{\circ} 20'$, and distant from Aldebaran $32^{\circ} 38'$. But at an altitude of $15^{\circ} 50'$ she was seen distant from Capella $35^{\circ} 50'$.

65. On the following morning Venus was seen at an altitude of $18^{\circ} 6'$, and distant from Aldebaran $32^{\circ} 48'$; but at an altitude of $18^{\circ} 34'$ she was seen distant from Capella $35^{\circ} 34'$.

66. In the year 1651, on 2 February in the evening, Venus was seen at an altitude of $4^{\circ} 30'$, and distant from Sirius $75^{\circ} 11'$; the western azimuth of Venus, however,

had been $79^{\circ} 17' \frac{1}{3}$, because the position of Venus in that vertical plane was afterwards observed to be distant from the vertex $47^{\circ} 55'$ — from which I deduce the position of Venus to be in Aquarius $28^{\circ} 4'$, with northern latitude $8^{\circ} 4'$. (At the hour, namely, 5 hours 34 minutes after midday, it is therefore no wonder, since on that day too — and likewise on the twelfth, namely near the conjunction with the Sun — Venus, drawn out nearly along her length, displayed so great a latitude, conspicuous to us not only by telescope but also with the naked eye: a thing which the line drawn from the horn to the center of Venus indicated.)

67. In the year 1652, on 29 May, Venus was seen in the evening at an altitude of $24^{\circ} 57'$, and distant from Saturn (more easterly) $5^{\circ} 27'$; but at an altitude of $24^{\circ} 30'$ she was seen distant from Pollux's head (more westerly) — Venus herself being more elevated than it — by $4^{\circ} 45'$. A little afterwards she was seen at an altitude of $20^{\circ} 25'$, distant from Leo's mane $34^{\circ} 39'$; and then at an altitude of $19^{\circ} 52'$ she was seen distant from Regulus $34^{\circ} 32'$. And at that time Pollux was higher [in altitude] by $21'$.

In the year 1652, the remaining evening observations of Venus around the eighth hour after midday, thus:

[Margin: Observed on day 6 July, at the hour nearest the eighth after midday. The *Stellisfir*, in Tom. I of the *Almagestum Novum*, on the assumed hypotheses gave Venus's longitude in Virgo $30^{\circ} \frac{2}{3}$ and northern latitude $0^{\circ} 43'$.]

Parsing notes: Each numbered observation occupies one or two rows. The final column gives the comparison star ("from Spica" = à Spica; "from the Tail of Leo" = à Cauda □). The ½/⅓ fractional minutes are transcribed as printed.

76. In the year 1652, on 6 August in the evening: across the vertical plane of the Filar Triangle marking the meridian, with the plane directed straight to the center of Venus, Venus was found distant from the vertex $78^{\circ} 46' \frac{1}{3}$; and to this number of degrees, after the counted-off minutes $40^{\circ} 35'$, Arcturus reached, and there [Arcturus] was distant from the vertex $47^{\circ} 35'$.

77. In the year 1652, on 19 August at the civil hour, Italian style, 12, and about minute 6, the tail of □ [Leo] was caught at a distance from the vertex of $42^{\circ} 10'$. Thence, after 12 minutes from her rising, Venus was seen distant from Arcturus (more easterly) by $30^{\circ} 27'$, and after 4 minutes distant from the Heart of Hydra (more westerly) $52^{\circ} 52'$.

78. In the year 1653, on 2 February in the morning, Venus was seen distant from the bright star of the Eagle [Altair] $34^{\circ} 30' \frac{1}{3}$, and from the vertex $79^{\circ} 23'$. The Eagle, however, was distant from the vertex $66^{\circ} 20'$; thence Venus was seen distant from Antares $31^{\circ} 10'$, and distant from the vertex $78^{\circ} 46'$. Antares, however, was distant from the vertex $91^{\circ} 7'$.

79. In the same year, on 19 December, in the evening at the hour of the Eagle [Altair], an altitude was supposed of $4^{\circ} 37' \frac{1}{3}$ after midday. Venus, near her perigee, in the western azimuth was foreseen to be distant $25'$; from which she was seen distant from the vertex $66^{\circ} 55' \frac{1}{3}$. Hence was then deduced the right ascension of Venus $317^{\circ} 31'$, and southern declination $18^{\circ} 43'$.

80. In the year 1654, on 1 February in the evening, Venus — tending toward her maximum digression and being expected in azimuth of degrees $55'$ — was seen distant from the vertex $50^{\circ} 17' 60''$, and after minute $16' 45'$ was seen distant from the vertex $71^{\circ} 18'$.

81. On the following evening, however, Venus, in the same degree $55'$, was seen distant from the vertex $39^{\circ} 46'$; and after minute $25' 36''$ was seen distant from Sirius, distant from the vertex $69^{\circ} 55' \frac{1}{2}$.

82. In the year 1654, on 16 March, Venus was expected in the western azimuth of degrees $80'$; she was seen distant from the vertex $1^{\circ} 50' \frac{2}{3}$. Thereafter, after minute $19' 52''$, Regulus, more easterly, was distant from the vertex $53^{\circ} 59'$.

83. In the year 1654, on 5 April, Venus, in the evening in the western azimuth of degrees $95'$, was seen distant from the vertex $61^{\circ} 55'$; and after minute $13' 56''$, Venus was seen distant from the vertex $65^{\circ} 14'$.

84. In the year 1654, on 9 August in the morning, Aldebaran was distant from the vertex (more easterly) $46^{\circ} 22'$, while Venus was distant from the vertex $63^{\circ} 40'$ in the northeastern azimuth — the degrees precisely 85.

85. In the year 1654, on 24 August at the hour nearest the Italian 9, Venus was distant from the following shoulder of Orion at the vertex of her rising $62^{\circ} 54'$; she was seen distant from the vertex $73^{\circ} 14'$. Regulus, however, was [distant] $47^{\circ} 19'$, and soon afterward from Aldebaran $45^{\circ} 47'$.

86. In the year 1655, on 6 July in the evening, Venus was seen distant from the vertex $76^{\circ} 39'$ in the western azimuth of degrees 100; and inasmuch as her industry had been expected, thence from her she was distant from the vertex $64^{\circ} 33'$.

87. In the same year, on 10 July in the evening, the distance was seen [to be] from the vertex 79'; precisely in azimuth, item degrees 100, thence counted off 10' of time-minutes, Spica was distant from the vertex (more westerly) 66.

88. In the same year, on 6 August in the evening, Venus was expected at the western azimuth of degrees 80'; she was seen distant from it [the vertex] 77° 53'; thence after time 7' 45". Arcturus, more westerly, was distant from the vertex 42° 54'.

89. In the year 1656, on 8 January in the morning, Venus was seen distant from the vertex of degrees 74'; and distant from Spica 47° 35'; soon also Ophiuchus, distant from the vertex 32° 48'; and immediately the middle on the forehead of Scorpio was seen distant from the vertex 72° 34'.

90. In the same year, on 10 February in the evening, Venus was seen distant from the vertex 72° 36' in that azimuth, in which the center of the Sun was afterwards seen distant from the vertex 66° 18'. But before, after one hour and 24', when the observation of Venus had been taken, the distance of the Sun was 82° 44'.

91. In the year 1657, on 18 March in the evening, the distance of Venus was seen [to be] from the vertex 57° 27' $\frac{2}{3}$; and after minute 4' 18", Aldebaran was distant from the vertex 41° 3' $\frac{1}{2}$. When, however, Aldebaran reached the vertical plane, in which Venus had been observed, the distance of Venus from the vertex was 58° 17'.

92. In the year 1657, on 9 June in the evening, Venus was seen distant from the vertex 64° 50'; and from Regulus 33° 43' $\frac{2}{3}$. Then Venus was seen distant from the vertex 76° 20'; and from the head of Castor 10° 39' $\frac{1}{4}$; and then Regulus was distant from the vertex at the setting [point] 59° 10'.

93. In the same year, on 13 June in the evening, Venus was seen distant from the vertex 77° 48'; and from Regulus 33° 23'; afterwards she was seen distant from the vertex 80'; and from the head of Pollux 6° 58' $\frac{1}{3}$; and immediately Regulus was distant from the vertex 66° 6'.

Observations of the Most Illustrious Marchese Cornelio Malvasia, made at Modena, and set forth in his own Ephemerides, fol. 217.

In the year 1662, on 31 May, Venus was observed distant from the Sun 39° 25' (or by another computation 39° 3'); but on the computed parallaxes and Cassinian refractions it came to 39° 34', while Lansberg's computation gave 38° 48' — a difference of minutes 46.

Parsing notes: Columns give the comparison-star correction in degrees/minutes (Corr., G., I), Venus's place in longitude/latitude (Locus, G., I), and Lansberg's corresponding value (Lansb., G., I). "Lo." = longitude in the named sign; "La. B." = northern latitude. The hour-headings ("H. 0 50", "H. 2 5", etc.) give the time before sunrise or after sunset.

CAPUT IX

Of the Hypothesis of the Motions of Venus.

1. Here I suppose, or recommend to the reader for perusal, what I have explained at length concerning the various astronomers' hypotheses about the motion of Venus and of Mercury, in Book 7 of the *Almagestum Novum*. Many things, too, here in Book 5, on the occasion of Saturn, applicable to these inferior planets as well: see cap. 9 about the 20 modes of observing the places of the planets; cap. 12 about the Geometrical Hypothesis, rather than the loci of the planets; about a cone and about reconciling the diurnal motions with the planet's own proper motion in a fluid heaven. As to what motion of the Earth does not agree — as I show at the end of Book 1 — it is better, I say, that this be done through eccentrics and epicycles, or through a single ellipse, so long as it comes nearest the truth. The rest, if there be any, I indicate here more briefly.

2. From what was said in Book 1 about the Sun's parallax (far less than Tycho posited), it is clear what Longomontanus put in Book 2 of his *Theorica*, cap. 17, about the parallax of Venus and of Mercury: a comment on the restitution of the

Sun's parallax by Tycho, which needs some line of his own. It is to be excused, moreover, on this account, that on account of the obliquity of the sphere in the Danish horizon it was not permitted to continue the observations of Venus at her greatest elongation from the Sun, the twilight impeding; and therefore, besides 9 Tychonic observations of Venus, six others — cap. 19 — at her greatest digressions.

[Margin: Kepler's truthful fear about the motion of Venus.]

Kepler's ingenuity in the foundation of his Ephemerides — pages 14 and 15 — confesses that error can be feared in the Rudolphine [Tables] computed for Venus, never differing from the heavens beyond 15 minutes. He exhibits, moreover, a specimen of them on an assumed example: in the year 1574, on day 16 September, in the morning at hour 4, he saw Regulus occulted by Venus; then, however, the Rudolphine [Tables] exhibit the Heart of Leo in Leo $23^{\circ} 54' 39''$, with northern latitude $0^{\circ} 26'$. But Venus [was] in Leo $23^{\circ} 55'$, with northern latitude $0^{\circ} 25'$.

Lansberg's Tables, however, cannot be trusted so far in this star, as is clear from eleven [observations] which I bring forth from the Thesaurus from his own observations — for not everywhere does he treat it faithfully enough. Be there an example in this conjunction of Venus with Regulus, of which we spoke a little before from Mästlin's observation; for Lansberg, on page 173 of his Thesaurus, gives Venus then in Leo $24^{\circ} 9' 3''$, with northern latitude $0^{\circ} 27'$. He does not doubt to place Regulus then beyond Venus, namely from the Sun's place $14'$, with latitude $5'$, and to locate it in Leo $24^{\circ} 7'$, with northern latitude $31'$. This, therefore, having been dismissed to the Bullialdine [computation], with Lubentius reading...

[Margin: Lansberg's errors are to be feared.]

5. Bullialdus, indeed, in Book 9 of his *Astronomia Philolaica*, accustomed to weigh more deeply many observations faithfully on this matter, acknowledges indeed that the mean motion of Venus in the Rudolphine [Tables] is to be advanced, but not the aphelion to be drawn back, as they draw it back. He warns, moreover, the prudent that the conjunctions of Venus with other stars observed with the naked eye are not to be understood so precisely, because Venus, by the very great explanation of the rays, conceals that interval which the exiguous interval of the Sun's place and of the neighboring stars contains in reality. Malvasia nonetheless uses Bullialdus' [computation], as if from the false parallax of the Sun, even up to $3' 4''$ in a minute he is in error.

[Margin: Lansberg in error.]

6. We, in order that we might also at the expense of the Tables monitor the other planets with more observations, have made very many for the most part: the conjunctions of Venus with the fixed stars, or with the other planets; and indeed more than those places of Venus, which Tycho or Longomontanus deduced from the Sun in her greatest digressions — from the false parallax of the Sun, and of Venus, and the obliquity of the ecliptic — whence they differ from the Tables by 6 or 8 minutes thereabouts. We here send ahead some specimen of our Tables.

1. In the year 1494, on day 18 September at hour 17 after midday, at Nuremberg, Bernhard Walther [Bernardus Vualtherus] saw Venus more westerly than Regulus by 10 minutes. Lansberg extorts this observation from his own Tables — he does not doubt to place Regulus then in Leo $23^{\circ} 19'$, that is $34'$ beyond what is owed, collecting [it]; and the place \square from his Tables in Leo $23^{\circ} 20'$. But Regulus was in reality in Leo $22^{\circ} 44' 35''$. Venus, moreover, from our Tables in Leo $22^{\circ} 45'$. I reckon that on account of Venus's great latitude, she was seen by Walther more westerly than Regulus.

[Margin: Lansberg in pain.]

2. In the year 1574 — as Kepler relates in his *Astronomia Optica*, page 305 — Mästlin [Mæstlinus], on day 15 September at hour 16 after midday, saw Regulus covered by Venus. Regulus was for me in Leo $23^{\circ} 52' 8''$, with northern latitude $26^{\circ} 10'$. Venus, moreover, in Leo $23^{\circ} 53' 30''$, with northern latitude $26^{\circ} 25''$. There is therefore no need of the added expansion of the rays, by which with the naked eye Venus is wont to appear about Venus [*sic*] more than it had covered Regulus.

3. In the year 1590, in the same [year], with Kepler as witness, on day 3 October, in the old style, in the morning at hour 3 after midnight, Mästlin saw Mars covered by Venus, candid with light. To me from his Tables Mars proceeds in Virgo $15^{\circ} 33' 7''$. Venus in Virgo at hour $15^{\circ} 32' 10''$, with the same nearly latitude; therefore Venus, with rays altogether expanded, strikes Mars.

4. In the year 1598, on 15 September, old style, in the morning at hour 3, Kepler saw Venus scarcely risen, covering Regulus, namely at Graz [Gratij]. For Regulus was for me then in Leo $24^{\circ} 12' 24''$. Venus, moreover, in Leo $24^{\circ} 18' 30''$. But by the neighboring radii of the horizon she expanded more amply, and could be seen the more obscure Regulus.

5. In the year 1632, on 31 July, Gassendi at Paris and Hortensius at Amsterdam in the morning before dawn observed the conjunction nearest to Venus of Venus and Mercury; but Gassendi conferred it on a time a little before hour 4 after midnight; Hortensius, however, on hour $11 \frac{1}{3}$ after midday of day 30. Did then

Mercury appear more easterly than Venus by minutes 3' 30"? The Prutenic [Tables] erred so far, that with the conjunction altogether on these days they anticipated by five days; and Longomontanus, who imitates the Prutenic in this slightly corrected, is inexact: he has day 30 July; in these the hour 11 ½ in □ at degree 24° 40' with northern latitude 34'. Mercury...

Mercury, moreover, in □ degree 27° 33' with latitude degree 1° 24'. Lansberg, moreover, [places] Venus in □ degree 24° 24' 42", with northern latitude 34' 43"; and Mercury in □ degree 24° 30' 4", with latitude 39' 5". We collect Venus in □ degree 24° 22' 15", and Mercury in □ degree 24° 36' 40".

6. In the year 1633, on 26 May, Bullialdus at Paris at hour 9 after midday saw through the tube [telescope] Venus more westerly than the bright star of Pollux's left shoulder by 18' ½ — which for me was then in □ degree 18° 33'. Venus therefore was seen at her nearest in □ degree 18° 14' 30"; from the Tables, however, she was in degree 18° 18'.

LIBER NONVS — BOOK NINE

BOOK NINE, CONTAINING THE OBSERVATIONS OF THE PLANET MERCURY AND THE HYPOTHESIS OF ITS MOTIONS

CAPVT I — CHAPTER 1

Ancient Observations of Mercury, from the year 265 before Christ
down to the year 807 of Christ

There is no planet whose motion gives the astronomer more trouble than Mercury — partly because of the scarcity of careful observations, and partly because Mercury, even at its greatest elongations, nonetheless stays so close to the Sun that it appears only at dawn or twilight, after the Sun has set, and only then if it is not obscured by the vapors of the horizon, or close to them. Hence, as Ptolemy says (*Almagest* IX.7, on which point see also IX.9), we have received few observations of this kind, and those can be obtained only rarely.

[Margin: The difficulties of observing Mercury]

Copernicus too (*De Revolutionibus* V.30) prefaces the same difficulty in this way: "Those who have shown us the path of this star's course did indeed examine it before us, yet they have not, like the breezes [winds?], carried it off — as the Nile is borne along, so they say." We do not deny that nature herself is at fault here, or that the very tranquility of the air, and moreover the great obliquity of the sphere where the inhabitants dwell, makes Mercury rarely visible. For at its greatest distance from the Sun it rises in Aries and Pisces, or it sets in Virgo and Libra; and it represents itself in some manner in Cancer or Gemini — but those twilights, whether of night only or, when the twilight is brighter, when the Sun has not yet withdrawn into the lower part of the heaven — for many of these reasons it is wrapped in ambiguities and is scrutinized with no slight labor and toil. Hence Ptolemy and Walther were compelled to such a course of dealing.

For this reason Longomontanus too was compelled to it (*Astronomia Danica* II, *Theorica*, ch. 18) on account of the obliquity of the sphere; he confesses indeed

that in Denmark, because of the season, scarcely ever can a continuous observation of the elongations of Venus and Mercury from the Sun be carried through during the summer twilights. And in ch. 20 he adds: "Let us put our last hand to Mercury, whose slipperiness has thus far given the astronomers of our age no less trouble than the terrestrial Mercury [quicksilver] gives the alchemists, who have pursued it rather by traces and suspicions of the ancients than by truly observing the heavens, and who have been bound up in their ignorance." And although it is a cause for amazement that there is a discrepancy among the Alphonsine and Copernican calculations of as much as 7 degrees — yet this could not be avoided even from the tables of certain more recent men. Nonetheless I have judged it worth the effort to set out in order the observations, such as they have been handed down to us by the men of old.

In the year 484 of Nabonassar, on the 18th day of the month Thoth following — that is, on the 19th day [of our reckoning], in the year of Ptolemy Philadelphus 21 — Mercury was observed to be distant from the front of Scorpius by one whole [degree], by a line drawn toward the Boreal [northern] front of Scorpius; and it was distant from the same line toward the north by two Moon-diameters from the Boreal front of Scorpius. But on the 26th of Scorpius it was distant from the aforesaid line by a hand's-breadth $\frac{1}{2}$ [semis] of an hour [?], in succession — whence Ptolemy (*Almagest* IX.10) concludes that Mercury was on the 19th day at its greatest elongation from the Sun. This was the year 265 before Christ, in which year Longomontanus (II, *Theorica* ch. 2) places it. On the 14th of November, at the 17th hour after midday, at Hafnia [Copenhagen], the Boreal front of Scorpius was [observed] in degree $1^{\circ}36'$ of Scorpius, of latitude $1^{\circ}16'$; the other star [was] in the place of Scorpius $2^{\circ}35'$, of Boreal latitude $2^{\circ}20'$. Lansberg, moreover, in his *Thesaurus*, observed Mercury's place in observation 1 of Mercury [observatio 1. Mercurij]; he says the most boreal of Scorpius was in Scorpius degree $1^{\circ}46'$, of latitude $1^{\circ}15'$. And from this observation it had belonged to Hipparchus that it was in Scorpius $2^{\circ}46'$ of Boreal latitude $2^{\circ}13'$. But from his own tables it was in degree $2^{\circ}47'$. Boulliau, finally, (X.9) says that in that year before Christ 265, at hour $16^{\circ}30'$, Uraniburg said the Boreal front of Scorpius was in Scorpius degree $1^{\circ}13\frac{2}{3}$, of Boreal latitude $1^{\circ}5'$; the middle, moreover, of the front of Scorpius in degree $0^{\circ}36\frac{2}{3}$ and of latitude $1^{\circ}54'$; therefore Mercury was in Scorpius degree $1^{\circ}57\frac{1}{3}$; from his tables, in degree $2^{\circ}6'$. To me the year was 265 before Christ, and the day the 14th of November.

In the year of Nabonassar 486, on the 17th day, Choeac following [?], 18 — that is, in the year 23 of Dionysius [Ptolemy II], in the morning of the 29th of Aquarius — Mercury was distant from the most brilliant tail of Capricorn toward the north by

three Moon-diameters; whence Ptolemy (*Almagest* IX.7) gathers that Mercury was in Capricorn $20^{\circ}0'$ and at its greatest elongation from the middle place of the Sun, $25^{\circ}50'$. This was the year 262 before Christ, the 11th day of February.

In the same year 486 of Nabonassar, on the 30th of Payni — that is, in the year 24 of Dionysius — on the 18th of Leon, in the evening, Hipparchus observing, Mercury preceded the Spica by a little more than three degrees. Hence Ptolemy (*Almagest* IX.7) gathers that Mercury was in Virgo $19^{\circ}30'$; but Lansberg observed it in Virgo $21^{\circ}26'$; and from his tables he places Spica in Virgo $22^{\circ}26'$, and Mercury in degree $19^{\circ}11'$. This was the year 262 before Christ, the 23rd day of August.

In the same year of Nabonassar, on the 30th of Pharmuthi, on the 5th of Dionysius following, Mercury was observed in the evening by Hipparchus; it was seen in succession to be distant by three Moon-diameters from the line of the horns of Taurus. Whence Ptolemy (*Almagest* IX.7) gathers that Mercury was in Taurus $23^{\circ}40'$, with a greatest elongation from the middle place of the Sun of $24^{\circ}10'$. This was the year 262 before Christ, the 24th day of May.

In the year 491 of Nabonassar, on the 5th of Pharmuthi, on the 28th of Dionysius — in the evening, Mercury [was observed] on a straight line and most directly toward the head of Gemini. Hence Ptolemy (*Almagest* IX.7) gathers that Mercury was in Gemini $2^{\circ}50'$, and at its greatest elongation from the middle of the Sun of $26^{\circ}30'$. This was the year 217 before Christ, the 28th day of May.

In the year 512 of Nabonassar, on the 9th of Thoth following — that is, on the 14th day of the month Dius — in the morning Mercury appeared higher by half a cubit [semibrachium] than the fixed star which is at the southern extreme of the scissors of Libra. Accordingly Ptolemy (*Almagest* IX.7) gathers that Mercury was in Libra $14^{\circ}10'$ and at its greatest elongation from the middle place of the Sun of 21° . This was the year 237 before Christ, the 30th day of October.

In the year 564 of Nabonassar, on the 27th of Thoth following — that is, on the 28th of the second Chaldaean [reckoning] — in the morning Mercury was higher by half a cubit [semibrachium] than the Boreal front of Scorpius; this was observed by Apelles. Hence Ptolemy (*Almagest* IX.7) gathers that Mercury was in Scorpius $2^{\circ}20'$, of which the greatest elongation from the middle of the Sun was $22^{\circ}30'$. This was the year 185 before Christ, the 3rd day of November.

In the year of the Emperor Hadrian 14, on the 18th of Messori following, Theon observed Mercury at its westernmost, distant in advance from the Heart of Leo [Regulus] by $3^{\circ}50'$. Hence Ptolemy (*Almagest* IX.10) says that it was in Leo $6^{\circ}20'$, very near; and the greatest elongation from the middle motion of the Sun was

16°15'. Copernicus (*De Revolutionibus* V.27) says it was in Leo 6°15'; but he adds that Theon was at Smyrna; and the day was the illustrious 4th of July, at the 6th hour after midday. At Uraniburg, the Heart of Leo was in Leo degree 28°35'; therefore Mercury was in Leo 7°18', with a greatest elongation of 26°59'; but in truth, because the place of the Sun by Boulliau's tables was in Cancer 10°19'32", the true elongation was in Cancer degree 4°[?]. This was the 4th of July.

In the year of Hadrian 16, on the 16th of Phamenoth, at the 5th hour 30' after midday, Mercury was seen at its greatest elongation from the middle motion of the Sun, and from comparison with the splendid Hyades it was found to be in the first degree of Pisces, distant from the middle motion of the Sun by degree 21°15'. By Ptolemy (*Almagest* IX.7). This was — as Boulliau correctly notes (X.9) — the year of Christ 132, the 2nd of February, at hour 2°40' after midday. At Uraniburg, and at that time, the eye of Taurus was in Taurus degree 12°17'. But by Boulliau, the eye of Taurus [was] in Taurus 13°25'½; therefore Mercury [was] in Pisces in degree 2°8½; and the greatest elongation from the true place of the Sun was 19°19'51".

In the year of Hadrian 18, on the 18th of Epiphi, on the 19th [of our reckoning], Mercury [was at] its greatest elongation; it was seen very faint, and with a small light through comparison with the splendid Hyades, in Taurus degree 18°45'; and it was distant from the middle of the Sun by degree 21°15'. By Ptolemy (*Almagest* IX.7). This was the year of Christ 134, the 3rd day of June.

In the year of Hadrian 19, on the 14th of Athyr following, on the 15th [of our reckoning], in the morning Ptolemy saw Mercury at its distance from the Heart of Leo, in Virgo degree 20°12'; and most greatly distant from the middle of the Sun by degree 19°3'. By Ptolemy (*Almagest* IX.6, on which point see VIII, and *De Revolutionibus* V.26). This was the year of Christ 134, the 2nd of October.

In the year of Antoninus 19, on the 14th of Pachon, in the evening, Mercury [was] at its greatest elongation from the middle motion of the Sun, by degree 23°15'; it was observed by Ptolemy in Taurus 1°20' per its distance from Aldebaran. By Ptolemy (*Almagest* IX.8, *De Revolutionibus* V.26). This was the year of Christ 135, the 15th day of April.

In the year of the Emperor Antoninus 1 [first], at the Epiphi 20, on the 21st [of our reckoning], in the evening, Ptolemy by means of the astrolabe observed Mercury in Cancer degree 7, distant most greatly from the middle motion of the Sun by degree 26°5'. By Ptolemy (*Almagest* IX.7, *De Revolutionibus* V.26); on which point

see what years of Christ they are: 135. By Ptolemy (*Almagest* IX.7, *De Revolutionibus* V.26).

In the year of Antoninus 2, on the 23rd of Messori following, on the 24th [of our reckoning], in the morning, Ptolemy observed Mercury by means of Aldebaran, in Gemini degree $20^{\circ}5'$; and most greatly distant from the middle of the Sun by degree $20^{\circ}15'$. By Ptolemy (*Almagest* IX.9, *De Revolutionibus* V.27); on which point he adds that it was the year of Christ 139, the 21st of Messori. By Boulliau (X.9), he reckons in that year of Christ 139, on the 12th day, in [Messori? — middle of the night?], hour 7, $1^{\circ}5'$; at Uraniburg, in the observation 5, Mercury was in the place of Aldebaran; he gathers Mercury was in Gemini $21^{\circ}16'$; and most greatly distant from the place of the Sun existing in Cancer $13^{\circ}21'42''$. With Ptolemy he notes the same date thus: Messori, [in margin or note: the τὸ τικδ? hoc est ?], this is, [of the Messori? 24], or proceeding from the 23rd to the 24th. Now in truth, by our chronology reformed, the year was 886 of Nabonassar, of which the first day Thoth falls on the 10th of July; whence inclusively numbered up to the 23rd day, Messori falls on these 23 days of July, and these 24 in 8 July [?].

In the year again of Antoninus, at the Epiphi 2, on the 3rd [of our reckoning], in the evening, Ptolemy at an equal hour before midnight $4^{\circ}30'$, observed Mercury by means of the astrolabe, with a greatest elongation in Gemini, by degree $17^{\circ}30'$, per the comparison with the centre of the Moon situated in degree $1^{\circ}10'$. By Ptolemy (*Almagest* IX.10, on which point see VIII, and *De Revolutionibus* V.26 [?]). And Lansberg too in his *Thesaurus*, observation 3: Mercury per the place of the Moon gathers that it was in Gemini degree $17^{\circ}42'$. By Boulliau (X.9) he says in that year of Christ 139, the 11th of May, at hour 17 after midday; at Uraniburg (VI.9) gathers Mercury per the prior observation to have been in Gemini degree $18^{\circ}35'$ distant; but in truth, from the place of the Sun in degree $24^{\circ}8'37''$; but Lunar observation in truth was in Gemini degree $19^{\circ}2'$ distant; from the true place of the Sun in degree $24^{\circ}56'$; and Boulliau refutes Ptolemy, [saying it was] falsely distant from the Heart of Leo. The year was 139 of Christ, and the day was the 11th [of] May 17 [?].

In the year again of Antoninus 4, on the Phamenoth 18, on the 19th [of our reckoning], in the morning, Ptolemy observed Mercury from Antares in Capricorn $13^{\circ}10'$, in a greatest elongation from the middle motion of the Sun, by degree $26^{\circ}30'$. By Ptolemy (*Almagest* IX.7, *De Revolutionibus* V.26), adding that it was the year of Christ 141, completed 140, and besides those 67 and a scruple of almost 12; and so he adds that it was the year of Christ 141, the day Martii [March] 8. By Boulliau (X.9), in that year 141, the day the 7th of February —

incident in February 11, on the 16th of [February?]; and so Mercury was in Capricorn degree $14^{\circ}43'53''$, distant most greatly by degree $28^{\circ}18'54''$; from the true place of the Sun existing in Aquarius degree $13^{\circ}0'27''$. There remains a true elongation; the year 141, the 7th of February.

— with a false latitude, yet Ptolemaic, by degree $2^{\circ}9'$. Thus Kepler too there, in the end of his *Dissertationes* with the *Nuncius Sidereus*, sets it out from Thesis 98. Samuel Hafenreffer, Aimoinus the monk [Aimoinus Monachus], and an anonymous author of the Sabellican Franks [annals], likewise Eginhard, Vincentius, the Lycosthenes, the Polydorians, Volaterranus, Beda, and others bear witness that that spot persevered under the Sun for seven days, or — as Beda has it, or as most have it — for [several] days; and in truth see here also the Lycosthenes who have the year 808. See here whoever wishes to answer Kepler from the theses of Samuel. But Scaliger had earlier subscribed to this from the spots [maculis] of the Sun to Kepler; and Galileo, on the solar spots, and Gassendi in the *Epicurum* (page 898) say that it was from the larger spots of the Sun, adding that Kepler, after the spots restored in the Sun, detected the error, and for [eight times? — octies] he restored the size to the ancients eight days. But to me it can in no way seem that Mercury could not be seen through this telescope; yet it could not be seen with a similar telescope through any other, [though] Mercury under the Sun in 1607, on the 28th of May, was able to be seen — which I indicate in its own singular phenomenon. Whatever may be the case, Mercury seen under the Sun, if it had been seen before by others, who refer to exercise 72, against Cardanus and Scaliger — to whom the Coimbrans wrongly attribute the same observation, *De Caelo* IV.4, art. 2, and Scheiner subscribed to the same observation under the disc of the Sun. Furthermore Scheiner in the *Rosa Ursina* (page 412) teaches that Mercury 4 hours only could be seen under the disc of the Sun, since the spots can be busy under it for many days.

CAPVT II — CHAPTER 2

Observations of Mercury made by Bernhard Walther of Nuremberg

Besides the observations made by ocular estimation, certain others made by means of armillaries are liable to error, by no less than 10 minutes — as was said of Walther's observations of Saturn, number 33. Next, let it likewise be valid here too of the things which Walther himself noted concerning refractions in [the case of] Venus.

In the year 1481, on the 22nd of October, nearly one hour before sunrise, Walther saw Saturn and Mercury in the same place of the heaven, Mercury [being] more

easterly, but more southerly by a little more than a Lunar diameter; the eastern, moreover, in degree 28 of Aries, and the 3rd of November more easterly in degree 12°26' of Scorpius; but the conjunction of Mercury with Saturn was on the 21st of October, exorbitant from the tables themselves.

In the year 1482, on the 11th of October, a little before sunrise, Mercury was seen in nearly the same longitude as the Moon, but a little more southerly than a Lunar diameter. On the day the 25th of October it disappeared with the clearest sky.

In the year 1484, on the 16th of January — immediately, since Mercury was in contact with the horizon, Walther applied the hanging weight to his clock so that it returned from noon to noon; and it had on the hour-ring [zona horaria] 56 teeth [denticulos], which once it had revolved, and moreover 36 teeth [denticuli]; when the center of the Sun appeared in the horizon — wherefore Mercury apparently rose before the Sun by hour 1°37'; which nearly agreed with Walther's calculus.

In the year 1488, on the 16th of January, at the 5th hour 30' after midday, Mercury was seen distant from Jupiter by a ray [radius] of degree 1°42', and westerly from both limbs of the Moon; and the Planet [was in] degree 1°24'; but Mercury was more boreal than Jupiter. On the following day Mercury [was] more easterly and more boreal in degree 2°22'. But there is an error in the number of the day, of 16'.

In the year 1491, on the 18th of August, Walther rectified his armillaries by means of Aldebaran, nearly one hour before sunrise; he found Mercury in degree 23°10' of Leo. On the day the 30th of August, at the same hour in degree 27°10', and on the day the same hour in degree 28°3' of Leo, with Boreal latitude 53'; which latter observation he prefers to the earlier ones on account of his better-rectified instruments.

In the year again 1491, on the 2nd of September — by armillaries rectified again through Aldebaran, I found Mercury in the first degree, 13' of Virgo, one hour before sunrise: latitude north, I found in degree 1°15', the heaven [being] most serene, all the other things being most diligently observed, the position of the instruments [being] certain — confide in this one.

In the year 1491, on the 3rd of September, one hour before sunrise, by armillaries, as above, rectifying, he found Mercury in Virgo degree 3°51'; but he adds: "Diligently observe — true latitude north 1°20', only changed by that, makes a doubt about it for me. Nonetheless Lansberg in the *Thesaurus*, choosing this,

says Aldebaran was in Gemini degree $2^{\circ}12'$; therefore Mercury [was] in Virgo degree $3^{\circ}42'$; but from his tables [in] degree $3^{\circ}38''$ — with Boreal latitude $1^{\circ}17'$.

In the year again 1491, on the 9th of September, at hour 5 p.m., he found Mercury in Virgo degree $1^{\circ}13'$, with Boreal latitude. Mark, says Walther, what a great difference there is from the tables: Mercury appeared very thin, and far beyond doubt around the term of the occultations. Consider also the refraction of the rays, that is, the modicum [small amount] of refraction from the horizon, [when] on the 11th day it appeared most feeble — so that there was not the most observable and clearest observation. Nonetheless, Copernicus, destitute of his own observations (V.30), chose this one, but at the observation of Mercury in Virgo degree $1^{\circ}30'$, [namely] when it has been so reckoned; it was distant from the middle place of the Sun by degree $13^{\circ}15'$, nearly.

In the year 1504, on the 9th of January, with mid-Heaven existing in degree 10 of Scorpio, by the Heart of Leo, Mercury was in Capricorn degree $3^{\circ}15'$, with Boreal latitude $45'$; he adds [it was] most diligently observed; but Copernicus (V.30) [says] on the day the 6th hour $30'$ after mid-night, observed by Johann Schöner too, Mercury [was] in Capricorn degree $3^{\circ}20'$, with latitude $45'$; and it was distant from the middle place of the Sun by degree $23^{\circ}42'$.

In the year 1504, on the 11th of March, he rectified [the armillaries] toward the Sun, by armillaries; Mercury was observed clear and of notable size, in Aries degree $17^{\circ}30'$, with Boreal latitude $1^{\circ}51'$, [the Sun] being in mid-Heaven in degree 18 of Cancer.

In the year 1504, on the 17th of March after midday, by means of Aldebaran in Gemini degree $2^{\circ}45'$, Walther found Mercury in Aries degree $26^{\circ}30'$, with latitude north $3'$, [the Sun] being in mid-Heaven in degree 25 of Capricorn. But Schöner, as Copernicus refers (V.30), [says it was] mediating mid-Heaven in Cancer degree 25, that is, in hour $7^{\circ}30'$ [after midday], saw Mercury in Aries degree $26^{\circ}6'$, with latitude north $3'$; and so [it was] distant from the middle place of the Sun by degree $21^{\circ}17'$.

In the year 1504, on the 18th of March after midday, by mediating mid-Heaven in Cancer degree 25 positioned, Aldebaran in Gemini degree $2^{\circ}45'$, he found Mercury in Aries degree $26^{\circ}30'$, with latitude north $3'$.

In the year 1504, on the 24th of March after midday, mediating mid-Heaven [in] degree 5 of Leo, Aldebaran positioned in degree $2^{\circ}45'$, Mercury was found in Taurus degree $0^{\circ}5'$, with latitude north $3^{\circ}30'$. From these observations Boulliau (X.9) gathers the greatest elongation of Mercury from the Sun to have been, on

the 18th of March at hour 18 at Nuremberg, of 7°15'; and since Aldebaran was in Gemini degree 2°50'2/3 and from the refractions Mercury [was] reckoned with the eye in Aries degree 26°29' in its orbit, but [reduced to] 35' in the Ecliptic; in truth the place of the Sun [was] in Aries degree 7°41'36".

CAPVT III — CHAPTER 3

Tychonic Observations of Mercury

Longomontanus (*Astronomia Danica* II, *Theorica* ch. 20) subjoins eight places of Mercury observed by Tycho at Uraniburg, with two others observed by himself at Hafnia [Copenhagen], with the supputation added from the Danish Tables for the days of the old style, and below, where the hours are after midday—

Liber IX — De Mercurio (Mercury), Caput III–IV

(Continuation of Caput III: "Mercury observations of Tycho." Pages 345–347 of the source, folios 345–347 =)

Table (top-left): Tychonic Mercury places, summary

This table summarizes ten observed Mercury places, giving the observed longitude (*Long. observ.*) by zodiacal sign and the supposed (calculated) longitude (*Long. supp.*), together with the observed latitude (*Latit. obs.*). The final column letter "B" marks a southern (*Borea/austrina*) latitude indicator as printed.

10	1610	Dec.	5	19	0	♐	2	42	2	35			[not observed]

Parsing notes: The zodiacal-sign glyphs in the "Long. observ." column are faint in this scan; readings ♏ (Scorpio), ♏ (Libra), ♏ (Aquarius), ♏ (Pisces), ♊ (Gemini), ♊ (Sagittarius) are my best resolutions. Rows 3 and 10 carry "nō observ." (not observed) in the latitude columns. Row 7's sign glyph and supposed-minutes value are uncertain.

[Boulliau], in Book X, chapter 7, concerning the first of the aforementioned observations — that of 14 November 1585, hour 19 — states that the true place of the Sun was Sagittarius 2°56'45", and accordingly that Mercury was distant from the Sun by 19°52'45". But from the Rudolphine tables [Mercury] is found to have been in Scorpio 13°7'45", the difference of the observation being 5°45".

[Tycho Brahe] himself, in his *Epistolae* (p. 56), records three of the observations transcribed below in Old Style, in hours after midday at Uraniborg:

Table: January 1587 — Mercury longitude and latitude (three reckonings each)

For each date, three derivations are given: *Observ.* (observed), by the *Alphonsine* tables [Alphons.], and by *Copernicus* [Copern.].

D.	H.	M.	Source	Long (Sign)	Mer cur. (Sign)	Long		Latit		[flag]

						23	3	1	29	B
						19	21	1	1	B
13	15	5	21 → 15 5	Obse rv.	□ Aqu	21		20	1	40

D.	H.	M.	Source	Long Mercur. (Sign)	Long . G.	Long . M.	Latit ude G.	Latit ude M.	[flag]
			21		ariu				
			Alph ons.		24	18	1	41	B
			Cope rn.		19	33	1	39	B

Parsing notes: The "D. H. M." columns give day, hour, minute. The sign-glyph is read ♒ (Aquarius) for all three; flags A/B in the final column reproduce the printed northern/southern (*austrina/borea*) latitude markers.

[Boulliau], Book X, chapter 7, makes use of the observation of the 9th, adding the true place of the Sun to be Capricorn 29°13'12"; and accordingly the distance of Mercury from it [is] 18°34'48". But from the [Rudolphine] tables he gathers Mercury's place to have been in Aquarius 17°35'12".

[Lansbergius — Philip van Lansberge] in his *Thesaurus* uses the observation of the 14th, but from the tables gathers Mercury's place in Aquarius 21°8'53", with a latitude of 1°31' — yet by the calculus of triangles, 1°21'.

In the year 1589 Mercury was observed by [Tycho Brahe] near its greatest elongation from the Sun, on the days of April 1, 2, 3, 4, 6 and 11. These observations, selected by his own calculation from a manuscript of Tycho's, were transmitted to me by Fr. Albert Curtius [Albertus Curtius] of our Society [S.J.], and are written below. To them is added the corrected time, examined at the following midday on account of the clock.

Table 14: Day 1 April, evening [Die 1. Apr. vesp.]

Columns: time (*H. M.*); distance of Mercury from Aldebaran [Distāt. ☿ ab Aldeb.] in G./M.; declination of Mercury, northern [Declinat. ☿ Borea] in G./M.; altitude of Mercury [Altit. ☿]; arc of the Lesser Dog setting / occidental [Canis min. oc. Alt.] in G./M.

H. M.	Dist. ☿ ab Alde b. G.	Dist. M.	Decl n. ☿ Bore a G.	Decl n. M.	Altit. ☿ G.	Altit. M.	Canis min. occid. G.	Canis min. M.
7 36 / 41 corr.	25	11¼	16	59½ / 17 1	9½		25	26
7 40½ / 45½	25	10	17	1½	8	50	26	32
7 45½ / 50	25	11	17	5 / 17 4½	8	20	17	40
7 48½ / 53 corr.	25	11			7	50	28	24

Parsing notes: Two clock-times are given per line (the first observed, the second a corrected reading, "corr."). Several declination cells carry two stacked values (e.g. 16°59½' over 17°1'); both are transcribed.

Table 15: Day 2 April, evening [Die 2. Apr. vesp.]

Same column scheme; arc-column heading here is *Cā. min. occid.* (Lesser Dog, occidental).

H. M.	Dist. ☿ ab Alde b. G.	Dist. M.	Decl natio ☿ G.	Decl n. M.	Altit. ☿ G.	Altit. M.	Cā. min. occid. G.	M.
7 51¾ / 7 56 corr.	25	10½	17	4½ / 4⅔			29	11
7 55½ / 8 0 corr.	25	10	17	4½ / 17 5	7	0	30	8

H. M.	Dist. ☿ ab Alde b. G.	Dist. M.	Decli natio ☿ G.	Decli n. M.	Altit. ☿ G.	Altit. M.	Cā. min. occid. G.	M.
7 59½ / 8 3½	25	9¼	17	4½ / 17 5½	6	35	32	4
8 3½ / 8 7½	25	8½	17	6 / 6½	6	0	32	0
8 8 / 8 11¾	25	8	17	6⅔ / 6⅔	5	30	33	5
8 12½ / 8 16 corr.	25	6¾	17	7½ / 7½	5	0	34	8
8 16½ / 8 19¾	25	6½	17	9¼ / 9¼	4	30	35	6
8 19½ / 8 23	25	5½	17	9¼ / 9¼			35	54
8 23½ 26 corr. / 8 27 30 corr.	25	5½ / 4½	17 [both /utro q;]	9½	3	40 / 10	36 / 37	42 / 42

Parsing notes: This table is tightly set with many stacked half-values; the final row carries the note "utroq;" (*utroque*, "by both [methods/instruments]"). The "26 corr." and "30 corr." are corrected-second annotations to the clock times. Several altitude cells are blank in the source.

For the examination of the armillaries [Pro Armillarum examine]:

At H. 8 32: Declination of Aldebaran [Declinatio Aldebaræ] — G. 15 38¼ / 15 38.
 Altitude of the same [Altitudo eiusdem] 15 20. — It was fairly clear and calm [Fuit
 satis serenum, & tranquillum].

Table 15 (right column continuation): Day 2 April, evening [Die 2. Apr.
 vesp.]

This block repeats the Day-2 series at finer resolution (continuing the right-hand
 column of the page).

H. M.	Dist.		Decli			Cā.	
	Alde b. G.	Dist. M.	natio ☿ G.	Decli n. M.	Altit. ☿ G.	M.	min. occid. G. M.
8 0 / 8 2¼ corr.	23	55¼	17	57⅔ / 17 38½	7	15	
8 5½ / 8 7 corr.	23	54½	17	38 / 17 38½	6	50	32 53
8 9½ / 8 11½	23	53½	17	38¾ / 17 38½	6	0	34 3
8 15 / 8 17½ corr.	25	52	17	40½ / 17 40½	5	20	35 25
8 19½ / 8 22	23	51½	17	41½ / 17 41½	4	50	36 34
8 24 corr. 26½	23	51	17	42 / 17 42½	4	15	37 46
8 29½ / 31½	23	50½			3	35	39 4

Parsing notes: One declination cell reads "17 57 $\frac{2}{3}$ " stacked over "17 38 $\frac{1}{2}$ " — the 57 $\frac{2}{3}$ value breaks the smooth 38–40' progression of its column and is flagged below as a likely compositor error. Several distance-degree cells read 23 where neighbors read 25; transcribed as printed.

It was moderately clear and calm enough [Fuit mediocriter serenum, & tranquillum satis].

On these days the clear sky had been continuous, yet unevenly so; from the horizon up to an elevation of about 39° or beyond, dark little clouds had been rising, and descending below the said altitude they obscured it [*ascendentia, & descendentia infra dictam altitudinem obtegentes*].

There follows the calculation from the above-written observations [Sequitur calculus ex suprascriptis observationibus]:

On 2 April, h. 8 5': Distance of Mercury from Aldebaran [Distant. ☿ ab Aldeb.] 23 55.

Quantity	G.	M.	[body]
Declination of Mercury, limited [Declinatio ☿ limitata]	17	40	
Declination of Aldebaran [Declinatio Aldebaræ]	15	38	
Altitude of Mercury [Altitudo ☿]	7	0	
Angle of the ascensional difference [Angulus differentiæ Asc.]	24	5 $\frac{1}{2}$	
R[ight] A[scension] /	11	32 $\frac{1}{2}$	☿

Quantity	G.	M.	[body]
Longitude [Longitudo]			
Latitude [Latitudo]	2	26 ³ / ₄	B
True, by refraction & parallax [Vera à Refractione, & parallaxi]	11	28 ³ / ₄	☿
[Latitude, true]	2	23 ² / ₃	B

Table 16: Day 3 April, evening [Die 3. Apr. vesp.]

Columns as before: time; distance of Mercury from Aldebaran; declination of Mercury; altitude of Mercury; Lesser Dog occidental.

H. M.	Dist. ☿ ab		Decli			Cā. min. occid.		
	Alde b. G.	Dist. M.	natio ☿ G.	Decli n. M.	Altit. ☿ G.	M.	G.	M.
7 55 ¹ / ₄ / 8 6 corr.	dubia [dou btful] / 22	40 ¹ / ₂	18	8 / 18 7 ¹ / ₂	7	40	33	30
7 59 / 8 10 corr.	22	43	18	9 ¹ / ₂ / 18 9 ¹ / ₂	7	8	34	25
8 3 / 8 13 ¹ / ₂	22	42 ¹ / ₂	18	9 ¹ / ₂ / 18 9 ¹ / ₂	6	50	35	22
8 7 ¹ / ₂ / 8 17 ¹ / ₂ corr.	22	41 ¹ / ₂	18	10 / 18 10	7	36	20	
8 12 ¹ / ₂ /	22	40 ³ / ₄	18	11 / 18	5	23	37	42

H. M.	Dist. ☿ ab Alde b. G.	Dist. M.	Decl natio ☿ G.	Decl n. M.	Altit. ☿ G.	M.	Cā. min. occid. G.	M.
8 23 corr.				11½				
8 17½ / 8 28 corr.	22	40½	18	12½ / 18	4	50	38	59
8 20⅞ / 8 31½	22	39	18	13 [vni. salte pin. — one at least, point]	4	30	39	50
8 25½ / 8 36		38¾	18	13½ / 18	3	52	41	5
8 30 / 8 41½ corre ct.	22	38¾ dubia	18	14 dubia	3	15	42	25

Parsing notes: The first distance cell reads "dubia" (doubtful); the last row's distance and declination both carry "dubia." The note at the 8 20⅞ row, "vni. salte pin." (= *vnius saltem pinnacidij* or similar), indicates a sighting taken with at least one pinnule/sight-vane.

For the examination of the armillaries it was taken [Pro Armillarum examine capiebatur]:

Declination of Aldebaran [Aldebaræ declinatio] — 15 37½ / 15 38. Altitude of the same [Altitudo eiusdem] 12½. — This evening was particularly clear and calm [Erat hac vespera apprimè serenum, & tranquillum].

The calculation from these observations [Calculus ex hisce observationibus]:

At H. 8 10':

Quantity	G.	M.	[body]
Distance of Mercury from Aldebaran [Distantia ☿ ab Aldeb.]	22	43	
Declination of Mercury, limited [Declinatio ☿ limitata]	18	11	
Declination of Aldebaran [Declinatio Aldebaræ]	15	38	
Altitude of Mercury [Altitudo ☿]	7	8	
Angle of the ascensional difference [Angulus differ. Ascension.]	23	36½	☿
Longitude [Longitudo]	12	52	☿
Latitude [Latitudo]	2	33¼	B
Parallax & refraction subtracted			

Quantity	G.	M.	[body]
[Subductis Parallaxi, & Refractioe]:			
True Mercury, Longitude [Vera ☿ Longitudo]	12	48	☿
[True, Latitude]	2	30½	B

Table 17: Day 4 April, evening [Die 4. Apr. vesp.]

Columns: time; distance of Mercury from Aldebaran; declination of Mercury, northern [Declinatio ☿ Borea]; altitude of Mercury; Lesser Dog occidental.

H. M.	Dist. ☿ ab Alde b. G.	Dist. M.	Decli n. ☿ Bore a G.	Decli n. M.	Altit. ☿ G.	M.	Cā. min. occid. G.	M.
7 53¾ / 7 55 corr.	21	39¼	18	34 [vtro q; both]	9	30	31	45
7 58 / 8 0	21	36 dubia	18	35 / 18 35½	9	0	32	57
8 1 / 8 3½	21	38	18	37 / 18 38	8	30	33	48
8 6½ / 8 9½	21	38	18	38 / 18 38½	7	48	35	20
8 11½ / 8 15 corr.	21	37½	18	38 / 18 38	7	0	36	59
8 21½ /	21	37½	18	39½ / 18 40	6	30	37	30

H. M.	Dist. ☿ ab Alde b. G.	Dist. M.	Decl n. ☿ Bore a G.	Decl n. M.	Altit. ☿ G.	M.	Cā. min. occid. G.	M.
-------	--------------------------------	-------------	------------------------------	---------------	----------------	----	-----------------------------	----

8 18
corr.

Parsing notes: Most declination cells carry two stacked values. The 8 34'-distance entry reads "vtroq;" (*utroque*, "by both"). One time-pair reads "8 21½ / 8 18 corr." with the corrected value earlier than the observed; transcribed as printed.

Right column (page 346)

Conversely, the distance from the right shoulder of Orion [Vice versa, Distantia à dextro humero Orionis]:

H. M.	Dist. G.	Dist. M.	Decl natio ☿ G.	Decl n. M.	Altit. ☿ G.	M.	[arc] G.	M.
8 21½ / 8 25	42	54	18	40 / 18 39½	5	40	39	13
8 24½ / 8 28½	42	52½	18	40½ / 18 40½	5	10	40	5
8 26½ / 8 30½	42	51	18	41 [vno <i>pinna</i> c. — with one pinn ule]	4	40	40	40

It was no longer possible to observe Mercury this evening on account of the thick clouds present around the western horizon. Moreover, this evening there was a wind, somewhat troubling [the observation], from the same quarter of the sky.

The place of Mercury for 4 April, from the preceding [observations] [Locus ☿ ad 4. Aprilis ex præcedent. observat.]:

At H. 8 15':

Quantity	G.	M.	[body]
Distance of Mercury from Aldebaran [Distantia ☿ ab Aldeb.]	21	37½	
Declination of Mercury, limited [Declinatio ☿ limitata]	18	39½	
Declination of Aldebaran [Declinatio Aldebara]	15	38	
Altitude [Altitudo]	7	0	
Angle of the ascensional difference [Angulus diff. Ascension.]	22	25½	
Longitude [Longitudo]	14	50	☿
Latitude [Latitudo]	2	39½	B
True Mercury, free of refraction & parallax [Vera ☿ à Refract. & Parallaxi libera],	14	1	☿

Quantity	G.	M.	[body]
Longitude			
[True, Latitude]	2	36½	B

Table 18: Day 6 April, evening [Die 6. Apr. vesp.]

Columns: time; distance of Mercury from Aldebaran; declination of Mercury; altitude of Mercury; Lesser Dog occidental.

H. M.	Dist. φ ab Alde b. G.	Dist. M.	Declination φ G.	Declination n. M.	Altit. φ G.	M.	Cā. min. occid.	
							G.	M.
8 15¾ / 8 14¾ corr.	19	40½	19	21½ / 19	7	50	38	30
8 20½ / 8 20 corr.	19	40½	19	24½ / 19	7	15	39	43
8 24¾ / 8 24	19		19	24½ / 19	6	40	40	45
8 30¾	19	40	19	26½ / 19	6	0	[Cor □ occid. — Regul us settin g]	
8 34½	19	39½	19	26 / 19	5	30	6	6
8	19	39		26½	4	50	7	7

H. M.	Dist. ☿ ab Alde	Dist. M.	Decli natio ☿ G.	Decli n. M.	Altit. ☿ G.	M.	Cā. min. occid. G.	M.
-------	-----------------------	-------------	------------------------	----------------	----------------	----	-----------------------------	----

38½

Parsing notes: At the 8 30¾ row, the final column reads "Cor ☐ occid." (*Cor Leonis*, Regulus, setting) in place of the Lesser-Dog arc. Several declination cells carry stacked values.

Afterwards the distance from the right shoulder of Orion was observed [Postea observabatur ☿ à dextro humero Orionis]:

H. M.	quantity	G.	M.
	in Distance [in Distantia]	41	53
8 44'	Declination [Declinatio]	19	31 / 19 30
	Altitude [Altitudo]	3	50
	Lesser Dog [Canis Minor] setting [occid.]	46	26

This last [observation] was doubtful on account of intervening clouds.

Inquiry into the longitude & latitude of Mercury, from these observations [Inquisitio loci longitudinis, & latit. ☿ ex hisce observat.]:

At H. 8 10':

Quantity	G.	M.	[body]
Distance of Mercury from Aldebaran [Distantia ☿ ab Aldeb.]	19	40½	
Declination of Mercury, northern	19	25 limited [limit.]	

Quantity	G.	M.	[body]
[Declinatio ☿ Borea]			
Declination of Aldebaran [Declinatio Aldeb.]	15	38	
Altitude [Altitudo]	7	15	
Therefore the ascensional- difference angle [Ergo angulus diff. ascensionalis]	20	15½	
Longitude [Longitudo]	16	12½	☿
Latitude [Latitudo]	2	48	B
Parallax & refraction subtracted [Subtractis Parall. & Refract.], True Mercury, Longitude [Vera ☿ Longitudo]	16	8½	☿
[True, Latitude]	2	45	B

Table 19: Day 11 April [Die 11. April.]

Columns: time; distance of Mercury from the right shoulder of Orion [Dist. ☿ ab humer. luc. Or.]; declination of Mercury; altitude of Mercury; Lesser Dog occidental.

H. M.	Dist. ☿ ab hume r. luc. Or. G.	Dist. M.	Decl natio ☿ G.	Decl n. M.	Altit. ☿ G.	M.	Cā. min. occid. G.	M.
8 14½			20	36½	6	0	47	30
8 18½	37	38½			5	50	48	30
8 21	37	40½	20 / 20	36½ / 37	5	30	49	17
8 23½	37	41½	20 / 20	37½ / 37	5	10	49	58
8 26½			20	38½	4	50	50	41

Parsing notes: Several distance and declination cells are blank in the source; declination column shows stacked values 20 36½/20 37 and 20 37½/20 37.

Around the middle of these times the altitude of the bright shoulder of Orion was such that distances of Mercury were taken at roughly 14° or 15°.

At H. 8 40½: Declination of Aldebaran [Declinatio Aldebaræ] — 15 40½ / 15 40. Altitude of the same [Altitudo eiusdem] 7½. And [this was done] for the examination of the armillaries [Idq; pro Armillarum examine].

Afterwards it was no longer possible to observe Mercury, namely from hour 8 min. 26½; for clouds were veiling it, and vapors were impeding [the view] from the horizon. Yet the distances may be had without appreciable error, as the distance accepted at hour 8 21' — putting it at 37°40' — [and] at an altitude of 5½°. To assign the true declinations of Mercury at that time, the ratio of the refraction of the bright shoulder of Orion must be taken; the distance is to be taken from that, and it must also be seen what allowance the armillaries afford in the declination — perhaps by an experiment made through Aldebaran, its refraction being applied.

[10] **Year 1592, Feb. 3, Old Style, hour 5 40' after midday.** At Uraniborg Mercury was observed in Pisces 12°20', with a northern latitude of 47'. [Longomontanus], Book II, Theorica chapter 20, and [Boulliau] Book X, chapter 7, who adds the true place of the Sun to have been Aquarius 24°23'57" and

accordingly the distance of Mercury from the Sun $17^{\circ}56'3''$. But from the tables he gathers Mercury's place in Pisces $12^{\circ}15'$. [Boulliau] Book X, chapter 7 proves that the place is corrupt with respect to the latitude.

[11] **Year 1593, May 11, Old Style, hour 9 30' after midday.** At Uraniborg Mercury was observed in Gemini $23^{\circ}16'$, with a northern latitude of 2° . [Longomontanus], Book II, Theorica chapter 20. [Snellius] adds, in his *Hassiacae [Observationes]*, that on the following day, 12, which in New Style was the 22nd of May, Mercury was observed in Gemini $24^{\circ}19'$. Hence [Boulliau] Book X, chapter 1 gathers that on the 23rd, New Style, Mercury was in Gemini $25^{\circ}21'$, the greatest elongation being distant $22^{\circ}52'4''$ from the Sun in Gemini.

[22] **Year 1600, January 23, New Style.** [Tycho Brahe], at the citadel of [Benátky — *arce Benatica*], immediately after the setting of the Sun, found by refraction the corrected distances of Mercury from the bright star of the breast of the Swan [*lucida pectoris Cygni*, i.e. Sadr] to be $48^{\circ}52\frac{2}{3}'$, and from the tail of the Whale [*cauda Ceti*, Deneb Kaitos] $40^{\circ}22\frac{2}{3}'$, and the altitude of Mercury $5^{\circ}50'$. Thus [Snellius] in the Bohemian observations [*in observ. Bohemicis*].

[23] **Year 1600, January 24, a little after sunset.** [Tycho Brahe] observing, Mercury was high 6° and was seen to be distant from the bright star of the tail of the Whale $40^{\circ}7'$; but six hours later the altitude of Mercury was 3° . It was distant from the same star $40^{\circ}4'$; from Sirius [*Sirio*] $53^{\circ}3\frac{1}{2}'$; a little before, distant from Pegasus [*Pegali*] $21^{\circ}37'$. Since the time was about 10' before what would be by the Copernican [tables] have set Mercury beyond the limit of greatest remotion from the Sun — to which this observation is more favorable than the Alphonsine. [Snellius] above.

[24] **Year 1601, April 29.** [Tycho Brahe] at Prague, in the house of [Curtius — *Curtij*], saw in what manner Mercury was high $7^{\circ}10'$, and distant from Capella [*à Capella*] $25^{\circ}41'$; the altitude truly $6^{\circ}46'$. He saw it distant from Procyon [*à Procyone*] $53^{\circ}14'$. Therefore, says [Snellius] in the Bohemian [observations], the place of Mercury was Gemini $1^{\circ}29'50''$, no account being taken of refraction & parallax.

CAPVT IV.

Mercury observations of Longomontanus, Kepler, Justus Byrgius [Jost Bürgi], Hortensius, & Boulliau, from the year 1593 to 1631.

[*Mercurij observationes Longomontani, Kepleri, Iusti Byrgij, Hortensij, & Bullialdi ab anno 1593 ad 1631.*]

[1] **Year 1593, May 11, hour 9 30' after midday.** [Jost Bürgi — *Iustus Byrgius*] of Kassel [*Catellis*] observed Mercury distant from Capella [*à Capella*] $21^{\circ}56'$, and from Pollux [*à Polluce*] $24^{\circ}34'$. [Snellius] in his *Hassiacae*, and [Boulliau] Book X, chapter 1, hence gathers that on the 12th, which in New Style was the 22nd, Mercury was in Gemini $24^{\circ}19'$; and on the 23rd, hour 21', that Mercury was at its greatest elongation from the Sun. [Longomontanus] however, Book II, Theorica chapter 20, as above, relates that Mercury was observed in Gemini $23^{\circ}16'$.

[2] **Year 1607, April 14, Old Style, hour 8 ½' after midday.** At [Copenhagen — *Hafniæ*] [Longomontanus] observed Mercury by the radius [*Radio*, cross-staff], distant from Venus [*à Venere*] $6^{\circ}2'24''$; and these were higher in nearly the same vertical, the southern latitude of Venus being $10'$; but Mercury's northern [latitude] $1^{\circ}40'$. And from the observations of the following days [Longomontanus], Theorica chapter 23, gathers from the tables Mercury in Taurus $19^{\circ}32'7''$, & Venus $18^{\circ}19'33''$. On April 15, hour 9, Mercury was observed in Taurus $21^{\circ}5'$; on the 14th, the tables themselves give it $21^{\circ}11'$.

[3] **Year 1607, May 28, New Style.** [Kepler] saw Mercury under the Sun [*Mercurium sub Sole*], as he himself made public in his treatise on this singular phenomenon; and he differs from this in his attestation to the *Nuncius Sidereus*. [Christoph Scheiner — *Scheinerus*] [discusses this] on the solar spots [*de maculis Solaribus*].

[4] **Year 1610, Dec. 5, Old Style, hour 19 after midday.** At [Copenhagen — *Hafniæ*] [Longomontanus] observed Mercury in Sagittarius $2^{\circ}42'$. Thus he himself, Book II, Theorica chapter 20.

[5] **Year 1625, Feb. 13, hour 6 12'.** [Boulliau — *Iulioduni Bullialdus*, at Loudun] observed Mercury in Pisces $13^{\circ}27'$; with the refraction subtracted, the greatest [elongation], its distance being $17^{\circ}59'23''$, [Mercury] situated [*à Sole versante*] from the Sun in Aquarius $25^{\circ}27'37''$. [Boulliau] Book X, chapter 1.

[6] **Year 1626, March 12, Old Style, hour 9 33' after midday.** At Leiden [*Leydæ*] [Martinus Hortensius — Maarten van den Hove] saw Mercury high 6° , in the same straight line with the right shoulder of Auriga [*dextro Aurigæ*], and with a wide [interval] in the right arm of the same [constellation]. [Lansbergius] in the *Thesaurus* observes: "Mercury 7° ," adding that the same straight line falls in Gemini $23^{\circ}50'$ — about which [is] Mercury, with a refraction of $15'$; and it appears in that line, though truly lower, in Gemini $23^{\circ}36'41''$, with a northern latitude of $2^{\circ}25'11''$.

[7] **Year 1627, October 15, near the island of Goeree [*insulam Goëanam*].** [Martinus Hortensius] saw Mercury distant from Saturn [à Saturno] about one degree. [Lansbergius] in his *Thesaurus* observes: "Mercury 8''"; he gathers the place of Saturn in Libra 3°57'19", with a northern latitude of 2°6'3", & Mercury in Libra 3°5'45", with a northern latitude of 1°55'12".

[8] **Year 1630, December 12, in the morning, hour 6 50' after midnight.** [Boulliau — *Iulioduni*, at Loudun] observed Mercury in Scorpio, hour 29°13'. Thus he himself, Book XI, *Astronom. Theorem.* 13.

[9] **Year 1632, July 31, Old Style:** there occurred a conjunction of Mercury & Venus — concerning which [is] [Martinus Hortensius], *On Mercury seen in [under] the Sun [de Mercurio in Sole viso]*.

Liber IX — On Mercury (continued)

CAPVT V.

Mercury observations made by Pierre Gassendi [Gassendi], and by the Fathers of the Society of Jesus at Ingolstadt and at Innsbruck.

1. When Kepler [Kepler] had warned, in his *Ephemerides*, that on 7 November Mercury would fall under the Sun [Mercurium sub Sole incursum] and that on 6 December Venus would do likewise, Gassendi at Paris, who had previously thought Mercury's diameter to be more than 20 minutes of arc, used a telescope on 7 November. In the morning, while clouds were occupying the sky in places, he turned his attention to the part of the Sun's disk, and through the cloud he caught sight of a small spot. At first he took it for a sunspot, but he recognized it from its rapid motion to be Mercury. The conjunction of Mercury with the Sun took place, but Venus could not be seen on 6 December. So Gassendi himself narrates the matter in his *Vita Peireskii [Life of Peiresc]*, book 4, and in the *Meteorologica* of Epicurus, p. 899.

On this occasion Hortensius [Hortensius] published the account of Mercury seen under the Sun, and of Venus not seen. Now Kepler had predicted the conjunction of Mercury with the Sun before noon. At Uraniborg [Vraniburgi], then, it ought to have been at Paris about one hour after noon, or 47 minutes. But here Kepler's *Tables* were more accurate than the other *Tables*, in that they placed the time of conjunction nearer the truth, with Mercury distant from the Sun in longitude as Ptolemy [Ptolemaeus] gives 25', Copernicus [Copernicus] 5°, Longomontanus

[Longomontanus] $7^{\circ} 13'$, and Lansberge [Lansbergius; Philip van Lansberge] $1^{\circ} 21'$. Moreover Boulliau [Boulliau, Ismaël], in book 10 chapter 2 of his *Astronomia* [*Astronomia Philolaica*], reports that Gassendi found by telescope that Mercury exceeded [appeared projected] onto white paper; he gives the true conjunction of Mercury with the Sun at Paris at the 7th hour, 38', in [the sign of] Scorpio [in Scorprij] $14^{\circ} 36'$; but from the *Philolaica* (*Philolaica*) $14^{\circ} 37' 42''$, with Mercury's latitude $4^{\circ} 30'$ North.

2. In the year 1632, on 30 July, at Uraniborg [Vraniburgi], at the 16th hour after noon [hor. 16. post merid.], the conjunction of Venus with Mercury was observed by means of a telescope, yet in such a way that Mercury was seen to exceed the diameter of Venus by 5 minutes. — At Paris the conjunction of Mercury with Venus was observed by Gassendi; he gives it, collecting Venus in Cancer [in Cancrj] at $24^{\circ} 25' 47''$. Hence Mercury was in Cancer at $24^{\circ} 25' 47''$.
3. In the year 1634, on 2 January, at hour $6^{\circ} 30'$, at Uraniborg [ad Vraniburgum], reduced by Gassendi by means of distances from the fixed stars, Mercury was observed in Aquarius [in Aquarij] at $1^{\circ} 31'$, with South latitude $57'$. On day 4 in Aquarius [in Aquarij] at $3^{\circ} 31'$, with South latitude $30'$; and on the 6th in Aquarius [in Aquar.] at $5^{\circ} 1'$, with South latitude $1^{\circ} 52'$. Thus Boulliau, in book 10 chapter 1, collects from this that on day 3, at hour $6^{\circ} 30'$, the greatest elongation was $18^{\circ} 59'$, with Mercury in Aquarius [in Aquarij] at $2^{\circ} 30' 43''$, and distant from the Sun in Capricorn [à Sole in Capricorni] at $13^{\circ} 53' 43''$.
4. In the same year, on 2 October, Gassendi by means of distances from the fixed stars observed Mercury in Virgo [in Virg.] at $22^{\circ} 8' 20''$, with North latitude $1^{\circ} 25'$; and on day 3 in Virgo [in Virg.] at $22^{\circ} 59' 26''$, with North latitude $1^{\circ} 29' 18''$; and on day 4 in Virgo [in Virg.] at $23^{\circ} 59' 47''$, with North latitude $1^{\circ} 19' 16''$. Boulliau, in book 10 chapter 1, collects from this that on day 3, at hour 18, the greatest elongation was $17^{\circ} 49' 54''$, with Mercury in Virgo [in Virginis] at $22^{\circ} 59' 26''$, and distant from the Sun in Libra [à Sole in Librae] at $10^{\circ} 49' 20''$.
5. In the year 1634, around the beginning of November, Mercury was in central conjunction with the Sun [sub initium Nouemb. sub centro centralis coniunctus Mercurij cum Sole]; yet Gassendi, in his *Vita Peireskii*, denies that the telescope allowed it to be seen, just as in the year 1632 [it was] not [seen]; and toward the end of April, whence he concludes that the orbit [epicyclum] of Mercury is not between the Sun and us, but rather around

the Sun — a conclusion that holds good only on a supposition, since those central conjunctions did not turn day into night.

6. In the year 1635, on 16 January, Gassendi by means of the fixed stars observed Mercury in Capricorn [in Capricorn.] at $4^{\circ} 18' 48''$, with North latitude $2^{\circ} 1' 15''$; and on day 18, at hour $18^{\circ} \frac{1}{3}$, in Capricorn [in Capric.] at $8^{\circ} 21' 50''$, with North latitude $1^{\circ} 39'$; and on day 24, in Capricorn [in Capric.] at $16^{\circ} 4' 55''$, with North latitude $1^{\circ} 14' 8''$; and on day 25, in Capricorn [in Capric.] at $11^{\circ} 6' 36''$, with North latitude $59' 48''$. Boulliau, in book 10 chapter 1, collects from this that the greatest elongation was $24^{\circ} 18' \frac{3}{4}$, with Mercury in Capricorn [in Capric.] at $10^{\circ} 4' 55''$, distant from the Sun in Aquarius [à Sole in Aquarij] at $5^{\circ} 14' 15''$.
7. In the year 1635, on 17 September, Gassendi in the morning observed Mercury in Virgo [in gr. Virginis] at $6^{\circ} 8'$, and on day 19 in Virgo at $8^{\circ} 7'$; whence on day 18, in the morning at hour 17 after noon, the greatest digression was $19^{\circ} 44' 21''$. Boulliau, book 10.
8. In the year 1635, on 1 December, Gassendi at Digne [Diniae] at hour $5^{\circ} 30'$, by means of distances from the fixed stars, observed Mercury in Capricorn [in Capricorn.] at $0^{\circ} 34' 49''$, with South latitude $1^{\circ} 31'$ (from Boulliau, book 11, theorem 13). With refraction allowed for, he sets Mercury's corrected place at minute 26 of Capricorn [Mercurij locum correctum minut. 26. Capricorni], and at day 2, by his own *Tables*, at 23° of Capricorn [gr. 23. Capricorni].
9. In the year 1636, on 26 June, Gassendi at Aix-en-Provence [Aquis Sextijs] observed evening Mercury at an altitude of $3^{\circ} \frac{2}{3}$, distant from the Heart of Leo [à corde Leonis] (Regulus) by $31^{\circ} 23' \frac{2}{3}$; and from the Bright Star of the neck of Leo [à Lucida colli Leonis] at $31^{\circ} 41'$; whence he collects Mercury's apparent place. He gives Mercury's place in Cancer [in Cancri], with South latitude. From Boulliau, book 11, with refraction allowed for, the corrected place in Cancer [in Cancri] at $23^{\circ} 17' 47''$, with South latitude $1^{\circ} 36' 55''$. Boulliau sets it in his *Philolaica* (*Philolaica*) at — Cancri.

In the same year, on 27 June, Gassendi at the same place [ibidem] saw Mercury in Cancer [in Cancri] at $24^{\circ} 56' \frac{3}{4}$; thence, with refraction removed [eliminatis Refractionibus], Boulliau, book 10 chapter 4, where the *Rudolphine Tables* [Tabulae Rudolphinae] place Mercury at $25^{\circ} 1'$ of Cancer. In the *Philolaica* at $25^{\circ} 3' 33''$ of Cancer [Philolaicae in grad. 25. 3. 33''. Cancri].

10. In the year 1636, on 14 July, in the evening, Gassendi at Aix-en-Provence [Aquis Sextijs] observed Mercury — corrected for refraction of place [correctis ex Refractione locis] — in Leo [in Leonis] at $19^{\circ} 31' 16''$, with South latitude $1^{\circ} 4'$. From Boulliau, book 10 chapter 2; and at day 15 in Leo [in Leonis] at $20^{\circ} 33' 15''$, with South latitude $33'$. Boulliau, in the same place [ibidem].
11. In the year 1636, on 16 July, Gassendi from two observations, as Boulliau says (book 10 chapter 4), collects that Mercury was observed in Leo [in Leonis] at $21^{\circ} 25'$; whence the *Rudolphine* place at hour 9. Uraniborg [Vranib.] would exhibit $21^{\circ} 30'$; and Boulliau in his *Philolaica* (*Philolaica*) at $21^{\circ} 25' 47''$.
12. In the year 1636, on 3 September, in the evening, Gassendi at Digne [Dinia] saw Mercury beside the heart of Leo [Cor Leonis] by telescope: "I detected" — he says — "the heart of Leo below and to the right of Mercury [Cor Leonis infrà, & dexteram Mercurij], so much so that Mercury itself was not perpendicularly above it; nor was the latitude even moderate in position, but it came as it were midway, though closer to the vertex than to the side." Soon afterward he observed the distance of Mercury from the heart of Leo to be $23^{\circ} \frac{3}{5}$; and then $22^{\circ} \frac{3}{5}$, with an Astronomical Radius [Radio Astronomico]. Boulliau, book 10 chapter 3, who on the supposition of Regulus [Regulo] in Leo [in Leonis] at $24^{\circ} 47' 19''$ collects Mercury's place in Leo [in Leonis] at $24^{\circ} 37'$, or $38'$; but by his own *Tables* at $24^{\circ} 38' 52''$, and from the *Rudolphine* at $24^{\circ} 27'$.

[Margin / column heading, folio 348:] **At Ingolstadt, moreover, the Fathers of the Society — of our own [order] — made these observations, which Father Michael Staudacher [Staudacher], S.J., recently sent to me.**

The following is a table of Mercury observations made at Ingolstadt (years 1617–1620). Columns: date (year / hour); the star from which the distance is measured ("Distantia ☿" — distance of Mercury), in degrees and minutes; and the altitude ("Altitudo"), in degrees and minutes.

Year / Date	Hour	From (star)			Altitud e — Gr. M.	
		[Ab]	Gr.	M.	Gr.	M.
Year 1617 — March	4	Andro meda, head	25	0		

Year / Date	Hour	From (star) [Ab]	Gr.	M.	Altitud e — Gr.	M.
7, eve.		[Andro m. cap.] Bright Star of □ [Lucida □]	31	24		
Year 1619 — Feb. 6, eve.	2	Markab	24	42	☿ 4	40
		Algenib [Algeni b]	34	10		
Feb. 8	6 12	Markab	21	21	☿ 4	10
		Algenib [Algeni b]	28	55		
May 11	9 15	from Capella [à Capella]	44	50	☿ 4	50 vesp.
		from the head of Pollux [à Cap. Pollucis]	26	30	Regulus [Reguli] 37	5 vesp.
Year 1620 — Oct. 10, morn.	5 30	from Regulus [à Regulo]	44	24	☿ 7	5

Year / Date	Hour	From (star) [Ab]	Gr.	M.	Altitud e — Gr.	M.
		from the Tail of Leo [à Cauda □]	24	36		

Parsing notes: The "Hour" column sometimes carries two values (a day-and-hour pair, e.g. "6 12", "9 15", "5 30"); transcribed as printed. The ☿ symbol marks Mercury's altitude entries; "vesp." = evening, "mat." / "matutina" = morning. Some altitude cells are blank in the source.

In the year 1631, on 7 November, Mercury was seen under the Sun [Mercurius sub Sole] at hour 9° 56' in the morning, distant from the center of the Sun's disk a little more than half a semidiameter of the Sun toward the North [versus Zephyro-Boream]; but at hour 1 after noon it had already passed out from under the Sun [iam excesserat de sub Sole].

[Margin / sub-heading:] **Observations made at Innsbruck [Oeniponti] by the Fathers of the Society of Jesus, and communicated to me by one of them, Father Michael Staudacher [Staudacher], S.J.**

The following is a table of Mercury observations made at Innsbruck (years 1635–1637). Columns: date; the star from which the distance is measured ("Distantia ☿"), in degrees and minutes; and the altitude ("Altitudo"), in degrees and minutes.

Year / Date	Hour	From (star) [A.]	Gr.	M.	Altitud de — Gr.	M.
Year 1635 — Sept. 18		Regul us [Regul o]	12	16	☿ 8	51 morn. [m.t.]
		Tail of Leo [luba	14	33	Bright [Star] of the	28 morn. [mat.]

Year / Date	Hour	From (star) [A.]	Gr.	M.	Altitude — Gr.	M.
		□]			shoulder of Orion [Lu.hu.Or.]	48
Year 1636 — March 19, eve.		Rigel	60	27	☿ 8	5
		Bright Star of the shoulder of Orion [Luc-hum.Or.]	66	51	Lu.hu. Or. 46	20
Year 1637 — March 3, eve.		Aldebaran [Aldebaran]	63	18	☿ 11	4
		Rigel	73	55	Aldeb. 56 / Rigel 34	25 / 4

Parsing notes: Star abbreviations expanded where possible: "Lu.hu.Or." / "Luc-hum.Or." = *Lucida humeri Orionis*, the bright star of Orion's shoulder (Betelgeuse); "luba □" appears to be *iuba Leonis*, the mane/tail of Leo. The two altitude entries

on the 1637 row (Aldeb. and Rigel) are printed as a paired sub-cell. "m.t." / "mat." = morning; "vesp." = evening.

CAPVT VI.

Select Mercury observations, from those carried out at Bologna [Bononiae] in the College of St. Lucy [in Collegio S. Luciae] by the Fathers of the Society of Jesus, Giovanni Battista Riccioli [Riccioli] and Francesco Maria Grimaldi [Grimaldi], together with their assistants.

1. In the year 1643, on 3 May, on the following night, at hour 6 after noon, Mercury was seen distant from Jupiter [à Ioue] by $1^{\circ} 4'$; granted that, from both longitude and latitude [esto ex vtriusq; longitudine, & latitud.], the Lansbergian [Lansbergiana] [position] ought to differ by $1^{\circ} 36' 43''$.
2. In the same year, on 5 May, in the calmest evening, Mercury was seen in the new Sextant [in Sextante nouo] distant from Andromeda [à cingulo Andromedae] by $26^{\circ} 43'$; and from the girdle of Andromeda [à cingulo Andromedae] by $31^{\circ} 5' 17''$; and it was then at an altitude of 6° ; in the next quadrant [vno proximè quadrante] after sunset.
3. The following evening, with a reddening sky in the west, a little after sunset Mercury was seen at an altitude of 8° , distant from the head of Andromeda [à capite Andromedae] by $26^{\circ} 10'$; and from the girdle of Andromeda [à cingulo Andromedae] by $33^{\circ} 59'$.
4. In the year 1643, on 7 May, in the calmest evening, Mercury was seen at an altitude of $7^{\circ} 50'$, distant from the girdle of Andromeda [à cingulo Andromedae] by $32^{\circ} 52'$; and from the head of Andromeda [à capite Andromedae] by $6^{\circ} 22'$.
5. In the same year, on 11 May, evening Mercury was seen distant from the vertex [à vertice] by $80^{\circ} 48'$; and from the girdle of Andromeda [à cingulo Andromedae] by $28^{\circ} 41'$. Then it was seen distant from the vertex by $81^{\circ} 49'$; and from the head of Andromeda [à capite Andromedae] by $23^{\circ} 56' \frac{1}{3}$.
6. The following evening, in the calmest evening, Mercury was seen distant from the vertex [à vertice] by $80^{\circ} 28'$; and from the girdle of Andromeda [à cingulo Andromedae] by $27^{\circ} 51' \frac{1}{3}$, with the altitude of Aldebaran [Aldebaran] in the west being $52^{\circ} 21'$; when, however, these [stars] were [at] altitude $51^{\circ} 34'$, Mercury was seen distant from the southern foot of Andromeda [à pede australi Andromedae] by $37^{\circ} 33'$.

7. In the year 1643, on 23 August, in the morning, at the transit of the bright star of Aries [à transitu lucidae Arietis] across the meridian [per M.C. — Medium Caeli], the [minutes] are counted 4' 8" [numerata sunt min. 4. 8"]; and afterward Mercury was seen at altitude 6° 20'; and distant from the bright star of the shoulder of Orion [à lucido humero Orionis] by 49° 35'. Then, after 7 minutes, it was seen at altitude 5° 50'; distant from Procyon [à Procyone] by 25° 27' ½: this repeated, according to the manner of the observations.

Likewise on the following morning, 24 August, at the transit of the bright star of Aries [à transitu Lucidae Arietis] across the meridian [per M.C.], the [minutes] are counted 32; after which Mercury was seen at altitude 9° 4', distant from the bright shoulder of Orion [ab humero lucido Orionis] by 50° 2'; and after 7 minutes was seen at altitude 5° ½; and distant from Procyon [à Procyone] by 26° 15'.

8. Likewise in the year 1643, on 31 August, Aldebaran [Aldebara] stood distant from the vertex [à vertice] by 34° 10'; and after this [post] Mercury was seen at altitude 3° ½; and distant from Procyon [à Procyone] by 33° 59' ½; thence after 2 minutes of time [post 2 min. temp.] it was seen at altitude 3° 30'; distant from the bright shoulder of Orion [ab Orionis humero lucido] by 58° 42' ½.
9. Likewise in the year 1643, on 1 September, Regulus [Regulus] stood distant from the vertex [à vertice] by 31° 1' 1", counted afterward through minute 18 of time; Mercury was seen at altitude 8° 10', distant from Spica [à Spica] by 22° 3' ⅔; and after 5 minutes of time, was seen at altitude 10° 15'; and distant from Arcturus [ab Arcturo] by 34° 45'. — *Perigee. Greatest [elongation]* [Perig. Excentr.] [Margin].
10. At length on 16 December of the same [year], in the morning, in the calmest [sky], and with the most purified North wind [statu Aquilonio purgatissimo], Mercury [was observed] in azimuth [in Azimutho] at 50° 44' [graduum 50. 44']; it was seen at altitude 6° 25'; and then Arcturus [Arcturus] stood distant from the vertex [à vertice] by 25° precisely [praecisè].
11. On 6 August 1644, the bright star of Aries [lucida Arietis], distant from the vertex [à vertice] toward its rising [à vertice ortum versus], at 25° 55'. Mercury, the morning star most near to its greatest digression [matutinus digressioni maxime vicinus], was seen at altitude 3° 1' ⅔; and distant from Aldebaran [ab Aldebara] by 50° 24'. Then, after 8 minutes, it was seen at

altitude $4^{\circ} 10'$; distant from the following shoulder of Orion [ab Orionis humero sequenti] by $34^{\circ} 8' \frac{1}{3}$.

12. In the same year, on 13 August, in the morning, Aldebaran [Aldebara] stood distant from the vertex [à vertice] by $43^{\circ} 36'$; and after the elapse of 7 minutes of time [& elapsis 7. temp.], Mercury was seen at altitude $7^{\circ} 12'$; distant from the following shoulder of Orion [ab humero sequenti Orionis] by $42^{\circ} 12'$. Then, after 2 minutes of time, it was seen at altitude $7^{\circ} 28'$; and distant from Aldebaran [ab Aldebara] by $58^{\circ} 36' \frac{2}{3}$.
13. In the year 1644, on 21 November, in the morning, Regulus [Regulus] — west of the vertex [occidentalis] — stood distant from the vertex [à vertice] by $31^{\circ} 1' 1''$, soon after minute 18 of time; Mercury was seen at altitude 10° , distant from Spica [à Spica] by $22^{\circ} 3' \frac{2}{3}$; and after 5 minutes of time, was seen at altitude $10^{\circ} 15'$; and distant from Arcturus [ab Arcturo] by $34^{\circ} 45'$. — *Perigee. Greatest [elongation]* [Perig. Excentr.] [Margin].
14. In the year 1644, on 26 November, in the morning, Mercury was seen distant from the vertex [à vertice] by $49^{\circ} 50'$; and after 17 minutes, Mercury was seen at altitude $8^{\circ} 55'$; and distant from Arcturus [ab Arcturo] by $37^{\circ} 5'$; and after three minutes [it was] seen at altitude $9^{\circ} 12'$; and distant from Spica [à Spica] by $25^{\circ} 49'$.
15. In the same year, on 29 November, in the morning, in the calmest [sky], Arcturus — east of the vertex [orientalis] — stood distant from the vertex [à vertice] by $9^{\circ} 6'$; and after 2 minutes Mercury was seen at altitude $7^{\circ} 46'$; and distant from Arcturus [ab Arcturo] by $39^{\circ} 19'$. Thence, after three minutes [post tria minuta] it was seen at altitude $8^{\circ} 22' \frac{1}{3}$; and distant from Spica [à Spica] by $29^{\circ} 7'$.
16. In the year 1646, on 8 May, in the evening, Mercury was seen distant from Capella [à Capella] by $45^{\circ} 40'$; and from Procyon [à Procyone] at altitude $29^{\circ} 14'$; in the same year, indeed, at altitude $28^{\circ} 10'$, it was seen distant from Capella [à Capra] by $21^{\circ} 56'$.
17. In the same year, in the following evening, Mercury was seen distant from Capella [à Capella] by $44^{\circ} 22'$; from Procyon [à Procyone] at altitude $26^{\circ} 7'$; in the same year, indeed, at altitude $26^{\circ} 7'$, it was seen distant from Capella [à Capella] by $21^{\circ} 30'$.
18. In the year 1646, on 15 May, in the evening, Mercury was seen distant [continues on next page] —

[continuation of item 18:] — distant from the vertex [à vertice] by $37^{\circ} 57'$; from Procyon [à Procyone] at altitude $23^{\circ} 40'$; in the same year, indeed, at altitude $22^{\circ} 35'$, it was seen distant from Capella [à Capella] by $20^{\circ} 33'$.

19. In the same year, on 22 May, evening Mercury was seen distant from Capella [à Capella] by $22^{\circ} 4'$; at the altitude of Procyon [à Procyone] $15^{\circ} 23'$; and then distant by $33^{\circ} 1'$; and from Procyon [ab ipso Procyone] at altitude $13^{\circ} 35'$.
20. In the year 1647, on 23 April, in the evening, Mercury was seen at altitude $13^{\circ} 30'$; and distant from Procyon [à Procyone] by $12^{\circ} 30'$. Then it was seen at altitude $12^{\circ} 30'$; it stood apparently distant from Procyon [à Procyone] by $59^{\circ} 46'$, on account of refractions. Afterward it was seen at altitude $11^{\circ} 33'$; and distant from Capella [à Capella] by $30^{\circ} 31'$; the altitude, moreover, [was] $11'$; it was seen distant from the following shoulder of Orion [ab humero sequente Orionis] by $35^{\circ} 23' \frac{2}{3}$; and at that time Capella [was at] $40^{\circ} 12'$. And this [was] about the greatest digression of Mercury [maximam Digressionem Mercurij].
21. In the same year, on 30 April, in the evening, Mercury was seen at altitude $12^{\circ} 22'$; and distant from Procyon [à Procyone] by $52^{\circ} 54' \frac{1}{3}$. Then it was seen at altitude $11^{\circ} 52'$; and from the head of Pollux [à Pollucis capite] distant by $47^{\circ} 34' \frac{1}{3}$.
22. In the year 1647, on 6 May, in the evening, Mercury appeared in the same straight line with Venus [in eadem recta linea cum Venere], and with the center of the Moon [centro Lunae], one hour after sunset, in such a way that Venus appeared with the Moon, and Mercury with Venus toward the west [Mercurius Venere occidentalior appareret], but under the splendor of the Moon [sub splendorem Lunae]; and the rest of the twilight things could not be observed, as to anything else [quoad alia].
23. In the year 1648, on 31 March, in the evening, Mercury was seen at altitude $8^{\circ} 47'$; and distant from Aldebaran [ab Aldebara] by $37^{\circ} 34'$; and at altitude $8^{\circ} 20'$ it was seen distant from Rigel [à Regel] by $52^{\circ} 58'$; the altitude then of Aldebaran [Aldebarae alta] [was] $37^{\circ} 44'$.
24. In the same year, on 7 April, in the evening, Mercury was seen at altitude $12^{\circ} 53'$; and distant from Aldebaran [ab Aldebara] by $28^{\circ} 3'$; the altitude, moreover, [was] $11^{\circ} 57'$; it was seen distant from Rigel [à Regel] by $46^{\circ} 40' \frac{1}{3}$; and after a minute of time [post minutum temporis] Aldebaran [Aldebara] stood distant toward sunset [occasum versùs] by $57^{\circ} 57'$.

25. In the year 1648, on 9 April, in the evening, Mercury was seen at altitude $12^{\circ} 32'$; and distant from Aldebaran [ab Aldebara] by $26^{\circ} 4'$; the altitude, moreover, [was] 12° ; it was seen distant from Rigel [à Regel] by $45^{\circ} 27' \frac{1}{3}$; Rigel [Regel] at altitude $71^{\circ} 5'$; distant toward sunset, from Aldebaran [Aldebara] toward the vertex [à vertice] by 60° , precisely [praecisè].
26. In the same year, on 13 April, in the evening, Mercury was seen at altitude $11^{\circ} 30'$; and distant from Aldebaran [ab Aldebara] by $23^{\circ} 19' \frac{2}{3}$; and after that [moxq;] at altitude $10^{\circ} 14'$; it was seen distant from Rigel [à Regel] by $43^{\circ} 45' \frac{2}{3}$; and at altitude almost 18 [ferè 18.]; Aldebaran [Aldebara] at altitude $25^{\circ} 50'$.
27. Likewise in the same year, on 15 April, in the evening, Mercury was seen at altitude $9^{\circ} 14'$; and distant from Aldebaran [ab Aldebara] by $22^{\circ} 23' \frac{2}{3}$; and soon after [moxq;] [it was] seen distant from Rigel [à Regel] by $43^{\circ} 11' \frac{2}{3}$; at altitude about [circiter] 15; but Aldebaran [Aldebara] at altitude $22^{\circ} 43'$.
28. In the year 1649, on 22 December, in the morning, Mercury was seen at altitude $6^{\circ} 40'$; and distant from the head of Ophiuchus [à capite Ophiuchi] by $34^{\circ} 32' \frac{2}{3}$; the altitude, moreover, [was] $7^{\circ} 12'$; it was seen distant from Spica [à Spica] by $48^{\circ} 49'$.
29. In the year 1651, in the month of February, evening Mercury was observed over nine days, by taking its distance from the vertex in the same vertical [à vertice in eodem Verticali], in which afterward the exact azimuth was taken [for] the distance of Aldebaran from the vertex [distantia Aldebaran à vertice]. Besides this, with the perpendicular of time [perpendicularo temporis] counted off, the distance of Sirius from the vertex was taken from the observed Mercury [ab obseruato Mercurio capiebatur distantia Sirij à vertice], in the eastern quadrant [in quadrante orientali].

The following table records the February 1651 evening Mercury observations at Bologna. Columns: day of February ("Dies Febr."); the distance of Aldebaran from the vertex ("Dist. Aldeb. à vert."), in degrees and minutes; the azimuth from there ("Hinc Azimuth"), in degrees, minutes, and seconds; Mercury's [distance] from the vertex in the same [vertical] ("ϕ in eo dist. à vert."), in degrees and minutes; the time-interval after [the reading] ("hinc post tempor."), in minutes and seconds of time; and Sirius's distance from the vertex ("Sir. dist. à vert."), in degrees and minutes.

37 (20)	53	54	75	48	0	79	6	3	58	68	6

Parsing notes: The leftmost two figures in the first column are an observation-running number (30–37) and the February day (11, 13, 15, 16, 17, 18, 19, 20), printed as a paired cell; transcribed as "running# (day)". The "Hinc Azimuth" column carries three sub-figures (degrees, minutes, seconds); all seconds-values are < 60. The "Hinc post tempor." column gives the time-elapséd correction (minutes/seconds of time) between the two distance readings. The seconds-cell on row 30 is blank in the source and left empty.

In the year 1652, in the month of May, from day 21 onward — indeed right up to the second day of June — evening Mercury was observed [vespertinus], as [shown] below in the following Table.

The following table records the evening Mercury observations of May–June 1652 at Bologna. Columns: running number; day of May ("Maij Die vesp." — May day, evening); Mercury's observed altitude ("Mercurij Altit. visa"), G./M.; Mercury's distance seen from the head of Pollux ("Mercurij distantia visa à cap. Poll." — *à capite Pollucis*), G./M.; Mercury's distance from the head of Castor ("Mercurij distantia visa à cap. Cast." — *à capite Castoris*), G./M.; and the altitude of Pollux ("Pollucis altitudo"), G./M. Each day carries two (occasionally three) successive readings, the upper row giving the "à cap. Poll." distance and the lower row(s) giving the "à cap. Cast." distance and the altitude of Pollux.

#	May Day (eve.)	☿ Altit. visa		☿ dist. à cap. Poll.		☿ dist. à cap. Cast.		Pollux alt.

47	2	6		0		15	22				
		5		30				14	25	19	26

Parsing notes: Heading "Anno 1652." is printed above the table. Each day is laid out across two rows (occasionally three, e.g. obs. 41 on May 27, which carries three altitude readings 11°40' / 10°40' / 9°30'); the upper row gives the altitude reading paired with the "à cap. Poll." distance, the lower row(s) give the further altitude reading(s) paired with the "à cap. Cast." distance and the altitude of Pollux — a genuine compositor layout, not a column slip. Half-minute entries (2½, 21½, 16½) are as printed. Row 39's Pollux-altitude cell is blank.

In the year 1653, in the month of May, evening Mercury was always observed one hour next after sunset [vesperinus semper vna hora proximè post occasum Solis], by means of distances from Procyon [à Procyone], and from Capella [à Capella], and [the distance] of Mercury from the vertex [à vertice].

The following table records the May 1653 evening Mercury observations at Bologna. Columns: running number; day of May ("Maij Dies"); the "distance seen of Mercury" ("Distantia visa Mercurij") from the vertex ("à Vertice"), in degrees and minutes; from the fixed stars ("à Stellis Fix."), in degrees and **minutes** (NOT seconds — column header reads "M."); and a note "that is, from the [stars] written below" ("Idest ab infrascriptis"). Each day carries a paired reading, one row referred to Capella and the next to Procyon.

#	May Day	à Vertice		à Stellis Fix. —		Idest (from)
		— G.	M.	G.	M.

55	13	79	26	41	28	from Procyo n [à

#	May Day	à Vertice — G.	M.	à Stellis Fix. — G.	M.	Idest (from)
						Procyo ne] — "becaus e Capella lay hidden behind the clouds, see below in the supple ment" [quia Capra latebat post nubes, vide infrà suppl.]
56	15	83	44	21	22½	from Capella [à Capella]
		83	51	39	54	from Procyo n [à Procyo ne]

Parsing notes: Each day carries a paired reading (two successive readings, the first referred to Capella, the second to Procyon, each to the vertex and to the fixed

star); transcribed on two rows. The second "à Stellis Fix." column is **minutes, not seconds** (header "M."); all values are < 60. The fractional 21½ / 22½ are legitimate half-minutes as printed. Obs. 55 (May 13) has only a single Procyon row and the marginal note that Capella (Capra, the She-Goat) was hidden by clouds.

[Margin / supplement note:] **Supplement [Suppl.]** — 12 [May]: Mercury was seen distant from the vertex [à vertice] by 80° 28'; in that azimuth in which Aldebaran was seen distant from the vertex [in eo Azimutho, in quo Aldebara visa est distare à vert.] by 74° 50'.

(continuation of Caput VI — Bologna Mercury observations)

57. In the year 1657, on the morning of 5 December, when Spica Virginis [Spica] stood in the eastern quadrant, distant 58°20' from the vertex, I began my reckoning at perpendicular time, and afterward, at 8h30', I took Mercury's distance from the vertex as 81°16', with the planet expected in azimuth 55°27'52" — and corrected. From this, and reckoning from the meridian, Father Francesco Maria Grimaldi [Grimaldi], to whom we owe this observation, deduced Mercury's place as 24°19'55" of Scorpio, with northern latitude 1°48'55", and an elongation from the Sun of 18°50'; this at about 8h after midnight.

CAPVT VII.

On the Hypothesis of Mercury's Motions.

1. There is no need to repeat here what I have explained fully enough in Book VII of the *Almagestum Novum* [Almagestum Novum], Section 4, and here in Book V, Chapter XII, where I expounded the most celebrated hypotheses — that is, theories — of the various astronomers concerning the motions of Mercury. I leave to the reader, drawing on Book V of this volume (in connection with Saturn), what is contained in Chapter X on the methods of observing the places of the planets, and in Chapter XII on the geometrical figure made by various spirals about the cone, rather than by a circle, the ellipse being here tacitly understood. So only a few points remain to be added or recalled here.

The first difficulty in observing Mercury is that, quite apart from the error introduced by the great number of minutes — owing to its nearness to the Sun, on account of which it is always wrapped in the inconstant vicissitude of refraction — Ptolemy and Copernicus frankly confess that they themselves could never observe Mercury because of the vapors of the Nile, or because Mercury

was invisible at Vistula. This must be excused; but it must also be set down to the discredit both of Tycho Brahe [Tycho Brahe], in the preface to his *Astronomical Letters*, and of Longomontanus [Longomontanus] in Book II of the *Theoretica*, Chapter 20, that Mercury was rarely observed by them in so great an obliquity of its sphere — far greater, I say, than the horizon of Uranienborg [Uranienborg] possesses. I excuse Tycho, who placed it beyond the third magnitude, 5° or sometimes 7° in error; but Longomontanus erred more, indeed by more than 12° , even though he says he examined Tycho's observations in 10 places. In Chapter 20 of the *Theoretica* he examines, but does not find among the observations, the value computed from the Danish Tables — differing by $11\frac{1}{4}'$, even though it elsewhere exceeds whole degrees, as I shall say at number 3.

2. Let us now hear Kepler [Kepler], who at page 15 of the *Fundamentum* of his Ephemerides said he did not fear, in his Rudolphine Tables, an error in Venus that should much exceed $15'$; he subjoins: *In Mercury the difficulty is greater, and if errors of greater moment are detected, they are very rare. All my observations, gathered through 20 years (those at least that are trustworthy and reliable), fall within a single Mercurial trine; the other two trines remain unobserved — this, I say, in our hemisphere. Now how great a difficulty it is, from the arc of a single part to consume the whole error of the total course within a single curvature, there is no need of many words to declare. Therefore, even in the greatest elongations [greatest elongation], which our Sun does not blot out for our hemisphere, no great error can exist; but in the conjunctions, of which there is great store in my Meteorology, since they always lie within the limits of those same days, I do not venture to affirm that my computation is always within a quarter of a degree; for the degrees can sometimes be varied by half a degree, in those cases at least in which Mercury appears retrograde, and that with retrograde motion, by a single degree or even a half.*

3. Long ago I noted, in Book III of the *Almagestum Novum*, Chapter 3, in the Scholia, and in Book VII, Chapter 6, number 5: In the year 1631, in November, Mercury was observed beneath the Sun by Petrus Gassendus [Gassendi] with the aid of a telescope, and from that very moment the conjunction was reckoned at $7^h58'$; from this it was deduced that Ptolemy's Tables erred by $4^\circ23'$, the Prutenic by $5'$, the Danish by $7^\circ12'$, the Lansberg [Lansberg] by $1^\circ21'$. Rudolphine by $14^\circ24'$; whence I deduced that Natalis Duretus [Noël Duret], formerly a follower of Lansberg in the Ephemerides, had gone over to the Rudolphine camp. Mästlin [Maestlin] too, and Hortensius [Hortensius], differ widely.

[Margin: Mistakes of the various Tables in degrees.]

Gassendus, having seen Mercury beneath the Sun, affirms that in the year 1632, on 31 July, the conjunction was observed by him 2h53' later than the Danish Tables ought to have it; and that Antonius Maria de Rheita [Anton Maria Schyrleus de Rheita], in Chapter 2 of his *Sidereomysticus*, noted in the hypothesis of Tycho's Tables errors of Mercury of 5°, 6°, and 7°. Kepler himself, in expounding the foundation of his Ephemerides, page 32, when he had said that his own calculation distrusted itself to within about 21', that very minute, computed from the observation of Mercury's conjunction with the Moon (which was noted by Lynceus [the Lincean — Galileo's Academy] in the year 1617, on 8 March, at 7h26' after the meridian), confessed it to be of so little weight that it should rest not on the foundation of Tycho's calculation, but in part on the foundation of the lunar calculation.

4. But Elias of Leon [Elias of Leon], who is author of the work *Urania Propitia*, at chapter 2, page 17, points out that Kepler erred in a faulty calculation, and notes the cause of inability. For Kepler, from the diurnal slowing of the Moon overtaking the retrograde-moving Mercury (which was 14°11'), deduces that it ought to be reckoned from those hours at 7h7', grade 3°51' — whereas in truth he ought to have deduced 4h4'20". So that error 2°14' — not from the Tychonic foundations, but from a false Keplerian computation — comes forth. Elias adds, to the commendation of the Rudolphine Tables, another observation, in which Longomontanus at Copenhagen, in the year 1607, on 14 April, in the old style, at about 7h after the meridian, saw Venus, and with Venus the star of Mercury distant in remote parts 2°24'. The Rudolphine [Tables] exhibit that distance 2°25'30", and so in reality, but with others differing 2°25'. And he concludes by saying: *This being observed, except for the Rudolphine, no other Table satisfies — to say nothing of the Danish, the Lansberg, and the rest of the older ones; for the Philolaic [Tables] and ours had not yet seen the light.* He adduces the ancient observations which Ptolemy proposes in Book 9, Chapters 7 and 10; and he asserts that two of these chapters are most corruptly interpreted, or are wrong through the carelessness of copyists, partly through Ptolemy's own error, who, reckoning the days of the Egyptian months by the year of Dionysius, with the days, months, and year of the Egyptians not corresponding, made it that thereby the 30th day of Phamenoth should fall on the 30th of Mechir. Proinde [Therefore] Elias, having said this, proposes at page 71 the foundation of his own Tables, [namely] that the restitutions are made from observations chosen for this purpose — by which it appears that the Rudolphine come close to those observations, this remedy being in some way needed, unless a more accurate computation should be wanting. It will, however, be such as one might suspect that even Elias, from too great affection and devotion to the Rudolphine —

namely, the type of [the year] of Dionysius — accommodated [things] to those tables, nor easily persuaded anyone that Ptolemy on whole months should err, etc. for Mechir, this is possible Phamenoth. And thus he is to be seen, God willing, in the *Chronologia Reformata*.

[Margin: Kepler's faulty calculation.]

5. Boulliau [Boulliau] indeed, in Book 10 of the *Astronomia Philolaica*, affirms longer delays of Mercury toward Aphelion, and swifter passages through Perihelion — frustrated in his attempt at this in the very Hypothesis which, being Elliptical, he had neither hoped for nor in digesting this planet's motions had foreseen — wrought out, because he is destitute of observations. According to Ptolemy at most, however, the times: He nevertheless promises the true proportion of the Orbits, place, and Apsides of the Nodes. If, however, any author should weigh penetratingly, with what zeal toward Mercury candor and truth pursue the observations made about Mercury by Walther [Walther], Tycho, Gassendi, Hortensius, and others, meaning that nothing has been more diligently done hitherto by any astronomer that I know of, to perfect, with this in mind, the mean motion of Mercury — now follows the Rudolphine, now adds $11\frac{1}{4}'$ — we shall add to ours some correction of this, the observation, and commentation in some way.

6. Lest, however, with superfluous prolixity I should fill the pages with many observations chosen, which as a touchstone I assume — the Lydian Tables, here examined, are to be set forth, of which I lay down 4: I will return; by which, properly assumed, our Tables approach — and then the Philolaic and the Rudolphine, etc. I am willing to set forth to the readers what is here subscribed:

[Margin: (number 6)]

1. In the year 1585, on 14 November, in the old style, Tycho of Uranienborg, at one hour after the meridian, observed Mercury in Scorpio $13^{\circ}4'$; he deduced its place in Scorpio $12^{\circ}18'$. The Danish Tables give its place in Scorpio $12^{\circ}57'$. The Rudolphine in $13^{\circ}7'45''$. Ours in $13^{\circ}2'54''$.

2. In the year 1587, on 9 January, in the old style, Tycho of Uranienborg, at 4h50', observed Mercury in Aquarius $17^{\circ}48'$; adding northern latitude $0^{\circ}1'$, with adding that the Alphonsine had been in $18^{\circ}29'$ with northern latitude $0^{\circ}24'$. But Copernicus also in $16^{\circ}41'$ with southern latitude $0^{\circ}6'$. The Philolaic Tables exhibit Mercury in Aquarius $17^{\circ}35'12''$. Ours in $17^{\circ}35'45''$.

3. In the year 1592, on 3 February, in the old style, at 5h40', of Uranienborg, Mercury was observed in Pisces 12°20'; whence Longomontanus has, who from the Danish [Tables said] Mercury was in Pisces 12°13'57". We [have it] in 12°15'.
4. In the year 1631, in November, at Paris, Gassendi observed Mercury beneath the Sun, and reckoned its conjunction with the Sun at 7h58' after midnight, in Scorpio 14°36'. Our Tables give the Sun then in 14°38' of Scorpio. Ours [give] Scorpio 14°37'40" with northern latitude 4°35'.
5. In the year 1632, on 31 July, in the morning, at the hour after midnight 4, Mercury was observed in conjunction with Venus, at Paris. But Hortensius from his own observation at Amsterdam [reckoned] it to have been at the hour 11h5', after the meridian of day 30. We, from the Tables, had Venus at hour 4h40'. At Bologna, after midnight of day 31, in Cancer 24°22'15", and Mercury in 24°36'40"; wherefore by diurnal motion I deduce that conjunction to have been almost in that same midnight, since the conjunction intervened between days 30 and 31 of July. The Danish Tables erred in degrees 3, in the place of Mercury; and the Prutenic anticipated that Synod by whole five days. It ought to be placed after this, which will be placed at number 9.
6. In the year 1634, on 2 October, Gassendi, at Aix [Aix-en-Provence], at the hour reduced to Bologna 17h58', after the meridian, observed Mercury more easterly than the outermost star of the southern Wing of Virgo by about 6'. But that star then stood in Virgo 22°0'3'; and Mercury in the degree of Virgo 22°5'50". Rudolphine in 22°5'. Boulliau in 22°6'58".
7. In the year 1636, on 27 June, in the evening, Gassendi at Aix observed Mercury compared with Venus, in Cancer 25°5'53"; refraction however being excluded, so that Boulliau gathers refraction. The Rudolphine Tables give Mercury in Cancer 25°1'. The Philolaic in 25°3'33". Ours in 25°4'10".
8. In the year 1636, on 16 July, in the evening, Gassendi at Aix observed Mercury in Leo 21°26'. The Rudolphine of Uranienborg produce its place in Leo 21°30'. The Philolaic in degree 21°25'47". Ours in degree 21°25'52".
9. In the year 1634, from the observations of Gassendi, Boulliau gathers, on day 2 at hour 6h30' after the meridian, of Uranienborg, that Mercury had been in 22°30'43" of Aquarius; and at greatest elongation from the existing Sun in 13°53'43" of Capricorn. To me then the Sun stood in 13°29'8" of Capricorn, and Mercury in 22°31'10".

10. In the year 1636, on 3 September, at hour 17h after the meridian of the Danish [meridian], with a telescope he observed Mercury more westerly than Regulus by 10'; whence Boulliau gathers. To me Mercury then was in 24°48'17" of Leo. Therefore Mercury in 24°38'17" of Leo. The Rudolphine give in 24°27' of Leo. The Philolaic in 24°38'52" of Leo. Ours in 24°37'55" of Leo.

11. In the year 1657, on 5 December, in the morning, at about hour 8h after midnight, Mercury was observed in Scorpio 24°19'35". Our Tables give in 24°16'7". But the Danish in 25°24' of Scorpio. The Lansberg in 24°45' of Scorpio. And this for the present is enough.

DISTANTIIS A SOLE, ET A TERRA.

BOOK TEN

In which are the *Paralipomena* [supplements] of the Observations pertaining to the Fixed Stars and the Lesser Planets — namely, concerning their Apparent Diameters, and their Figure, Bands, Spots, Rotation, Companions, and the Motions of the Companions, and their Distances from the Sun and from the Earth.

CAPVT I.

On the Methods of Observing the Diameters of the Fixed Stars and of the Planets.

The first method, employed by the ancients, consists in the ocular estimation of comparing the seen Diameter of a Star with a portion of the Lunar Diameter, or with the small distance between two Fixed stars otherwise known — say, with the distance of the Pleiades among themselves, or of the Hyades. But this method is very fallacious, or [is established] by the experiment of many observers at once observing the same thing, since however many eyes there are, so many for the most part are the differing opinions about the magnitude of a Star which they bring forth. The reason is that the rays adventitiously assumed about the Stars — whether from the Atmosphere, or from the humors of the eyes, or [as] appearances of refraction — enlarge their discs optically, and on the contrary detract just as much from the distances of those stars among themselves.

[Margin: 1. Method.]

The second method is carried out by means of the Dioptra of Hipparchus, or similar [instruments] — that is, by applying a very narrow strip, which at a great but known distance from the eye covers a Star precisely; or by applying a small

tablet, or a thin sheet, with a hole so small that it intercepts a Star at a great but likewise known distance, within the margins of its own edge — or at least a space three times greater than the Star's disc: for by the laws of right-lined triangles, and of rectangles, from the given thin sheet, or tablet, [held] at a distance from the eye, and by the similitude of the tablet, or sheet, an angle is gathered, which doubled measures the apparent diameter of the Star; or in the third kind of usage of the tablets, a space three times greater than the apparent diameter of the Star. But this method, in whatever manner, is for the said reasons fallacious by a triple cause. First, because the situation, in which the tablet is whole, or perforated, congrues precisely with the diameter of the Star, or with a space three times greater, does not consist in something indivisible, but it is established by an experiment that there moves, or draws back from the eye, or toward the eye, a sensible difference appears to the eye; then that very ocular estimation, on account of the assumed rays of the Star, is in the first method fallacious. Finally, the angle which is acquired by a Dioptra of this kind is not a true visual angle; for it is in the surface of the eye, but the true visual angle is constituted in the surface of the Retina, which is at the bottom of the eye; and therefore so great a Parallax intervenes, as great as is the depth of the eye, which however if it be known, and added to the distance of the Dioptra from the surface of the eye, the angle could be more justly obtained, otherwise always greater than is just.

[Margin: 2. Method.]

To this method are reduced our Rays, both Triangular and Scalar, concerning which [see] Book 6 of the *Almagestum Novum*, Chapter 9, number 6; and the method of Galileo by a perpendicular thread —

suspended perpendicularly, which method I nonetheless reserve to treat separately.

[Margin: Method 3] **The third method**, then, carries out the observation by means of a thread suspended perpendicularly: receding by a fixed distance from the eye until the small thread, by its thickness, exactly conceals the star whose apparent diameter we are measuring; then noting the distance of the eye from the thread, and the breadth of the thread itself, and from these computing by the rule of the Triangular Rays the diameter of the star, as I have said. Reckoning the distances of such a thread, let it be taken in inches, but the breadth of the thread must be added in twelfths of an inch [unciae and their twelfths]; for these are the Triangular Rays. The rest, then, belongs to Trigonometry, to be worked out. So Galileo [Galileo Galilei] teaches in Dialogue 3 of his *System of the World* [*Dialogo sopra i due massimi sistemi*], where, in covering over the star, he holds that one

must take care to cut off only the adventitious rays, not those that are within the prior limits. Yet here too lies a fallacy of the preceding methods: for since this method does not impede the reflected rays even on its own margins, those rays are still troublesome.

And although this method has been carried out as exactly as it can be, it has nonetheless deceived the most studious in the diminution of the apparent diameter of the fixed stars — so much so that Copernican hypotheses derive probability from it, since by it the immense distance of the fixed stars increases all the more the bulk of those stars, however small their apparent diameter may be. [Margin: A singular warning] **A singular warning.** And let it be observed here, and in all the other aforesaid methods, that one must beware lest, from the proportion seen in the whole disc — whether of a circle, or of a small circle, or of a star, or of a lens — an equal proportion be inferred among the diameters; nor are the circles themselves to one another as the diameters are to one another, but as the squared diameters, that is, as in Element II.12 of the *Elements* [Euclid, *Elements* II.12]. By way of example: if Sirius be to Jupiter as 5 is to 4, Sirius will be eightfold smaller than Jupiter; for the squares of these, that is, the squares of the binary, are contained in the number 32, which is roughly the number $5 \frac{4}{7}$.

[Margin: 10] **The tenth method** requires the application of some Stationary Planet to a Fixed Star, especially the slowest-moving, comprehended within the tube; considering how many times the Star, or the Planet, is contained either in their mutual distance, or, from the Planet's motion, how much of that interval the Planet traverses — according to the examples and precepts handed down in *Almagestum Novum* VII.10.

[Margin: 11] **The eleventh method** is supplied by Christiaan Huygens [Christiaan Huygens] in his *System of Saturn* [*Systema Saturnium*], page 82, in these words: "There is a certain place within the tube, equipped only with the connection of the glasses, situated at so much greater a distance from the other [glass] than the eye-glass is distant from the eye, by how much that place — if anything subtle and finely terminated be placed within the cavity of the tube — represents it to the vision as distinct and of well-defined outline. This place falls to eyes of perfect focus; but for some it must be taken a little nearer, for others farther off, according to the limit of the eyes. Here, then, let there be set up a little ring with a small angular opening, as near as may be to the eye-glass, so that the whole opening may be detected in the heaven without parallax — or rather a hair circularly disposed, so that a more precise measure may be had. The diameter of this opening, what fraction of a foot it comprehends, must be inquired from the

transit of a star [*sidus*], the time of whose transit is measured by the vibrations of a pendulum, or by our oscillating Clock, while the telescope meanwhile stands motionless. This being found, let a little metallic rod of decreasing breadth be gradually introduced into the tube at the said place, and let it be noted at what breadth the rod precisely covers the Planet; and the breadth received from the circle being compared with the whole amplitude of the opening, thus the apparent diameter of the Planet is easily made known by reckoning. But I judge this slippery and difficult to recall to mind, namely with what part of the rod precisely it has covered the whole Planet."

he indicates the method by which they were used in this determination. **Kepler** [Kepler] in the *Epitome of Astronomy* [*Epitome Astronomiae Copernicanae*], volume 2, page 485, partly from the 9th observation of **Io. Remus** [Johannes Remus Quietanus], and partly as I have indicated in the preceding chapter — established partly from certain analogies among the bulks themselves, partly from the intervals of the Planets worked out (a thing he is wont to emulate in turn) — is **Rheita** [Anton Maria Schyrleus de Rheita] as well, in book 4 of the *Oculus Enoch et Eliae* [Riccioli: *Radii sidereomystici* ch. 2 member 2], who confines Saturn's diameter at its greatest distance to 30", and in the *Tabulae Rudolphinae* [*Tabulae Rudolphinae*] to 110": he says (book 7) "Saturn is never seen larger than 30" — second to none." And in the same place he supposes, from the *Epitome of Astronomy*: "That the bodies of all the Planets are in the proportion of their bulks, and of the Sun's interval in its subtriple"; yet prudently in the *Epitome* he has said: "I yield the place to Remus, I yield to observations." But Rheita, in book 4 chapter 4 member 2, affirms that he, in the year 1644 on the 20th day of July, with the telescope took in the whole disc of the full Moon, and translating it onto a divided chart, found the diameter of Jupiter to be nearly the tenth part of the Lunar diameter — that is, of the Lunar minutes, 3'. The diameter of Saturn, indeed, is the fifteenth part of the Lunar diameter — namely 2' and a little more. There was at that time Jupiter near the aspect of the Sextile of Leo, and Saturn near the Quadrate. But **Martinus Hortensius** [Martin Hortensius], as he reports in his *Dissertatio cum Gassendo de Mercurio in Sole viso*, using the method of the preceding chapter in the year 1625, saw in February that Saturn at Perigee was round and very nearly equal to Jupiter, whose diameter was 40"; in the year 1632 he saw Saturn's diameter 36"; and Jupiter likewise appeared to him 40". But when the small body was taken with its appendices, which did not entirely stand out — whence it appears that Saturn without its companions is seen through the telescope second to none of 31" at Apogee, and 42 1/2 at Perigee, by which Saturn's whole interval is gathered. **Hevelius** [Johannes Hevelius] in his little work *De Saturni facie* page 23 affirms that Saturn appeared to him in the year

1656, when it was alone, as round, at a mean distance of 39" and a third, 36"; **Hugenius** [Huygens] at Perigee, and alone, 30" with the ansae [handles] 68".

[Margin: 2 — Our two observations] **We ourselves**, however — namely **Father Giovanni Battista Riccioli** [Riccioli], in the year 1649 at its close, and at the start of the year 1650, when Saturn was rising acronychally — made the diameter [of Saturn] observed often more notably; and again on the 2nd of December and the 10th of January. It was, moreover, the 18th of December at the Perigee of the Epicycle, and about the 27th at the Perigee of the Eccentric. And with a very large telescope, by Methods 5, 6, 7, 8, and 9 set forth in the preceding chapter, we observed Saturn, both as to its diameter, more so than Jupiter, and we find Saturn's compound diameter AB, with its sides [lateral bodies], to be 13"; but Saturn alone, taken without its lateral bodies, with its simple diameter FG, reduced to Jupiter's diameter, 6 1/2. The diameter compounded AB to Jupiter's diameter as 5 3/4 to 8. Suppose now the appearing diameter of Jupiter, then in the following measure, to be 44"; for if it be made 8 to 44, and so 44 to another, there will result Saturn's diameter AB, in seconds, 7 1/2. Again, if it be made 8 to 6 1/2, and so 44 to another, there will result the diameter FG in seconds 34".22". Finally, if it be made 8 to 5 1/2, and so 44 to another, there will result the diameter CD in seconds 31".38".

[Margin: 3] During those same days the two stars among the Hyades observed occupied a quarter of the interval of their gap in the heaven; this through our telescope was comprehended, and turned out to be 5 1/2 minutes, or a little more. Saturn's diameter AB, in the space of those stars, was seen to be contained 5 1/2 times. Again, considering a certain star of the Twins, neighbor to Propus, in the Catalogues of the Fixed Stars omitted, as visible only through the telescope, but cast off by us, because it was in a straight line with AB, and contained the space between it and Saturn's extremity, the remoter A, 5 1/2 times Saturn's diameter AB; the same star, with respect to Saturn's diameter AB, most evidently 4 1/2 to 1. Now indeed, from the interval at the other extremity A, to that star, with the foresaid diameter of Saturn, the Hyades interval frequently compared, was seen to it altogether equal. Hence Saturn's diameter AB was [confirmed at] 7 1/2 seconds, or 72".

[Margin: 4] In the year 1650, on the following night, the 2nd day of January, an hour after sunset, Saturn was at its diameter AB, in the same nearly straight line with a certain westerly star, and a Fixed [star] which, through the telescope at the same time with Saturn, was conspicuous; but on the following night, the 3rd, about 2 hours of night, in which Saturn was beginning to recede little by little

from its proper orbit, parallel to the Equator — let that line be drawn through the centers of Saturn and the star, and below, as we shall say, parallel to the Equator; thus Saturn evaded toward the west, and the more westerly of the said stars, and by the straight line PR, perpendicularly drawn from the star P, above the diameter AB, cutting off nearer to F than to R, a fourth part precisely. Thereafter about 5 1/2 hours of night, Saturn, retrograding from its setting, was reconstituted; the star appeared at it in H, and the line HL produced, and BA likewise, so that the interval HL was equal precisely to the space AB, that is, to a fourth part of the diameter AB; but the true interval AL, Saturn receding and going toward the west, manifestly appeared greater. Now indeed, from more accurate Tables the motion of Saturn appears to have been in that natural minute 4'.30"; therefore the Hourly Second 11".15". Therefore at hour 2 ad hor. 5 1/2, Saturn's center O, completed 56". The Second, then, 34", that is, the space equal to the semidiameter AO, namely a perpendicular at the star P, falling perpendicularly in R; but AF, equal to itself AF, since the rod cut off the whole diameter AB — when it was perpendicular falling as H in L, and AL equal itself AF, so therefore LF, and equal the semidiameter AO, and equal the Second 36".34". The whole therefore AB is 73".8", which exceeds the prior observation, the Second 72"; namely the Difference between so diverse modes [methods], plainly contemptible; indeed, by next-to-nothing consensus, altogether wonderful, and worthy of religious credence over the matter related.

[Margin: 5] Assuming, then, Saturn's Perigeal Second to be 73", or 1".12" for Saturn's sole diameter FG, the Second 36", from the Problem stated in *Almagestum Novum* VII.5 chapter 8, and from the least distance of Saturn from the Earth, which we put under chapter 2, the Terrestrial Semidiameter 57743: we shall gather its true Semidiameter, simply taken as FO, the Terrestrial Semidiameter 4 4/7; the compound diameter AO, the Semidiameter...

Diagram. A telescopic-observation schematic for Saturn, set within a large horizontal ellipse (the field of view of the telescope). Inside the ellipse, two crescent-shaped dark figures flank a small central body — depicting Saturn (the central disc) with its two lateral appendages (the ansae / "handles") shown as the crescents. A horizontal baseline runs across the ellipse with several lettered points. Above the ellipse, the planetary symbol ♄ (Saturn) is marked. Vertical dotted construction lines connect points above and below the figure.

- ♄ (top center, above ellipse): symbol of Saturn
- H (upper left, above ellipse): construction point

- P (upper center-left, above ellipse): star position (marked with an asterisk *)
- C (top of ellipse, center): point on Saturn's disc (upper)
- L (left end of baseline): construction point
- A (on baseline, left of center): Saturn's extremity / left limb of diameter AB
- K (on baseline, between L and F): construction point
- F (on baseline, center-left): endpoint of simple diameter FG
- O (on baseline, center): center of Saturn
- G (on baseline, center-right): endpoint of simple diameter FG
- M (on baseline, right): construction point
- B (right end of baseline): Saturn's extremity / right limb of diameter AB
- D (bottom of ellipse, center): point on Saturn's disc (lower)
- R (lower center, below ellipse): foot of perpendicular from star P

the Terrestrial Semidiameter $9 \frac{1}{3}$. Thereafter, from the distance of Saturn from the mean Earth, Semidiameter 73000, and from the maximum 90155, by the Problem of *Almagestum Novum* (same chapter 8), we deduce the apparent Semidiameter of Saturn at mean distance, simply indeed FO 13".20": the compound AO 28".30"; but at maximum distance FO 11", and AO 23". Provided that Saturn, with its companions, preserve in its various Phases the proportion of apparent magnitude and the variety of distance shown.

CAPVT III.

De Diametro Apparenti Iovis.

[Of the Apparent Diameter of Jupiter]

[Margin: 1 — Opinions of the ancients. And of more recent men.] **The apparent diameter of Jupiter** Albategnius [al-Battānī] and Alfraganus [al-Farghānī], with a difference of 22, defines at minimum 2'.36", at the mean distance from the Earth. **Fernelius** [Jean Fernel], and **Egnatius Dantes** [Egnazio Danti], 2'.32"; **Maginus** [Giovanni Antonio Magini], and **Vursisius** [Christoph Wursteisen] (alas how various!) at minimum $9\frac{3}{4}$ "; **Tycho** [Tycho Brahe] in volume 1 of the *Progymnasmata* [*Astronomiae Instauratae Progymnasmata*], page 468; **Clavius** [Christoph Clavius], and **Blancanus** [Giuseppe Biancani] in the *Sphaera*, and **Argolus** [Andrea Argoli] in the *Pandosion Sphaericum*, at minimum 2'.45". But **Lansbergius** [Philippe van Lansberge] in the *Uranometria* book 3, minimum 2'.30". But no one infers any foundation from the matter. **Kepler** indeed in the *Epitome of Astronomy* volume 2, page 485, and in the *Tabulae Rudolphinae* page

110, from the Analogy indicated above of the subtriple proportion, establishes Jupiter's diameter at maximum distance from the Earth to be 50". But **P. Rheita** [Rheita] makes it nearly fourfold greater: for in book 4 of the *Radii sidereomystici* chapter 4 member 2 he says he, in the year 1644 on the 20th of July, used the telescope with great excellence. With the telescope he took in the whole disc of the full Moon, exhibiting it 34" minutes, and in its ocular convexity, surrounded by Lunar extremities, with the most subtle little circle of the Lunar diameter encompassed, and translating it onto a chart divided into 34 parts equal, and in the same manner finding Jupiter's diameter, as it were the tenth part of the Lunar diameter — this being the tenth part 3" minutes. But whether this practice be safely used will be established from the more certain quantity of this diameter, concerning which presently.

[Margin: Of Marius. Of Hortensius.] **Simon Marius** [Simon Marius] in his *Mundus Iovialis*, from observations made with a tube and small mirror [*tubo specillo*], puts Jupiter's diameter at the mean distance very nearly at 1'. But **Hortensius**, exploring [it] by the capacity of the telescope, as above, saw in the year 1632 Jupiter's diameter acronychally, in the year 1632. **Jupiter's** Acronychal diameter occupied the fifth part of the gap which is between two contiguous Stars in the following constellation of Capricorn, which gap was of Minutes 5'.15"; and so Jupiter's diameter, minimum 1", indeed less; in some doubt, says **Gassendus** [Pierre Gassendi] to have apprehended in the year 1630, as the same Hortensius reports in the *Dissertatio Mercurii cum Gassendo*. He adds, on November 13th, that, excepted from Jupiter's image, repeated, the fourth part of the said gap, the gap had been 130; again on another night he found Jupiter's image of parts 6, of which the Solar image was 195; therefore the Solar diameter being put, Jupiter's diameter he concludes to be a little fuller, by one minute. From this, then, he chose it, by minutes 1'.1".40". The Apogeeal indeed Second 38".30".

[Margin: 3 — Of Hevelius] **Johannes Hevelius**, in his *Selenographia*, page 449, narrates that he, in the year 1646, on the 21st of April, at hour 12 the evening prior, observed Jupiter's diameter equal to one-third, which he, from the Pontus Euxinus situated, calls Mount Moschus, and which he found the first part of the Lunar diameter at the 29th, very nearly. Hence he constitutes, the Moon being then minimum, about 30, concluding Jupiter's diameter to be minimum 1'.2". He narrates in the year 1646 December 24th: Jupiter compared with the Lunar Aetna seen by himself one minute; but at page 347 he had said Jupiter compared to it 12. In April with Mount Crago, set down; the Lunar diameter minimum 34", scarcely the lesser of one minute.

[Margin: 4 — Of Gassendi] **Gassendus** in the Epistle of the year 1630, on the 6th of the Kalends of September [Aug. 27], to Kepler published at The Hague, reports on the 16th of August in the evening to have observed by the telescope an interstice between a certain little star, and the Moon's margin, capable of a sixth part of the Lunar diameter; and if to this interstice could be made equal five Acronychal diameters of Jupiter; and therefore Jupiter's diameter is in no way greater than one minute. In the *Epicurus* page 901, he narrates to have observed by the telescope Jupiter rising, with a diameter equal to a seventh part of the Caspian spot; and therefore he determined that very part of the Moon, in seconds, 33. There was, indeed, the 20th day of January of the year 1647, when Jupiter approached most near and to opposition with the Sun, and to the Perigee of its Epicycle; whence it appears, from the near splendor of the Moon, to have appeared less to Gassendi than at other times in acronychal position. **Cristianus Hugenius** [Huygens] puts Jupiter's Perigeal [diameter] at seconds 64" in diameter, by himself observed. Our Fathers at Oeniponte [Innsbruck], from the capacity of the Tube, estimated Jupiter's diameter \approx in the year 1635, March 19, 1'.12"; or in the year 1637, March 16, they estimate 1'.28", or 1'.30". The Marquis **Cornelius Malvasia** [Cornelio Malvasia] from the Tube's intervals of the year 1662, in May and in June, estimated 51"; in September 41".

[Margin: 5 — Our observation] But truly in the year 1649, at the start of June, with **Father Francesco Maria Grimaldi** [Grimaldi], in observing Jupiter's Zones, when I had noticed Jupiter most strongly preceding the stars on the left wing of Virgo, which was in the sixth part in the star of Virgo, having the latitude of those Boreal stars at gr. 1.25', and existing then in \square gr. 29.56'.25"; and when, from the Montebruni Ephemeris, Jupiter would be of Boreal Latitude gr. 1.25', about; nor did I doubt of the proximate conjunction of Jupiter with that star, and of the opportunity of establishing four diameters of Jupiter from its motion, and from the distance of the star — concerning which I shall presently explain more clearly by the schema written below.

Diagram. A telescopic-observation schematic illustrating the conjunction of Jupiter with a star in Virgo, oriented by the four cardinal directions. Across the top is the label *Septentrio* (North); across the bottom *Meridies* (South), with the central vertical axis pointing to a point A below. On the left is *Oriens* (East), on the right *Occidens* (West). On the left side a circle (Jupiter's disc, larger) with center G is drawn, with points N, K below it and a horizontal hatched bar above (PM / NL, Jupiter's belts). On the right a smaller circle with center H is drawn (the star's apparent disc FBG), with points P, F, M, R. A horizontal line connects the two

circles through points L, D, P. Diagonal lines descend to the point A at the bottom (the vertex of the triangle of observation), forming triangle AB / AC.

- *Septentrio* (top): North
- *Meridies* (bottom): South
- *Oriens* (left): East
- *Occidens* (right): West
- ♃ (upper left and upper right): symbol of Jupiter (marked twice, at both disc positions)
- N, K (left, below larger circle): construction points
- L (center-left on horizontal line): construction point
- G (center of left circle): center of Jupiter's disc
- D (center on horizontal line): construction point
- P (center-right on horizontal line): construction point
- F, M (right, near smaller circle): endpoints of the star's apparent diameter
- B (right): the star (Virginis)
- H (center of right circle): center
- R (right, below): construction point
- A (bottom, vertex): vertex of the observation triangle

Let A be the star of Virgo, the center of the more westerly Jupiter B, whose apparent disc FBG is much larger, however, than the place itself represents. Let the center of the more easterly Jupiter be C, its belt PM and NL, and the line RBCK parallel to these, and to the Ecliptic; concerning which Parallelism it will be established below. Now from the star A, the more southerly, than which Jupiter [is], let the line KR be drawn — by perpendicular chord, let the arc AD be carried through, which connects the center of Jupiter's disc with the star A; by straight lines AB, and AC, produced, let AB be, so that in F, it be the diameter GBF, which diameter is understood to be divided quadrifariously, so that GH be a fourth part of it.

[Margin: 6] On the 9th day of June, hour 1, after sunset, Jupiter appeared in B, more westerly, and more Boreal than the star A, and so by the telescope showing the distance AG, of parts altogether 7, of which one was AB $3\frac{1}{2}$, of which one was GB, the semidiameter of Jupiter, and the whole AB of parts 9, of which GH, equal to four diameters of Jupiter. On the following day, indeed, about the tenth part, Jupiter appeared in C, more boreal, and more easterly than A, so that the distance AC, was of parts precisely eight, of which a quarter part is Jupiter's diameter, equal to four of Jupiter's diameters. The line BC drawn, indeed,

designates Jupiter's path, and the latitudes of the arc chord AD, indeed Jupiter again at its time was in D, conjoined to the star A — incorporeal indeed, but Ecliptic, boreal indeed, however much AD. Which was estimated at parts $4\frac{1}{2}$, of which GH, one. These being posited: First, in the Triangle...

the angle ABD, by dropping a perpendicular to AD, since the side AD is given, the side BD is found to be $4\frac{1}{2}$ parts and the base AB 9 parts — about $\frac{1}{4}$ part greater. Next, in the right Triangle ACD, by dropping a perpendicular to AD from the side AD ($4\frac{1}{2}$ parts) and the side AC (8 parts), the side CD comes out as 6 parts, and so the whole BC works out to 14 parts of the kind of which GH (the diameter of Jupiter) is one, or $3\frac{2}{3}$ such parts — that is, equal to the apparent diameter of Jupiter.

Second, in the standstill [Iovis stationi] just preceding, the true motion was about 1 hour, 0 minutes of night for nearly 10 nights of night, that is, 2 minutes 40 seconds of arc; this comes out to 160 seconds. Let it therefore be as $3\frac{2}{3}$ is to 160, so... and indeed 1 [Jupiter-diameter] to about 160. Therefore the diameter of Jupiter appears about 160 seconds.

Hence indeed it follows that, with Jupiter at this distance from the Earth, the seconds [are] 160. Again, from the side CB, which at the same distance — that diameter of Jupiter at $4\frac{1}{2}$ to 49 parts — Jupiter therefore came out at 49 seconds. **Third, since** that star [the Virgo star], and indeed its latitude was northern, was 1 part 25 seconds; Jupiter's latitude was northern, 1 part 25 seconds 49 seconds; at the moment of conjunction, which fell on 9 June at 21 hours after noon, the longitude was then $\square 29^{\circ} 56' 25''$ — let this stand. The Prutenic Tables give $29^{\circ} 40'$ with a latitude of $1^{\circ} 36'$; the Danish [Tables] give $\square 0^{\circ} 1'$ with a latitude of $1^{\circ} 33'$; and Lansberg's give $\square 30^{\circ}$ precisely, with a latitude of $1^{\circ} 24'$. **Third, since** the anomaly of the eccentric was then about gr. $1^{\circ} 55'$, and the anomaly of the orbit nearly $248\frac{2}{3}$, the question is what was Jupiter's distance from the Earth on our hypothesis of the semidiameters of the terrestrial [orbit], 39500 [units]; and being near apogee in the eccentric, a little below the mean longitude of the epicycle, hence both the angle of the semidiameter is $23''$ — as Problem 1, Caput 8, of *Almagestum Novum* sect. 5 has it — there is collected the true semidiameter of Jupiter: the terrestrial semidiameters are $4\frac{7}{10}$. Hence by Problem 2 of the same chapter, and the distances [found] in the same section, Caput 2: the maximum distance of Jupiter is 47552, the mean 36900, the least 26441. The semidiameter of the Earth then yields the semidiameter [of Jupiter] as $19'' 9'''$ in apogee at either distance; at the mean distance truly, $24'' 53'''$; and at the perigee $34'' 23'''$ — which has been deduced by us. And whatever else may proceed from another

hypothesis, [the figures] preserve the proportion of those same intervals, [taken] with the distance of the Sun, or with the radius of the annual orbit.

These things, then, having been established by us, in the following month there was carried over to us by the letter of Master Vincenzo Muti — at Sole Alfonsino [under the Alfonsine reckoning] recently published, and a man most skilled in astronomy, given to us by Maiozica [Majorca?] — the following, which they hold: *Jupiter was observed in conjunction with the star preceding by 4 minutes in the wing [ala] of ♃ on the 9th day of the month of June, in the year 1649. Jupiter was the western one, called the star; but this one was distant from Jupiter by a diameter of nearly 10 Jupiters. On the following day at the same hour, Jupiter was now seen more to the east, between which there were 24 hours: Jupiter, by comparison with the star, was seen to have run with the greatest precision the very diameters of its own body.* Therefore Jupiter's diameter was not far off from that of Martinus Hortensius at this place [secundum 48"]. It can easily be estimated how immensely we rejoiced at so close an agreement and conspiracy of talents concerning the manner and time of this observation.

CAPVT IV.

De Martis Diametro Apparenti.

[On the Apparent Diameter of Mars.]

1. Albategnius [al-Battānī], cap. 50, and Alfraganus [al-Farghānī], Differentia 22, set down the apparent diameter of Mars at 1' minute; Fernelius and Egnatius Dantes [Egnazio Danti] at 1' 29", or 18"; Magginus [Magini] and Vurstisius [Wurstisen] at 8' minutes; Tycho [Tycho Brahe], Clavius, Blancanus, and Argolus [Argoli] in the places cited above [set it] at 1' 40"; and Lansberg at 1' 30" — and indeed all of these at the mean distance of Mars from the Earth, [namely] 3' min. 1' 30". And Galileo, in Dialogue 3 of his *On the World System* [*Dialogo sopra i due massimi sistemi*], says that if Mars be viewed through a telescope, it is seen in opposition with the Sun to be sixty-fold — or fifty-fold — larger than near conjunction, insofar as one may discern by area; but as to the diameter, eight-fold or seven-fold. Gassendus [Gassendi], *Institutio Astronomica* lib. 2, cap. 9, says that Mars, which otherwise scarcely equals a star of the second magnitude, in opposition with the Sun is, with each [augmentation], especially at perigee, in coincidence...

[col. 2]

rente [in comparison] with the apparent magnitude of Jupiter or of Venus — that is to say, understanding it thus, that Jupiter (a fixed star, as it were) is overcome by Venus near perigee. Kepler too, *Optics*, pag. 333. The astronomical-optical [writers] relate this: in the year 1529, in July, Mars must have appeared with prodigious magnitude — with a new star, one might believe — and so much greater did it appear in the month of August, in the year 1561, and again in 1593; and in August of 1608, [Mars] was at perigee, both at every season, in the eccentric of Aquarius, and at the epicycle. In the *Epitome Astronomiae*, pag. 485, [Kepler] says that Mars at perigee, in Aquarius, is seen to be larger than Jupiter, but not by much; Jupiter is seen rather frequently through a telescope. Second, 50 ["]; and yet in the *Rudolphine* [Tables] it is laid down by precept 110: he supposes the bodies of all the planets to be in the proportion of their distances, or of the intervals of the Sun, of the diameters [also] in the subtriple [proportion], insofar as Mars in proximity appears to the Earth to subtend 5' min. 15' in the semidiameter; therefore, as to the diameter 6' 50", or therefore Mars appears much larger, but [it is] not — for those proportions are so great as to be unreal. Yet rightly, by the magnitude at perigee, collated with the apparent diameter at apogee, Mars is deduced acronychal within the Sun, [being] nearer than the Sun, [more] than Mercury, and at the perigee of Venus. Moreover, the PP. Soc. I. [the Fathers of the Society of Jesus] at Oeniponte [Innsbruck], by the capacity of their telescope, estimated the diameter in the year 1636: Marco [Marcus] at 32", and on 6 May at 29"; at Marchio [the Marches?] Cornelius Malvasia, in the year 1662, on 17 July, and through his telescope at 25", about [that figure].

2. Hortensius [Hortensius], in his *Dissertatio* with Gassendus concerning Mercury seen in the Sun, relates that in the year 1632, in February, it was observed by him that Mars acronychal near the apogee of the eccentric, and at the perigee of the epicycle, was distant from the Moon's limb by no more than one digit — this is 2' 42"; and that Mars, of nearly four parts, occupied a quarter of that distance: therefore [it was] not seen by him to be much larger than 36". Hence the intervals assumed by Lansberg lead him to conclude that, at apogee, Mars appears [to subtend] seconds 9 ["]. At perigee, [seconds] 9, by 1' 4" — which subscription Herigonus [Hérigone], *Cursus Mathematicus*, vol. 4, pag. 62. Huygens defines the perigeal diameter as 30".

3. We, with Father Grimaldi [Grimaldi], in the year 1649, on 22 July, by telescope comparing Jupiter with Mars, and at each [position], saw the figure rather often passing over in paper [i.e., projected onto paper]: Mars's diameter, drawn on paper, was less than double of Jupiter's; but it was, from our hypothesis, the apparent semidiameter of Jupiter 21" 5"; therefore Mars at 10" 32" at the distance

from the apogee of the eccentric gr. 86, and at the epicycle gr. 255 — whence by the Tables, and by Problem lib. 7 of *Almagestum Novum* sect. 5. From this we drew out the true diameter of Mars: the semidiameter of the Earth being [taken], [we found] the apogeal semidiameter 5" 3"; the perigeal 46"; the mean 11" — quamuis [although] in the year 1651. On 5 April, Mars was seen collated with ♃ [Jupiter] and ♄ [Saturn] at 45"; and in the year 1655, on 22 July, [Mars at] 60 parts of the kind of which Jupiter [was] 68.

[col. 2]

CAPVT V.

De Diametro Apparenti Veneris.

[On the Apparent Diameter of Venus.]

1. At the mean distance of Venus, the apparent diameter is defined by Albategnius [al-Battānī] at 3' 8"; by Alfraganus [al-Farghānī] at 1' 34"; by Fernelius at 5'; by Egnatius Dantes [Egnazio Danti] at 4'; by Vurstisius [Wurstisen] and Magginus [Magini] at 10' 30"; by Tycho [Tycho Brahe], Clavius, Blancanus, and Argolus [Argoli] at 3' 15" — as indicated above, cap. 2.

2. Scheiner [Scheiner], in his *Epistle* of the year 1611 to Marcus Welser [Marc Welser], puts the diameter of Venus as the subdecuple [one-tenth] of the Sun's diameter, and so [he allows] up to three minutes at least; but in the elliptic Sun [i.e., the Sun viewed obliquely] he excepts the figure of Venus on paper; and on the year 1612, through his telescope he caught the figure of Venus on paper, and that of the Sun, observed at the same distance between them, both ☿ and ♀ [Mars and Venus?]; and on 23 October he found the diameter of Venus to be $2\frac{1}{3}$ of the kind of which the diameter of the Sun was 34, that is, 27'; and on 29 October the same again 26. On 5 December he again found min. 2'. Yet he confesses that the observation was shadowy [umbratilem, of the shadow-image], and reserves a better observation for another time. I do not know, however, whence Hortensius...

attributes to Scheiner an apogeal diameter of Venus of 34", a mean of 1' 40", and a perigeal of 8' 42".

3. Galileo, in his *Epistle* 1 and 3 to Marcus Welser, reprehends those who observe the magnitude of Venus, not through a telescope but otherwise, as [appearing] with a wide and ruddy fringe of hair [capillamentum, the radiant fringe]; for one

ought either to observe through a telescope, or in either way; for in this manner [Venus] is denuded of that hairy fringe, and one perceives Venus in morning conjunction; and at apogee [its diameter is] scarcely the two-hundredth part of the solar diameter, this being 10". But Hortensius writes to Gassendus that he directly compared the diameter of Venus, through a telescope, with the interval contiguous to the Hyades, when [Venus] was approaching apogee with the Sun, in opposition to 15" 20". Hence the distance of Venus from the Sun, viewed at 15", or 40" — at which intervals Lansberg sets down the diameter of Venus at 1' 40"; which Hortensius subscribed above. But Hortensius had not seen Venus at perigee, just as [neither did] Kepler. By Kepler's precept 110 of the *Rudolphine* [Tables], from the proportions, [those] concerning which [we spoke] above, he computes the perigeal diameter of Venus at 7' 6". Finally, Hevelius, *Selenographia*, cap. 55, says that he saw Venus around the year 1644 himself [to subtend] 46"; and on the year 1646, on 22 April, [Venus] compared with the Sun's spot ☉, seen at perigee in the epicycle, [to subtend] min. 1' 22".

PP. Soc. nostrae Ingolstadii, & Oeniponti ex sui Tubi capacitate aestimarunt diametrum □ sic [The Fathers of our Society at Ingolstadt, and at Innsbruck, estimated the diameter of Venus from the capacity of their telescope as follows]:

Year	M. [Month]	D. [Day]	'	"
1619	Febr.	11	2	12
	vel [or]	2	0	
	Febr.	20	3	0
	Mart.	27	1	37
	Maij	1	0	54
	Maij	30	0	30
	Iulij	5	0	54
	Octob.	12	2	0
	Nou.	18	1	0
1621	Nou.	30	1	0
	Nou.	11	2	15
1622	April.	1	2	15
	Iulij	9	1	7
	Aug.	6	0	45
1635	Ianu.	7	1	42

Year	M. [Month]	D. [Day]	'	"
	Ianu.	11	2	0
	Ianu.	28	2	29
	Febr.	1	2	19
	Sept.	19	0	51
1636	Mart.	23	0	53
	Maij	16	0	44

Parsing notes: The minutes (') and seconds (") columns are headed by single and double prime marks in the source. The "vel" (or) row gives an alternative reading for the 1619 February 11 entry (2' 12" or 2' 0"). Two sub-tables side by side in the source (1619–1621 on the left, 1622–1636 on the right) are merged here in chronological order.

4. We too, with rare good fortune, in the year 1649, on 29 June, observed Venus in the evening through a telescope, [it] being about to conjoin with the Sun on 7 July; but a great latitude favored [the observation], and Venus appeared with a huge sickle [falx, crescent], rivaling the Moon; and on 26 July in the morning, through a telescope of thirty [-fold magnification], with diminished [light], its diameter was observed; and from the capacity of that telescope, in four parts, its diameter was observed; from the interval pricked off [punctum], by comparison also with the diameter of Jupiter, then in the same month, and again in the year 1650 — entering upon these the apparent diameter of Venus at apogee at 33½ seconds, by 4" 16" true; then the perigeal diameter at 4" 16" true: at length, by the distances [given by] *Almagestum Novum* lib. 7, sect. 6. Nor does Gassendus, in his *Epistle* to Schickard saying that Venus would scarcely be seen below the Sun at the appearance of one minute, [stand] in the way — for I would not concede this to him, unless the optical splendor of the Sun greatly diminishes the phase of Venus; nor again does Christian Huygens stand in the way, [who] in his *Systema Saturnium*, saying that it [the perigeal diameter] cannot exceed 85", allows Venus at perigee, as we [allow it], and [as] he observed; and how slippery is Huygens's method in observing the diameters of the planets, I have indicated cap. 1, lib. 11. I remember, indeed, that this same thing was settled with Father Grimaldi requiring [it], and that the diameter of Venus is diminished somewhat, but not so much as to exceed 2', and [it] approaches near to 3'.

[col. 2]

CAPVT VI.

De Diametro Apparenti Mercurij.

[On the Apparent Diameter of Mercury.]

1. Albategnius [al-Battānī], cap. 50, puts the apparent diameter of Mercury at the mean distance from the Earth at $2' 5'' \frac{1}{2}$; Alfraganus [al-Farghānī], *Differentia* 22, at min. $1' 15'' \frac{1}{3}$; Fernelius and Dantes [Egnazio Danti] at $2'$; Vurstisius [Wurstisen] and Magginus [Magini] at $7'$; Tycho [Tycho Brahe], Clavius, Blancanus, and Argolus [Argoli] at min. $2' 10''$; Lansberg, lib. 3, at min. $3'$. Vranometria [Lansberg's *Uranometria*] [puts it] in the *Dissertatio*: Mercury, with Mercury at the mean distance, [and] with Gassendus's inverted tube [tubo inverso, the inverting telescope], caught the figure of Mercury approaching apogee with the Sun in conjunction, and thence deduced its diameter at apogee [as] seconds 10; and hence, by the distances of Lansberg, the mean diameter at $3'$; and at the perigee at $8'$. Perigaeum $28''$.

2. Petrus Gassendus [Gassendi], in the year 1631, on 7 November, through a telescope caught the lucid little circle of the Sun in a most obscure camera [obscura], whose diameter was equal to three-quarters of a Parisian foot [dodrans pedis Parisini]; and it [the circle], divided into 60 equal parts, [each part] equal to half a minute; and when Mercury had passed under the Sun's disk, caught [its] little shadow [umbella] on the same paper, [Mercury] repeated [appearing] not larger than a third part of one minute, this being $20''$. Hence he concludes Mercury's diameter does not, in the middle [region], exceed the ninetieth part of the solar diameter. Thus *Epistle* 3 ad Schickardum [to Schickard], concerning Mercury seen in the Sun; and in the *Epicurus* [Gassendi's *Animadversiones in Epicurum*], pag. 899, that there existed a splendid little shadow [umbella] of the solar figure, optically circumscribed, [namely] Mercury, and somewhat less appeared.

3. Io. Hevelius [Johannes Hevelius], cap. 4 of his *Selenographia*, relates that in the year 1644, on 22 November, in the morning at 11 [hour], Mercury was seen by him minimal — smaller than Mars; and in the year 1645, on 16 May, in the evening at hour 8 [h. 8] $\frac{2}{3}$, still with a sickle [falcatum, crescent] seen, [it appeared] with the rays of which the little circle of the fixed [stars] of the first magnitude — which we hold as the diameter of Mercury, seconds 17 — about [that].

PP. Soc. I. Ingolstadij, & dein Oeniponti ex Tubo aestimarunt Diametrum ☿ sic [The Fathers of the Society of Jesus at Ingolstadt, and then at Innsbruck, estimated the diameter of Mercury from the telescope as follows]:

Year	Mens. [Month]	D. [Day]	'	"
1620	Octobr.	23		32
1636	Martij	23		15

Parsing notes: The heading uses the planet sign for the diameter (printed ☿ in the rubric, though Mercury is the subject — likely a compositor slip for ☿). The minutes column is blank for both rows; only the seconds values are given.

4. We too, in the year 1650, on 2 January, in a most serene sky [serenissimo Horizonte], drew the image of Mercury in a chart [in chartam] in the manner we have set out, lib. 7, cap. 1, & 2, and compared [it] with the diameter of Jupiter, which was then 44"; we found it [Mercury] to be 18", that is, nearly 18"; and by the distances and by Problema lib. 7 of *Almagestum Novum* sect. 6, we deduced the true semidiameter of Mercury [to be] the fourth part of the semidiameter of the Earth; and the apparent diameter, at each [distance], at apogee, seconds 9' 20"; in the mean distance 13' 48"; and at each [position], at perigee, 25' 12".

CAPVT VII.

Synopsis Opinionum de Diametris Apparentibus Planetarum Minorum.

[Synopsis of Opinions on the Apparent Diameters of the Lesser Planets.]

In *Almagestum Novum* lib. 7, sect. 6, cap. 9, there are set down both the apparent and the true diameters of the planets, [these] being posited for the Lansbergian semidiameter [as] diameter. Here we add a few things.

Diametri Apparentes Planetarum Minorum in Apogaeo, Media Distantia, & Perigaeo utroque.

[The Apparent Diameters of the Lesser Planets at Apogee, Mean Distance, and Perigee — at each.]

The table gives, for each authority and for each distance-condition (Med. = mean, Apog. = apogee, Perig. = perigee), the apparent diameter of each planet in minutes (′), seconds (″), and thirds (‴). Planet columns: ♄ Saturn, ♃ Jupiter, ♀ Mars, ♀ Venus, ☿ Mercury.

Authori ty	Diam. Appar.	♄ ′ ″ ‴	♃ ′ ″ ‴	♀ ′ ″ ‴	♀ ′ ″ ‴	☿ ′ ″ ‴
Albateg nius	Med.	1 44 28	2 36 40	1 34 0	3 8 0	2 5 20
Alfraga nus	Med.	1 44 28	2 36 40	1 34 0	1 34 0	1 15 12
Ferneli us	Med.	1 40 6	2 30 50	1 29 0	5 0 0	2 12 0
Egnatiu s Dantes	Med.	1 49 0	2 32 0	1 28 0	4 0 0	2 12 0
Vurstisi us, & Maginu s	Apog.	5 0 0	8 0 0	6 0 0	9 0 0	5 0 0
(Vurstis ius, & Maginu s)	Med.	6 0 0	9 30 0	8 0 0	10 30 0	7 0 0
(Vurstis ius, & Maginu s)	Perig.	7 0 0	11 0 0	10 0 0	12 0 0	9 0 0
Tycho, Clavius, Blanca nus,	Med.	1 50 0	2 45 0	1 40 0	3 15 0	2 10 0

Authori ty	Diam. Appar.	h' '' '' ''	q' '' '' ''	□' '' '' ''	□' '' '' ''	ϝ' '' '' ''
(Nos cum P. Grimal do...)	Med.	0 26 40	0 49 46	0 22 0	1 4 12	0 13 48
(Nos cum P. Grimal do...)	Perig.	0 36 0	1 8 46	1 32 0 (vel)	4 8 0	0 25 12
(Nos cum P. Grimal do... — alt)					2 45 0	
Sed de h cum Comitib .	Perig.	1 12 0				
(Sed de h cum Comitib)	Med.	0 57 0				
(Sed de h cum Comitib)	Apog.	0 46 0				
Simon Marius	Med.		1 0 0			
Heueliu s	Perig.		1 2 0			
Gassen dus	Perig.		1 0 0			0 20 0
Scheine r apud Horten sium	Apog.				0 34 0	

Authori ty	Diam. Appar.	♄'""'''	♃'""'''	♂'""'''	♀'""'''	♃'""'''
(Schein er apud Horten sium)	Med.					2 40 0
(Schein er apud Horten sium)	Perig.					3 42 0
Anton. Maria Rheita	Med.	2 0 0	3 0 0			
Galilae us	Apog.					0 10 0
Io. Heueliu s de ♄ solitari o, ac rotund o	Med.	0 39 36"				
Cristian us Hugeni us cum ansis	Perig.	0 30 0	1 4 0	0 30 0		1 25 0
(Cristia nus Hugeni us cum ansis)	Perig.	1 8 0				

Parsing notes: The table is laid out with three sub-columns ('""''' — minutes, seconds, thirds) under each planet sign (♄ ♃ ♂ ♀ ♃). Many cells are blank in the source where an authority gave no value for that planet/condition. The "Diam. / Appar." double heading labels the second column (distance-condition: Med./Apog./Perig.). The Hevelius "de ♄ solitario, ac rotundo" row gives 0 39 36"

for Saturn (Saturn taken alone and round, i.e., disregarding the ring/ansae). The bracket grouping { in the source joins the multi-row entries for "Martinus Hortensius...", "Nos cum P. Grimaldo...", "Sed de h̄ cum Comitib.", and "Scheiner apud Hortensium" across their Apog./Med./Perig. rows; I have repeated the authority name parenthetically on continuation rows. The "vel" (or) under the Mars perigee cell for "Nos cum P. Grimaldo" gives an alternative value 2' 45" 0". The Cristianus Hugenus "cum ansis" (with the handles/ansae) entry gives two Saturn perigee values (0 30 0 and 1 8 0 — the latter presumably including the ansae span).

CAPVT VIII.

De Apparenti Diametro Fixarum.

[On the Apparent Diameter of the Fixed Stars.]

1. Galileo, in Dialogue 3 of his *On the World System* [*Dialogo*], Giordano Bruno [Iordanus Brunus] in his *De Immenso et Innumerabilibus* [*lib. de Maximo, & Immenso, & Innumerabili*], and Kepler in his *Dissertatio* with the *Sidereal Messenger* [*Nuncio Sidereo*], hold the fixed stars to be just as many Suns; as to their apparent [diameter], however, Galileo, by the very [magnitude] of the stars — concerning whom in cap. 1 — asserts that Lyra, and the rest of the first-magnitude [stars], do not exceed a diameter of 5"; and so by the distance of the fixed stars (which the Copernican [system] requires so great, and [such] as excludes all parallax sensible to the inhabitants of the Earth passing through the annual orbit) the fixed stars do not follow [from] being larger than the annual orbit. Kepler, however, who in his book *De Stella Nova* cap. 16 & 21, before the use of telescopes, had conceded Sirius 4 minutes, and the stars of Orion's belt 2'; afterwards, in his *Epitome Astronomiae*, pag. 498, says: *Skilled craftsmen [artificers] deny that any quantity of a body as if round can be detected by the inspection of an instrument through a telescope, since rather, magnitudes of the fixed stars are so represented through a telescope that a pure point, from which lucid rays go out into the figure of a head of hair [crinium], is dispersed.* And in the same place he holds the mass of the fixed [stars] to be smaller than the Sun. Huygens too assimilates [them] to points.

[col. 2]

2. Lansberg, lib. 3, *Uranometria*, element 20, has this: *The apparent semidiameter of the fixed stars of the first magnitude Albategnius [al-Battānī] defines at 45", and*

Tycho [Tycho Brahe] at one scruple [scrupulum primum, i.e. one arc-minute]. We [reckon] one scruple [as] half. For [though] at the first scruple [minute] the star appears much smaller, why therefore should one not believe the disks of the stars freed [denuded] by the tube [telescope] from the fallacy of the adventitious rays? — especially since Hortensius himself, [though] so friendly to Copernicus, labors to free the Copernican hypothesis from the absurdity of the immense mass of the fixed [stars], following from their immense distance, so that, by comparing the fixed [stars] through a telescope with the image of Jupiter, Sirius is only 10 ["], a second [magnitude star] only [so much]; the rest he leaves only 8" — falsely, however, because [the comparison] errs in Jupiter, as said in cap. 3.

3. Furthermore, We, with Father Grimaldi [Grimaldi], having stretched over [the lens] a little perforated leaf of brass-foil [bracteola, the perforated diaphragm] objected to the lens of the telescope, saw the disks of the stars without the rays, in three rounds [forms]; and the figure being received on a chart, the disk of Jupiter — and likewise Sirius — divided into 160 parts, without [its] companions [comitibus]; Jupiter then into 200 parts, of the kind of which an uncia [is] 100 parts in a foot; thence very many lesser little circles, and lesser, on the same chart, [were] 20 such parts, the largest 100. The stars of the fixed [heaven] having been inspected, [and the disks] obtained, the proximate ones [were] conspicuous, with very keen eye and judgment, [by] the most acute judgment of Father Paulo Casati [Casati] and Matthaëus Tabernae [?]; at length, from a certain diameter of ♄ [Saturn] and ♃ [Jupiter] then determined for us, we investigated the following sub-inscribed apparent diameters of the fixed [stars], from which the true [diameters] we investigate in *Almagestum Novum* lib. 6, sect. 9 [recte: as in the prior citation, lib. 6, *Almag. Novi*, cap. 9].

Caput VIII (continued) — The Apparent Diameter of the Fixed Stars

The apparent diameter of the fixed stars as observed by us, when the diameter of Saturn alone was 35" and that of Jupiter 44".

The following table gives, for each named star, the apparent diameter in seconds (") and thirds (").

Fixed star (1st mag.)	Diam. apparent ''	Diam. apparent '''	Other stars	Mag.	Diam. apparent ''	Diam. apparent '''
Sirius	18	0	Procyon	2	12	20
Lyra lucida [Vega]	17	24	Aquila lucida [Altair]	2	11	0
Arcturus	16	42	Cingulis Orionis [the Belt of Orion]	2	8	50
Capella	16	8	Coronæ lucida [the bright star of the Crown]	2	8	21
Aldebaran	15	24	Polaris	2	7	54
Spica Virginis	15	5	Medusæ caput [the head of Medusa, Algol]	3	7	3
Regulus	14	5	Propus [η Gemino- rum]	4	6	10
Rigel Orionis	13	40	Pleiadi lucida [the bright star of	5	5	16

Fixed star (1st mag.)	Diam. appare nt "	Diam. appare nt "'	Other stars	Mag.	Diam. appare nt "	Diam. appare nt "'
			the Pleidae s]			
Fomah ant [Fomal haut]	13	25	Alcor, seu Equus in cauda Ursæ maioris [Alcor, the "Horse" in the tail of the Great Bear]	6	4	24
Antares	13	12				
Hydræ [lucida, Alphar d]	12	45				
Cauda Leonis [Deneb ola]	12	30				

Parsing notes: the first three columns give the twelve first-magnitude stars; the right-hand block gives stars of lower magnitude with their assigned magnitude and apparent diameter. The seconds/thirds ("/'") headers are repeated over each numeric pair in the source.

The apparent diameter of the fixed stars reduced to seconds, according to the opinion of other authors.

Author	1''	1'''	2''	2'''	3''	3'''	4''	4'''	5''	5'''	6''	6'''
Lansberge]												
Hortensius] & Gassendi]	8		6		5		4		3		2	
Galilæus] & Galileo]	5											

Parsing notes: each numbered column (1–6) corresponds to a star magnitude (1st through 6th), so a row gives one author's diameters across the six magnitudes. Single-entry rows (al-Battānī, Galileo) give only a first-magnitude value; Kepler's row gives two. Only the seconds (") sub-column carries values in every row; the thirds (') sub-columns are blank in this table.

See Gassendi, *Institutio Astronomica*, Book 3, ch. 11; Magini, *Theoricae*, Book 1, ch. 19; Tycho, vol. 1, *Progymnasmata*, p. 481; Longomontanus, *Astronomia Danica*, Book 1, *Theoricae*, ch. 1; Blancanus, at the end of his *Sphaera*; Herigone [Hérigone], vol. 4, ch. 4, where he follows Hortensius; and vol. 5, Book 2, *Theoricae*, where he reports Tycho's value.

CAPVT IX — On the Figure, Belt, Companions of Saturn, and Their Position with Respect to the Equator or the Ecliptic

[De Saturni Figura, Fascia, Comitibus, eorumque situ, respectu Aequatoris, vel Eclipticae.]

1. Among the phenomena revealed to our age by the telescope, none is perhaps more remarkable — and none has so far given astronomers more trouble — than the appearance of Saturn. Three things in particular deserve note. The first is the **belt** [*fascia*], a kind of oblique zone that seems to gird Saturn across its middle. The second is the **two companions** [*comites*, the *ansae*], aligned with Saturn's central body along a line parallel to the equator for the most part — though sometimes they are seen parallel to the ecliptic. The third is the incredible variety of shapes that these companions, or the lateral appendages, present both by themselves and together with Saturn.

For at different times Saturn appears differently. Sometimes — though rarely — it is solitary, without companions, and then it is nearly round, presenting itself with two attendant round bodies; sometimes these adhere closely to it, while at other times they gradually thin out as they fail toward the rounded ends, drawing inward into the *ansae* [handle-shapes]. At times the companions appear somewhat hyperbolic; at times almost half-moon-shaped, ending in arms; sometimes the body of Saturn itself is thick at the middle, sometimes thinner, with the companions on either side now deficient; sometimes Saturn is round and more conspicuous, conforming itself into an ellipse. What others have so far observed about these phases, and what we ourselves have observed, must be set out distinctly and in order.

On the Belt of Saturn [De Fascia Saturni]

2. In the year 1655, from the 20th of March up to the beginning of June, Father Grimaldi and I saw Saturn with a belt [*fascia*], as in the preceding Figure VI — a belt situated below, somewhat obscure, and narrower than

Jupiter's belt; it appeared elliptical, parallel to that of Jupiter, on the 23rd of April and the 9th of May.

In the year 1656, from the 9th of February onward, it was repeatedly seen by us, just as in the figure already described, from then up to the 12th of December; and on the 24th, Father Grimaldi again saw Saturn with the belt parallel to the ecliptic. After an interval, with the sky preventing observation, finally in the year 1657, on the 11th of January in the morning, Father Grimaldi saw Saturn separated from its companions, with the aforesaid belt; and so on the 19th and 26th of February and on the 13th of March, when the oblong companions were placed in the ecliptic, the belt was likewise transverse in the ecliptic position. But at that time the companions were very much oblong, slender, and notably separated from Saturn, drawing close to it as it approached the Sun; and the belt appeared most evidently. But on the 20th of April and the 6th of May the oblong companions were scarcely seen, though still separated, and the belt was barely distinguishable, though most of all throughout June, and at the beginning of July. Finally, on the 2nd of August, with the companions still oblong, the belt was no longer distinguished — perhaps because of the nearness of the Sun, or because of the vapors of the horizon, since by then it appeared as a morning star. But on the 23rd of January 1658 the belt was an oblique line across the companions, and a little below the center of Saturn's disk.

On the Line of Saturn's Companions and Its Parallelism to the Equator, or to the Ecliptic [De Linea Comitum Saturni, eiusque Parallelismo ad Aequatorem, vel Eclipticam]

3. Galileo, in his 3rd Letter to Marcus Welser [*Marcum Vuelserum*], p. 148, asserts that the line drawn through the centers of Saturn and its companions, and through them, is parallel to the equator. Father Francesco Maria Grimaldi and I have observed the same thing many times.

For in the year 1646, on the 10th and 16th of October and the 16th of November, we found that the aforesaid line was parallel to the line drawn from the bright star of Aries [α Arietis] to Aldebaran, which is parallel to the equator. And again in the year 1647, on the 15th of October, the aforesaid line, produced by ocular estimation, would pass through the southern Horn of Taurus [the southern tip of the bull's horn], and through the southernmost of the Pleiades, as the telescope showed — a line which is established to be parallel to the equator by sense. Again, in the year 1649, on the 20th of July, the aforesaid line was parallel to the line drawn through the Pleiades; and the center of Saturn was then situated in the 25th degree of Gemini [\square], with a southern latitude of $1^{\circ}\frac{1}{3}$.

In the year 1650, on the 18th of March, Father Grimaldi saw the centers of Saturn and a companion in the same straight line, together with a certain unnamed little star, distant from the nearest companion toward the east by about half a Moon's breadth; but on the following night, the 23rd, he saw Saturn having overtaken that little star, yet so that to it the companion appeared more southerly by as much as four times the diameter of Saturn was greater. Whence he concludes that the line of Saturn and its companions is not parallel to the ecliptic, otherwise on the 23rd that little star would have remained on it.

In the year 1653, on the 6th of December and the following days, Father Grimaldi observed that the aforesaid line was moved by the diurnal motion of the *primum mobile*, and therefore was parallel to the equator.

In the year 1654, on the 6th of January and up to the 12th of February, and on the 1st of March, by comparing the aforesaid line with the ecliptic position,
[continues below]

[the line], at that time, appeared by no means parallel to the ecliptic; indeed, when Saturn was at the meridian, we saw it parallel to the horizon, and therefore to the equator — for Saturn was then near the end of Leo [□].

Finally, in the year 1655, from the 20th of March up to the beginning of June, more often by these same arguments, of which above, the line of Saturn and its companions was seen parallel to the equator.

4. Notwithstanding these observations, Hevelius, in his *Dissertatio de Saturni facie* [Dissertation on the Face of Saturn] published in 1656, with the great kindness and generosity shown to me, concedes that the aforesaid line of Saturn is indeed parallel to the equator while Saturn is moving through Sagittarius [□], Capricorn [□], Gemini [□], and Cancer [□]; but in Aries [□], Aquarius [□], Scorpio [□], and Leo [□] he contends that it is neutral, that is, neither parallel to the equator nor to the ecliptic; and in the remaining signs, especially in Aries [□], Taurus [□], Libra [□], and Scorpio [□], that it is parallel to the ecliptic. (He admits, however — though he himself observed this with great labor in the years 1643, 1644, and 1645 — that in Aries [□] it is easier to observe that it is most parallel to the equator in the four aforesaid signs, indeed in nearly six.)

To this opinion of his, however, the table he exhibits on p. 15 does not agree. For in it the direction of Saturn's *ansae* is set down as ecliptical throughout the whole

sign of Taurus [♉] and Libra [♎], and nearly throughout the whole sign of Taurus [♉] up to the 23rd degree; for from the 24th degree of Taurus [♉] up to that point, and to the 24th degree throughout Gemini [♊], it is set down as ecliptical; thence *neutral* up to the 24th degree of Leo [♌]; then from the 24th degree of Leo [♌] and throughout Virgo [♍] it is set down as *equinoctial* [parallel to the equator]; thence again *neutral* up to the 24th degree of Virgo [♍], and afterward ecliptical. Hevelius too — as I shall say below — does the same. for the reconciliation pass.]

5. From our own observations, however, in which that line was seen parallel to the equator, the position contradicting [Hevelius] appears: in the year 1646, on the 16th of November, in Taurus [♉] 14°, where for Hevelius it is ecliptical; and in the years 1647, on the 15th of October in Taurus [♉] 1°; and in 1650 on the 18th of March in Gemini [♊] 24°; and in 1653 on the 6th of December in Cancer [♋] 6°; and in Leo [♌] on the 26th of January 1654 in Leo [♌] 25°; and in 1655 on the 20th of July in Gemini [♊] 5°, and at the beginning of July in Leo [♌] 20° — in all of which Hevelius's [assignment] is *neutral*.

And in the year 1658, on the night between the 29th and 30th of July, Father Grimaldi and I saw with the telescope that Saturn moved its setting toward the west, as the line drawn through the centers showed, and the extremity of the companion moved manifestly according to the motion of the *primum mobile*, through the line parallel to the equator. We also confirmed the position of the equator [as] known to us by our observation, and by comparison with the ecliptic, which the line drawn through the heart of Scorpio [Antares] and through Spica nearly indicated. Therefore Hevelius will have seen — most friendly to us — what he calls on p. 27 the aforesaid line, pronouncing it *without any doubt*, namely that the aforesaid line, while Saturn is in Libra [♎], will be parallel to the ecliptic — not to have been true. The same is confirmed from the position of the sickle [the Sickle of Leo], of which at number 2, year 1657, with Figure 17 added.

On Saturn Seen Solitary [De Saturno solitariè viso]

6. First, Scheiner, in his *Disquisitiones Mathematicae* [Mathematical Disquisitions], conclusion 44, says of Saturn: "*Now single, now three-bodied*" [Modò vnus, modò triceps]. He appears at one time taller [elongated], at another round. Would that he had added the time at which he saw it solitary and round!
7. In the year 1612, Galileo writes to Marcus Welser that Saturn around the summer solstice of that same year was seen by him three-formed

[*triformem*], but with the observations interrupted, because nothing of the sort was suspected; at length, toward the end of November of the same year, solitary, and round; and so it persisted from the beginning of December, just as he conjectures — though I fear lest perhaps around the summer solstice of the year 1613 Saturn would appear with its companions; and after two months it was disappearing for some months; and in the year 1615, at the summer solstice [*aestivo Solstitio*] it [appeared] not whole, but appearing in part; and after great and good [appearances] through many years, without any concealment of the apparitions.

8. In the year 1642, Gassendi and Bullialdus [Boulliau] at Paris, around August, saw Saturn solitary, and round, until its occasion of heliacal setting, which was in February of the year 1643; therefore Gassendi too — having observed Saturn at the Acronychal point [in opposition] on the 5th of September, the year 1612 — sets down Saturn as appearing also to the naked eye so small. He adds toward the end of the following May, that with the belt seen on this side and that, by two globules of the same whiteness, and that it so persisted under the varied form of the companions, up to March of the year 1644. So he, in his *Iudicium de 9 Stellis* [Judgment on the Nine Stars], near the number 6, and in the *Epicurum*, p. 905. Hevelius too, p. 42 of the *Selenographia*, and in his *Dissertation on the Face of Saturn*, p. 7, affirms that around the 20th degree of Pisces [♓] in opposition to the Sun, and after that, it represents itself round to him in the perigee of an eccentric ellipse.
9. In the year 1656, on the 9th of February up to the 14th of May, we saw, together with Father Grimaldi, Saturn solitary without companions, with the belt drawn transversely, as in the subsequent Figure II. Then it began to be seen round with the belt, and so it was seen up to the 17th of July. From that point it ceased to be observable on account of the nearness of its heliacal setting, then also from the vapors of the horizon. But after the heliacal setting it could not be observed, with the surrounding clouds, before the 23rd day. On the 8th of October, when in the morning it appeared with the companions separated, as in Figure V, Bullialdus too at Paris on the 25th of January, and Hevelius at Danzig in the same year 1656, on the 25th of February and the 1st of May, saw it round; and the same Hevelius reports it, p. 7, in his *Dissertation on the Face of Saturn*. Of Huygens I shall speak below.

The Figure of Saturn Collected from Our Observations and Those of Others [Figuræ Saturni ex nostris, et aliorum observationibus collectæ]

10. Among the following Figures, Hevelius calls Figure I *Saturnus Monosphaericus* [single-sphered Saturn]; Figure III, *Saturnus Trisphaericus* [three-sphered Saturn]; Figure XI, *Saturnus Sphaericocuspидatus* [sphere-and-points Saturn]; Figure XII, *Saturnus Sphaericoansatus* [sphere-and-handles Saturn]; Figure XIII, *Saturnus Ellipticoansatus diminutus* [diminished elliptical-handled Saturn]; and Figure XIV, *Saturnus Ellipticoansatus plenus* [full elliptical-handled Saturn]. The remaining figures he does not display.

Diagram. A full-page plate, enclosed in a single ruled rectangular border, displaying ten numbered telescopic figures of Saturn (labeled I through X, in two columns of five rows) showing the successive observed shapes of the planet — the pre-Huygens "ansae" forms referenced in Caput IX. The figures are arranged left column (odd numerals I, III, V, VII, IX) and right column (even numerals II, IV, VI, VIII, X). Each depicts Saturn's central disk with its lateral companions (*ansae*) and, in some, the transverse belt (*fascia*).

- **I.** (top left): a single plain circle — *Saturnus Monosphaericus*, Saturn seen solitary and round, without companions or belt.
- **II.** (top right): a single larger circle crossed by a transverse, slightly oblique hatched band running across its upper-middle — Saturn solitary with the belt (*fascia*) drawn across it (the form of §9, Figure II).
- **III.** (second row, left): a central circle flanked on each side by a small rounded lobe touching the disk — *Saturnus Trisphaericus*, the three-bodied/three-sphered Saturn with two adhering round companions.
- **IV.** (second row, right): a central circle with two small detached round companions, one on each side, set apart from the central disk (the separated round-companion form, cf. §9, Figure V).
- **V.** (third row, left): a central circle flanked by two detached oblong (oval/lens-shaped) companions, one on each side — the oblong-*ansae* separated form.
- **VI.** (third row, right): a central circle crossed by a transverse oblique hatched belt (*fascia*), flanked by two detached oblong companions on each side — Saturn with both the belt and separated oblong companions (the form of §2, Figure VI).

- **VII.** (fourth row, left): the central disk overlapped on each side by two crescent/half-moon-shaped companions whose inner edges are shaded (hatched) — the half-moon ("brachia"/arms) ansate form, companions adhering and shaded toward the disk.
- **VIII.** (fourth row, right): similar to VII — a central disk with two shaded crescentic companions overlapping on each side, slightly more open in form.
- **IX.** (bottom left): an elliptical/ovate outline enclosing a central round disk, with the lateral interior regions (the ansae) heavily shaded (hatched) and a brighter ring — *Saturnus Ellipticoansatus diminutus*, the diminished elliptical-handled Saturn.
- **X.** (bottom right): a larger, more open elliptical outline enclosing a central round disk, with broadly shaded (hatched) lateral ansae forming an open ring around the disk — *Saturnus Ellipticoansatus plenus*, the full elliptical-handled Saturn.

The shaded (hatched) regions in figures II, VI, VII, VIII, IX, and X represent the obscure belt and the shadowed inner faces of the *ansae*; the open (unshaded) circles in I, III, IV, V represent the bright round body and companions. All labels (Roman numerals I–X) are clearly legible. This plate is the visual key to the figure-numbers cited throughout Caput IX (e.g., "Figure II," "Figure V," "Figure VI"); the higher-numbered Hevelian forms (XI–XIV) named in §10 are not on this plate.

[Liber X — continuation of Caput IX: De Saturni Figura, Fascia, Comitibus]

Diagram. A full-page plate, set within a ruled rectangular frame and surrounded on both sides by the two columns of body text. It presents the higher-numbered telescopic shapes of Saturn (Figures XI through XVII), continuing the ten-figure Saturn-shape plate of the preceding page (Figures I–X). The forms shown are the more elaborate "handled" (*ansatus*) and tri-bodied appearances reported by Hevelius, Galileo, Gassendi, and others, together with the fully ring-like and the two-companion appearances. From top to bottom:

- **XI** — a central round globe flanked on each side by a roughly crescent/cusped form turned toward the globe (the *Sphaerico-cuspidatus* type): a bright sphere with two dark, hook-shaped arms.
- **XII** — a central globe with two large dark crescents on either side enclosing bright tips, an elliptical-cusped form (companions broad and dark, the *Sphaerico-cuspidatus Maior*).

- **XIII** — a broad elliptical figure: a central globe set within a wide flattened ellipse, dark toward the body and bright at the elongated tips (the *Elliptico-ansatus plenus*, full elliptical-handled form).
- **XIV** — a central globe within a narrower ellipse, with the dark interstices visible between globe and handles (the *Elliptico-ansatus*, elliptical-handled form).
- **XV** — a central globe crossed by a thin straight band extending to bright tips on each side (the *Sphaerico-ansatus*, sphere-with-handles form, the band passing in front of and behind the disc).
- **XVI** — a large central globe encircled by a flat, fully detached ring that crosses in front below and behind above, the dark ring-plane standing clear of the disc on both sides (the fully ring-like appearance).
- **XVII** — a central globe set within a pointed (lens-shaped) dark ellipse, with a small separate round companion globe standing just beyond each tip (the two-companions-plus-arms form, *Trisphaericus* with detached round companions).

[Margin (left of plate, keyed to the running text): observational notes and figure citations interleaved with the plate.]

[Margin: *Anni Christi* (Years of Christ) — the left column gives the year of each observation.]

Chronological catalogue of observations of Saturn's figure

1609. Galileo [Galileo], in his Letters 1, 3, and 5 to Marcus Velserus [Mark Welser], reports that Saturn appeared to him three-bodied [*Tricorporem*], with the globes touching but not perfectly separated — owing to the imperfection of his tubes, which adhered to one another — as in Figure IV. Scheiner [Scheiner] too, around that time, says it appeared three-bodied to him, though at other times solitary; see in the *Disquisitiones Mathematicae*, p. 6.

1612. Saturn was seen round, without companions, by Galileo, as you may see in Figure 7 and Figure I.

1614, February 12, 13, 14. Scheiner saw Saturn with the globes separated, as in Figure IV, but in such a position that the left-hand globe — which lay in the higher place — appeared the more brilliant, since it was the more remote from Saturn. So in the *Disquisitiones Mathematicae*, conclusion 44.

1616. Father Joseph Blancanus [Biancani], in October, as he relates in the *Sphaera*, Book 15, Ch. 7, saw Saturn oval-shaped [*Ouiformem*] with two round

spots toward the top. And in the same way in 1619, in November, but he had an imperfect tube.

1625, February 17. Martinus Hortensius [Hortensius] saw Saturn with the globes nearly as in Figure IV, and they were not far from the Sun; and Hevelius [Hevelius] reports this from Saturn's "face," p. 7.

1630, June. Francesco Fontana [Fontana] at Naples saw Saturn with the globes separated, as in Figure IV, and he has it in his published Treatise, Ch. 7.

1632. Hortensius, July 16, saw Saturn handled [*ansatum*].

1633. Petrus Gassendus [Gassendi], in June, observed Saturn with handles [*ansulis*], as in Figures VII and VIII — just as he reports in the *Judicium de 9. Stellis circa Iouem*, and in the same way Fontana, above.

1634, April. Gassendi, as in the *Judicium de 9. Stellis*, and Fontana, in his Treatise, saw Saturn with handles, as in Figure VII; see Gassendi, as in Figure XIV.

1636. Gassendi in November saw Saturn with handles, as he has it in the aforesaid *Judicium*, and Fontana too — so that Saturn itself was not entirely round, as in Figure VII.

1637, November — indeed before, in February and July — Gassendi saw Saturn with handles. In the *Judicium de 9. Stellis*, and at PP. Soc. I. [the Fathers of the Society of Jesus], on October 19, on March 26, the companions had been seen in their nearer contact; see p. 16. August.

1638. Gassendi, as above, in December saw Saturn round but by no means perfectly so, as in Figure IX or X.

1640, May 23. Father Nicolaus Zucchius [Zucchi] observed Saturn with the companions separated and curved, or imitating the form of a pear, but of great magnitude — a figure transmitted to me from Rome by Zucchi himself.

1642. Gassendi and Boulliau [Boulliau], and in October Hevelius, observed Saturn solitary and round, as in Figure I; see Figure III.

1643. Toward the end of May, Saturn was seen Heliacally [near the Sun] with its arms round and almost adhering, as in Figure V; so Gassendi affirms, in a Letter to Wendelin [Wendelin], p. 905, and Epistle 3 to Wendelin, adding that it persisted so for a long time. We too, with Father Grimaldi [Grimaldi], on October 29, observed its companions, as in Figure V.

1644. Gassendi, as he relates in the Letter, p. 905, in March and June saw Saturn, as in Figure IX; and afterward in December, as in Figure XI. Father Daniel Bartolus [Bartoli] at Naples, with Father Sirsalus's [Sirsale's] excellent telescope, observed the lower companion smaller and dimmer, its shadow less dark, thence into a moon-shaped obscure little body, as in Figure XII — that is, the union of the upper companion with Saturn. With the companions thus not appearing to cohere, the observation of Fontana, or that of Father Matthaeus Taberna [Taberna] under Figure XVII, under which it was nevertheless never permitted to us to see it, may be reconciled.

1645. Hevelius in September, October, November saw Saturn handled, but Ioan. Lyphus the Monk at the very beginning saw it solitary, as in Figure IV. Gassendi, as he relates in the Letter to Epicurus, p. 905, sub-figure, again saw the companions gradually producing cusps, so that on each side they touched the obscure middle globe intercepted thence into a moon-shaped obscure interstice; the little globes themselves, as it were, displaying a parabolic-shaped surface and, by reason of cohesion, exhibiting it almost as handles, and therefore he took them for handles — because that obscure interstitium appeared as if there were perforations, as in Figure 13. Yet Fontana, on December 3 and 13, saw it nearly as in Figure XVII.

1646. Eustachius de Divinis [Eustachio Divini] up to 1647 and 1648 affirms he saw Saturn oval-shaped, as in Figure X, or [continued next column]

XIV. And Father I. Bapt. Hodierna [Hodierna] says that today it appeared to him very like an oily countenance [*olei... vultu*], most constant, on April 10 of the year 1646, up to 1653. But Gassendi, above, reports it for the year 1646. He captures that dark obscurity, those interstices obliterated to the cusps, and the handles whitish from their own globe commingled, as if from a whitish middle globe less perceptibly distinguished from the handles themselves. But with Father Grimaldi, on October 10, we saw the eastern companion smaller than the other, and nearer to Saturn; but on November 16, the companions appeared equal, and equally distant from Saturn.

1647. Hevelius, on September 7, saw Saturn elliptical-handled [*Ellipticoansatum*], as above, as in Figure XII. Gassendi too, above, reports the same form, which preserved the same shape throughout the preceding years; but the broader appearance, the confusion, and the interstices blunted at the rounded cusps make for a fuller shape, with a promotion of the vestiges toward the rounded, as in Figure XV. Hevelius says this shape lasted right up to Saturn's heliacal setting in

the year 1648, in the month of April; and for the year 1647, Io. Lips [Lipstorp] exhibits Figure XIV.

1648, February 26 and April 16. We saw, with Father Grimaldi, the companions equal between themselves and equally distant from Saturn; thus the brightness of the parts on each side was so great that the Semidiameter of Saturn's disc was greater than that, and they faced one another with an oval Figure X.

1649. Toward the end of March, and from the beginning of April up to the beginning of May, and on May 6 and 20, July — when Saturn rose and likewise set on the 27th — July it was seen, as in Figure XIV; indeed in August on the 23rd and September 29. Father Grimaldi and ourselves: Hevelius too in December on the 23rd saw it elliptical-handled, as in Figures XIII, or XIV, as Father Grimaldi did on days 12, 13, and 21 December, as in Figure XIV.

1650, January 2, and March 18 and October 12. Saturn appeared to Father Grimaldi, as in Figure XIV — Hevelius does not dissent. Hevelius too, above, saw it elliptical-handled in October.

1651, April 23. Saturn was seen by Father Grimaldi with a figure midway between Figures X and XIV. Hevelius, however, in November, saw it nearly spherico-handled, as in Figure IX.

1652, May 29. Father Grimaldi saw it, as in Figure XIV. Hevelius too, in October, saw it elliptical-handled, as in Figure XII.

1653. Toward the beginning of February, Father P. de Rheita [de Rheita] saw the companions of Saturn drawn out like flames in pyramidal torches — that is, as in Figure V; nay, Father I. Bapt. Hodierna in December saw it such, as in Figure 3. Father Grimaldi in December saw Saturn's companions separated from it and pear-shaped, or in either way elongated, so that it was as in Figures 13 and 18, in longitude. But Gassendi, on April 6, saw it as in Figure XIV.

1654, January — through nearly the whole month — we saw, with Father Grimaldi, Saturn's companions slenderer and acutely produced, as in Figure XV. But Father I. Bapt. Zuppus [Zupi] at Naples, on January 16, saw it, as in Figure XVI — which to us does not differ from that one, except in magnitude on account of the conspicuous prolixity of the telescope.

1655. From the 10th of March to the end of June, but chiefly on the 23rd of April and the 9th of May, Saturn was seen first, as in Figure V; then on the 6th of May — though Hevelius on the 30th of May saw it three-bodied — as in Figure IV; but Gassendi in June and July.

1656. From the 9th of February to the 17th of July, it was seen by us round, without companions; but on the 14th of May, with the band [*fascia*], as in Figure II. Boulliau too, in January, and Hevelius on the 25th of February and the 2nd of May, saw it Monospherical [*Monosphaericum*].

In the same year, a certain Canon of Leiden wrote to D. Antonius Roccam [Antonio Rocca] — as I have it by his letters — that D. Christianus Hugenius [Huygens], a noble Hollander, by multiplying the diameter of his telescope fifty times, had with certainty discerned around Saturn two companions; thirdly, a planet, which they called Saturn's Moon, distant about three of those lesser diameters, and completing its revolution in 16 days; and that he had had another tube multiplying a hundredfold, by which D. Rocca suspected that this to be a fixed star — but of this in the observation following.

1657. Father Grimaldi saw Saturn's companions at one time, as in Figure V, at another in Figure VI, according to the said number 2, under this same year. And toward the end of December, the companions in part [continued — Saturn

[Margin: *Anni Christi* (Years of Christ).]

nearer now and concave, as in Figure XI, and with a very narrow band. In the same year, on July 18, Father Nicolaus Zucchius wrote to me from Rome thus: Saturn proceeds to be seen, his greater Star [the disc] sundered from the two lesser ones; but with a more powerful telescope it seems to be observed near that very Star — that the lesser ones change their position now upward, now downward, and rightward or leftward, and sometimes vanish. But in order that it may be established whether the same Stars meet with the same situation among the firmaments, or with various ones, great diligence and perseverance in observing is needed.

1658, January 1. Saturn was seen by us, as in Figure XI, and at the end of January nearly so, as in Figure XV, but with a band toward the center of Saturn, and an oblique line of the companions. And on February 21, similar to Figure XV, observed by Father Grimaldi. The longitude of the candid part of each companion was equal to the Semidiameter of Saturn's disc, but the obscure part a little shorter: in March the companions were longer, but shorter, and more so in the month of May, up to the 24th of June. On July 10 Saturn was seen to fail from Figure XV, and the arms of the companions near Saturn to grow slender.

1661, May 13. On the following night, Saturn was observed handled, and with the companions arranged as before, as in Figure XIV — among those set forth.

Appendix of the observations of Christianus Huygens [Huygens], which I have received as written after the foregoing

1656, January 16. He saw Saturn Monospherical [*monosphaericum*], as in Figures I and so up to June; nay, up to the December of the year 1655. But in October, on the 13th of the year 1656, he reports the handles already manifestly recovered, earlier than he had predicted.

1657, December 17. After Saturn's Heliacal rising, the arms of Saturn taken up in narrower handles, as in Figure XVI.

1658, November 10. Saturn, much before the heliacal rising, with the arms drawn apart into wider latitudes, appeared, as in Figure XIV.

1659, February 12. Saturn's handles appeared most broadly, as in Figure XIV; see Figure I. Through tube-feet 12, the handles spread to tube-feet 6: Saturn appeared three-bodied, as in Figures IV or V; whensoever round, and at times solitary; the Zone variously cut his disc; and at other times below, the upper middle solitary appeared.

The Theory of others concerning the aforesaid Phenomena is indicated

[Margin: *Indicatur argumenta contra Heuelium* — The arguments against Hevelius are indicated.]

11. What Father Antonius Maria de Rheita devised, in Book 4 of the *Radius Sideromysticus*, Ch. 4, by way of cause for the aforesaid phenomenon, I have set forth, and in part discussed, in Book 7 of the *Almagestum Novum*, Section 6, Ch. 14, Scholium 3 — among which is the probable cause, and I judge that Saturn rotates about its own center, which I confirm from this, that being itself solitary, it appears now round, now oval-shaped, and at times with a band; and sometimes round, the band appearing — its sides varied by motion around it, above, and below, may be able to be moved, as I have indicated, but below I add another Theory.

12. Hevelius, however, for the celerity and acumen of his ingenuity, in the little work lately issued concerning the "face" of Saturn, has endeavored to render reason for so admirable a vicissitude. He reckons Saturn to exhibit so diverse phases, on account of the diverse aspect under which we behold it now from the right side, now from the oblique. For since it is established by optics that a Cylinder and an Ellipse, by reason of distance, appear oblique to the eye placed

circularly — hence, by his asserting it, Saturn appears at its Apogee elliptical-handled rather than at its Perigee Eccentric (where the truly middle is distant from the Earth, or from the Sun), it appears Monospherical, that is, solitary and round, as in Figure I. In other places truly it is moved by various motion around it, above, and below, so that Saturn may be variously seen, as I have indicated, but below I add another Theory.

[Margin: *Heuelii Hypothesis de ♄* — Hevelius's Hypothesis concerning Saturn.]

Hevelius, however, since this Apogee of Saturn is in degree 27 of ♐ [Sagittarius], and the Perigee in 27 of ♊ [Gemini], the middle distance in degree 27 of ♍ [Virgo] and of ♋ [Pisces] — therefore through all of the Eccentric, he distributes Saturn's phases by a most elegant figure, and likewise a Table, whose Epitome it pleases to subjoin in this place.

13. [Margin keyed:] *Phases ♄ ex opinione Heuelij* — The Phases of Saturn, according to the opinion of Hevelius.

Parsing notes: The table has five columns: a left descriptive column (Apogee / Decreasing / Mean Distance / Increasing / Perigee, etc.), the zodiacal Sign (*Sig.*, given as a glyph), the degree (*Gr.*), the Hevelian figure-name (*Denomin. Figurarum Heueliana*), and the figure number (*Fig.*). The bracketing of descriptor-labels (Decrescentes/Crescentes etc.) spans several rows; I have placed each on its first row. Several sign-glyphs are faint at this resolution; readings of the glyphs flagged [?] where uncertain. The last block's figure-number column for "Trisphaericus" reads III. in two places where I would have expected I.; transcribed as printed.

14. Where the Figures are wanting here, they are wanting also in Hevelius, p. 4. But from our Figures IV, VII, IX, XI — the Fourth, Seventh, Ninth, Eleventh — and likewise the Twelfth, Eighth, Tenth, Decimaquarta (Fourteenth), Decimaquinta (Fifteenth) — or [our] Decimaquarta and Decimaoctava — there is no slight violence done to the Hevelian Hypothesis [*Hypotyposim*]. Moreover, from our observation of the year 1656, concerning which above, on May 14, Saturn was in degree 15 of ♍ [Virgo] and was solitary and round, although it differed by 11 degrees from the place of perfect roundness according to Hevelius; therefore in degree 1 of ♍ on October 1; and again on October 1, when at the said place of perfect roundness it did not differ by whole degrees, it ought nevertheless to have appeared round; and yet it was seen manifestly with the companions separated, as in Figure V. Hevelius, however, in nowhere of the many places of his Hypothesis is thence chiefly to be improved, because before he saw Saturn round in October of the year 1656, and at September of the year 1657, and yet on the 13th of October of the year 1656 he already recovered the handles. But in the year 1656 from Hevelius's positions Saturn was in degree 18 of ♍, and on December 22.

At the solstice it ought to be seen round, and on the 1st of December it was seen three-bodied; and in December of the same year that very Galileo would have appeared at the solstice three-bodied, and on the 1st of December solitary, and round.

[Margin: *Indicata argumenta contra Hevelium* — The arguments against Hevelius indicated. // marginal cue numbers 1, 2.]

15. [Margin: *Robervallij Hypothesis de Saturno* — Roberval's Hypothesis concerning Saturn.] Robervallius [Roberval] supposed that the causes of the phenomenon of Saturn could be explained, if it be said that out of its Torrid Zone vapors go forth, which reflect to us the rays of the Sun, when they are denser, not elevated indeed toward the poles. But to this cause the inconstancy of the vapors of natural Physics is not obscure, nor is it probably bound to certain zodiacal places; yet it is established that Saturn in the two opposite signs of the Zodiac appears now round and now band-marked in each, of its revolution to be seen round, and within a quadrant from the said distances to appear most broadly handled, as Hevelius himself admits.

16. Io. Baptista Hodierna [Hodierna], as Christianus Hugenius reports, p. 43, in his *Systema Saturni*, judged Saturn to be spheroidal in the manner of an egg, or a plum, and elongated by Hevelius, as in Figure X or XIV: but he converts Saturn around its own axis, in the same period that Hevelius establishes, and turns it round so that it is seen sometimes round, when the longer spheroid appears to us not directed; nevertheless, says Huygens, since Saturn for the most part appears round as often as it is bare of arms, how is it explained that the lacunae are filled — which lacunae two black spots would [continued: super-

would [cover the] surfaces — does Hodierna himself admit? Finally, if anyone were to compare these spots with the markings observed circling about the axis, he will see that many phases appear far different from those that are seen on Saturn.

Christiani Hugenii Systema Saturnium. [The Saturnine System of Christiaan Huygens]

§17. First of all, Christiaan Huygens [Huygens] states that, using a telescope of 12 Rhineland feet, he reached the very threshold of these matters by 19 February 1656. Thereafter, however, with a telescope of 23 feet, and having fashioned a thin plate [bractea] whose aperture served either to remove the surrounding glare or to deepen the [field of view], it became established for him from twin

neighboring [pins] joined together, a single convex glass equivalent — [Margin: The excellence of Huygens's telescope] — fitting individual lenses, the diameter of which is 1 [unit]; gathering the rays, [these] yield a lens-objective of such excellence and of so brief a convexity, that it can be reckoned beyond the ordinary.

The distance of the objective glass, as seen through the optical tube, compared with the appearance seen by the naked eye, he held to bear that ratio which the distance of the predicted objective glass — being 23 feet, or 276 inches — bears [to the rest]. The distance of the ocular glass, however, is somewhat less, namely under 2 inches; whence, following the [established rule], the telescope would multiply the object a hundredfold; whereas Galileo's tubes multiplied only thirtyfold.

When, moreover, he had demonstrated this in the *Dioptrics*, he set forth the appearance seen through an optical tube as it relates to the appearance seen by the naked eye, holding it to bear a reasoned proportion such as the distance of the predicted objective glass — which was 23 feet, namely 276 inches; but the distance of the ocular glass is somewhat under 2 inches; whence, following the [rule], the telescope would multiply the object a hundredfold, whereas Galileo's tubes multiplied it only thirtyfold.

By such a telescope, then, he always saw Saturn furnished with arms [ansae]; but in the year 1655 he saw it round, and at other times solitary [bare], and round, when he saw the arms of Saturn jointly with the telescope; but he saw it solitary and round when, around the year 1658, he saw it tricorporeal [three-bodied] on 10 November. From this he concludes that the tricorporeal appearance arises from the imperfection of the tube, [making it seem] as though it were tricorporeal. As often, moreover, as he saw Saturn round, he saw a zone bisecting its disk crosswise; at other times, in the year 1655, [a zone] in the upper middle, and [zones] lower down — and these I produce [as evidence]; but with the body of Jupiter set aside as the lucid [bright body], he observed [the contrary]; whereas in Mars he observed a dark zone, and a zone obscuring the middle part, broad, the parts of which were such that the diameter of the disk was 5. Having measured the diameters of the fixed stars, with the ocular glass previously gently smeared with soot, he saw them as though a lucid point: the middle Fixed star in the sword of Orion he saw to be not one but 12 stars, very distinctly constant [resolved]. Finally, by such a tube he was the first to observe for himself a little planet wandering about Saturn, which he calls the Moon of Saturn [Titan].

§18. From the year 1655 on 25 March, Gregorian style, and in the year 1659 on 26 March, at the 10th hour, he set forth observations of this Moon — nearly 70 of them — from which it is established that the Companion encircles Saturn in 16 days; and that it returns to the same position over the same number of days, and that twice over, in this manner [moving] more in nearness than in distance, and so [returns] hither and thither over a [period] which does not exceed the first scruple [first minute] of 3' 16" from the center of Saturn, computed. From these things, therefore, set forth, he constructs a Theory of the Moon of Saturn, described from Saturn's globe being observed, divided into parts equal [to those] of [16]; the diameter of which, AP, runs into our eyes, in which —

Diagram. A circular dial-figure for the orbit of Saturn's Moon (Titan), graduated 1 through 16 around the circumference, with a central cross (axes) marked C at center. The numbers 1–16 are distributed clockwise around the circle, with letters A, P, Q, B, C marking cardinal positions.

- A (top): point 1 / A / 16 (the apogee position, top of the orbit)
- 16, 15, 14, 13, 12, 11, 10 (descending down the right side)
- B (left): point near 3
- P (bottom): point 8 / P / 9 (the perigee position)
- Q (lower-right region): marked near 9–10
- C (center): the center of the figure (Saturn)
- Numerals 1 through 16 ring the circle marking the daily positions of the Companion in its 16-day revolution.

The Companion [Comes] is here carried, according to the order of the Signs, from apogee A, through C, into perigee P. In the first observation of the year 1655, on 25 March, [it was at] number 12, removed from perigee P by parts $3\frac{1}{3}$, [of the kind] of which the whole circumference ACPD is 16; and on 26 March it was at number 13, and on 14 March at [number] 3, in April...

lacking up to number 5, and so on thereafter: provided that anything is to be added or taken away, the period being one of 16 days. For he finds that the Companion was at perigee P in the year 1659, on 14 March, about the evening hour 8, and earlier in the same perigee in the year 1656, on 23 March, at hour 8 after noon. This makes an interval of 1086 days; and this divided by 16 days yields 67 revolutions, and there remain in addition 14 days. There come to be 68 revolutions with respect to our [reckoning], an absolute number; but with respect to the Fixed stars, on those days [there are] over and above 14 — [Margin?] — therefore so many degrees were measured along its circle as Saturn meanwhile

traversed among the predicted Fixed stars, ever at gr. 40. 48'. Wherefore from this circle [it follows], on 16 days, 1086 absolute periods 68; and besides at gr. 40. 48'. and again, with one day with respect to the Fixed stars [at] gr. 22. 34'. 44"; whence it appears that over 68 days, by 360°, there come to be degrees 2448, and these added at gr. 40. 48'; whence at gr. 24. 34'. 44", and these divided over the 1086 days. With the mean motion of Saturn removed, which is 2' 1", there remains of the motion of this Companion at gr. 22. 32'. 44"; which to retain as the mean he says is possible meanwhile, until after several more years it should become evident how much is to be emended. He then adds a Table, and an Epoch, and a precept for computing the motion, and the position of this Companion, on whatever date of the times — these things which in the second volume we shall set out, where we give the Tables of the Motions of the Lesser Bodies, with their precepts and examples.

§19. With the Theory and Practice of the Companion of Saturn settled, Huygens passes to the figure [shape] of Saturn, and, having refuted the hypotheses of Hevelius [Hevelius], Roberval [Roberval], and Hodierna [Hodierna], he subjoins his own, which he includes in this proposition:

Saturn is girdled by a ring [annulus], thin, flat, nowhere touching [the body], and inclined to the Ecliptic. Which [ring] is represented in the following diagram.

Diagram. A schematic of Saturn surrounded by Huygens's ring. The globe of Saturn is shown as a central sphere lettered A (top) and C (bottom, on the body), encircled by an inclined flat ring whose extremities are lettered B (left) and D (right). The ring is drawn as an ellipse seen obliquely, separated all around from the body of the planet.

- A (top of globe): top of Saturn's body
- B (left extremity of ring): the western ansa
- C (lower part of globe): the lower point of Saturn's body
- D (right extremity of ring): the eastern ansa

This ring BD, although separated from the globe of Saturn AC, nevertheless in the Zodiac follows it with an equal pace [par passu], and is constituted by an equal force about the center of Saturn as the Earth is supported by no props — even so, the ring itself is always moved, and yet, since it is itself moved, whatever its distance from the center of the Earth — which is the center of gravity [centrum gravium]. When, however, Saturn appears perfectly and most amply furnished with arms, as in Figure XIV we showed, the diameter BD appearing [as an] ellipse

of a diameter smaller than [the body], holds itself as 1 to 2. He then proceeds to the observations of his predecessors — Galileo [Galileo], Gassendi [Gassendi], Bullialdus [Bullialdus], and Riccioli [Riccioli] — concerning the greater diameter BD, [arguing] it to be parallel to the Equator. — [Margin: Riccioli vindicated from Huygens's censure] — On this point, nevertheless, Riccioli says that the contrary holds for himself, because from one side he shows the line of the arms to be parallel to the Equator, but from the other [side] he made on 18 March of the year 1650, [the observation], because of the [matter], a [counter-claim], that this line was not parallel to the Ecliptic, since Saturn was then near the beginning of Cancer (it was indeed in gr. 24. of Gemini), [and] could not have been parallel to the equator, because it was deceived through P. Grimaldi [Grimaldi]; and to have been thought the same, which [observation] was different, [is shown] near *Almag. Nov.* p. 7. — *Almag. Nov.* p. 723. Huygens supposes, moreover — I know not from what observation, which he does not adduce — that with Saturn existing in gr. 20. of Gemini, ♊, or Sagittarius, the line of the arms escapes [from being] parallel to the Ecliptic. — But this Riccioli does not suppose, the line [to be] parallel; but [holds] that then only the line of the arms is parallel both to the Equator and to the Ecliptic at once, when Saturn is in the very beginning of Cancer, or of Capricorn, for the reason that the [line] Parallel to the Equator does not then intersect the Ecliptic, but touches [it]; outside this position, however, for the same reason, because the line of the arms [is] parallel...

parallel to the Equator, and parallel to the Equator intersects the Ecliptic; the line, that [line], necessarily inclined to the Ecliptic — which is evident from gr. that 24. The twin observation was the observation of P. Grimaldi, who, having most studiously watched this, did not deceive himself in the observation, having Saturn on different days, with a fixed star taken for another, with respect to which Saturn was acceding from elsewhere — neither does Huygens affirm, except that this observation may destroy his own opinion, of the Line parallel to the Ecliptic beginning at gr. 20. of Gemini, ♊, and Sagittarius. Not yet, therefore, from the things said thus far, does Huygens show, against Riccioli, what is contrary to him, and that of Grimaldi to be deceived — but let these things be by the way. Let us pass on to the rest of Huygens's Theory.

§20. The orbit of Saturn, absolved [completed] in roughly 30 years, he places in the same plane with the Ecliptic, the inclination of gr. 2½ being neglected. He holds the Axis of Saturn, circulating about itself, to be always parallel to itself, and that the plane of the ring circling about it stands erect [perpendicular], so that about this center the [parts] gyrate, and the globe of Saturn — so that all its parts in turn are by the Sun illuminated — and the ring itself, [is] in the plane of

the ring, the Companion [Comes], or Moon of Saturn. He places the Axis of Saturn nearly equidistant from the axis of the Earth, with an angle of gr. $23\frac{1}{2}$; and the plane of the ring inclined to the plane of the Ecliptic. With the plane of the ring placed parallel to the plane of the Equator, the greater diameter of the ellipse appearing, to which the Ring is likened, [is] esteemed parallel to the Equator. Hence it comes about that, with Saturn existing at the beginning of Cancer, ♋, and Capricorn, it ought to appear to us furnished with arms most broadly of all, because then our eye is raised above the plane of the ring by gr. $2\frac{1}{2}$; on the contrary, it ought to appear most narrowly [furnished] at the beginning of Aries, ♈, and Libra, ♎; with the plane of the ring then falling [edge-on] into our eyes. But by observation it is established to be most broad, ♋, [the ring's] ellipse drawn out [to appear] at gr. $20\frac{1}{3}$, and most narrow at gr. $20\frac{1}{3}$ of Virgo, ♍, and of Pisces, ♉; whence one may conclude, that in [the rule], the line of the arms is always parallel to the plane of the Equator, but inclined to the Equator by gr. 4. 8'; with Saturn existing at gr. 25. 15'. of Gemini, ♊, and Sagittarius, ♐, more so, indeed, in this [present age]. Twin, therefore, are the loci in the orbit of Saturn diametrically opposite, in which the ellipse appears most broad, and twin in which [it appears] most narrow; in other loci, narrower and broader appears [the ring], as Saturn recedes more or less from the said loci, that is, according as our eye is raised more or less above the plane of the ring.

§21. Furthermore, if from the Earth we should look at Saturn, the [appearances] would be the same — a perpetually dual [appearance] of those loci, in which the plane of the ring is brought to bear directly upon our eyes; but [if] from the Earth we look at Saturn, certain inequalities [appear], and so the ring [is such that], following the *latus rectum* [side?] inspected, not in itself the line referring [to it], neither of the planes of the superficies of the ring appears; and so, when nothing of the surfaces of the ring is parallel, hence Saturn appears round, and as though without arms. Whatever phases, indeed, [appear] over a whole half-year [semestri], and more — when Saturn exists at the initial point of Aries, ♈, and Libra, ♎; the plane of the ring (through imagination) passes between us and the Sun, by which it would be impossible for the surfaces of the ring to be looked upon, which [are] illuminated by the Sun — but in another manner, which our eyes' vicissitudes suffer, because the exterior limb of the ring is somewhat of a thickening predicted [edge-on], [a thing] of such nature that it reflects almost nothing of the rays of the Sun; and therefore the globe of Saturn appears girdled with a dark zone. Just as, on the surface of the Moon, certain parts appear darker, because they are less apt to reflect the light of the Sun. Which [happens] all the more to all the parts of the ring, the more obliquely they are illuminated by the Sun; as happens when Saturn's locus is eccentric, [being] far off, gr. $20\frac{1}{3}$, ♍, and ♉,

beyond, gr. 6. By all these things, then, his causes [account for] the concurrences of the round Phases of Saturn dimmed [edge-on]: so that the surfaces of the ring [appear] equal, and not rough with mountains. He concludes, therefore, [does] Huygens, that whoever's [be] the locus, eccentric, or seen from the Sun, not more than gr. 6. distant by gr. 20. of Aries, ♈, and Libra, ♎; never can the arms of the same be observed by ordinary tubes; but by perfected tubes [they can] in [a place] up to the gradus 6. distant from the said termini (which termini Huygens calls the Equinoxes of Saturn), some little flow of the arms could be observed.

§22. Therefore Saturn, according to Huygens's hypothesis, either appears round about gr. 20. of Virgo, ♍, and of Pisces, ♓, or furnished with arms; but always [its] arms [are] connected with it, if it is looked at by a perfected telescope.

§23. It remains that, with Huygens himself, [for] the times of this age, and for those of the future, we determine: [Saturn] will appear round, that is, without visible arms; in which [position], by contrast, the arms drawn most amply diminished, and by which the tenuous [arms] would be exhibited, or are about to be exhibited; [in] which [positions] the telescopes are perfect, when the arm emits the heliacal proportion, but recovers [itself] after the heliacal arc. — [Margin: The lacuna] — For of these Phases the [appearances] cannot be bound up [computed] in the tenth-month period, or in the tenth-month [reckoning], in any year; both on account of the Anomaly of Saturn, and on account of the Retrogradations of the same, [which] intercede between one Phase and another. To this is added that Huygens establishes the limits at gr. $20\frac{1}{3}$ of Gemini, ♊, and ♋, for the most ample arms, and ♌, and ♍, for the round Phase; nor are these established at gr. $20\frac{1}{3}$ for the most ample arms, and ♎ and ♏ for the round Phase; but the same [holds] either, [namely] that the orbit and the Ecliptic are inclined by some [angle] of Saturn, and perhaps versus the libration; certainly with the arms toward the Poles of the World [Mundi Polos]. Meanwhile, by observation his opinion [stands], that these times of the Phases were [so].

§24. The first of the Solitary [round] Phases of Saturn, by perfected telescopes, ought to have been seen in the years 1613, 1626, 1642, 1655, about April, [yet] ought to appear in the year 1671 on 12 January, and 1685 in September; and about the middle of the year 1701, with Saturn existing at the eccentric locus in gr. $20\frac{1}{3}$ of Virgo, ♍, or of Pisces, ♓. About six months, moreover, before the predicted Phase, the telescopes [show], by perfected telescopes [Saturn] appears furnished with the slenderest arms, [and] would be about to lose [them] a little after, on account of the access and the occasion of the heliacal [conjunction]. By contrast, indeed, about six months after the predicted Phase, [Saturn] ought to

recover the predicted arms, after the heliacal rising; the telescopes [being] perfect, but imperfect, on account of [their] slenderness, and as yet [it] could be seen to be round, or solitary. The intervals of the predicted Phase vary, [these being] produced on account of the Retrogradations of Saturn. The second of the extreme Phases [follows], that is, the telescopes [being] perfect, [when] Saturn appears most amply furnished with arms, with Saturn existing at the eccentric locus in gr. \square , or $\square 20\frac{1}{2}$. [This] ought to occur in the year 1619, and 1634, and between 1648, and 1649; likewise [it] ought between 1663, and 1664, and between 1678, and 1679, and between 1693, and 1694, and between 1708, and 1709, and so on thereafter.

The third variety of Phases, namely of the increasing arms, was, and is, [reckoned] from the time of the recovered arms, until the time of the second Phase.

The fourth, finally, was, and is, [reckoned] from the time at which Saturn loses its arms, [and] with the arms lost is the second Phase. These intervals then [will] more certainly the Astronomers define, when by more numerous observations, with more perfected telescopes, the arms of Saturn will catch [them] as if by hand [readily].

Iudicium de Theorica Hugenii, & Indicium de Nostra. [Judgment concerning Huygens's Theory, and an Indication concerning Our Own]

§25. Although we owe very much to Huygens for the Theory of the figure of Saturn, so ingeniously and learnedly devised and discovered by him, there are nevertheless certain things which we still hold suspect. For first, as we indicated at number 21, Huygens does not adduce...

does not adduce a [sufficient] cause, whence the projected shadow of that arm [does] not appear to the neighboring parts of Saturn; [the tubes being] imperfect telescopes; just as he asserts the reason, on what account by the same telescopes, by our example for instance, the whole Saturn appears now in tricorporeal manner, now with companions piriform [pear-shaped], now furnished with arms; for the [matter] of [its] longinquity, the round extremity [appearing] of that round [body], ought to appear [tricorporeal]; [such things] ought to appear to the same telescope. It is to be added, therefore, that it seems Saturn is not far off from apogee, [being] piriform; when [it] is more distant, [and] in [its] access to perigee, more and more, the more, and the more [it] reflects the rays of the Sun toward us.

§26. Secondly, the Hugenian Hypothesis [Huygens's hypothesis] always implies that the globe of Saturn, even when most amply furnished with arms, projects beyond the plane of the ring, with the ring nevertheless [appearing], as from Figure cap. 1, & from Figure 10. cap. 9, it is established to have appeared to us [as a] whole within the arms; nor could it have ascended [risen above] the imperfection of the Tube; but if it represents to us the parts nearest to Saturn, the [parts] of the Arms [which are] more difficult to see — [Margin?] — than Huygens admits the extremities [to be]; much more luminously would it have represented the whole [of] Saturn standing out beyond the arms, and [this] is truly thus eminent.

§27. Thirdly, there is no necessity of positing the plane of the ring parallel to the plane of the Equator, observed parallel to the Equator; nor is it necessary [that] it appear [as] that ellipse, which exhibits Saturn furnished with arms, [or] that the ring be from it on every side sequestered and equally [separated]. But it can be said that Saturn is girdled by an elliptical ring coherent with it at the extremities of the diameter of the smaller Ellipse; and this [is] all the more probable, the more [closely] joined to Saturn, [and] parallel [it is], with the body, as it were, [coming round] to meet [itself]; [and the ring] also [may] go about [it]. It can moreover be said that the body sequesters itself; [there being] thus also the diameter of the greater elliptical ring, as it were about the axis parallel to the Equator, or [in] perfect revolution turned, that [the parts] librated, [are] such that the ring's parts, which [are] of the middle for us, [it] bisects optically, when by the elliptical [figure] [it] appears in the highest part, at other times in the lowest part, [and] thus the whole [of] Saturn within itself represents to us, [as] in Figure X. cap. 9, & then [we] see [it] most amply furnished with arms. From the observations of [our] predecessors, however, it could perhaps better be established what times, & [what] intervals of libration. — Save [unless] one [should] posit the plane of the ring of this Huygenian [scheme] parallel, [whether] solitary, or librated, [these] could equally well, if I am not mistaken, save all the phenomena of the figure of Saturn, even if there be posited, in place of the Huygenian ring, an Armilla coherent with Saturn, and [so it] be said:

Saturn is girdled by a thin, flat, Elliptical armilla [armillary band], coherent in two places; or [it is] parallel to the Equator; or it revolves in itself or about the Poles of the World, with a libratory [motion].

§28. It is also more probable that the surface of the predicted Armilla is not equally broad in all its latitudes, but [is] broader in the parts extreme, and [the parts] remote from the globe of Saturn, [and is] narrower in the parts indeed

coherent with the globe of Saturn. For thus it is more easily understood, for what cause, [in] imperfect tubes, the parts of Saturn neighboring [it] more often appear not round, but somewhat round, [and] would be such that the extremities are joined to the armilla [as if] by tubes; but with the armilla everywhere perfect [it] would not be seen, [as] when some of the parts of the Armilla coherent with Saturn appear, but the parts extreme, as more remote, [appear] in the form of a pear [pyri], or in a semi-pear-shaped oblong, [these] appear; [in] all [these] tubes, however, when Saturn appears most amply furnished with arms, [the] arms [appear] broader in the parts more remote.

§29. But neither is it improbable, [for] the principal cause, on what account Saturn [in] this age furnished with most ample arms gr. $20\frac{1}{2}$ \square \square , to be, [is] not because our eye is raised above the plane of the Armilla by gr. $23\frac{1}{2}$, but [because] [there is] something declined of the Ecliptic from the Equator; for [the line] enters [in] this same \square \square ; nor again is anything varied of the parallelism to the Equator, which is probable, [it being] always...

to be continued, as long as the axis of the Armilla, but from the libration of the Armilla; or [from] the revolution, which can be so great, that our line of sight may incident upon the plane of the Armilla at a right angle; the limits of this libration, however, or of the revolutions, [are] able [to migrate], against the order of the Signs to migrate from \square in \square , & \square in \square ; or against the second order of the Signs to change, [namely] from the beginning of the world at the principle of Aries, \square , & \square , also to migrate at gr. $20\frac{1}{2}$. \square , & \square ; [it being] false therefore always [to hold them] parallel to the plane [of the ring], but always [coherent] to the Armilla, & to the Equator. Whether, however, any of these may happen, or [it be] constituted, [it is something] destitute of observations of past ages, and of future [ones], [and so we are] not able to determine.

De Figura Saturni nuperrimè observati à D. Iosepho Campano. [Concerning the Figure of Saturn most recently observed by Sig. Giuseppe Campani]

§30. Sig. Giuseppe Campani [Giuseppe Campani], most excellent in Telescopes, [and] by his own industry, [his] fame won by the very fabric [he] constructs, observed in the month of April of the years 1663 and 1664 Saturn girdled by an elliptical circle apparent, the Figure of which I [have] from him as a gift, [it being] sent by P. Daniele Bartoli [Daniele Bartoli], [it being] very like the Figure rather of XIV. than X. From the premises of number 10. but [he] adds the superior part, that is, [the part] toward the Arctic pole of the body of Saturn, [to be] covered as

[if] by the armilla [itself]; by contrast, indeed, the inferior [part], the Armilla toward the Austral part [being] turned, [to be] covered, or covered by the body itself, or [by the] globe of Saturn. Besides he relates, the lower [part] of the globe candid [bright], or [with] iron-like thread, [it being] of the manner of a diameter through the globe, & the Armilla thus deepening; with the Armilla also so depressed, [and] thus also collocated in the convenient light; [and] thus [as] observed by a small Telescope [it] represented to itself all the phases different for [different] elevations, or [for different] depressions of the armilla, [these things] which now [are] discerned among the future years. The Tube, moreover, with which [he] made use, [was] of 27. April of the year 1664. of the length of palms Roman 55. of those things which the architects use.

§31. I, indeed, inferring from this [figure] in [the] armilla [to be] in reality Elliptical, observed the diverse Phases represented no less near to the diverse armilla [in] libration. With the armilla, however, thus far perfectly round of Saturn, [it can] never [appear] furnished with arms, [the] telescopes [being] perfect [enough] to round [it]; [it could] not [be that] [Saturn] stand for [be] Elliptical, as long as [it is] not demonstrated [to be] impossible [for it] to be Elliptical in reality, & [as long as it does] not appear [other] than Elliptical, [it] represents all those phases, which appear in Saturn.

CAPVT X. [CHAPTER X]

De Iouis Figura, Fasciis, earumq; Parallelismo ad Eclipticam, & Satellitibus. [Concerning Jupiter's Figure, [its] Belts, and their Parallelism to the Ecliptic, and [its] Satellites]

§1. Whatever be the case concerning the vaporous Sphere [Sphaera vaporosa], which P. Antonio Maria de Rheita [Anton Maria Schyrleus de Rheita] asserts to himself to have seen circling about Jupiter with an ample perspective glass — [Margin: ∽ A vaporous atmosphere] — (*Rad. Sideromyst.* cap. 1. memb. 2. & 6.), and D. Leander Bandtius, Abbot of Dispergen [Leander Bandtius], in the year 1643, on 2 November, that is, on 21 [November] after [the conjunction of] ☽ with the Sun observed, [Jupiter] together with two lesser spots, & two greater, or hollows [cavities], the one round, the other oval — [Margin: ∽ rough or hollow] — equaling the seventh part of the diameter of Jupiter in longitude, as I have from the Schema sent from Flanders to me, [a thing] which rarely [happens], because rarely [and] by long perspectives can these be discerned; — these, I say, being omitted, & similar things both concerning the spots, which [Jupiter] has [as]

a quadrate in Jupiter conspicuous in [its] figure [it has?], & the asperities — concerning the Belts [Fasciae] and the Satellites, as ordinary \sphericalangle phenomena, which by observing have been ascertained, we shall expound. — [Margin: of the Belts and the Satellites] — Hevelius [Hevelius] testifies (*Selenograph.* p. 42, 44).

Diagram. A bordered woodcut plate containing nine telescopic drawings of Jupiter's disk, arranged in a three-by-three grid and numbered I through IX (Roman numerals engraved above each circle). Each drawing shows Jupiter as a circle crossed by one or more horizontal belts (*fasciae*), rendered as hatched bands. The figures illustrate the different belt-configurations described in the observational list that follows.

- I (top left): a disk with two thin belts, one above and one below the center.
 - II (top center): a disk with two belts, somewhat broader, both rendered as dense hatched bands near the center, with a slight obliquity.
 - III (top right): a disk with two thin belts close to the center.
 - IV (middle left): a disk with two thin belts.
 - V (middle center): a disk with three belts — a broad central band flanked by two thinner ones.
 - VI (middle right): a disk crossed by a single belt set obliquely (slanting), running diagonally across the disk.
 - VII (bottom left): a disk with a broad, densely hatched belt occupying much of the central region.
 - VIII (bottom center): a disk with a single belt below the center; the lower portion of the disk appears contracted relative to the upper.
 - IX (bottom right): a disk with a single belt in the upper portion, curving toward the south (the belt drawn somewhat in the upper part and bowed).
-

2. Belts running crosswise that gird the whole disk of Jupiter — or rather, that are the more prominent, or rather the deeper, parts of it — were first noted (so far as I know) at Naples by Father Giovanni Battista Zupi [Zupus] and by Daniel Bartoli of our Society, although Francesco Fontana [Fontana] had observed them there even earlier. Afterwards we ourselves at Bologna, together with Father Francesco Maria Grimaldi [Grimaldi], saw the same belts distinctly through the telescope. They appear sometimes two, sometimes only one, and occasionally several at once, bounded on both sides, sometimes hedged in, and sometimes single. Moreover, one of them sometimes appears in the middle of Jupiter's disk, sometimes higher,

sometimes lower; nor are they always straight, but sometimes curved, sometimes turned convex upward, sometimes convex downward. These curvatures are indeed a fairly clear sign of Jupiter's rotation [*vertigo*]; for concerning the parallelism of those belts to the ecliptic, and to the path of the satellites, I must speak separately further on, after I have given the history of the number of the belts. As for the fact that sometimes no belt at all appears — as is evident from the first schema of Giovanni Lippi of Munich [Io. Lippius Monachiensis] — this is no wonder, since Gassendi [Gassendus], in Book 3 of his *Institutio Astronomica*, denies having seen any himself.

Observations of Jupiter's Belts.

In the year:

- **1630.** On 17 May, Father Niccolò Zucchi [Zucchius] at Rome saw two belts on Jupiter, as in Fig. II.
 - **1633.** Francesco Fontana at Naples — as is recorded in his tract 6 of his own observations — observed three belts, as in Fig. I; and likewise at the beginning of the year 1643.
 - **1634.** Jupiter, which had appeared with three belts, nevertheless from the beginning of October up to the 13th — that is, up to the time it was seen with the Sun [in conjunction] — was observed by Father Grimaldi with two belts, one darker, the other brighter, than.
-

the rest of the disk — as in Fig. III, but after the conjunction with the Sun, right up to 20 October, three belts were seen, the same as before: one dark, the rest bright, and curved, as in Fig. IV. But from the beginning of November onward, up to the 22nd of December, often two straight belts appeared, chiefly in the meridian, as in Fig. V.

- **1644.** Father Giovanni Battista Zupi at Naples observed two belts on Jupiter, as in Fig. II, but much broader, on account of the excellence of his telescope, which represented Jupiter's diameter [as large as] half a foot.
- **1645.** On 1 and 22 January, Fontana saw two belts on Jupiter, as in Fig. II, but on the 28th he saw a third near the margin, as in Fig. I.
- **1647.** On 23 January, I too saw Jupiter girt with two zones [*zoniae*] when in conjunction with the Sun, as in Fig. II.
- **1648.** Father Grimaldi, from the 24th of February to the 16th of March, observed on Jupiter two now-straight belts, as in Fig. VI, which represent

the observation of 11 February, at 1.5 hours after sunset, when Jupiter was in the eastern quadrant and stood moderately distant from the meridian; and the upper belt was narrower and darker in appearance, while the lower was broader, less obscure, and the part of the Jovian disk [below it] had been left much brighter, as in Fig. VI [reading as printed; cf. note]. This had been [observed?] on 22 February.

- **1649.** On 28 March, at the second hour of the night, the belts appeared in the same line with the four satellites, as in Fig. V, but at an angle. On 14 August, Father Grimaldi noted a single belt above the middle, in the line of the satellites, the others not being conspicuously visible.
 - **1650.** In the month of July, two belts were observed by Father Gri-
-

- maldi in the upper part, turned toward the south, as in Fig. IX.
- **1651.** On 29 May, Jupiter was seen with two dark belts enclosing a great bright space, as in Fig. II; but on the 11th of July it was seen with two obscure belts, of which the middle [region] was broader and more obscure, and a little above [it] toward the south the disk appeared brighter, but toward the lower limb [it appeared] more austere [darker], as in Fig. VII.
- **1652.** On 1 June, Father Giovanni Battista Hodierna [Hodierna] wrote to me that the same had been seen by him on Monozonium [Jupiter "of one belt"], in June and July.
- **1653.** On 21 July, Father Grimaldi saw Jupiter "Three-belted" [Trizonium].
- **1654.** Father Giovanni Battista Zupi observed Jupiter, as in Fig. VIII, in which the lower half-disk appeared contracted [narrower] than the upper.
- **1656.** Father Grimaldi, on 2 August, beheld Jupiter with two obscure belts comprehended within bright zones, as in Fig. VI, of which the lower [zone] was a little broader, and in the line of the satellites, as in Fig. VII; but on 5 October, and on 2 December, [Jupiter appeared] with three belts, as in Fig. VII.
- **1657.** From 17 October on, and on 6 November, Father Grimaldi observed three belts, as in Fig. II; but on the 12th and 19th of November, the third was wanting, as in Fig. VII — for the two dark belts were then more like those of Figure IX; and the third nearest the southern limb, on the 4th of October, was obscured. On 9 December, he saw three obscure [belts] enclosed within two bright ones, almost as in Fig. VII; but on the 13th [he saw them] as in the margin [reading as printed], where a certain shading appeared toward the south, like a fourth belt.

- **1664.** On 1 July, Don Giuseppe Campano [Iosephus Campanus], with a most excellent telescope made by himself, observed two dark belts on Jupiter and two bright ones, as the most excellent Doctor Giovanni Domenico Cassini [Io. Dominicus Cassinus] testifies. But because I have not yet obtained the schema of these, I cannot exhibit a synopsis of them to the reader.

On the Parallelism of the Belts, the Path of the Satellites, and the Ecliptic.

3. That the belts of Jupiter, the path of the satellites of the same, and the ecliptic are parallel to one another — as regards the satellites — was noted by Galileo [Galilaeus] in his *Nuncius Sidereus*, and by Simon Marius [Simon Marius] in part 2 of his *Mundus Iovialis*; and as regards the belts, by Hevelius [Hevelius] in his *Selenographia*; and on both counts by us also, and often by Father Grimaldi, who saw the lines [of the belts] drawn parallel to the two lines [drawn] toward the two satellites — the parallelism of the belts and of the path of the satellites being established by direct sighting [*ductus*] on both counts. There is no need to fill many pages with the multitude of observations of this matter that present themselves.

On the Number of Jupiter's Satellites.

4. Although the satellites of Jupiter may be reckoned equal to fixed stars of the sixth magnitude, just as such stars are scarcely apparent to the naked eye, so neither do the satellites of Jupiter appear without a telescope — both because they can scarcely be seen, on account of their brightness, when so near to Jupiter, and because none of them is more than 12 minutes distant from Jupiter. No wonder, then, that they lay hidden from the eyes of mortals up to our own age, when, by the concession of God, the beginning and the greater [share of glory] of this our age, Simon Marius in Germany — as he relates in his *Mundus Iovialis* — on 29 November 1609, on the occasion of Jupiter's [appearance], and Galileo, when Jupiter began to rise with the Sun, began to notice three little stars around Jupiter, [their] distance being varied from observation to observation, confirmed these to be wandering. On the 8th of January [1610], he saw three [stars] in a straight line, twelve [minutes] toward the west. On the 19th of the year 1610, on the 12th [of January], at the beginning of [his observations], Marius too acknowledged [them], yet [held] those little planets to be wandering; Galileo, however, conscious of nothing pertaining to Marius's observation, [was] the first of all in Italy, in the year 1610, on 7 January, at the first hour of the night, [to] observe around Jupiter at first three [little

stars], and then never more than four; nor did more than four wandering little stars [appear] around Jupiter, and [these were distinguished] from the fixed stars by this token — that they rapidly changed their distance from one another, as.

he relates more fully in the *Nuncius Sidereus*. And although Scheiner [Scheinerus], in his first letter to Welser [Vuelserus], suspects that there are several of these satellites — more than four — in his *Disquisitiones Ingolstadii* [the Ingolstadt Disquisitions], and although at Rome, from observations made, he acknowledged only four, yet he asserts the same number in his observations, [as does] Blancanus [Blancanus] in *Sphaera* fol. 14. Kepler [Keplerus], in his *Dissertatio cum Nuncio Sidereo*, and in his *Epitome Astronomiae*; Herigone [Herigonius] in tome 5 of his *Cursus Mathematicus*; Charles Malapert [Carolus Malapertius] of the Society of Jesus, who calls them *Sidera Austriaca*, just as Galileo [calls them] *Sidera Medicea*; D. Vincenzo Reinieri [Vincentius Reinerius], who for whole 10 years observed them every year; likewise Peiresc [Peirescius] and Gaultier [Galterus], as in the *Life of Peiresc*, and in the *Discourse of the Nine Stars* — these observed them at Marseille [Massiliae], naming the first the *Cosmus Minor*, the next-to-last the *Cosmus Maior*, [and] the outermost the *Catherina Medicea*; although Marius had called the innermost *Iovialem Mercurium* [the Jovian Mercury], the next-to-last *Venerem* [the Jovian Venus], the next-to-next *Iovem* [the Jovian Jupiter], the outermost *Saturnum* [the Jovian Saturn]. And [there is] Father Giovanni Battista Hodierna, who recently in the *Medicean Ephemerides* — or rather, by the patronage of the prince of Etruria — names them: first, from *Victoria*; second, from *Cosimo Cosmifer*, the husband of the Grand Duchess; third, from *Ferdinando Fernandifer*; finally, fourth, from *Ferdinando Stampioni*. Finally, [as recorded] in a letter to me of the year 1647, and by Hevelius in his *Selenographia* at page 45, and by Gassendi [Gassendus] above at page 45, and by Phocylides Holwarda [Phocyllides Oluuarda] — and we ourselves, with Father Grimaldi, never observed more than four.

[Margin: Fontana observing.]

5. But Father Anton Maria de Rheita [Rheita], besides the four inner Jovian satellites, claims to have seen others, more remote and larger, not visible except through a larger telescope, which space in the sky he calls the Urbanoctavian [*Urbanoctavianus*] [in honor of Urban VIII]; and this in the year 1642. On 29 December, [he saw them] still more, [than] Francesco Fontana [had], in tract 6, observation cap. 2, in the year 1630, [Jupiter]

surrounded by 8 stars distant from it by more than 10 Jovian diameters; and on the 8th of January [16]36 and [16]43 [he saw] Jupiter with 8 stars, and in [16]45, on 31 December, [Jupiter] with seven, as also in the year [16]43; on 1 and 22 January [he saw it] with 6; on the 28th [he saw it] with 6 stars — these not preserving the same distance among themselves: this needs to be extended for examining them [requires] that the telescope be drawn out [extended] in order to see them, [whereas] for seeing the fixed stars perfectly, there is need to contract the tube.

[Margin: Campanus and Lippius.]

6. But Father Giovanni Battista Zupi of the Society of Jesus, at my request, observed the stars around Jupiter for nearly a whole [period] in the year 1644. On the 1st of January, and in February — [as] he wrote at Naples in letters [dated] from Naples — Jupiter was seen with 6 [stars], Jupiter with 21 and 22 [...]; on the 22nd of January, those that had been reckoned to be in the [region] toward Jupiter, and on the 23rd, it was explored by him that there were not only six but rather nine, sometimes twelve, around Jupiter — among which he reckoned 9 or sometimes 12 to be errant [wandering], both because they did not scintillate, and because of the change of telescope, and because of the change of distance among themselves; he asserts nothing [definite], yet what he asserts Father Rheita adds, that new stars are born and afterward grow faint, which is the opinion of Giovanni Caramuel [Io. Caramuelis] and Giovanni Stampioni [Io. Stampionius].

[Margin: Caramuel, and Holwarda.]

[Margin: Gassendi opposes; and Reinieri.]

7. As for the rest — besides the four [satellites] common [to all], Rheita [claims] that the others he had seen were fixed stars [located] in the constellation Aquarius, as Gassendi reckons in his *Iudicium de 9 Stellis* — for in the year 1642, on 29 December, he did not see [them] change their distance among themselves; and for other arguments, which Gassendi adduces in *Almagestum Novum* Book 7, cap. 3. But D. Vincenzo Reinieri, mathematician of Pisa, stoutly affirms to me that in his observations, made over a whole decade, he never saw more than 4 around those little stars of Jupiter [the satellites]. Hevelius likewise, in his *Selenographia* at page 45, affirms that from the year 1642 to 1645 he most diligently watched [for them], and detected no more than 4 planets; and the other stars seen by Rheita were fixed stars of the same Asterismus [asterism] of Aquarius, but

not ordinary ones, nor visible to the naked eye; and (as at page 65) [these are] far more worthy [of the name] of fixed stars, against Caramuel and Rheita; against the Rheitan [view], on this account and [for] other reasons, too bitterly inveighed Giovanni Phocylides Holwarda.

[Margin: Gassendi the wise; and Reinieri.]

[Margin: And Hevelius.]

[Margin: And [against] Holwarda [reading as printed].]

On the Position and Motion of Jupiter's Satellites.

8. Since on individual clear nights the motions of the satellites around Jupiter are observed to vary, [as well as] their interval [from Jupiter], if [their] altitude [is considered], and the form of our observations — were we willing to transcribe [them] in this form, [following] the practice of Galileo (after his Epistle to Welser) and of Hevelius in his *Selenographia*, page 526 — we would fill very many leaves indeed, without [any] hope of gathering fruit for the reader's weariness. It is enough, however, to see a specimen of these [observations], both among the aforesaid [authors], and among Scheiner in his *Disquisitiones* num. 39, and likewise with Simon Marius, who also constructed *Ephemerides* of these motions, as did lately Father Giovanni Battista Hodierna; from [Marius's] long diligence, and the more excellent [observations], both [those drawn] from Vendelin's [Vuendelinus's] *Epistle* to me, and from the Rheitan [source] Book 4, cap. 2, member 2, and from Gassendi in his *Epicurus* page 904, and from *Almagestum Novum* Book 7, sect. 1, cap. 3 — and at last from D. Vincenzo Reinieri — I have gathered our compendium written below, more worthy [to be] known [than] the propositions [themselves].

[Margin: Proposition]

1. They are flat circular [bodies], in number 4. The 4 satellites moving around Jupiter, above Jupiter, indeed decline toward the south from the ecliptic, while below [Jupiter they decline] toward the north — whence it comes about that the latitude of these [satellites] is southern in the upper part, and northern in the lower part. Gassendi reckons this [to hold] if Jupiter himself, [he] says, has southern latitude.

2. The latitude of the first [satellite], or innermost, is greater than [that] of the second; [that] of this [second] greater than [that] of the third; and [that] of the third greater [than that] of the fourth, or outermost.
3. They move in the upper part of [their] orbit directly, and according to the consequence of the signs [in the order of the zodiac], from west to east; but in the lower part [they move] retrograde, from east to west.
4. They move in [quadrature?] [□], with the greatest excursions [*digressiones*] from Jupiter; at conjunction with Jupiter [♃] [they move] most slowly, at opposition [♁] with Jupiter most swiftly.
5. In the upper part, when they decline toward the south, even though they be more remote from the center of the earth, they nevertheless appear higher with respect to the horizon; but in the lower part [it is] the contrary.
6. They appear larger when tending from a higher [position] toward a lower one [♃ with Jupiter]; but from this [lower position] tending toward the higher [♁], they appear smaller.
7. When Jupiter is in the ecliptic, [the satellites] more often and more easily eclipse one another, and are eclipsed by Jupiter's shadow; and such eclipses are conspicuous to us. At other times, however, they escape us, [as do] other eclipses of them, on account of the differing latitude of Jupiter, and the inclination of Jupiter's shadow-cone. But concerning the vicissitude of these eclipses, [see] the more numerous [observations] of Galileo in his *Macula Solis* page 162; Hevelius page 46 of his *Selenographia*; and Hodierna in part 2 of his *Medicean Ephemerides* cap. 7.
8. The periods of these [satellites] are better computed at conjunction [♃] and opposition [♁] with Jupiter than from other aspects. Scheiner hands down other rules in his *Disquisitiones* num. 42. For the rest, see the little tables written below.

Excursions [Digressions] from Jupiter, expressed in Jovian Semidiameters.

	Rheita	16	18	9
	Hevelius	16	18	9
	Hodierna	16	18	14
	Vendelin	16	18 755/1000	

Parsing notes: the rightmost column carries either an arc-minute value or a qualifier (*ferè* "nearly," *circ.* "about"). The Vendelin rows give a fractional day-part (e.g. 18 768/1000 of a day) rather than separate hour/minute columns; transcribed as printed with the fraction in the Hours column.

From this Vendelin concludes that, just as in the major planets the mean distances of those [planets] from the Sun stand in the sesquialterate ratio [3:2 power] of their periodic times, so the distances of the Jovian planetlets from Jupiter stand in the sesquialterate ratio of their periodic times.

Diurnal and Hourly Motion in each one's own orbit, divided into 360 degrees.

				[readi ng as printe d]			
	Hodie rna	21	28	48	0	53	42

Parsing notes: the Galileo rows give only the hourly motion (diurnal columns left blank in the source). Some seconds-cells carry the qualifier *circ.* / *ferè* in place of a numeral. Where the source prints a fractional second (e.g. 29½, 5½), transcribed as a decimal in brackets.

More tables besides, with their canons, together with roots [radices] for constructing ephemerides and for predicting eclipses of these satellites, Simon Marius and Father Giovanni Battista Hodierna have; selections from which, in their own places, we shall give after the Tables of the Second Movables [Secundorum Mobilium], if Almighty God so pleases.

CAPVT XI.

On the Figure of Mars [De Martis Figura]

1. Near quadrature [☐] with the Sun, Mars is seen almost halved [dichotomous], says Kepler [Johannes Kepler] (*Epitome of Astronomy* [Epitome Astronomiae], p. 843); but at other times it appears gibbous between quadrature [☐] and opposition [♁] with the Sun, and is only rarely round, as Rheita [Anton Maria Schyrleus de Rheita] firmly asserts (*Selenographia* [Oculus Enoch et Eliae / *Selenographia*], bk. 4, ch. 5). Hevelius [Johannes Hevelius] (*Selenographia*, p. 42) presents a figure of Mars gibbous in itself, and on p. 67 denies that Mars can be seen horned [corniculate]. Yet Mars was seen halved in the year 1645. Francesco Fontana [Francesco Fontana], in his *Observations* (treatise 6, ch. 1), presents a round figure of Mars for the year 1636 with a dark spot in the middle, which he judges to be a cavity rather than a shadow [umbo]; but he shows it gibbous with a spot, again in the year 1638. On 24 August Fr. Niccolò Zucchi [Niccolò Zucchi], in the year 1640, and on 23 May, saw Mars gibbous between quadrature [☐ and △ — i.e. between quadrature and trine? *as printed*: "inter △" (?) and opposition [♁] with the Sun, but without a spot — perhaps because of the motion of its rotation [vertigo], or of a libration about the center of its body. Fr. Daniel Bartoli [Daniele Bartoli] wrote to me from Naples in the year 1644, on 24 December, that with an excellent telescope of Fr. Sersale [Cristoforo Sersale — printed "P. Sirsali"] he had seen Mars almost round, with two spots within.
2. Finally, with Fr. [Francesco Maria] Grimaldi [Grimaldi], in the year 1651 — on 4 April, and on 6 April — we saw Mars with a black spot, as if formed of many parts, and likewise on 18 April and 29 May. And again repeatedly in the year 1653, throughout the whole of July, and in the year 1655, on 22 July and 28 August, and finally in the year 1657, on 15 and 11 October, on 17 and 21 October, and on 6 November. Moreover, from its halving [dichotomy] and gibbosity, astronomers take an argument that its light is received from the Sun in just the same way as if Mars were the Moon; and if it were permitted to see Mars near and in conjunction with the Sun, we should see it horned.

CAPVT XII.

On the Figure of Venus [De Figura Veneris]

1. That Venus moves around the Sun, and receives light from it — now appearing nearly full when close to superior conjunction [♁], now gibbous, at other times halved or horned [falcate] — is plain to any observer, both from the renowned telescope, whether in the evening or in the morning, and from the observations of Galileo [Galileo], Scheiner [Christoph Scheiner], Fontana, and Hortensius [Martinus Hortensius]; from Kepler in the *Epitome of Astronomy*, p. 762; from Rheita (bk. 4, ch. 5, member 2); from Gassendi [Pierre Gassendi] in the *Epicurus*, p. 859. The remaining places, together with figures drawn from our own observations as well, I cited in the *Almagestum Novum* (sect. 1, ch. 7). I have noticed Venus with two horns, and with spots, as Fontana saw — but never by us, nor by Gassendi (bk. 3, *Institutio Astronomica*). To all these add the figures of Hevelius [Hevelius] in his *Selenographia*, from p. 68 to p. 74.
2. That Venus is moreover sometimes visible in broad daylight is established from the observations of Tycho [Tycho Brahe] and Longomontanus [Christen Sørensen Longomontanus], and of Hevelius above, who with Galileo adds that it is observed better and longer by day than by night, since it is then stripped of adventitious rays. We too, with Fr. Grimaldi, saw Venus with the naked eye in the year 1649. On 1 April it appeared nearly gibbous, and on 20 April halved [dichotomous]; on 1 September again halved, as on 4 September, as far as the first hour after midday; from then until 8 September, seen halved from the rising of the Sun all the way to midday; but on 18 April, exactly halved; and on 26 April more than halved, until the 9th hour after midday — always with the naked eye; and in the year 1651, on 1 February, the two horns [cusps] ran out beyond its own diameter, and on 12 February a line drawn through the horns was parallel to the ecliptic. This is indeed a very rare but remarkable phenomenon of Venus.

Diagram. A large telescopic figure of Venus occupying nearly the full height of the page's right column, showing Venus as a thin crescent (horned/falcate phase), its concave side facing inward and the cusps drawn out into long thin points. The crescent's convex (lit) edge faces toward the right. Two astronomical symbols for Venus (♀) are placed along the figure — one near the upper part and one near the

lower part of the crescent — and an additional Venus symbol appears at the very bottom. The figure is labelled with directional words.

- Top: **Occidens** — "West"
- Upper crescent: ♀ (symbol of Venus)
- Lower crescent: ♀ (symbol of Venus)
- Below, at foot of figure: **Occidens** — "West" (repeated; this is a layout/show-through artifact — a partial table edge bled through from the adjacent leaf — not a second phase-figure; not independently transcribable)

(Beneath this figure, faint show-through of a table from the following leaf is visible but is not part of this page's content.)

CAPVT XIII.

On the Figure of Mercury [De Mercurij Figura]

As many witnesses as we adduced in the preceding chapter, just as many stand for the motion of Mercury around the Sun, and for its light received from the Sun. For if Mercury is observed with a very powerful telescope, then around its greatest elongations from the Sun it appears nearly halved [dichotomous]; but when it is retrograde, approaching conjunction [♄] with the Sun, or moving away from it toward its second station, it appears like the Moon when it is about 60 degrees distant from the Sun, and as it were horned [falcate]. Hevelius (*Selenographia*, p. 74) says that in the year 1644 he himself observed Mercury in the morning on 22 November, its light a tenth part of its whole diameter, as illustrated in his Figure III; and on 30 November illuminated to one-eighth, and on 8 December to five-twelfths; and now horned, as in the following figure. But in the year 1645, on 16 May, [Johannes Phocylides] Holwarda [?] saw Mercury illuminated, one-third part, as in his Figs. I and 20; on 20 May halved [dichotomous], and slightly more than halved, as in Fig. III. But before that, in the year 1639, Fr. Giovanni Battista Zupo [Giovanni Battista Zupi] at Naples, with a telescope of Fontana, saw it horned and illuminated to five-twelfths in the evening, nearly as in Figure I — in the manner he saw it likewise in the year 1646; and on 16 January [printed "Ianuatij" — compositor error for *Ianuarij*] in the evening.

2. We too, with Fr. Francesco Maria Grimaldi, in the year 1643, on 5 March, saw Mercury in the upper part of its epicycle, in an evening position, and not yet 15 degrees moved away from the Sun, gibbous, as in Fig. III; just as

in the year 1656, on 24 December. But in the year 1643, on 25 August, we saw it halved, distant from the Sun 19 degrees, as in Figure II; in just the way [we had seen it] also in the year 1644, on 6 August, when it was 20 degrees distant from the Sun. Yet in the year 1647, on 30 April, we saw it [☿ — printed ☿, a glyph-sort substitution; the *De Mercurii Figura* context requires Mercury] as an evening star and distant from the Sun 20 degrees, as in Fig. I; and in the year 1650, likewise as an evening star and distant from the Sun nearly 18 degrees, horned [falcate], as in Fig. I.

Diagram. At the foot of the left column, a vertical series of telescopic phase-figures of Mercury (a stacked column of small disk-figures showing successive phases — gibbous, halved, and horned), each annotated with the date of observation and a phase symbol (☿ for Mercury, with the lit fraction shaded). The figures are interleaved with an engraved decorative woodcut of cherub-heads, scrollwork, and a radiant IHS-type emblem behind them. Readable labels:

- **Vespertinus** — "Evening [star]" (heading the upper figures)
- **1639 Maij 23. 1646 Iun. 26.** — "1639, 23 May; 1646, 26 June"
- **1647 April. 30.** — "1647, 30 April"
- **Matutinus** — "Morning [star]" (heading a middle figure)
- **1643 Aug. 25. 1644 Aug. 6.** — "1643, 25 August; 1644, 6 August"
- **Vespertinus** — "Evening [star]"
- **1643 Martij 5.** — "1643, 5 March"

(Each label sits beside a small ☿ phase-disk with the illuminated portion shaded; the disks themselves are partly overrun by the decorative engraving and the page's central woodcut emblem. The date line atop the "Matutinus" middle figure is overlapped by the decorative central emblem show-through and cannot be read with confidence [?].)

CAPVT XIV.

On the Rotation of the Planets About Their Own Center [De Vertigine Planetarum circa suum centrum]

This rotation [vertigo] was asserted by Vuakerius [Wackher / Johann Matthäus Wacker von Wackenfels] [?] in the *Dissertatio cum Nuncio Sidereo* of Kepler; by Kepler himself in the same place, and in the *Epitome of Astronomy*, p. 549; and by Huygens [Christiaan Huygens] in his *Systema Saturnium* it is seen as probable,

from the varied situation of the belts [fasciae] and of the spots, concerning which see above under Saturn [♄], Jupiter [♃], Mars [♂], and the Moon [☾] — though perhaps these phenomena might be attributed to libration. Moreover, Fr. Anton Maria de Rheita affirms that this rotation of theirs was observed by him, from their setting toward their rising, and that its period is monthly — and he promises observations to be carried out [editae] on this matter.

If a rotation [vertigo] is chosen, this advantage emerges: namely, that all the parts of the surface succeed one another in turn, which is not the case for the Moon. As for the rotation of the Sun [☉] about its own center, it falls within 27, 28, or 29 days — as Scheiner, Galileo, and Bullialdus [Ismaël Boulliau] asserted from the apparent motion of the spots; or it is divinely [reckoned] according to Kepler, or is to be seen as a yearly one according to Rheita — concerning which we said much in *Almagestum Novum* bk. 3, ch. 4, and bk. 4, sect. 4, ch. 12. So many things are these, that they cannot here be reduced into a compendium without the loss of much erudition.

Diagram. A second stacked column of telescopic phase-figures, this one for **Mars** [♂] (the Mars symbol ♀ appears beside each disk), showing successive observed phases (round-with-spot, gibbous, and halved), each dated. The disks are again overlaid on the decorative cherub-and-scrollwork engraving and the central radiant emblem. Readable labels:

- **Vespertinus** — "Evening [star]"
- **1639 Maij 23. 1646 Iun. 26.** — "1639, 23 May; 1646, 26 June" [?]
- **1647 April. 30.** — "1647, 30 April"
- **Matutinus** — "Morning [star]"
- **1643 Aug. 25. 1644 Aug. 6.** — "1643, 25 August; 1644, 6 August"
- **Vespertinus** — "Evening [star]"
- **1643 Martij 5.** — "1643, 5 March"

(Note: the date-labels in this lower stack repeat the same dates as the Mercury stack above; the engraving is dense and the symbols ♂/♀ are hard to separate from the decorative work — labels flagged where the planet-symbol/date pairing is uncertain.)

CAPVT XV.

On the Distances of the Planets from the Earth and from the Sun, and on [the Distances] of the Fixed Stars [De Planetarum Distantijs à Terra, & à Sole, vbi & de Fixarum]

In the Prolegomena of this volume, Article 4, I taught that the distance of the Sun from the Earth is neither greater than 30,000 terrestrial semidiameters nor less than 6,430. Within these limits I proposed two other probable hypotheses: one nearly that of Posidonius [Possidonius] and Wendelen [Govaert Wendelen], the other that of Christiaan Huygens, twofold, as I set it out in bk. 1, chs. 13 and 14, and ch. 17. But in bk. 3, ch. 9, *On the Distances of the Moon* [Lunae distantiae], and in bk. 5, chs. 6, 7, 8, and 9, I reckoned the greatest distances, and the least, of the five lesser planets from the Sun — but in parts of which the radius of the Sun's annual orb [Radius Orbis Annui Solis] is 100,000, just as I set out the species of [these] parts in Volume 2, Table 97. To these I shall add their distances from the Sun at every degree of anomaly [Anomalialia], or at every five degrees together with their greatest and least distance from the Earth. Here indeed we set down only the greatest distances, and the least, not solely with respect to the parts of the radius of the Sun's annual orb, but also in semidiameters of the Earth — and that according to the four hypotheses of the Sun's distance from the Earth indicated above, the rest being rejected (along with the others that we set out above, or as fictitious within the aforesaid limits, or as easily, indeed evidently, false, as we showed in their place). We shall always suppose the distances of the planets from the Sun according to our own hypothesis; but whenever those [distances] are to be combined with the said distances of the Sun from the Earth, we shall take these [latter] from the four said hypotheses.

For example: when we say that the greatest distance of Mercury [☿] from the Earth, according to Wendelen, is 21,754 terrestrial semidiameters — it is to be understood as taken, and as compounded of two elements: namely from Wendelen, in that the radius of the Sun's annual orb is, in terrestrial semidiameters, 14,656; and on the other hand, that the greatest distance of Mercury from the Sun, which for us is 148,430 [printed "148430" — the worn final glyph is a 0; a sort-oddity for 148430], is of such parts as that the Radius of the Orb is 100,000. For 14,656 multiplied by 148,430 [printed "148430"], and the sum divided by 100,000, yields terrestrial semidiameters 21,754; and so of the rest.

[End of Caput XV / Liber X / Tomus I — tables and colophon]

The following two tables give the distances of the planets from the Earth and from the Sun. The first table (left column of folio 374) expresses distances in parts of which the radius of the Sun's annual orb is 100,000; the second (right column of folio 374, continued) expresses each planet's distance from the Earth in terrestrial semidiameters, according to the four hypotheses (Summa = Maximum; Vuendel. = Wendelen; Nobis = "by us / ours"; vel Infima = "or Least").

Table 1 — Distances of the Planets from the Earth and from the Sun, in parts of which the Radius of the Sun's Annual Orb is 100,000

Heading (verbatim): *In partibus Qualium Radius Orbis Annui Solis est 100000.*

Distances of the Planets from the Earth [Distantia Planetarum à Terra], from our own Hypothesis [Ex Nostra Hypothesi]

Planet	Minimum [Minima]	Mean [Media]	Maximum [Maxima]
☉ Sun [Solis]	98260	100000	101740
☿ Mercury [Merc.]	67780	—	148430
♀ Venus [Veneris]	26656	—	174715
♂ Mars [Martis]	36534	—	268164
♃ Jupiter [Iouis]	395418	—	649629
♄ Saturn [Saturni]	797563	—	1111033

Distances of the Planets from the Sun [Distantia Planetarum à Sole]

Planet	Minimum	Mean	Maximum
☿ Mercury	30480	38585	46690
♀ Venus	71825	72598	72973
♂ Mars	138274	152348	166424
♃ Jupiter	497134	522511	547889

Planet	Minimum	Mean	Maximum
♄ Saturn	899103	954198	1009293

Distance from the Earth in Terrestrial Semidiameters [Distantia à Terra in Semidiametris Terræ]

☉ Sun à Terra	(value)
Summa [Maximum]	28974 / 29487 / 30000
Vuendel. [Wendelen]	14407 / 14656 / 14905
Nobis [Ours]	7175 / 7300 / 7427
vel Infima [or Least]	6438 / 6552 / 6661

Parsing notes: the Sun's "Distance from Earth in terrestrial semidiameters" sub-block presents three columns of values (corresponding to minimum / mean / maximum) for each of the four hypotheses; I have rendered them slash-separated within each hypothesis row since the column headers are not repeated in this sub-block. The "Mean" column for the upper *Distantia à Terra* block (Mercury through Saturn) is left blank in the source. The Mars-from-Sun "Media" value reads 152348; the column is monotone Minima < Media < Maxima.

Table 2 — Distances from the Earth in Terrestrial Semidiameters, per the four hypotheses (right column of folio 374)

For each of the five lesser planets, the source gives a four-row block: **Summa** (maximum), **Vuendel.** (Wendelen), **Nobis** (ours), **vel Infima** (or least). Three numeric columns appear per row (corresponding to minimum / mean / maximum distance from the Earth). Transcribed left-to-right as printed:

Planet (à Terra)	Hypothesis	col. 1	col. 2	col. 3
☿ Mercury	Summa	19986	31446	42906
	Vuendel.	9934	15844	21754
	Nobis	4948	7690	10435
	vel Infima	4441	7083	9725
♀ Venus	Summa	7860	29689	51518
	Vuendel.	3904	14656	25406
	Nobis	1946	7350	12754
	vel Infima	1745	6596	11447
♂ Mars	Summa	10773	44923	79074

Planet (à Terra)	Hypothesis	col. 1	col. 2	col. 3
	Vuendel.	5354	22328	39302
	Nobis	2670	11120	19576
	vel Infima	2394	9982	17570
♃ Jupiter	Summa	116595	154075	191556
	Vuendel.	57952	76580	95208
	Nobis	28864	37266	45669
	vel Infima	25907	34235	42564
♄ Saturn	Summa	235110	281360	327610
	Vuendel.	116862	139847	162833
	Nobis	58207	69656	81105
	vel Infima	52263	62529	72795

Parsing notes: the three numeric columns per block are unlabelled in this right-hand panel but correspond (by analogy with Table 1 and with the planet's minimum / mean / maximum geometry) to least / mean / greatest distance from the Earth. Wendelen's row for Venus (col. 2 = 14656) and Mercury (implied) reproduces the Sun-distance radius figure 14,656, consistent with the worked example in the prose. Values transcribed as printed; both p. 374 distance tables further verified cell-by-cell — these are part-counts of 100000 (and Earth-semidiameter counts), not sexagesimal, so the >59 rule does not apply; none breaks an obvious monotone progression, so no impossibles flagged. (Jupiter Summa col. 2 reads 154075 — faint middle digits, moderately confident.)

Closing couplet (set beneath Table 2, verbatim):

Hic modus Errorum est; hi certi denique fines, Quos vltra citraq; nequit consistere verum.

"This is the measure of the errors; these, in the end, are the fixed limits, beyond which and short of which the truth cannot stand." (An adaptation of Horace, *Satires* I.1.106–107: *est modus in rebus, sunt certi denique fines, / quos vltra citraque nequit consistere rectum.*)

Laus Deo, Beatissimæq; Virgini.

"Praise be to God, and to the Most Blessed Virgin." (Colophon closing Liber X and Tomus I.)

Tomus II — Title Page

ASTRONOMIAE REFORMATAE [REFORMED ASTRONOMY]

TOMUS II. [VOLUME II]

The first part of which contains the precepts for the use of the tables; the latter part contains the 102 astronomical New-Almagest tables themselves.

[17]	Dierum Naturalium, seu Civilium] Time given under the Meridian of Bologna to transfer to another place on Earth, or from those [places] to the Meridian of Bologna; and likewise to learn the Altitude of the Pole of such places [Tempus datum sub Meridiano Bononiensi transferre ad alia Terrae loca, vel ab illis ad Meridianum Bononiensem: unaque addiscere talium Locorum Altitudinem Poli]	3
18	To distinguish Bissextile [Leap] Years from non- Bissextiles in the form of the Julian Year reckoned backward before the Epoch of Christ, and after [Annos Bissextiles discernere a non Bissextilibus in forma Anni Iuliani retrosum pati ante	4

Precept no. [Praecept. ordo]	Precept	Page [Pagina]
	Epocham Christi, & post]	
19	The same to distinguish in the Years of Christ, but in the form of the Gregorian Year, and the excess of the Gregorian Year above the Julian days [Idem discernere in Annis Christi, sed in forma Anni Gregoriani, & excessum dierum Gregoriani Anni supra dies Iulianos]	4
20	To find the Cycle of the Sun before and after Christ [Cyclum Solis reperire ante, & post Christum]	4[?]
21	To find the Weekday [Feria] of a given day in a Julian Year [Feriam datae diei in Anno Iuliano reperire]	5
22	To find the Weekday in an Arabic Year of the Hegira, by means of the Arabic Cycle [Feriam in Anno Arabico Hegirae reperire, beneficio Cycli Arabici]	5

Precept no. [Praecept. ordo]	Precept	Page [Pagina]
23	To add the reckoned Days of the Years, and of the Months of different nations, and the concurrence of the Months of those same [nations] [Dies collectos Annorum, ac Mensium diversarum nationum, & concursum Mensium earundem addiscere]	6
24	To convert the Years before or after the Epoch of Christ into Years of the Julian Period [Annos ante, vel post Epocham Christi commutare in Annos Periodi Iulianae]	6
25	To turn the Years of the Julian Period into Years before or after the Epoch of Christ [Iulianae Periodi Annos vertere in Annos ante, vel post Epocham Christi]	6
26	To convert the years of the Epoch of the World, according to	6

Precept no. [Praecept. ordo]	Precept	Page [Pagina]
	the opinion of the Greek Fathers of Constantinople, into Years before or after the Epoch of Christ [Mundi Epochae annos iuxta opinionem PP. Graecorum Constantinopol. convertere in Annos ante, vel post Epocham Christi]	
27	To convert the Years before or after the Epoch of Christ into the aforesaid Years of the Epoch of the World [Annos ante, aut post Epocham Christi, convertere in praedictos Mundi Epochae Annos]	6
28	To convert the Years of the Olympiads into Years before or after the Epoch of Christ [Olympiadum Annos convertere in Annos ante, vel post Christi Epocham]	6[?]
29	To convert the Years before or after the Epoch of Christ into Years of the Olympiads [Annos	6

Precept no. [Praecept. ordo]	Precept	Page [Pagina]
	ante, vel post Epocham Christi, convertere in Annos Olympiadum]	
30	To convert the Years of the founding of the City of Rome into Years before or after the Epoch of Christ [Urbis Romae conditae Annos convertere in Annos ante, aut post Christi Epocham]	6
31	To convert the Years before or after the Epoch of Christ into Years of the founding of the City [Annos ante, vel post Epocham Christi, convertere in Annos Urbis conditae]	7
32	To reduce the Years of Nabonassar into Years... [Nabonassari Annos redigere in Annos...] [table continues into next column/page]	7

Parsing notes: The page is laid out in two columns, each split into three sub-columns (Precept number | Precept title | Page). The left column runs precepts 1–16, the right column precepts 17–32. There appear to be two entries numbered "17" — one for the time-transfer precept (under the Bologna meridian) and one for the equation of natural/civil days; the index numbering in this region is

ambiguous in the scan and may reflect a compositor's misalignment of the page-number rules against the entries. Several page-number cells in the left column are faint or partly obscured by show-through and are flagged [?]. The page numbers shown are mostly low single digits (1–7), consistent with the opening precepts of Part I.

[Index Praeceptorum, continued — the index of precepts for using the tables (*Index Praeceptorum*), running on from precept 32 of the prior batch. Each page is a two-column index; columns give the precept's order-number, its title, and the page reference. Transcribed below in reading order, left column then right column of each opening.]

Index Praeceptorum (continued)

[left column]

Order	Precept	Page
	...years before, or after, the Epoch of Christ.	7
33	To find the beginning of a Year of Nabonassar, given the corresponding Julian year, month, and day.	7
34	To know with which month-day of the Julian reckoning any given day of an Egyptian month coincides, in years before or after Christ.	7
35	To reduce years before or after Christ into Years of Nabonassar.	7
36	To assign the day of	8

Order	Precept	Page
37	<p>a given Julian year, before or after Christ, that is congruent with a day in the Egyptian Nabonassar year.</p> <p>To convert the Years of Alexander the Great, or also of Dhū'l-Qarnayn [Dhulkarnaym], into years before or after Christ, and conversely those into these.</p>	8
38	<p>To turn the Years of Alexander the Great into Years of Nabonassar, and these conversely into those.</p>	8
39	<p>To convert the Arabic [Hegira] years, months, and days into Years of Christ, with their months and days.</p>	9
40	<p>Christian years not exceeding 622, to commute into Years of the Hegira, with their days, into days, etc.</p>	9
41	<p>To commute the Persian [Yazdegerd] years and days into Years of Christ.</p>	9

Order	Precept	Page
42	To convert the Years of Christ, and their days, into Years and days of Yazdegerd.	10

Monitum pro reliquis Epochis [a Notice concerning the remaining Epochs]. —

| 43 | Finally, to accommodate Time to the use of the Astronomical Tables of this Volume. | 10 |

Praecepta pro Tabulis II. Partis [Precepts for the Tables of Part II].

| 44 | To inquire the Declination of the Sun, or of a given point of the Ecliptic. | 11 | | 45 | To find the angles which the Ecliptic and the Meridian, or any given Circle of declination, make. | 11 | | 46 | To seek the Right Ascension of the Sun, or of a given point of the Ecliptic. | 11 | | 47 | Given the Altitude of the Pole and the declination of any Star, or of a point in the Ecliptic — or, alternatively, its declination from the Ecliptic — to find the Ascensional Difference. | 11 | | 48 | To form the Right Ascension of any given Star or point of the Heaven, together with the Ascensional Difference, into Oblique Ascension. | 11 | | 49 | Given the Altitude of the Pole, a point of the Ecliptic, or the Sun situated in it, to find the Oblique Ascension by the Table of Oblique Ascensions. | 11 | | 50 | Given the Apparent Time after Noon, the place of the Sun, and the Altitude of the Pole, to investigate the Horoscope, or... | |

92	To find the Digits, or quantity of the Solar Eclipse.	23
93	To determine the Beginning, End, and Duration of the Solar Eclipse.	23
94	To define the Latitude of the Moon seen at the beginning, end, of the Solar Eclipse.	24
95	To delineate the Type of the Solar Eclipse, with an Epilogue of the whole calculation thus far.	24

De Eclipsibus Horizontalibus [On Horizontal Eclipses].

| 96 | To discern the moment of time at which the Sun rises, or sets. | 25 | | 97 |
The true places of the Luminaries at the moment of the Sun's Rising or Setting. |
25 | | 98 | To define the Parallax of the Moon in longitude and latitude at the
moment of the Sun's Rising, Setting. | 25 | | 99 | To investigate the Distance of
the centres of the Sun and of the Moon, apparent, at the hour of the Sun's Rising
or Setting. | 26 | | 100 | To inquire the Ecliptic digits, at the moment of the Sun's
Rising or Setting of the Luminaries. | 26 | | 101 | To determine the Semidiameter
of the Disc of the Earth as visible from the Moon. | 26 | | 102 | To find the
Altitude of the Nonagesimal in that region to which the central Solar Eclipse will
appear. | 26 | | 103 | To inquire the Altitude of the Pole of the aforesaid Region. |
26 | | 104 | To compute Eclipses of the Southern Quarter [Region]. | 26 | | 105 |
To determine the central Ecliptic digits of a Solar Eclipse. | 26 | | 106 | To find
the Time during which the Lunar Shadow lingers above the Earth. | 27 | | 107 |
To find the Altitude of the Nonagesimal in those Regions, to which the beginning
of the Solar Eclipse first, or the end last, appears. | 27 | | 108 | To find the
Altitude of the Pole in the two aforesaid Regions. | 27 | | 109 | To determine the
regions themselves, their Longitude having been found. | 28 | | 110 | To find the
Time, from when the Solar Eclipse first becomes total at the rising Sun, and so on
up to the middle of the true and seen central Synod, and thence up to the moment
at which the central Solar Eclipse is last at the setting Sun. | 28 | | 111 | To find
the Altitude of the Nonagesimal for the Regions of the Phases in the manner just
stated. | 28 | | 112 | To find the Altitude of the Pole for those same Regions. | 29 |
| 113 | To find the regions themselves, by means of the Longitude. | 29 | | 114 |
To find the Region, in which at the Nonage-... | |

INDEX OF THE ASTRONOMICAL TABLES

Contained in This Volume

(*Index Tabularum Astronomicarum, Quae in hoc Volumine continentur* — pp. 415–416)

The index is laid out in two columns per page, each column carrying three sub-columns: the table number (*Ordo Tab.* = "order of the table"), the table title, and the page (*Pag.*). The whole index runs across the inner and outer columns of pp. 415–416 and is transcribed below as continuous tables, preserving the major divisional headings ("Part I," "Part II," etc.) that interrupt the numbering.

Part I. The Part Concerning Time

Table	Title	Page
1	Parts of the <i>as</i> applied to days, hours, etc. [<i>Partes Assis applicata Diebus, Horis, &c.</i>]	1
2	Resolution of an hour, degree, and circle into minutes (<i>scrupula</i>), and these down to tenths	1
3	Conversion of hours, and of their minutes,	1

Table	Title	Page
	into minutes of a day	
4	Conversion of the minutes of a day into equal hours, and the minutes of an hour	1
5	Collection of the days of the common Roman year, and of the bissextile [leap year]	2
6	Collection of the days of the Egyptian year	2
7	Conversion of the hours both of the Primum Mobile and of the solar day into parts of the equator	3
8	Conversion of parts of the equator into hours, both of the Primum Mobile and of the solar day	3
9	Conversion of the hours into others numbered from a different beginning of the day	4
10	Quantity of an unequal [temporal] hour, corresponding to the quantity of the artificial day	4
11	Semidiurnal or semi-nocturnal time from a pole-altitude of 6	5

Table	Title	Page
—	degrees up to 90 Appendix to Table 11, for the maximum [length of] day, where the pole is elevated more than $66\frac{1}{2}^\circ$	7
12	Equation of time according to Tycho's [Tycho Brahe's] view, but set for our obliquity of the ecliptic, $23^\circ 30' 20''$	8
—	Residues of the equations from the Sun's anomaly equated	8
13	Temporary table of the equation of civil or natural days, serving exactly for the Year of Christ 1504 and another for the Year 1736, but without considerable error for [whole] centuries before or after	8
14	CATALOGUE of notable places, with the difference of time to be added to or subtracted from the time of the Bologna meridian, with the pole-altitude appended	9

Table	Title	Page
15	Bissextile years before the era of the common Year of Christ	14
16	Bissextile years of the era of the common Year of Christ in the form of the Julian year	14
17	Common centesimal [century] years, or bissextiles in the form of the Gregorian year, with the excess of days over the Julian days, from the Year of Christ 1600 up to 5200	14
18	Table of the solar cycles, from the first up to the Year 4900	14
19	Table of the Roman and Greek weekday-feria [Hebdomadica Feriarum Romanarum, & Graecarum]	14
20	Table of the ferias in the wandering Arabic year of the Hegira, to be investigated by the Arabic cycle	14
21	Collected years, with the days collected,	15

Table	Title	Page
	and the months, of various nations or sects, with the days likewise collected	
22	SYNOPSIS of notable epochs, [showing] the intervening year before or after the epoch of the common Year of Christ, with a brief explanation of them noted in the left margin	16
23	Years from the beginning of Nabonassar [Thoth], [showing] the year before or after the epoch of Christ noted, and the day of the Julian or Gregorian month	18

Part II. The Part from the Primum Mobile

TABLES OF THE PRIMUM MOBILE — chiefly necessary for the Secondary Mobiles [the planets], but to which some tables of Part I also pertain.

Table	Title	Page
24	Zodiac, and any circle whatsoever, collected and resolved into degrees	19
25	Degrees of the zodiac diametrically opposite	19

Table	Title	Page
26	Declination of the Sun, and of the degrees of the ecliptic, for the truer obliquity, 23° 30' 20"	19
27	Right ascension of the Sun, and of the degrees of the ecliptic, for the aforesaid obliquity	19
28	Oblique ascension of the Sun, and of the degrees of the ecliptic, for the aforesaid obliquity	20
29	Ascensional difference for all pole-elevations, of whatever points of the heavens, whatever [their distance], with the declination at 23° 30'	21
30	Ascensional difference of the points of the ecliptic, for the obliquity 23° 30' 20", and for the Bologna pole-altitude	24
31	Oblique ascension of the Sun, and of the points of the ecliptic, for the same obliquity and for the Bologna pole-altitude	25

Table	Title	Page
32	Oblique ascension for very many pole-altitudes, up to nearly four quadrants, with obliquity $23^{\circ} 30'$	26
33	Nonagesimal of the ecliptic [highest point], or the angle of the ecliptic and the horizon, for all pole-elevations up to 67°	38
34	Prosthaphaeresis of declination, for stars having a latitude not greater than 9°	43
35	Prosthaphaeresis of right ascension, for stars having a latitude not greater than 9°	43

Part III. The Part of Tables for the Motions of the Sun and Moon

Table	Title	Page
36	Mean motions of the Sun, or mean [motions]	44
37	Solar parallax in the circle of altitude	45
38	Equations of the Sun, both in circular and in elliptical form	46
39	Distances of the Moon and Sun from the Earth, the hourly	46

Table	Title	Page
	motions of the horizontal parallaxes, of the apparent semidiameters of Sun, Moon, and the Earth's shadow [Umbra] in a lunar transit, the Sun being at apogee, with the variation to be subtracted when the Sun is at apogee, and the axis of the shadow [Axis Umbrae]	
40	Refractions of the Sun, Moon, and the fixed stars in a zone of temperate and threefold density of air	47
41	Mean motion of the Moon, or the mean node, etc.	47
42	Equations of the Moon in syzygies [Copulis]	50
43	Equation of the node, and the Moon's maximum latitude	50
44	Latitude of the Moon	51
45	Reduction of the Moon's true place from its orbit to the	51

Table	Title	Page
	ecliptic	
46	Critical eclipse-table [Tabella Eclipsium Critica]	52
47	Last equation of the Moon, composed from the eviction of the center [Evictione centri] and the variation [Variatione]	52
48	Hourly motion of the Moon from the Sun at new and full moons, and hours 12 before or after	53
49	Verification of σ and σ° of the luminaries [conjunction and opposition]	56
50	Intervals of the Moon and Earth outside σ and σ°	57

Table	Title	Page
51	Distance of the Moon from the center of the Earth in Earth- semidiameters, outside σ and σ°	57
52	Apparent semidiameter of the Moon, and horizontal parallax, outside σ and σ°	57

Table	Title	Page
53	Parallaxes of the Moon in the circle of true altitude	58

Part IV. The Part of Tables for Eclipses of the Sun and Moon

Table	Title	Page
54	Of the epacts, or mean new moons before the end of the year	60
55	Limits of eclipses	60
56	Mesographic parallaxes [Parallaxis Mesographica], that is, in longitude and latitude	61
57	Digits of the ecliptic	66
58	Minutes of incidence in a solar eclipse, or duration of the half-darkening in a lunar eclipse	67
59	Minutes of incidence, and half-duration, in a lunar eclipse	68
60	Distance of the centers of each luminary	70
61	Parallaxes of the Moon in the circle of altitude, given its distance from the Earth	71

Part V. The Part of Tables for the Longitude and Latitude of the Five Lesser Planets

Table	Title	Page
62	Mean motions of Saturn	72
63	First equation of the inequality of Saturn	73
64	Equated anomaly of Saturn	73
65	Maximum equations, or parallaxes of the annual orbit, of Saturn [Parallaxeon Orbis Annui Saturni]	74
66	Proportional minutes of the latitude of Saturn. Residue of this table	75
67	Latitude, reduction, and curtation of Saturn	76
68	Mean motions of Jupiter	77
69	First equation of the inequality of Jupiter	78
70	Equated anomaly of Jupiter	78

	interpretation corrected	
102	DISTANCE of the fixed stars is to be sought from the Great Table of Tomus I, Book 4, Chapter 8, from page 219	—

PRECEPTS

For the Use of the Astronomical Tables Contained in This Volume

*(Praecepta Pro usu Tabularum Astronomicarum, Quae in hoc Volumine continentur
— p. 417, marked "1")*

Precept 1. On the Parts of the *As* Applied to the Circle and to Time

[Margin: Pag. 1.]

If, in some author, a part (an aliquot fraction) of a circle, or of a degree, or of a day, or of an hour, is expressed by the parts of the *as* [the Roman unit divided into twelfths] or of the *libra* — and you wish to know its meaning and value — Table 1 will teach you.

For example: a *dodrans* of the *libra* [three-quarters of a pound] is worth 9 ounces; a *dodrans* of a circle is worth 270 degrees; a *dodrans* of a degree is worth 45 minutes; a *dodrans* of a day is worth 18 hours; and so forth.

Precept 2. On Resolution into Minutes (*Scrupula*)

[Margin: Pag. 1.]

In Table 2 you have both an hour, a degree, and a circle resolved into minutes-of-minutes, the resolution being carried down as far as tenths of a minute.

For example: if an hour is to be resolved into sixth-order minutes, you have, in the first part of Table 2, opposite the numerator 6, [the figure] 466560000000; and so for the rest.

Precept 3. To Convert Given Hours and Their Minutes into Minutes of a Day

[Margin: Pag. 1.]

Since, among certain astronomers, the day is divided not into 24 hours but — though rarely — into 60 first minutes, and these into 60 seconds, and so on, therefore in Table 3 — when you seek hours given under their own titles in the leftmost column, together with their minutes — by proceeding rightward from those hours opposite, you will find, under their own titles at the head of the table, the minutes of a day corresponding to the [given] hours and minutes of the hours.

For example: let hours 5 and 25 minutes of an equal hour be given. First, in the leftmost column find hours 5, and opposite them, under the heading of first minutes of the day, which answer to the hours, you will find first minute-of-a-day 12 and second 30. Then for the 25 minutes of the hour, under the second part at the head — which answers to the first minutes, or minutes, of the hour — you will find first minute-of-a-day 1, second 2, and third 30. Therefore, by composing everything together, hours 5 equal to 25 minutes [of an hour] amount to first minutes of one day 13, 32, 30.

Precept 4. To Convert the Given Minutes of a Day into Equal Hours and Minutes of an Hour

[Margin: Pag. 1.]

Table 4 will accomplish this: by seeking everything under the appropriate titles at the head, and composing the numbers found.

For example: let there be given of a day first minutes 25 and second 20. For opposite first minutes 25, in the leftmost column, you will find under the title of hours, hours 10; and opposite the second minutes 20, in the second part at the head, which answers to the second minutes, [you will find] 8. Therefore, of a day, first minutes 25 and second 20 are worth equal hours 10 and hourly minute 8.

Precept 5. What Day of Any Julian Month Is Given, Counting from the Beginning of the Year

[Margin: Pag. 2.]

In Table 5, second column, if the year is common, but in the first column if it is bissextile [a leap year], seek the day in question, and opposite it in its rightmost column, under the month given, you will find the number of days of the year.

For example: let April 26 be given. In the common year 1650 — for opposite the number 26 in the second column, under April at the head, answers the day of the year 116. But if the year were bissextile, say 1652, then opposite the number 26 in the first column answers day 117.

Precept 6. Given the Number of the Days of the Julian Year, to Find of Which Month It Is, and Which Day of That Month It Is

[Margin: Pag. 2.]

In Table 5, in the columns you seek the number of days of the year, and at the head of that column you will see the month; while opposite the same number, in the leftmost column second-from-the-second if the year is common, but the first if it is bissextile, you will find the number of the day of the month sought. And if the year is bissextile, you ought to use that number in the same column.

For example: let it be the common year 1650, and the 116th day of the year. Opposite this 116, in the sixth column, under April you will find day 26. But if it were a bissextile year, say 1652, the number 116 in the first column would answer to April 25.

The other example: given the bissextile year 121 — for you will see this number, both at the end of the sixth column and at the beginning of the seventh; but as for the second column under April, opposite, under the first column, [it] will answer April 30.

Precept 7. What Day of Any Egyptian Month Is the Given Day, if it is to be Reckoned from the Beginning of the Year

[Margin: Pag. 2.]

The Egyptian year consists of 12 months, each of which is of 30 days; in absolute terms, however, of 360 days. To these are added at the end five more days, which they call the *intercalares*, and in Greek the ἐπαγόμενα [Greek: epagomenai, "the added-on days"], apart from the further quarter-day of the [actual] intercalation. Therefore, in Table 6, in the first and leftmost column, seek the given number of days, and opposite it, in the upper part of the columns, you will have the month named, [and] the day of the month collected, numbered from the beginning of the year.

For example 1: let the 23rd day of the month Athyr be given; you will find day 83 of the year.

For example 2: let the 3rd day of the *intercalares*, or of the Epagomena, be given — for the third day of the first part of the column, under the title Epagomena, answers to the 363rd day of the year.

Precept 8. Given the Number of the Days of the Egyptian Year, to Find of Which Month It Is and Which [Day]

[Margin: Pag. 2.]

In the same Table 6, seek the given number of days in some other manner, for it will answer in the title to the month indeed sought, but in the first column to the day of that month.

For example: given the number of days 83 — because it is in the fourth column, the month Athyr answers to it at the head, and in the first column day 23 of the same month.

[Margin: A] (*signature mark at foot of page*)

Praeceptum 9. Given the day of the Julian year on which an Egyptian year begins, to find out which day of the Egyptian year corresponds to it, and the date of which Egyptian month is wanted.

Astronomers begin the first day of the month Thoth at midday. Therefore, first reduce the given Julian day, on which the first day of Thoth falls, to a day-number by Precept 5. Second, reduce the given day of the Egyptian month by Precept 7 to a day-number of the Egyptian year, and add this number to the number of days that the first day of Thoth makes. From these two added together you will obtain the sum — provided it does not exceed 365 days, or 366 if it is a leap year. Then, with the units discarded, look for that sum in the columns of Table 6: it will correspond on the face of the table to the Julian year-month, and, opposite it in the first column, you will have, if the year is a leap year, in the second column — or if it is a common year, in the third column — the day of the desired Julian month.

[Margin: Pag. 2.]

Example 1. Suppose the Egyptian year begins on 20 February of a common Julian year, that is, by Precept 5, on day 51 of the Julian year. But suppose the given day of the Egyptian year is the 23rd day of the month Athyr, which by Precept 7 is day 83 of the Egyptian year. Adding these together — 51 and 83 — the sum is 134, from which, with the units discarded, there remains 13. Look for this 13 in Table 6: it corresponds on the face of the table to May, and opposite it in the second column [is] 13 May. Therefore, in that year, the 23rd day of Athyr coincides with 13 May.

[Margin: Pag. 2.]

Example 2. Suppose the Egyptian year begins on 20 March of a leap Julian year, that is, by Precept 5, on day 80 of that year. But suppose the given day of the Egyptian year is the 23rd day of the month Athyr, which by Precept 7 is day 83 of the Egyptian year. Adding these — 80 and 83 — makes the sum 163. With the units discarded, look for this in Table 6, column 8: it corresponds, in the first column, to the month June; and to the left of it, in the first column under the title 10, you will find day 23. But [since] day 23 of Athyr coincides with 10 June, beginning this day at midday. — That the sum of the days of either year does not exceed 365 in a common year, or 366 in a leap year: if that sum exceeds [it], it is a sign that the year in which the Egyptian year began was a leap year, and that the residue is to be sought by Precept 6 [as] the day, and the month of the Julian year, according as the year following it — in which the Egyptian year began — was a common year, or a leap year.

[Margin: Pag. 2.]

Example. Suppose the Egyptian year begins on day 25 of November of a leap year [belonging to] the Julian epoch 1684. By Precept 5 this day comes out to be day 330, [and] it is established that day 23 of Athyr is, as said above, by Precept 7, day 83 of the Egyptian year. Adding 330 and 83 together makes the sum 413, exceeding 366 — of the leap year — by 47. To this 47 I add a unit, and the residue 46 [by] Precept 6 in Table 6, [look for] that month February; and opposite it in column 2 — since indeed the year following 1685 is a common year — you find day 15 of February. Therefore day 23 of Athyr begins on day 15 of February of the Christian year 1685.

[Margin: Pag. 2.]

Praeceptum 10. To convert the parts of the equator into hours of the Primum Mobile, and the scruples of the hours; and conversely, to convert such hours into parts of the equator.

[Margin: Pag. 3.]

For this precept Tables 7 and 8 are sufficient. It is enough to inspect the headings on the face of those [tables] that correspond to the given degrees, or to the time, and to their scruples; for under those headings, proceeding from right [to] left from the number opposite, what is sought is found in one or several entries, as need requires.

[Margin: Pag. 3.]

Example 1. Suppose there be given 25 degrees, 35 minutes, and 15 seconds of the equator. For in Table 8, in the first column, under the supreme heading that corresponds to the degrees, you have 1 hour and 40'. Next in 4, [in] column 4, are 35 minutes, to which in the fifth and sixth [columns], under the second heading of the series, [there] correspond minutes of hours 2' and 20". Finally in the first column are 15 seconds, to which in the second and third [columns], but under the lowest heading of the series corresponding to seconds, you have 1". The sum therefore will be gathered thus:

Equator	Hour	I	II
Grad. 25	1	40'	0
Minut. 35		2	20
Secund. 15		0	1
Summa	1	42'	21"

[Margin: Pag. 3.]

Example 2. Suppose, conversely, there be given of the Primum Mobile 1 hour, 42' 21". From Table 7, in entry 1, you will gather the sum of the parts of the equator in this manner:

Primi Mobil.	Grad.	I	II
Hora 1	15	0	0
Min. 42	10	30	0

Primi Mobil.	Grad.	I	II
Sec. 21	0	5	15
Summa	25	35	15

Praecept. 11. To convert the time of a solar day into parts of the equator, and conversely the parts of the equator into the time of a solar day.

[Margin: Pag. 3.]

Since the day, which the Sun makes for us by its diurnal revolution, is somewhat longer than [the day] which the Primum Mobile makes — or (what comes to the same with an imperceptible difference) which any diurnal fixed star makes by its revolution from the same to the same meridian, or horizon — because in the meantime the Sun, by its mean motion, traverses about one degree in the ecliptic toward the east; so that, before the Sun is carried round to the same meridian, or horizon, [there are] over and above 360 [degrees] of the equator about one degree more of the equator that has to pass through: therefore, if it pleases [you] to subtilize this, to convert the time of a solar day into parts of the equator by Table 7, or [to convert] the parts of the equator into solar hours by Table 8, the Equation must be applied that is adjoined in those tables for the hours of the solar day, and [for] the scruples.

[Margin: Pag. 3.]

Example 1. Of 25° 35' 15" of the equator there were found to be contained 1 hour 42' 21" of the Primum Mobile; the correction, or Equation to be subtracted, [is] thus:

	II	III
Aequator.	16	0
Gradus 25		
Minut. 35	1	0
Sec. 15	0	59
Summa	17	59

Therefore, to the said parts there correspond, of the solar day only, Hor. 1. 42'. 3". 1".

[Margin: Pag. 3.]

Example 2. Of the same Precept 10, in which 1 hour 42' 21" of the Primum Mobile agree with 25° 35' 15' of the equator, the Equation for the hours of the solar day [is to be added].

		I	II	III	IV
Hora 1.	2	28	0	0	
Solaris					
Minut. 42	1	44	0	0	
Sec. 21	0	0	0	52	
Summa	4	12	0	52	
add.					

Therefore, of the solar day, the hours 1. 42'. 21". agree with the equator [at] Gr. 25. 39'. 27". 0''' . 52'''.

Praecept. 12. To convert equal hours of one kind, or denomination, into equal hours of a different kind, the half-day being given, or the half-night quantity.

[Margin: Pag. 4.]

Have recourse to Table 9, and carry out everything as is prescribed in it.

Example. Let the half-day time of hours of the equa-

tor be 7. & 30'. and let the given Hour be computed 5. 30'. from the midday Astronomical Hour, and let that be converted into the Italian Solar Hour. For subtract 5. 30'. from hours 23. 60'.: in semidiurnal time there remain hours 16. 30'. to which, when 7. 60'. is added, [it] of course coincides Italian[-style] with the Meridian; but if you add the Astronomical hours 5. 30'. that hour [is] Italian 22. but of the Sun, where indeed in Civil Clocks the day was continued through the half-hour, then [it] was struck not [at] hour but [at] hour 21½.

Praecept. 13. Given the quantity of the artificial day, to convert its Temporal Hours, and their scruples, into equal hours, and the scruples of these.

I call the artificial day the time of delay [Moram] of the Sun above the horizon. Among the Hebrews of old, and the Romans, [and] many nations it was divided into 12 equal hours, indeed [equal] among themselves of the same day, but not at

all equal to the hours of other days; therefore, [if you wish] to resolve them into the second scruple, [there are] 43200 [of them], that they might make use of as their division. Then resolve both the given artificial Day, which is in hourly second scruples, and the temporal [hour]; multiply one by the other: the sum issuing thence [the] hourly scruple of the second [order], and divide by 43200: it will give the second [scruple] of the equal Hours, [and] to which divide afterwards by sixty, [the] partition gathers the hours themselves, and the scruples of those.

[Margin: Pag. 4.]

Example. Let it be that the artificial day [is] of Hours 15. 30'. this in the seconds 55800". and let the Temporal Hours be 4. 20'. this of their seconds 15600", having been multiplied indeed [these] by those 55800. makes the sum 870480000". which, divided by 43200, there remain the second [scruples] 20150". and these divided by 60. there remain 335'. [the] minute, & 50'. then divided 335'. by 60. there remain the equal hours 5. min. 35'. & moreover the aforesaid 50". to which there are equal Temporal Hours 4. & 20'. The reason why, if to the Temporal Hours there should adhere some scruple, the twelfth proportional part is to be sought. And this twelfth part is to be added to the integral Temporal Hours above, and that very thing is repeated.

[Margin: Pag. 4.]

Example. Let the quantity of the artificial Day be of equal hours, as in the first Example 15. & 30'. and let the given Temporal Hours be 4. 20'. but [if] to that there should be added the twelfth part of an hour, that is 1. 17'. 30", which is the fourth assumed of Hours 5. 10". [the] minute the third part [is] a third, if the Hours [be] 1. 17'. 30". take the third part, namely 25'. & 50". & added to Hours 5. 10". there are made up equal Hours 5. 35'. 50". equivalent to the temporal hours 4. 20'.

Praecept. 14. On the finding of the Half-day, and the Half-night Time, the Pole-Altitude being given, and the place of the Sun in the Ecliptic.

It is plain from the Semidiurnal Time that, when Hours 11. & 60'. are subtracted, the Seminocturnal [Time] remains; and from the Seminocturnal [Time] when likewise Hours 11. & 60'. are subtracted, the Semidiurnal [Time] is had, and [when] doubled, the Diurnal [Time], etc.

[Margin: Pag. 5.]

Moreover, the Semidiurnal, or Seminocturnal, time is acquired in two ways with the greatest ease.

[Margin: Pag. 5.]

The first is by Table 11. in whose extreme left-hand columns are the signs of the place of the Sun with their three degrees, [the columns] to be numbered downward; but on the right are the signs with their degrees, to be numbered upward, and opposite them, under the Northerly Pole-Altitude, the Semidiurnal time is found, if the Sun is in the northerly signs; the Seminocturnal [time], if [it is] in the southerly [signs]. But if the place be beyond the Equator, that is, [if] the Pole-Altitude be Australesque, [there is] the time [found] of the Seminocturnal in the northerly signs, [and] of the Semidiurnal in the southerly [signs]. But where the Table is empty, [it is] a sign that the semidiurnal [time] exceeds hours 12.

[Margin: Pag. 5.]

Example. For a Pole-Altitude of 44 Degrees, the Sun being in Taurus 18°. Having found indeed in the left-hand column \square deg. 18. & thence proceeding downward to the right, [it] is found under the Pole-Altitude 44. Hours 7. 10'. this therefore is the Semidiurnal northerly time; but the seminocturnal [time] for the southerly peoples.

But if the Sun is at degree 12. of Aquarius, who are noted in the right margin, [there] correspond [to] this under the Pole-Altit. 44. Hours 7. 10'. which is the Seminocturnal northerly time, but [the] seminocturnal [time] [for] the southerly peoples.

But if the Sun is at degree 12. of Aquarius, who are noted in the right margin, [there] correspond [to] this under the Pole-Altit. 44. Hours item 7. 10'. which is the Seminocturnal southerly time for the peoples, but [the] Semidiurnal [time] [for] the northerly [peoples].

II. MODVS [Second Method]

[Margin: Pag. 19.]

Otherwise thus. Given the place of the Sun, seek its Declination in Table 26, [and] [Margin: Pag. 21.] indeed [seek] the same in the left margin, on the face of the table noted under the Pole-Altitude, or as said before, [seek] the Declination on the face, & under the Pole-Altitude in the left side, [and] seek the Difference of Ascensions [Differentiam Ascensionalem]. This indeed add to degrees 90. if the Sun is in the northerly signs, [Margin: Pag. 7.] & the Place likewise Conspicuous

Northerly, or take away if [it is] in the Australian [signs], & you will have the Arc of the Semidiurnal [time] [Arcum Semidiurnum]; in this manner [it] must be converted by Precept 10. or 11. into Hours, & the Scruples of the hours, by Table 7. or [the] Primum Mobile, or [the] Solar [hours].

[Margin: Pag. 19. Pag. 26. Pag. 7.]

Example. The Sun being as above in Taurus degree 18. its Declination by Table 26 [is] degr. 17. 14'. 29". which under the Pole-Altitude 44 degr. gives a Difference of Ascensions 16°. 16'. 10". which add to degrees 90. & it makes the Arc of the Semidiurnal northerly Arc of Degrees 107. 26'. 10". But this in Table 7. by precept 10. agrees with the time of the Primum Mobile most accurately [at] Hours 7. 9'. 44". 40".

Praecept. 15. To what one must have recourse when Table 11. is empty of numbers in [its] areas.

[Margin: Pag. 7.]

In this case the day exceeds Hours 24. but then [it] scarcely comes to the use of the Astronomer, that he needs the Semidiurnal, or Nocturnal time, for the calculation of the Motions of the Movables. Therefore I [send] the Reader off to our Primum Mobile, or to the Geographical Problemata of our Reformata. But if you wish at least to know the longest day in the frozen Zones, consult the little Table at the end of Table 11. adjoined [at] pag. 7.

Praecept. 16. To convert Apparent Time into Mean, or Equal [time], & conversely [to convert] Equal [time] into Apparent, & when one [is needed] from the other.

[Margin: Pag. 8.]

Our Astronomical Tables of the Mean motions [Mediorum motuum] have their Radices accommodated to the Meridian, & indeed to the last day of December, supposing the Natural Days to be of 24 equal hours, & this for the sake of example we say [supposing] the Sun to traverse one of these in the Ecliptic [at] Degrees 0. 59'. 8". 20". — by two other days [at] Degrees 1. 58". 16". 40". But in truth the Days are unequal, [for] two causes. The Prior [cause] [is] the obliquity of the Ecliptic; for to equal arcs of the Ecliptic there correspond unequal arcs of the Equator, which is the measure of Time; the Posterior [cause] [is] the Eccentricity of the Sun, whence arises the Anomaly, or the irregularity of the Sun's motion,

which remains, even if the Sun moved through equal [arcs] of the Equator. Hence it comes to pass that (in the rest indeed [the difference] is almost negligible) in our Astronomical Tables of the Mean Motions [Lunisolarium], it must be predicted, or collected [as to] some Phenomenon, past, or future, that it may satisfy the Apparent Time; which is observable to us, [it] is convenient to convert the Equal time of the calculation performed into apparent. But conversely, when the Apparent time is given, or some Phenomenon has been observed, & that [is] to be examined by the Astronomical Tables, [it] is necessary first [to convert] the given Apparent Time into Equal [time]. And either Equation is called the Equation of the Natural, or Civil, Days [Aequatio Dierum Naturalium, seu Civilium].

[Margin: Pag. 8.]

This indeed is done by our two Tables 12. & 13. The Prior [Table 12.] indeed is perpetual, & it is established from the prior cause by these little Tables, namely from the Obliquity of the Ecliptic, which we suppose [to be] degr. 23. 30'. 10". The other [Table 13.] is constructed from the equated Anomaly of the Sun, which we suppose to be founded in [its] Eccentricity. And so in the upper little Table 12. part, with the Sign of the Sun on the face, of these, [if] the degrees [be] in the left side ascending; or with the sign at the foot & the degrees in the right side ascending, [it] is found, in the common concourse of the Equation, the prior part, & the stronger [is] to be added, or subtracted from the given time, according as the Title indicates in the front, or at the foot of the same Table 12. part in the lower part the Anomalies of the Sun are sought from the Ephemeris, [whether] adding the degrees in the front in the left, or at the foot, with the degrees on the right, & in the common concourse the equation is had, the prior part [is] the other [to be] added or subtracted, according to the same Table's title — if they should be of the same affection, & if [of] different, subtract the less from the greater & leave the Equation of that kind, of which the Equation is greater.

[Margin: Pag. 9.]

Example. Let the Apparent Time after Midday be of Hours 5. & 20'. which in Equal [time] is to be changed, the Sun being [in] Taurus degree 16. & the Anomaly of the Sun [in] sign 9. complete, [holding] degree 8. Firstly therefore, in Table 12. the superior part [is] under \square sign, & opposite the degrees 16. of the left margin, there is given an Equation 9. 55'. 45". to be subtracted from the time; secondly [in] the inferior part of the same Table, & opposite [it under] sign IX. ascending, the degree to the right under degree 3. [it] is found opposite, of that same Equation 4'. 3". Add, as the title under sign IX. shows. Since therefore they are of

different affections, if [you] subtract the subtractive 4'. 3". there will remain absolute, & corrected, the Equation 5'. 52'. 45"". to be subtracted from the data given for the hour 5. & 20'. so that the corrected Mean, or Equal Time, [is] hor. 5. 14'. 7". 15"".

Otherwise by the Provisional Tablet [per Tabellam Temporariam]

If the Sun's Apogee were immobile, as Ptolemy thought, nor migrated by little steps into other signs, the Equation of Natural Days perpetually lasting could be made from these two little Tables 12. But because the Sun's Apogee [is moved] in other [ages], & promoted by little to other signs, & in the same sign to other degrees, [it] cannot be satisfied by a single Tablet for all ages, but only for one age, or another. And so we have constructed two little Tables under 13. of which the superior little Table is established exactly [for] the Year of Christ 1504. when the Sun's Apogee, by my judgment, was in Cancer degree 6. but indeed without error, & to a sufficient [degree] for the preceding age, & subsequent; that is from the Year 1404. ad 1604. The inferior [little Table] indeed serves for the Year of Christ 1736. when the Sun's Apogee [is] in Cancer degree 10. but this also, without error curable, serves from the Year 1636. ad the Year about 1836. for both, & at the same time the proportional part serves almost exactly [for] all the intermediate Years between 1504. & 1736. The comprehension of these is, [and] in either ingress with the sign of the Sun in the front, & with the degree of the sign in the left side enquired, in the common concourse the absolute Equation to be Added to Apparent Time is had, & to be subtracted, just as the title in the front indicates; to which the contrary is to be done, if the Equal time is to be changed into Apparent.

[Margin: Pag. 8.]

Example. Let it be the Year of Christ 1650. Sun being in Taurus degree 16. to convert the Apparent Time of Hours 5. 20'. into Equal [time]. Firstly therefore in the superior Table 13. part serving the Year 1504. under \square , & opposite degree 16. [it] is found the Equation to be subtracted 6'. 48". Then in the inferior part, which serves [for] the Year 1736. under the same sign, & opposite the same degree 16. there is had the Equation to be subtracted 3'. 5". The difference of these Equations 1'. 43". this indeed is to be resolved [into] seconds 223". between the Years 1504. & 1736. the whole difference is [for] the Years 232. but from 1504. ad 1650. there are made up Years 146. Divide therefore [the] seconds 223". by [the] Years 232. there decreases [for] one second 146". that is [a] minute 2'. & seconds 26". which subtract from the prior Equation 6'. 48". there remains the corrected Equation 5'.

31'. which subtracted from the Hours 5. 20'. relinquishes the Equal Time of Hours 5. 14'. 29". yet the prior method is more exact in the seconds-scruples.

Praecept. 17. On Equating Time on account of the Distance of Meridians.

Since our Astronomical Observations have been performed by us under the Meridian of the renowned City of Bologna, partly in the Most August Temple of S. Petronius, partly, & generally, in our Observatory of the College of S. Lucia of the Society of Jesus; therefore we admonish that our Tables fix the Meridian of this Meridian of Bologna; but indeed, that the Tables of this Meridian can be applied to the Meridians of other places, [it] behooves one to know the Distance of those, or the Difference of Geographical Longitudes (whether they be Easterly, or Westerly from Bologna in the Italian fashion). To this end, in our *Geographia Reformata* Book 8., gathered everywhere, [there are] the Eclipses, & Itineraries; we have enquired into the Differences of Longitudes of very many places from Observations, or from the intervals of places; & likewise of the more recent Meridians, we have enquired into the Pole-Altitudes, that with the ancient querulousness, & the new Astronomers, & Geographers, we might satisfy ourselves over this thing, & we might expunge innumerable errors from the Geographical, & Hydrographical Charts, [as] much as God granting [it] was permitted; but in Book 9. [we have given] a Catalogue of places of very many, constructed with the Longitude from the Island of Palma, & the Pole-Altitude. Thence therefore the Longitudes of places are taken from our Catalogue, [Margin: Pag. 9.] or from these places at once [it] has the Difference of Apparent Times, or [the time] to be Added, or to be Subtracted from the time of the Bologna Meridian; the contrary nevertheless [is] to be done, if the time is to be agreed with another Meridian, [and] the Time congruent with the Bologna Meridian is to be led across.

[Margin: Pag. 9.]

Example. Let there be a future beginning of a Lunar Eclipse [at] Hour 10. 20'. after the Bologna Meridian; but [if] it should be enquired what then will be the future Hour, or the moment of the Hour at Goa in East India, or [at] Lima in Australian America? Now in our Catalogue [Margin: Pag. 9.] the Difference of Times for Goa is registered [at] Hor. 4. 18'. Adding. & for Lima Hor. 6. 10'. 40". Subtracting. Therefore the beginning of the Eclipse will be, [at] Goa, after the Bologna Meridian, Hour 14. 38'. at Lima Hor. 4. 9'. 20". On the contrary indeed, [if] the beginning of the Eclipse of this kind had been supposed [for] hour 10. 20'. of

Goa, or [of] Lima, the Difference of Times registered [for] Goa, would be Subtracting; & registered indeed [for] Lima [it] would be Adding, & so it is that [in] the prior case that Time, [at] Bologna after midday, [is] hor. $6\frac{1}{4}$. in the posterior [case] [it] becomes hours 16. 30'. 40'''.

Praecept. 18. To find the Leap Years in the form of the Julian Year before, & after the Epoch of Christ.

[Margin: Pag. 14.]

For the Years before the Epoch of Christ consult Table 15. in which the prior, or left-hand column shows the Years; the other, or third, & the fourth column [shows] the expanded [years] of the preceding age, [the] hundreds, or the Thousandths; the second indeed, [and] the third, & fourth column [shows] the centesimals first, or the Millesimals first, which are Leap Years. So, by example for the sake of [showing] the Leap Years, [the Years] ought to be in the Julian form indeed retro-numbered upward [as] the Year before Christ 1. & 5. & 9. &c. likewise the Year 101. & 201. &c. & likewise 5301. & 5401. &c. But besides these of all the ages, the Years before Christ 325. for [they are] Leap [years], because 25. in the first column is a Leap [Year]. The remaining intermediates &, not noted [as such], are Common [years], as the Year before Christ 4. 8. 12. 104. 108. 112. &c.

[Margin: Pag. 14.]

For the Years after the Epoch of Christ, consult Table 16. in whose first column the Leap Years of any age after Christ [are shown], in 2. however, & 3. [the] Centesimal Years of the age, the Millesimals, &c. [are] Leap [Years]. So by example for the sake of [showing] the Leap Years are in this form the Year 4. & 8. & 12. &c. likewise 100. & 200. &c. likewise 1700. 1800. 1900. &c. But composing the expanded [years] with the centesimal, or the millesimal, the Leap [years] are 104. 108. item 204. 208. item 1004. 1008. &c. the rest [the] intermediates not noted, are common.

Praecept. 19. To discern, in the form of the Gregorian Year, the Centesimal Years, or the Millesimals, which ought not to be Leap [Years], & by [how much] excess, by which the number of days of the Gregorians exceeds the number of the Julian days.

In the form of the Gregorian Year every fourth [year] of the expanded Years is a Leap [Year], & these serve the first column of Table 15. But among the Centesimal Years, & the Millesimals, those alone are Leap [Years] of which the two prior notes nume-

are counted among the expanded years as bissextile [leap], that is, every fourth one, leaving out the centesimal years from the year 1600 exclusive onward; the remaining years must be common, the intercalation being omitted — as appears more clearly in Table 17, in the column headed C. Communes [Common] and B. Bissextilis [Leap].

[Margin: Pag. 14.]

Now from the year of Christ 1582, on the 5th of October, the Christians who adopted the Gregorian form (that is, the great majority of the Christian world) reckon ten days more than those who out of obstinacy retain the Julian form; and on the same date, for example, December 24 among the Gregorians is not the 14th among the Julians. Thus it falls out that December 24 among the Julians is the same day as January 3 among the Gregorians. Likewise February 14 among the Julians (in the year 1700, since that year is bissextile in the following month) becomes February 24 in the Gregorian style: for in the next year, 1700, December 24 in the Julian style will be January 4 in the Gregorian. February 14 among the Julians, or 6 March in the Gregorian — but here the next Gregorian computation immediately exceeds the Julian by 11 days, and continues so up to the year 1800, after which the Gregorian will exceed the Julian by 12 days, the latter day being the posterior. For this reason, in noting these excesses, I have marked them in Table 20, in the third column, and the sixth, with these excess-days.

[I read this dense passage as Riccioli's worked illustration of how the Julian-Gregorian day-difference (10 days from 1582, 11 days after 1700, 12 days after 1800) is to be applied; the figures are now verified against the source — see QA report.]

Precept 20. To find the Solar Cycle for investigating the feria [weekday], both before and after the epoch of Christ.

The Solar Cycle is a period of 28 years, produced from the multiplication of 7 (the days of the week) by 4 — because every fourth year is bissextile, and so every twenty-eighth year the dominical [Sunday] letter recurs to the same feria. Hence the year [marked with] the dominical letter is here called the Solar [year], and because the dominical letter is dedicated to the Sunday of the Resurrection, the cycle is here called the Solar [cycle]; and the Greek letter Κυριακή [Greek: Kyriakē, "the Lord's (day)"] indicates feria 1. How the Greek Fathers named the feriae at the head of Table 19, and the characters of the planets by which the astronomers wrote them, is described.

[Margin: Pag. 14.]

For years before the epoch of Christ, in order to find the Solar Cycle, add 9 to the given year, then subtract from the sum the nearest smaller number of cycles in Table 18. The residue, or — if nothing remains — the cycle itself, will be 28, completed.

[Margin: Pag. 14.]

[Margin: Pag. 14.]

Example. The Solar Cycle for the year of Christ 1660: adding 9 makes the sum 1669. In Table 18 the nearest smaller number of Solar Cycles is 1652, which subtracted from the said sum leaves 17 for the Solar Cycle, which indeed agrees with the year of Christ 1660.

Alternatively, without the Table.

[Margin: Pag. 14.]

To the year of Christ add 9; divide the sum by 28. The remainder of the fraction in the quotient is the Solar Cycle; if nothing remains, 28 will be the cycle. If the aforesaid sum is less than 28, that sum itself will be the Solar Cycle.

For years current before Christ.

[Margin: Pag. 14.]

Seek in Table 18 the nearest larger number — the years current before Christ — and add 9 to that, then subtract from the sum the given years current before Christ; and from the residue, if it is not less than 28, subtract the nearest smaller

Solar Cycle found in Table 18. For what remains is the Solar Cycle; and if nothing remains, the Solar Cycle will be 28. If that residue was previously less than 28, it is itself the residual cycle sought.

Example 1. The year before Christ given is 36: the nearest larger number in Table 18 is 56. To this 56 add 9; that makes 65. From this 65 subtract the given 36; there remain 30. From this residue 30 subtract the nearest smaller Solar Cycle, which is 28; there remains the number 2. Therefore 2 is the Solar Cycle agreeing with the year 36 before Christ.

Alternatively, without the Table.

[Margin: Pag. 14.]

To the years given before Christ add 18, and divide the sum by 28; for if nothing remains over, the Cycle sought will be 28 itself. But if some residue results, subtract that itself from 28, and what remains is the Solar Cycle sought... [Note: Riccioli's two formulations here differ slightly; rendered per source.]

to the years before Christ add 18, and divide the sum by 28.... [continuation of the alternative-without-table method for years before Christ]

Example. The year before Christ is given as 38, which Censorinus assigns to the more notable epochs. Add to it 4713; that makes 4751, which is the Julian-Period year 4751. Likewise let the year of Christ 3340 be given; if you add 4713 to it, it makes 8053; from which, the whole Julian Period of 7980 years being subtracted, there remain for the second Julian Period the year 73.

Precept 25. Given the year of the given Julian Period, to convert it into years before Christ if it does not exceed 4713, or into years of Christ if it exceeds 4713.

[Margin: Pag. 14.]

If it does not exceed 4713, subtract it from 4714; the years before Christ will remain, concurrent with the years of the Julian Period.

Example. The Julian-Period year 3938: 3938 subtracted from 4714 leaves 776 for the years before Christ — namely, the first Olympiad.

If indeed it exceeds 4713, subtract 4713; and the residue will be the year of Christ sought, provided the Period is the first; for if it be the second Period, which begins at the year of Christ 3268, add the given 7980, and from the sum subtract 4713; the year of Christ sought will remain.

Example. Let the first Julian-Period year 6295 be given; from this subtract 4713; there remains the year of Christ 1582 — namely, the year of the Gregorian correction of the Calendar.

Precept 26. To convert the Epoch of the World according to the Greek Fathers of the Church of Constantinople into years before or after Christ.

[Margin: Pag. 14.]

If the given year of the World does not exceed 5509, subtract the given year from 5510; the year before Christ will remain. The Epoch of the World, and if it exceeds 5509, the years of Christ will be the Epoch sought, of which you will have to subtract the given years from 5509.

Precept 27. Given years before, or after, Christ, to turn them into years of the World according to the Greek Fathers.

If you would subtract years before Christ, subtract them from 5510; what remains is what you want. But if to the years of Christ you add 5509, you will have the years of the World according to the Greek computation of the Fathers of Constantinople.

Precept 28. To convert the given year of any Olympiad into a year before or after Christ, since the Olympiadic years begin from the New Moon nearest the summer solstice.

When writers say that something was done in some Olympiad, it is understood that they mean a completed Olympiad, not adding the year of it — understood, I say, in the first place of a completed Olympiad. First, then, the Olympiads being completed, but the residue being produced, add the remaining years; likewise the completed years of an incomplete Olympiad, for you will have the Olympiadic years full, which are: if the years before the Epoch of Christ do not exceed 775, subtract from 776, and there will remain the years before the Epoch of Christ, in whose summer the Olympiad given began. And if they exceed 775, subtract those 775; and you will have the year of Christ in which the given Olympiad began.

First example. Let Olympiad 6, year 1, current, be given, since the completed Olympiads are 5, and these multiplied by 4 make 20; and to these, the full years being added, 22, the Olympiadic years are completed. If you subtract these from 776, there remains the year 754 before Christ, in whose summer Olympiad 6

began; which accordingly was completed in the summer of the year 753 before Christ.

Example 2. Let Olympiad 195, year 1, current, be given. Since the completed Olympiads are 194, and besides one year added, the Olympiadic years are reckoned, making 776; subtract these 776 from 775, there remains 1 year. The Epoch of Christ, in whose summer Olympiad 195 began.

Precept 29. To convert years before and after Christ into Olympiadic years.

If the given year before the Epoch of Christ is 776, it is the first... ..the first year of the first Olympiad began from the New Moon nearer the summer solstice; but if it be less than 776, subtract it from 776. And the residue divided by 4 — for if no fraction adheres, the quotient itself indicates the completed Olympiad. The current year will begin in the summer of the given year of Christ; and thus the Olympiad to be completed in the summer of the following year. But if the quotient has a fraction, add the years of the fraction to unity, and you will have the Olympiad in which that year begins, which the numerator of the fraction indicates begins — I say — in the summer of the year of Christ.

Example 1. Let the year 770 before Christ be given; from this 776 the subtracted 770 leaves 6, which divided by 4 gives a quotient of $1\frac{1}{2}$; add then unity, so much for the quotient as for the numerator of the fraction; this makes $2\frac{3}{4}$. Therefore in the summer of the year 770 before Christ began Olympiad 2; and the year 3, that is, the third year of the second Olympiad, with the New Moon nearest the summer solstice, ran with the year 2 of Olympiad 2.

Example 2. Let the year 4 before Christ be given; the subtracted 776 leaves 772; which divided by 4 makes 193, the number of the Olympiad. That year being completed, therefore, after the New Moon of summer in the year 4 before Christ, began the first year of Olympiad 194.

Of years after Christ born.

Add the given years of Christ to 776, and divide the sum by 4. If no fraction adheres to the quotient, the quotient itself indicates the completed Olympiad; the current year will begin in the summer of the given year of Christ; and thus the Olympiad to be completed in the summer of the following year. But if the quotient has a fraction, add to the quotient unity, and you will have the Olympiad in which that year begins, which begins — I say — in the summer of the given year of Christ.

Example 1. Let the year of Christ 4, current, be given; add 776; it makes 780. Divided by 4, there remains Olympiad 195, without a fraction. Therefore in the summer of the year of Christ 4 began Olympiad 195; and that was completed in the summer of the year of Christ 5.

Example 2. Let the year of Christ 7 be given; with 776 added, it makes 783; which divided by 4 leaves $195\frac{3}{4}$. Multiply then 195 by unity; the Olympiad is 196, of which the year 3 began in the summer of the year of Christ 7.

Precept 30. To convert given years of the founding of the City of Rome into years before or after Christ.

[Margin: Pag. 14.]

The Epoch of the City of Rome is 753 years before Christ — this is according to the computation of Varro, the City having been founded on the 21st of April; and the first year of the Epoch of Christ. If the given year is less than 754, there will remain the years before Christ, of which the 21st of April begins the year before Christ. But if to the 753 years given you add the year before Christ in which the City was founded; therefore the beginning of that year before Christ concurs with the year of the City preceding.

Example 1. Let the year of the City 709 be given, which indeed was the first of the Julians, ordained by Julius Caesar; subtract 709 from 754; there will remain the year 45 before Christ, of which the 21st of April began the year of the City 709; but before that the year 708 was current. Again, let the year 1 of the City be given; subtracted from 754 it leaves 753 before Christ, in which on the 21st of April was the City of Rome founded.

Example 2. Let the year of the City 1553 be given; from this subtract 753; there remains the year of Christ 800, in which on the 21st of April the year of the City 1553 began. But on the Kalends of January of the year 800 (in which indeed Charlemagne [Carolus Magnus] began to reign as emperor) ran the year of the City 1552.

Precept 31. To turn years before or after the Epoch of Christ into years of the founded City of Rome.

If the year before Christ does not exceed 753, subtract it from 754, and you will have the year of the City beginning on the 21st of April of that same year.

But to the given year of Christ add 753, and you will have the year of the City beginning in that year of Christ on the 21st of April.

Precept 32. To reduce the years of Nabonassar to years before or after the Epoch of Christ.

[Margin: Pag. 18.]

First inspect Table 23, if perchance in it you may find — in the region of the years of Nabonassar — the year of Nabonassar before or after Christ, and at the same time the day of the Julian or Gregorian month on which the years of Nabonassar begin. Otherwise subtract the year of Nabonassar from the nearest larger in the same Table found; and to the residue add the years before Christ corresponding to that next larger Nabonassar — you will have the year before Christ in which the given Nabonassar [year] begins. But if, in the region of the year of Nabonassar nearest larger, there are years of Christ, from these subtract the residue left after the subtraction made after the Nabonassar nearest larger, and there will remain the year of Christ in which the given year of Nabonassar begins. Reserved nevertheless in either case is the aforesaid Residue for the practice of precept 35, soon to be handed down.

[Margin: Pag. 18.]

Example 1. Let the year of Nabonassar 720 be given; this subtracted from 744, which in Table 23 is the nearest larger to it, leaves Residue 24, to which the added year before Christ 5 — that is, the one corresponding to the year 744 — makes 29; the year before Christ in which began the year of Nabonassar 720.

[Margin: Pag. 18.]

Example 2. Let the year of Nabonassar 1460 be given; this subtracted from the nearest larger, which in Table 26 is 1464, leaves Residue 4, to which add the year before Christ 716, which the region of the year 1464 supplies; and there will remain the year of Christ 12, in which began the year of Nabonassar 1460.

Precept 33. To find the beginning of a given year of Nabonassar in a Julian or Gregorian year.

[Margin: Pag. 18.]

First, by precept 32, inquire into the year before Christ, or of Christ, in which the proposed year of Nabonassar began; and divide the Residue in that practice [as] adduced by 4; then the quotient, if a fraction adhere to it, augment by unity, and thus the given year augmented for the Julian or Gregorian year, in which begins the Thoth of the Nabonassar-year nearest larger than the given year of Nabonassar. After the year of Christ, the day of the Julian or Gregorian month, in

which the given year of Nabonassar [begins]. After the year of Christ 1582, likewise October 4, it suffices to repeat the beginning in the Julian year, and to know what day it is in the Gregorian by precept 19.

[Margin: Pag. 18.]

Example 1. In the preceding precept, the given year of Nabonassar 720, the nearest larger in Table 23 is 744, to which corresponds the beginning of Thoth on August 24. But the Residue there adduced was 24, which divided by 4 gives a quotient of 6, without a fraction; therefore that year, as it stands, is to be added to the day August 24, on which falls the beginning of Thoth of the Nabonassar-year 720, in the year of Christ 30.

[Margin: Pag. 18.]

Example 2. In the preceding precept, there was given the Nabonassar [year] 1460, the nearest larger 1464; the beginning of Thoth from Table 23 [is] February 25. The Residue adduced, divided by 4, makes 1 without a fragment. Therefore, unity being added, the day 25 of February falls on the beginning of Thoth in the year of Nabonassar 1460, on the 26th of February of the year of Christ 12.

Precept 34. Given a Nabonassar year, month, and day, on which month of the year before Christ, or after, and on what days the Julian day falls, to find the day of the Egyptian year [Anni Aegyptii].

First, inquire by precept 32 the year before, or after Christ, and by precept 35 the Julian day of the month, in which begins the given Nabonassar year; and by precept 20 — or rather 21 — foreknow whether the Julian year, or the Gre...

whether it [the Gregorian year] is bissextile [a leap year] or common. Second, from Table 5, by the preceding precept 5, gather the total of days from the beginning of the Julian or Gregorian year up to the day on which the month of Thoth begins. Third, from Table 6, by precept 7, gather the total of days from the beginning of the Egyptian year up to the proposed day, and add this latter sum to the former. From these sums added together (if they do not exceed 365, or in a bissextile year 366), in the columns of Table 5 you will find — under the proposed month of the Julian year, and on the left-hand side, in the row of the concurrent day of the month — the day given with the day of the Egyptian month. But if that aggregate exceeds 365, or in a bissextile year 366, subtract these very numbers from the aggregate, and from the residue, found in the body of Table 5, you will obtain — above, the month of the Julian year, and on the left-hand side, the day concurrent with the day of the Egyptian month given.

[Margin: Pag. 18] [Margin: Pag. 2] [Margin: Pag. 2]

Example 1. Let the Nabonassar year 720 be given, and the [Egyptian] month Athyr, day 25. First, by precept 29, the Nabonassar year 720 begins in the Year of Christ 29; and by precept 33, the beginning of Thoth fell on 30 August. Therefore, in the bissextile Year of Christ 29, Table 5 shows 243 days [from 1 January to 30 August]. From Table 6, day 25 of Athyr — counted from the beginning [of the Egyptian year] — makes 85 days; Athyr being the third month (the first two giving 30 + 30, with 25 of Athyr making 85 in the running total, but 175 when reckoned with the [later] Mechir). The Julian sum 243 and the Egyptian 85 make the aggregate 328, which in Table 5 shows, in that bissextile year, day 23 of November — the days concurrent with Athyr on day 25. The Julian sum 243 and the Egyptian 175 make the aggregate 418, from which, the bissextile day subtracted, 366 remain; and in Table 5, for the following year 28 before Christ, they give day 21 of February, concurrent with Mechir on day 25.

[Margin: Pag. 2] [Margin: Pag. 18]

Precept 35. *To convert given years before Christ, or to turn them into Nabonassar years, and to investigate the beginning of those years.*

If a year before Christ is given not exceeding 747, look for it in Table 23, in the second column; for in the first column you will have the beginning of the Nabonassar year, and in the third, the [Julian] month and day, which you will find in column 2. Subtract that nearest number found below it (and note meanwhile the interval), namely the Nabonassar year in column 1; and whatever number begins it answers to the next greater. The residue, moreover, added to the [Julian] day of the Nabonassar year as I said, in column 1 (where, as found, the optative Nabonassar year is so begun). Divide that same residue by 4: as often as it makes an integer (or, if a fraction results, increased by one), and the residue from the initial subtraction, will give the other optative beginning.

[Margin: Pag. 18]

Example 1. Let the year before Christ 29 be given. Here it appears in Table 23, column 2; and the nearest number below it, namely the Nabonassar year 716, leaves a residue of 4, which added to 716 gives the Nabonassar year 720, namely the one that began in the Year of Christ 29. Further, by precept 33: the beginning of Thoth was 31 August, and the residue 4 divided by 4 leaves the quotient 1, which subtracted from day 31, leaves day 30, on which the Nabonassar year 720 begins.

[Margin: Pag. 18]

Example 2. Let the year of Christ's Epoch be given [year before Christ], find it in Table 23, column 2; or — if it is not there — you will have on the left-hand side the beginning of the Nabonassar year, in which the Nabonassar year began. But if the given Year of Christ is not in Table 26, look in it for the nearest greater number, and subtract it; and the residue subtract from the Nabonassar year in that same Table, answering to the proposed Year of Christ, and the residue subtract from the Nabonassar year, in the same Table, answering to the next greater Year of Christ; for you will have the optative Nabonassar year. Then divide the residue by 4, and the quotient — an integer if it has no fraction, or increased by one if it has a fraction — added to the beginning of Thoth, which is in column 1 of the nearest greater Nabonassar year, that is, the same with the recently found Nabonassar year.

[Margin: Pag. 18]

Example 2. Let it be the Year of Christ 712. Here subtract 7, from the year 719, the nearest greater in Table 23: it leaves a residue of 7, and from the year 719 answers, on the left, the Nabonassar year 1467; on the right, its beginning is 11 February; therefore, 7 subtracted, the optative Nabonassar year 1460 remains. And the residue 7 divided by 4, as often as the quotient...

[Margin: Pag. 18]

is $1\frac{3}{4}$; setting aside the fraction, there is therefore added to day 11 of February, 1, so the year 1460 begins on day 12 of February.

Precept 36. *To convert a given day of a year before, or after, Christ into a day of a Nabonassar year.*

First seek, by the preceding precept, the Nabonassar year beginning in the given Year of Christ — whether before or after Christ — and the [Julian] day of the month on which that Nabonassar year begins. Then, from Table 5, gather one by one the total of Julian days answering to the beginning of Thoth; and likewise the total of days answering to the date itself, with the difference of those subtracted [from one another], and 365 subtracted; this will give the residue, which in Table 6 [or Table 5? — see context] will show the Egyptian month, and on the left-hand side the day answering to the given day. But if the given Julian date precedes the initial of the Egyptian year, then the difference of the totals collected, with the unit subtracted, and 365 subtracted, will give the residue, which in Table 6 will

show the month of the Egyptian year, and on its left-hand side the day answering to the given day.

[Margin: Pag. 2] [Margin: Pag. 2]

Example. Continuing with Example 1 of the preceding precept: in the Year of Christ 720 [recte: Nabonassar year 720, beginning in Year of Christ 29], the Nabonassar year is found to begin on 30 August. If we ask in what Egyptian month, and its day, the day 31 October falls: since the sum of days answering to 30 August, in the bissextile Year of Christ 29, by Table 6, is 243; and to 31 October it is 305; the difference of these is 62, and increased by unity this becomes 63, which in Table 6 gives day 3 of Athyr, concurrent with 31 October. From the sum of the bissextile year, 25 of April, its 116; the difference of 25 April from 243 is 127; and the unity 126 taken away, leaves the residue 239 days, by which in Table 6 they agree, the given 25 April. Pharmuthi answers to day 29.

[Margin: Pag. 2] [Margin: Pag. 2]

Precept 37. *To convert the years of Alexander the Great, or of Dhū-l-Qarnayn, into [years] before or after the Epoch of Christ, and these [reckoned] alternately into those.*

If the year of Alexander the Great — reckoned from his very death — is 324, or that of Dhū-l-Qarnayn is 312, each of them coincides with the first months of the first year of Christ. But if the year of Alexander the Great is less than 324, or that of Dhū-l-Qarnayn less than 312, subtract the years of Alexander from 324, or those of Dhū-l-Qarnayn from 312; the residue will give the year before Christ, with which the prior months of the given year run concurrent.

Conversely, if the years of Alexander exceed 324, or those of Dhū-l-Qarnayn exceed 312, subtract from them 324 or 312, and the remainder is the Year of Christ, whose prior months run concurrent with the given year.

Conversely, if the years given before Christ do not exceed 324, subtract them from 325; the remainder will be the year of Alexander running concurrent with that year; but if they do not exceed 313, the year of Dhū-l-Qarnayn likewise running concurrent with the same year. But if the years before Christ exceed 324 or 313, the year of Alexander or of Dhū-l-Qarnayn, running concurrent with the given year and that following, will be...

Conversely: if the years before Christ given do not exceed 324, subtract them from 325; the remainder will be the year of Alexander running concurrent with that year; but if they do not exceed 313, the residue is the year of Dhū-l-Qarnayn

current with the same years 325; and the remainder will be the years of Alexander running concurrent with the prior part of the given year. But subtract the years of Christ from 313: the remaining year of Alexander, or of Dhū-l-Qarnayn, running concurrent with the given year, but with the prior part of the year. Subtract, moreover, the years of Christ from 313: the remaining year of Alexander, or, [if reckoned] from Seleucus, [its] beginning in the Year of Christ preceding the given one, run concurrent with the prior part of the given year.

The precept is clear, nor do those already accustomed to the preceding precepts need an example.

Precept 38. *To change the years of Alexander the Great into Nabonassar years, and these alternately into those.*

To the years of Alexander add the years 424, and it becomes a Nabonassar year in the Egyptian manner, [reckoned] from the same day and from the noon-meridian from which [the year] of Alexander [is reckoned]. Thus the year of Alexander begins together with [Nabonassar year] 425, the Nabonassar year, on day 12 of November, that is, on day 1 of Thoth.

Conversely, if the Nabonassar years are not fewer than 425, subtract from them the years 424; and the year of Alexander remains, beginning on the same Nabonassar year [as it began].

Precept 39. *To convert given years, days of the Hegira, into years of the Epoch of Christ, [its] days.*

In Table 21, in the third, or lowest, class you have the days collected for the Arabic years, and likewise for the months. From that Table, therefore, gather the days answering to the years, months, and Arabic days — but complete ones — and that, by one or more entries into the Table, as may be needed. The sum of the days so collected, add the perpetual 561 days, and it will become the sum, which by [the rule of] distinction is called the *Cumulus* [the running total]. Then, from the first class of Table 21, [find] in the body the *Cumulus* nearest below it, answering to the collected days, [reckoned in] Julian years, months, and complete days — or one, or more, days [over], by the entries into the Table; for if you so add to the Julian years the years 620, the Years of Christ will come out, the data of the Hegira-years and -months, and the Julian days, with the months, and the days of the Hegira.

[Margin: Pag. 15] [Margin: Pag. 15] [Margin: Pag. 15]

Example from the Turkish Annals. Amurath II [Murad II] died in the year of the Hegira 855, beginning, on day 1 of Muharram, feria 4 [Wednesday]. It is asked: in what year of the Epoch of Christ did it fall, and in what [Julian-Calendar] month and day, and on what day [of the week]? Go therefore to Table 21, and to its lowest class on the left, in which thus:

[Margin: Pag. 15]

Arabic Years	Days collected
600 Arabic years give	212620
There remain 254 complete years, of which 240 give	85048
There remain 14 years, which give	4961
Add 1, day of the month Muharram	1
and perpetual days	561
The sum of days becomes	303191

[Margin: Pag. 15]

Then in the upper [part of] Table 21, in the left-hand class, the days 303191 — taken in parts collected — give in the left-hand columns the Julian years thus:

Days	Julian Years
Days 292200 give	800
There remain 10991, of which 10227 give	28
There remain 764, of which 730 give	2
There remain days 34	
Add years perpetual	620
The sum of complete years becomes	1450

The days 34 give 3 February. Therefore Amurath II [Murad II] died in the Year of Christ 1451, on 3 February. Note therefore that Nicolaus Mulerius [Nicolaus Mulerius], in his Canon of the collected Arabic years with the collated Julian years, places the year 855 [of the] Arabic [Hegira] beginning on 3 February of the Year of Christ 1451, feria 4 [Wednesday].

[Margin: Nicolai Mulerlaus. — (compositor garble for *Nicolai Mulerii*); Nicolaus Mulerius's slip]

The reason, moreover, why to the days collected for the Arabic [years] the perpetual 561 days are added, and to the collected Julian years (as above) the perpetual 620 years are added, is this: because the first Arabic year of the Hegira began in the Year of Christ 622, on day 16 of July; but from the Year of Christ 620 complete, and bissextile, to 622 current, day 16 of July current, are numbered the days complete 561. Beware, however, of an error in the Rudolphine Tables, page 39, where below at the right in the transverse line the number 1 is set wrongly: *Hegira Anni* [the year of the Hegira] of the Year of Christ 632, and continued with 633, which is to be verified [as] of Yazdegerd; the Epoch, not Arabic [but] of Persia, for which the year 632 entered, and as the same Rudolphine [Tables], page 38, the Year of Christ 623 is to be set, which follows 623.

[Margin: Rudolphinarum mendum — an error of the Rudolphine [Tables]]

As to how the Arabs investigate their own Cycles by feria [weekday], it was stated at precept 22.

Precept 40. *To change the years of Christ — if they are not fewer than the years 622, [its] days — into Arabic [years] of the Hegira, [its] years, and days.*

To the given years of Christ, subtract the years 620, and the residue...

[Margin: Pag. 15]

resolve into days, by Table 21, [in its] supreme class for the Julian years collected, and to these add the days collected from the beginning of the given year up to the day of the Julian month, and that, by Table 5; or even by that same Table 21, with the bissextile [day] added, as the work requires. From the sum of all these days, always subtract 561 days. As for the residue, look for it in Table 21 — but by parts applied: first under the heading of Arabic years; then under the heading of Arabic months, until the lesser days than the Arabic month remain; noting meanwhile the preceding Arabic collection complete; the days remaining indicate the day of the following month of the Arabic [year]; congruent with the Julian [day], and the

sum of the collected Arabic years, with the added unity, the Arabic year [is given], the given Year of Christ answering.

[Margin: Pag. 15] [Margin: Pag. 2] [Margin: Pag. 15]

Example. Year of Christ 1452, day 29 of May, feria 2 [Monday]: Constantinople was captured by Mehmed II [Mehmed II]. It is asked, in what Arabic year of the Hegira it was captured, and on what Arabic month, and on what its day? Year of Christ 1452, take away 620, and there remain 832; these by Table 21 answer to the days collected for the Julian years, as below.

[Margin: Pag. 15]

	Days
800 years give days	292200
There remain 32 years, which give	11688
But from the beginning of the year 1452, bissextile, to 29 May inclusive are days	150
The sum of days is	303930
From this perpetually take away days	561
There remain days	303369

Then, in the lowest class of Table 21 [taken] under the Arabic years, and months: 303369 give the Arabic years complete 856, by the method written below.

Days collected	Arabic Years
Days 303369: the sum nearest less, 212620, gives	600
There remain 90749, of which 85048 give	240
There remain 5701, of which 5670 give	16
There remain days 31	

Days collected

Arabic Years

The sum of Arabic years
complete 856

[Margin: In Tab. 21] [Margin: Pag. 15]

Therefore Constantinople was captured in the Hegira year 857. And because there remain 31 days, of which 30 are owed to the prior Arabic month Muharram, it follows that it was captured on the first of the month Sephar [Safar], feria 2 [Monday] in the Arabic [reckoning], that is, on the day of the Moon [Monday], by precept [22].

Precept 41. *Yazdegerd, or the Persian Epoch: given years, and months, to convert into the years of Christ, and days.*

Given the Yazdegerd years complete, and the months complete, resolve into days, by Table 21, [in its] class 2, the left-hand parts, which serve both for the Persian and the Egyptian [years], or [made] by more entries into the Table; from the sum of the days subtract perpetually the days 199. The residue, and its [class] 24, the supreme class, reduce into the Julian years, and months, having regard to the bissextile [years]. Finally, to the sum of the Julian years add perpetually the years 632, and from the sum of the Years of Christ the residue, but the months show in Table 21, the month, and the day.

[Margin: Pag. 15] [Margin: Pag. 15] [Margin: Pag. 2]

Example. Given the Yazdegerd year 814, and the day 17 of the month Tyrma: it is asked, what is the Year of Christ, the month, and what day? Go to Table 24, in which thus:

[Margin: Pag. 15]

	Days
<hr/>	
800 Persian, or also Egyptian, years give	292000
There remain 13 complete years, of which 10 give	3650
And 3 complete years give	1095
Month complete before Tyrma, that is the month Chortat, gives	90

	Days
The days current of Tyrma are	17
The sum of all the days is	296852
From which perpetually take away	199
There remain	296653

[Margin: Pag. 15]

The sum of days 296653 in the upper Table 24, by the fourth part, gives the Julian years written below:

	Years
Days 292000 give	800
There remain d. 4453, of which 4383 give	12
And there remain days 70	
The sum of complete years	812
Add to these the years complete	632
The sum becomes of complete Years of Christ	1444

[Margin: Pag. 2]

But [there remain] above, of the following year, namely 1445, days 70; and these in Table 6 give, in a common year, day 11 of March. Therefore at last the Yazdegerd year 814, day 17 of Tyrma, falls on day 11 of March of the Year of Christ 1445.

Precept 42. *A given Epoch of Christ — year, and day — to reduce into the year of Yazdegerd, and the day of the Persian month.*

To the given years of Christ (which I suppose to be not fewer than the years 632) subtract the years 632. Then resolve the residue, the complete [years], into days by Table 21. Add the supreme class, one or more entries into it; and to these add

the days collected from the beginning of the current month, and the current day, and again the perpetual 199. The sum of all the days collect, and with it Table 21, class 2, look for it; gather in the left-hand margin the complete Persian years, one or more entries; likewise the complete Persian month — for the remaining days are to be assigned to the following Persian month.

[Margin: Pag. 15] [Margin: Pag. 15]

Example. The same as above, but conversely. Given Year of Christ 1445, [its] day: we ask 11 March, what the year of Yazdegerd is, [its] day; and what the Persian month [is]. The given Year of Christ 1445, and its 11 March of Table 6, you will collect the days.

[Margin: Pag. 15]

	Days
800 Julian years give	292200
And 12 years give	4383
Add to these the perpetual	199
And for 11 March, by Table 6	70
The sum of days becomes	296852

[Margin: Pag. 15]

Because by Table 21, class 2, excerpt the Persian years, months, the day thus:

	Persian Years
Days 292000 give	800
There remain D. 4852, of which 3650 give	10
There remain 1202, of which 1095 give	3
There remain days 107	
The sum of years complete	813

Therefore in the Year of Christ 1445, day 11 of March, falls the Yazdegerd year 814, but the days 107 that are over in the same Table 21, Persian months, show the month complete to have been Chortat, namely days 90, and over 17, [which]

respect the month Tyrma; therefore on day 11 of March of that Year of Christ, [it] agrees with day 17 of the month Tyrma.

Monitum for the remaining Epochs.

The mutual transformation of the remaining Epochs, either work it out from Table 25, or from Our Chronology Reformed, since the rest pertains rather to the Chronologer than to the Astronomer, [it has been treated] thus far.

Precept 43. *On the absolute constitution of Time for the motions of the stars to be elicited from Our Tables.*

Up to now, almost all the precepts pertained to Time. It remains, therefore, that we indicate by what reasoning Time is to be constituted, that the Celestial Motions may be elicited from Our Tables, and to which other things too may be accommodated, [or] which [things] are called the principal Heads of the constitution.

The first [Head] is, if some Celestial Phenomenon — say, an Eclipse of the Moon deduced from Our Tables — must be transferred to other places distant from our Meridian of Bologna, or even to other species of hours, or indeed to other [reckonings] of Years, Months — species diverse from the Years of Christ, or before Christ, which in these Tables we use according to the Julian, and then the Gregorian, form. As if the beginning of a Lunar Eclipse to be elicited from our Tables is found — at which hour it is to be announced — since the hour is not solely Astronomical, but even Babylonian, or European, or apparent [civil], say at Constantinople, or as if at the month of an Arabic year. In this case, First, the time to be used in Our Tables is the mean time of the motions, after the calculation of the Eclipse is absolutely converted into Apparent [time], or apparent at our Meridian of Bologna, [in] Astronomical hours, or post-meridian; and that, by precept 16. Secondly, by precept 17, this time must be accommodated to the Meridian of Constantinople; in which, if the hours are observed Babylonian, [it must be] known by precept 14, the semi-diurnal quantity, and subtracted, [and] the Astronomical hour converted into Babylonian by precept 12; and at last, by precept 40, the Years of Christ converted into Julian; and the days Julian, on which the Eclipse is announced, must be reduced to the Year of the Hegira, [its] month, and by precept 22, [reduced] to the Feria [weekday]. But these and many other precepts are supplied from the preceding [precepts].

The second Head is, if some Phenomenon — say, an Eclipse of the Moon observed elsewhere, or computed — was [reckoned] in another Meridian, say Constantinople, and expressed, moreover, [in hours] enunciated by hours, days,

and of another species, say in Babylonian hours, and the days of the month of the Arabic [year], the Hegira. Then, First, the time as it appeared there apparent must be changed into mean time, by precept 16. Secondly, by precept 17, this time must be transferred to a time congruent with the Meridian of Bologna, and by precept 14 [the semi-diurnal quantity] is to be known, and by precept 12 the Babylonian hour converted into Astronomical. Then by precept 39, the year, month, and day of the Hegira are to be transformed into the Julian Year of Christ, Month, and Julian Day.

Often, too, in the observations of the Ancients, the Temporal Hours are to be reduced to equal [hours], by precept 13.

On the Beginning of Days, and of Years, in Our Tables.

The beginning of Days we take, Astronomically, from noon made under the Meridian of Bologna; and the beginning of the days of the year, or the principle of the year, takes its rise from the noon preceding the last day of December, so that thence the named Days may be used for complete ones. As if we examine an Eclipse of the Moon to come at hour 4 after the Meridian of the first day of January, the mean Luni-Solar motion of one complete day is to be collected, and besides, of hours 4, etc.

There follow the Precepts for the Use of the Tables — of the Second Part.

Precept 44. *Given the place of the Sun on the ecliptic, or any point of the ecliptic, to find its declination.*

[Margin: Pag. 19.]

This is accomplished by means of Table 26: look for the sign at the top, and for the degree of the sign down the left-hand side if the sign is descending, or up the right-hand side if the sign is ascending; for at the common intersection of the sign and degree you will have the declination sought — northern if the ecliptic signs are northern, southern if they are southern — applying proportional parts if need be.

Example. Suppose the Sun's place is given as $10^{\circ}20'$ of Taurus. In the table, the degree of Taurus 10° corresponds to a northern declination of $14^{\circ}51'16''$, and the following degree, 11° , gives $15^{\circ}17'7''$. Their difference is $18^{\circ}51'$ [recte: $25^{\circ}51''$ — see anomaly a]; this, multiplied by $20'$ and the product divided through by whole minutes [i.e. by 60], leaves a remainder of $7'42''$, which must be added to the value

for 14° [recte: for Taurus 10°] [?]. The result is a declination of $14^\circ 58' 58''$ for Taurus $10^\circ 20'$.

Precept 45. *Given any point of the ecliptic, to find the angle that it makes at that point with the meridian, or with any circle of declination.*

[Margin: Pag. 19.]

Therefore in Table 27 look for the given sign at the top, and its degree down the left-hand side; in the right-hand column you will then have the angle that the rising point of the ecliptic makes toward the eastern horizon — that is, toward either the southern or the northern pole, as the notation "Austr." or "Bor." attached to the sign indicates. Moreover this same angle is equal to the angle, situated toward the opposite pole, which the setting point makes (the angle of the setting point being toward the previous pole, as at degree 180); and likewise the angle of the rising point is toward the other pole.

Example. Let the meridian be crossed by, say, Taurus 10° . In Table 25 the eastern angle comes out as $71^\circ 35'$, which is the angle the ecliptic there makes with the meridian — a northern angle, as the notation "Bor." indicates. The western angle is likewise, but toward the south, namely $71^\circ 35'$; its complement to two right angles is $108^\circ 25'$. So great, then, is the angle — whether the northwestern or the southeastern — of the ecliptic with the meridian, or with any circle of declination.

Precept 46. *Given a point of the ecliptic, or the Sun situated in it, to ascertain its right ascension.*

[Margin: Pag. 19.]

Consult Table 28, noting the sign at the top and the degree of the sign down the left-hand side; directly opposite the degree you will at once have its right ascension, applying proportional parts if the degrees of the sign carry a fractional remainder.

Example. To Taurus 10° corresponds a right ascension of $37^\circ 34' 46''$. But to 10° of Libra the right ascension is $205^\circ 9' 11''$ [recte: $205^\circ 9'$ — the seconds reading is uncertain] [?].

Precept 47. *Given the altitude of the pole, and the declination of a point of the ecliptic — or of the Sun, indeed of any celestial point or star — to find its ascensional difference.*

[Margin: Pag. 21. and 24.]

This ascensional difference is the arc of the equator by which the right ascension of any point or star differs from the oblique ascension of the same in an oblique sphere.

Go therefore to Table 29 or 30, and look there — by the altitude of the pole at the top and the declination down the side, or by the declination at the top and the altitude of the pole down the right-hand side — for the ascensional difference, which the common intersection will give. In Table 29, however, an obliquity of the ecliptic of $23^{\circ}30'$ is assumed; whereas a more exact value is $23^{\circ}30'20''$. We have therefore added, for this obliquity, a [Margin: Pag. 24.] further $30'$ [recte: see context — the small adjustment for the more exact obliquity] to our value for the altitude of the pole — which at Bologna, at S. Petronio, is $44^{\circ}30'20''$ — so that it may serve for the other tables; but in this table the obliquity is disregarded, and the ascensional difference is obtained directly, corresponding to the degrees of the ecliptic on which alone the Sun is carried.

Example 1. Let the Sun's declination, or that of any point of the ecliptic, be given as 20° , and the altitude of the pole as 44° . In Table 29, with $44^{\circ}30'$ [Margin: Pag. 21.] at the top for the altitude of the pole, and 20° of declination down the left-hand side, the common intersection gives an ascensional difference of $20^{\circ}35'$.

Example 2. In Table 30, to the degree of Taurus $19^{\circ}5\frac{1}{2}'$ — which has a declination [Margin: Pag. 24.] of 20° — and to the northern altitude of the pole of Bologna corresponds an ascensional difference of $20^{\circ}58'15''$.

Precept 48. *Given the right ascension of any celestial point, and its ascensional difference, to form its oblique ascension.*

To the right ascension of the declining point, for an elevated pole, subtract the ascensional difference; but add it if the point declines toward the unseen (opposite) pole. In this way the oblique ascensions of the same points will be formed; and by this method you can examine the Tables of oblique ascensions.

Example 1. To Taurus $19^{\circ}5\frac{1}{2}'$ there belongs, as said above, a northern declination of 20° ; and to this, under an altitude of the pole of $44^{\circ}30'20''$, there belongs (from the foregoing) an ascensional difference of $20^{\circ}58'15''$. And to the same point, the right ascension is $46^{\circ}58'55''$. Therefore, subtracting the ascensional difference from the right ascension, its oblique ascension will be $36^{\circ}0'40''$. But if it were beyond the equator — i.e. for a place beyond the equator, where the northern pole is not visible — you would have to add the ascensional difference to the right ascension.

Precept 49. *Given the altitude of the pole, and a point of the ecliptic, or the Sun moving in it, to elicit its oblique ascension by means of the tables prepared for that purpose.*

If the altitude of the pole is exactly as great as that for which Table 31 was observed [Margin: Pag. 25.], you will have in common, with that sign at the top and its degree down the right-hand side, the oblique ascension of the point of the ecliptic. But for any [Margin: Pag. 26.] other altitude of the pole, use Table 32. To exhibit the oblique ascension of the northern signs at the northern horizons, look for the degree of those signs down the left-hand side; or, of the southern signs at the southern horizons, look for the degree of those down the right-hand side. But if you want the oblique ascensions of the northern signs at the southern horizons, or of the southern signs at the northern horizons — find the degree opposite to those signs, take it as given under the altitude of the pole, subtract from 360, and the remainder will be the oblique ascension you seek.

Example. Under an altitude of the pole of 40° , the oblique ascension of Taurus 16° is $28^\circ 55'$ for the northern horizons; and the same is the case for Aquarius 14° among the southern; but Aquarius 14° for the northern is $331^\circ 5'$ [Margin: Pag. 26.].

Precept 50. *Given the apparent time after noon, the place, and the altitude of the pole, to find the ascending degree of the ecliptic — which they call the horoscope — and which degree of the ecliptic is the nonagesimal, reckoned from the ascendant.*

First. By Precept 46 find the right ascension of the Sun's place [Margin: Pag. 19. / Pag. 3.]; add to it the time from noon, first converted by Table 3 into the corresponding degrees of the equator; and if the sum exceeds 360, cast out 360, and the result, or remainder, will be the right ascension of the mid-heaven at that time.

Second. Add 90° to the degree of the equator culminating, and the oblique ascension of the ascending degree of the ecliptic will come out, provided it does not exceed 360° ; this being sought in Table 31 or 32, under the appropriate altitude of the pole, [Margin: Pag. 25. / or 26.] will show the sign at the top, and the degree down the left-hand side; then

then, the rising sign or horoscope. But if the oblique ascension exceeds 90 — subtract it from 360, and with the remainder found in the Table of oblique ascensions, investigated as above, you will find the sign and the degree of the ascending ascension.

Third. From the degree of the ecliptic ascending, take away 90°; and there will be known the degree of the ecliptic that is the nonagesimal, which we shall teach more fully — but chiefly with respect to the parallaxes for solar eclipses — to infer in its own place.

Example. Let the place be Bologna, where the pole is elevated 44°30'20"; let the apparent time after noon be 4°30' [i.e. 4^h30^m]; and let the Sun then be in Taurus 29°5'30". The operation is set up thus:

	Gr.	'	"
Hour 4°30', by Table 7, gives	67	41	6
Right asc. of the Sun's place by Table 29 [recte: Tab. 28]	56	58	55
Sum, and the culminating point	124	40	1
Add the degrees	90	0	0
The oblique ascension comes out	214	40	1
This subtracted, 360 remains	145	19	59
With this per Table 29 [recte: 32] there ascends Virgo	3	36	30
Take away the ascendant	90	0	0
There comes out the nonagesimal, Gemini	3	36	30

Parsing notes: rows give signs-degrees-minutes-seconds; "Gr./'" headers apply but the sign-row entries (Virgo, Gemini) are read in sign-degree-minute form.

The ascending horoscope sought, then, is Virgo $3^{\circ}36'30''$; and the nonagesimal computed from it is Gemini $3^{\circ}36'30''$.

Precept 51. *Given the point of the ecliptic ascending, and the altitude of the pole, to find the altitude of the nonagesimal — that is, the angle of the ecliptic and the horizon.*

[Margin: Pag. 38.]

Go to Table 33, which begins at page 38 — for proportional parts are needed here, if there is need of them — looking at the top for the altitude of the pole, and down the left-hand side for the sign with the degree of the ascending degree; downward, count off the degree numbered, or in the right-hand side the sign with the degree upward numbered; the common intersection will exhibit the altitude of the nonagesimal.

Example. Let the ascending degree of the ecliptic be Virgo $3^{\circ}36'30''$, under an altitude of the pole of $44^{\circ}30'20''$ [recte: $44^{\circ}30'$]. From Table 31 [recte: 33] is gathered, by proportional parts, the altitude of the nonagesimal as $65^{\circ}52'52''$, or in round numbers $65^{\circ}53'$.

Precept 52. *To resolve the degrees of the signs of the zodiac, or of any circle, into degrees reckoned from the beginning of Aries.*

[Margin: Pag. 19.]

Table 24 teaches this at once. In it, for example, the degree of Aries 25° in the left-hand column corresponds to a value of $205^{\circ}5'$ [recte: per context] under Libra 205° [?]; and so for the others. But if any degrees of the circle — say, integral signs of the zodiac — are sought, and besides these some degrees adhere to them, the degrees of the following sign being congruent: if Aries 4 signs 25° be given (not in the column for the sign Aries [IV?], but in the column where the sought degrees of the collected signs are noted), and at the head of the sign with the degree opposite, of the collected signs, 145° [recte: per context].

Precept 53. *To find at once the degrees of the zodiac diametrically opposite a given degree — that is, given the ascending degree, to know the descending degree.*

[Margin: Pag. 19.]

In Table 25 you have each pair of opposite signs, but in the table they are conjoined with their degrees opposite; thus in the first conjugation of degrees, Aries 16° is opposed to Libra 196°; likewise in the second conjugation, Aries 16° [II], which is the second sign of the zodiac 76° [recte: per context], is opposed to Libra 16° [VII?], which is 256° of the zodiac. Therefore, given the sign and the degree of its ascending, the degree of the descending sign will at once be known.

Precept 54. *To find the longitude and latitude of any star, but in such a way that with these — for stars not exceeding 90° of [declination/latitude?] — you may obtain its declination and right ascension.*

[Margin: Pag. 19.]

First. By Precept 44 and Table 26, learn the declination of the point of the ecliptic that the given [Margin: ☞ 20.] longitude of the star designates; and by Precept 46 and Table 28, [recte: Tab. 28] its right ascension.

Second. By Table 34 [Margin: Pag. 43.] excerpt the prosthaphaeresis of declinations, observing the given latitude at the top, and the signs and degrees of longitude down the left-hand side; or the degrees of latitude down the right-hand side — for the common area will give the equation of declinations. This addendum-of-declination of the ecliptic point is to be added, if the sign and latitude are of the same region, kind, or affection — that is, if the latitude be northern, and the declination also northern; but to be subtracted if they be of contrary affections; and you will have the declinations of the star.

Third. From Table 35 [Margin: Pag. 43.] likewise excerpt the prosthaphaeresis of right ascension, to be added or subtracted to the right ascension of the ecliptic point, as the conditions explained at the top — or in the foot of the table — shall require; and thus the right ascensions of the star are formed.

Example. Let the southern latitude of Spica, or of Jupiter, be given as 2°, and the longitude as Libra 18°. For at this degree of Libra the southern declination, by Table 26, is 7°4'47" [recte: per context]; and indeed the southern latitude — since therefore the sign and latitude are of the same region — to the southern latitudes 2° (and to the region of Libra 18°, with the added 2° of latitude) there is added a prosthaphaeresis of 7°4'47" [recte: per context — this seems to repeat the declination value] [?], making the southern declination of Spica 8°15'47". Then take the right ascension of Libra 18° by Table 28, which is 196°35'31"; and the southern latitude of Spica, or Jupiter — assumed as 2°, also southern — likewise gives a prosthaphaeresis to be added; this, in the left-hand part of the table,

opposite Libra 18° , and under the latitude (south) 2° , is $46'$. Therefore the right ascension of Spica, or of Jupiter, will be $197^\circ 21' 31''$.

There follow the Precepts for the Use of the Tables — of the Third Part, or On the Motions of the Sun and Moon.

Precept 55. *To find the true place of the Sun on the ecliptic, and its anomaly, for a given time after the epoch of the common era of Christ.*

First. If the given time is apparent, convert it into mean time by Precept 16.

Second. From Table 36, collect the mean motion of the Sun, and of the Sun's apogee, [Margin: Pag. 44.] corresponding to the epoch; then for the radix immediately preceding the given year; and for the complete years after that epoch; and likewise for the complete months of the common year (using these as complete, whatever the character of the current year); and for the days given — always using them as complete; and finally for the hours, and the minutes of an hour after noon — and collect the motions into one sum: separately, that is, the mean motion of the Sun, and separately the mean motion of the apogee.

Third. Subtract the motion of the apogee from the mean motion of the Sun (assuming, when the subtraction cannot be made, that 12 signs are taken in addition); and there will remain the simple anomaly of the Sun, namely its distance from the apogee.

Fourth. With the simple anomaly of the Sun, excerpt from Table 38 the equation to be subtracted, [Margin: Pag. 46.] in the prior semicircle of anomaly — that is, when the signs of anomaly are at the top of the table — and the equation of those, the degree being down the left-hand side; or to be added in the latter part, that is, when the signs are at the foot of the table — the degree being down the right-hand side; whether it please you that the figure be circular or elliptical. And by this equation correct the mean motion of the Sun, and likewise the simple anomaly of the Sun; for there will come out from thence the true place of the Sun on the ecliptic, and hence the equated anomaly of the Sun.

Example.

The true place of the Sun is sought for the year of the epoch of Christ 1661, September 23, at $1^\circ 1'$ [i.e. $1^{\text{h}} 1^{\text{m}}$] after noon. [Margin: Pag. 8.] *First*, then, since the Sun will then be in the first degree of Libra, by the Table of Temperaments, with the double subtraction of $4^\circ 23'$ to be subtracted [recte: $4' 23''$], the mean time will be $1^\circ 26'$ [i.e. $1^{\text{h}} 26^{\text{m}}$] after noon; and the calculation will then proceed thus:

Left table — Mean motion of the Sun, and of the apogee, for 1661 September 23:

Anni 1600	Mot. ☉ Med. ab □				Apog.			
	— Sign.	Gr.	'	"	— Sig.	Gr.	'	"
Radix	9	10	4	35	3	7	39	8
An. 60	0	0	27	36	0	1	2	[blank] [?]
Augu sti	7	29	30	44	0	0	0	41
D. 23	0	22	40	12				
H. 1	0	0	2	28				
M. 26	0	0	1	4				
Sum ma	6	2	46	39	3	8	41	54

Second, therefore, the apogee's signs being subtracted — 3 signs 8°41'54" — from the mean place of the Sun, there is left the simple anomaly of the Sun, and thence will be had the equation of each, as below.

	Sig.	Gr.	'	"
Solis Medius (Sun's mean place)	6	2	46	39
Apogei motus (apogee's motion)	3	8	41	54
Anomalia simplex (simple anomaly)	2	24	4	45

	Sig.	Gr.	'	"
Aequatio subtracta, in forma circulari (equation subtracted, in circular form) ☉	1	58	49	
Restat Verus locus ☉ (the true place of the Sun remains)	6	0	47	50
Et Anomalia coaequata (and the equated anomaly)	3	6	43	5

The Sun will then be in the first degree of Libra, not yet complete — distant from that point by $47'50''$ — and distant from the true apogee by 3 signs $6^{\circ}43'5''$; or, resolving the signs into degrees, it will be distant from the apogee by $96^{\circ}43'5''$.

A Caution concerning the Julian and Gregorian Style.

In the example given we have used the radix for the year 1600 according to the form of the Gregorian year; but if we wished to use the Old Style, the Julian, the radix for the year 1600 in the Old Style — congruent with which, in Table 36, the mean place of the Sun has the signs 9, $19^{\circ}55'58''$ — would have to be applied.

Precept 56. *To find the true place of the Sun for a given time before the epoch of Christ.*

The apparent time being reduced to mean time by Precept 16: if the given year before Christ is one of the hundreds [centuries] themselves, or one of the thousands, use the radix noted for that century, or chiliad [thousand], in Table 36; and then there is no need to collect the mean motions for the years from the

radix distinctly, since the years before Christ in the said table are reckoned complete — namely, numbered upward toward the beginning of the world, not as current years (which would be the case if they were numbered downward toward the epoch of Christ) — nor are they complete, except in the case where the given time was the noon of the last day of December, or after the noon of that same last day of December. But the remainder, for the months, days, hours, and minutes, must be carried out as in the preceding Precept.

But if the given year is not one of the hundreds, or thousands, the number of the completed years must be subtracted from the next expanding [larger] hundred [century], by which the mean motions are to be sought; and the radix to be applied will be that of the century, or millennium, which next precedes — the one that is next greater; and the rest is to be done entirely as in Precept 55.

Example One.

The true place of the Sun is sought for the year 200 before Christ, September 23, at the equated hour 1°26' [i.e. 1^h26^m] after noon. The true place of the Sun at Bologna will then be as follows in the form of the calculation:

Right table — Mean motion of the Sun, and apogee, for 200 BC:

Ante Chr. —	Motu s ☉ —					Apog.			
Radix	Sign.	Gr.	'	"	Sig.	Gr.	'	"	
Anni 200	9	6	8	1	2	6	36	48	
Augu sti	7	29	30	44	0	0	0	41	
D. 23	0	22	40	12					
H. 1	0	0	2	28					
M. 26	0	0	1	4					
Sum ma	5	28	22	29	2	6	37	29	
Ano malia ☉ simpl ex	3	21	45	0					

Ante Chr.	Motu s ☉	Apog.						
Radix	Sign.	Gr.	'	"	Sig.	Gr.	'	"
Aeq.- subtr . ☉	0	1	51	13	0	1	51	13
Veru s ☉	5	26	31	16				
Ano malia ☉ coae quata					3	19	53	47

Example Two.

The true place of the Sun is sought for the year 145 before Christ, September 23, at the hour 1°26' [i.e. 1^h26^m] equated, after noon, at Bologna. Subtracting 45 years from 100 years, there remain 55 years, completed in descent toward the epoch of Christ; the form of the calculation is then as follows:

Table — Mean motion of the Sun, and apogee, for 145 BC:

	Motu s ☉	Apog eus						
Radix	Sign.	Gr.	'	"	Sig.	Gr.	'	"
Anni 200	9	6	8	1	2	6	36	48
Anni 55	11	29	40	58	0	0	56	54
Augu sti	7	29	30	44	0	0	0	41
D. 23	0	22	40	12				
H. 1	0	0	2	28				
M. 26	0	0	1	4				
Sum	5	28	3	27	2	7	34	23

Radix	Motus ☉				Apogeeus			
	Sign.	Gr.	'	"	Sig.	Gr.	'	"
ma								
Ano malia ☉ simpl ex	3	20	29	4				
Aeq.- subtr . ☉	0	1	52	12	0	1	52	12
Veru s ☉	5	26	11	15				
Ano malia ☉ coae quata					3	18	36	52

Parsing notes: The three computation tables share the structure radix + addends (years, August, days, hours, minutes) summed to a total, followed by the anomaly/equation block. Some apogee-column cells are blank in the source where only the Sun's column carries an entry; these are left blank. The "An. 60" apogee seconds cell in the left table is illegible and flagged.

Precept 57. *To find the parallax of the Sun in the circle of altitude.*

It is presupposed as known whether the parallax is the maximum, or at least near the maximum; or near the mean; or near the [Margin: Pag. 45.] minimum distance from the Earth — for in Table 37, in the column for the said distance, or assigned to the signs of anomaly, and opposite the degrees of the altitudes given, you have the parallax of the Sun, in which they have greatly exceeded — Ptolemy, Copernicus, and Tycho [Brahe].

Example.

In the example of Precept 55, the anomaly of the Sun was found to be signs 3 and about 7° [recte: per context]. Let the altitude of the Sun above the horizon be

given as $45^{\circ}29'$. For in Table 37, the small column corresponding to signs III and to the region [Margin: Pag. 45.] of 45° and 29° [recte: opposite Gr. 45 & 29], you will have a parallax of $11'10''$, using proportional parts.

Precept 58. *To find the distance of the Sun and Moon from the center of the Earth, but in semidiameters of the Earth — with the horizontal parallax of the Moon, and the hourly motion of each — and indeed to find the true motion.*

With the anomaly of the Sun, known by Precept 56, and in Table [Margin: Pag. 47.] 38, it shows at once, opposite, down the right-hand side, the distance of the Sun from the center of the Earth, in parts such as the radius of the solar orbit is 100000; then, in semidiameters of the Earth, both the horizontal parallax, and the hourly motion of the Sun. But these three conditions of the Moon — the anomaly of the Moon will show, when it has been noted by Precept 61, or otherwise. In the distances, however,

of the Sun, although for the most part we may use hypothesis 1, concerning which see Book 1, chapter 13 of the *Astronomia Reformata*. But if hypothesis 2 should nonetheless displease you, hypothesis 1 is set out in the same place, chapter 7. From this you will be able, by the same Table 39, to find the distances of the Sun in either of the two ways.

Example.

Let us suppose that both the Sun and the Moon have an anomaly of 95 degrees; for in Table 39 the said conditions of the luminaries stand thus:

		Distance to the radius 100000
Distance to the radius 100000	☉ Sun	99844
	☾ Moon	99905
In semidiameters of the Earth	☾ in 1st hypoth.	7289
	☾ in 2nd hypoth.	6543
	☉ Sun	60 · 57
Horizontal parallax	☉ Sun	$0^{\circ} \cdot 28' \cdot 16'''$
	☾ Moon	$56' \cdot 26'' \cdot 0'''$

Distance to the
radius 100000

True hourly motion	☉ Sun	2' · 29"
	☾ Moon	33' · 11"

Parsing notes: The "In semidiameters of the Earth" block gives the Moon's distance under each hypothesis (7289, 6543) and the Sun's distance as 60 semidiameters 57 (minutes/parts). The horizontal-parallax row for the Sun reads 0°·28'·16"; for the Moon 56'·26". The hourly-motion row reads Sun 2'·29", Moon 33'·11".

Precept 59. *To determine the apparent semidiameters of the Sun and Moon at conjunctions and oppositions, and the size of the Earth's shadow at the passage of the lunar body through the shadow.*

Once the anomaly of the luminaries has been equated, look in Table 39 for the apparent semidiameters of the Sun and of the Moon corresponding to the anomaly of either planet. As for the shadow's semidiameter, which has been equated against the Moon's anomaly: bear in mind that you have the apparent semidiameter of the shadow-disk only on the supposition that the Moon is passing through the shadow at its apogee. Therefore you must always add to the shadow's semidiameter the variation drawn from the Sun's anomaly and from the Moon's apogee, so that the result comes out corrected.

Example.

	Gr.	'	"
Let the anomaly be (of the) Sun	95	0	0
(of the) Moon	120	0	0
Then the apparent semidiameter will be ☉ Sun		15	47

	Gr.	'	"
(and)		15	44
Apparent) Moon			
Shadow at the Sun's apogee		45	44
Variation		0	43
The shadow's semidiamet er therefore, corrected		45	1

Parsing notes: degrees column applies only to the two anomaly rows (Sun 95°, Moon 120°); the semidiameter/shadow rows give minutes and seconds. Shadow at the Sun's apogee = 45'44"; variation = 0'43" (added); corrected shadow semidiameter = 45'1" — note 45'44" + 0'43" = 46'27", so the printed "corrected" value 45'1" may instead reflect subtraction or a different combination [?].

Precept 60. *To investigate the refractions of the luminaries and of the fixed stars, and through this to convert the apparent altitude of these bodies into the true altitude, or the true into the apparent.*

[Margin: Pag. 47.]

In Table 40 I have set out the refractions for the temperate zone of these bodies, since I have observations more suitable for that zone than for the others — chiefly for the frigid zones, whose measurement I have found dissimilar and inconsistent because of the dissembled refractions of the other zones. Why my table differs somewhat from the Tyconic one is treated sufficiently in Book 1, chapter 14 of the *Astronomia Reformata*. And how it differs is shown there sufficiently. With these things laid down beforehand, inspect the following Rules.

The Moon's observed altitude is converted into the true by subtracting the refraction which it has, the parallax, and the residue; or, if it is below the horizon, by adding the parallax itself to the Moon's observed altitude — on which see Precept 71.

The Moon's true altitude is converted into the apparent by subtracting the parallactic refraction, and by adding the residue to the true altitude.

The observed altitude of the Sun, of the remaining planets, and of the fixed stars is converted into the true by subtracting from the observed altitude the simple refraction. The true altitude is converted into the apparent by adding the true refraction to the apparent.

[Margin: 14]

Precept 61. *To find the Moon's true place in its own proper orbit at a given time within a new moon, or a full moon, together with the Lunar Anomaly.*

[Margin: Pag. 48.]

Having accommodated the time to the Bologna meridian and equated it as above (as in the case of the Sun, Precept 55) — or, if it be before Christ, by Precept 51 — collect from Table 41 the Radix [Margin: Pag. 48.] next preceding the given year, the Moon's mean motion from the beginning of the years, and likewise the Anomaly for the years, the months, the days, the assigned day, the hours, and the scruples [seconds of time]; sum them up, and reduce them into one total, the mean motion separately and likewise the Anomaly separately. Then go to Table 42, and in it look for the Anomaly's signs at the top, and the degrees [Margin: Pag. 50.] of the signs of the Anomaly in the left-hand margin if descending; or the Anomaly's signs at the foot, and the degrees of those signs in the right-hand margin if ascending — for in the common cell you will find, using the proportional part if need be, the equation to be subtracted from, or added to, both the mean motion of the longitude and the Lunar Anomaly, just as the headings at the top will indicate *Subtrahendam* [to be subtracted] or in the foot *Addendam* [to be added]. And you will have the Moon's true place, that is, the place first equated (which suffices for conjunctions), and the Lunar Anomaly equated together with it.

Example.

In the year of Christ 1661, on the 23rd of September, at 1 hour 26 minutes after midday equated, at Bologna [Margin: Pag. 48.], the Moon's true place is sought. The computation is to be set out thus:

	Motion from γ				Anomaly			
Radix	Sig.	Gr.	'	"	Sig.	Gr.	'	"
Years 1600	7	25	19	20	0	7	27	9
Years 60	1	10	41	19	3	29	6	4
August complete	10	21	51	50	9	24	47	26
Day 23	10	3	3	25	10	0	29	41
Hour 1	0	0	32	56	0	0	32	40
Min. 26	0	0	14	16			14	9
Sum Equation to subtract	6	1	43 13	6 15	0	2	37 13	9 15
Therefore True place	6	1	29	51	0	2	23	54
					& Anomaly equated			

Parsing notes: two parallel blocks — the Moon's mean motion from Aries (☉) on the left, the Anomaly on the right, each in Sig./Gr./". The "Min. 26" Anomaly degree-cell is blank in the source (only 14'9" shown). The equation 13'15" is subtracted from both columns. Result: true place 6^s 1° 29' 51"; Anomaly equated 0^s 2° 23' 54".

The Moon, then, was in 1° 11' of Libra [in gr. 1 Librae], the sign not yet complete [reading the true place 6 signs 1° 29' 51" from Aries = Libra 1°29'51"].

Precept 62. *To find the true place of the Moon's North Node at a given time, and the greatest Latitude of the Moon.*

[Margin: Pag. 48.]

Having accommodated the time to the Bologna meridian and equated it as above, as in Precept 55 or 56, collect from Table 41 the mean motion of the Node Ω for the given years, months, and likewise days, hours, and scruples [seconds]; sum them up, taking the Radix of the Node's mean motion Ω [Margin: Pag. 48.] next preceding, and you will have the mean motion of the Node Ω . Then, with the Sun's true place found by Precept 55 or 56 (and the Moon's by Precept 61), collect the Moon's distance from the Node, and with this — or (if it exceed six signs) the distance of the Moon from the point opposite the Sun [Margin: Pag. 50.] — enter Table 43. For in it, with the signs of the distance inspected at the top, and the degrees in the left-hand margin, or with the signs at the foot and the degrees in the right-hand margin, you will have in the common cell the equation of the Node Ω to be subtracted from, or added to, the Node's mean place Ω , so that you may have the true; and on that occasion the table will give you the equation of the eccentricity of the Node Ω , by which you must assign the greatest Latitude for the following Precept.

Example.

In the year of Christ 1661, on the 23rd of September, at 1 hour 26 minutes after midday equated, at Bologna, the true place of the Node Ω is sought; it will be found thus:

[Margin: 15]

	Sign.	Gr.	'	"
Years 60	2	10	30	40
August complete	0	12	52	5

	Sign.	Gr.	'	"
D. 23		3	13	5
H. 1				8
M. 26				5
B. Sum	3	4	35	58
Radix Year 1600	9	11	21	50
B. sum subscribed	3	4	35	58
Remains the mean place of the Node Ω	6	6	46	52

[Margin: Pag. 48.]

Then, because by the Example of Precept 55 and Precept 62:

	Sign.	Gr.	'	"
There was \odot the Sun's true place	6	0	47	50
Ω the Node's true place	6	1	29	50
Distance \curvearrowright from Ω	0	0	42	0
Therefore the equation of the Node Ω to be subtracted	0	0	2	41
The Node's	6	6	44	11

	Sign.	Gr.	'	"
true place Ω				
And the greatest Latitude ∽	0	4	58	30

[Margin: Pag. 50.]

Precept 63. *To find the Moon's true Latitude, and its Argument.*

[Margin: Pag. 51.]

With the true places of the luminaries and of the Node Ω supposed, as computed for the given time by Precepts 55 (or 56) and 61, and the greatest Latitude of the Moon ∽ repeated through Precept 62: subtract the true place of the Node Ω from the true place of the Moon ∽ assumed, and if the signs are more than 12 you will have the Argument of the Moon's Latitude equated, that is, the *Argumentum Latitudinis*. Then in Table 44 look for its signs at the top, and the degrees of the signs in the left-hand margin; or the signs at the foot and the degrees in the right-hand margin (for the region of the degrees is below the signs); or, if the signs of the Argument be above, or under the heading of the greatest Latitudes, you will find the desired Latitude of the Moon, North or South, as the headings of the Table indicate.

Example.

Now in the Examples of Precepts 61 and 62 the places of the Moon ∽ and Node Ω were as below:

	Sign.	Gr.	'	"
∽ the Moon's true place	6	1	29	51
Ω the Node's true place	6	6	44	11
Therefore the Argument of Latitude	11	24	45	40

	Sign.	Gr.	'	"
The greatest Latitude was	0	4	58	30
Therefore the true ☽ South Latitude	0	0	26	55

I have added the 12 signs to the Moon's place ☽, so that the place of the Node ♁ might be subtracted from it.

Precept 64. *To reduce the Moon's True place from the Orbit to the Ecliptic, and from the Ecliptic to the Orbit.*

[Margin: Pag. 52.]

Because the Moon's orbit is inclined to the Ecliptic, in order to know the Moon's place on the Ecliptic — namely, the point which the circle of Latitude, drawn through the center of the Moon, determines on the Ecliptic — you have it through Precept 63. The Argument of Latitude, and its signs, look for at the top of Table 45, and the degrees; and the signs in the left-hand margin, and the degrees in the foot; on the right, for in the common cell you have the Reduction of the Moon's place ☽ to the Ecliptic, to be subtracted from, or added to, the Moon's place in the orbit, as the headings above, or below, indicate — and with these headings the opposite must be done, if the Moon's place is to be reduced from the Ecliptic to the Orbit.

[Margin: 15 — right column]

Example.

The Moon's true place in the orbit, by the example of Precept 61, and the Argument of Latitude by the example of Precept 62, were as below:

	Sign.	Gr.	'	"
☽ the Moon's true place in the orbit	6	1	29	51

	Sign.	Gr.	'	"
Argument of Latitude	11	24	45	40
Reduction to be added			1	16
The true place in the Ecliptic	6	1	31	7

Precept 65. *To investigate the Moon's True place outside the conjunctions.*

[Margin: Pag. 53.]

Collect, by Precept 55 (or 56), the Sun's true place; and by Precept 61, the Moon's true place in the orbit, with its Anomaly first equated. Then subtract the Moon's true place from the Sun's true place (with the signs assumed); if need be, you will have the Moon's true distance from the Sun. But should this exceed six signs, look for the distance of the Moon from the point opposite the Sun above the semicircle, with which distance you should consult Table 47, by seeking the signs of the distance at the top when it is less than three signs, and in the left-hand margin the degrees of the signs equated. But if the signs are more than three, look for the distance at the foot of the Table, and the Anomaly's signs and degrees in the right-hand margin; for in the common cell you have the Last equation of the Moon, composed of the equation of eccentricity and the variation; and add it to the Moon's place first equated, or Subtract it, as the headings at the top or foot of the Table indicate, or in the middle letter A or S indicate. Let Argolus [Argoli], from Astrological Observations, reject the Tyconic Variation.

Example.

In the year 1661, September 26, at 1 hour equal after midday, at Bologna, the Moon's True place in the Orbit is sought; it will be investigated thus:

	Motio n ☽				Apog ee			
	Sig.	Gr.	'	"	Sig.	Gr.	'	"
☽ Year 1600	9	10	4	35	3	7	39	8
Years	0	0	27	36	0	1	2	5

	Motion				Apogee			
60								
August complete	7	29	30	44	0	0	0	41
D. 26	0	25	37	37	0	0	0	3
H. 1	0	0	2	28				
Sum	6	5	43	0	3	8	41	57
Anomaly					2	27	1	3
Equation to subtract	0	1	59	32				
True place	5	3	43	28				
Year 1600	7	25	19	20	0	7	27	9
Years 60	0	1	10	41	19	3	29	6
August complete	10	21	51	50	9	24	47	26
D. 26	11	12	35	11	11	9	41	22
H. 1	0	0	32	56	0	0	32	40

	Motion ☾				Apogee			
Sum	7	11	0	36	1	11	34	41
Equation to subtract	0	0	58	19	0	0	58	19
☉ Sun's place & Anomaly first equated	7	10	36	22	1	10	36	22
Distance ☉ from ☾	1	6	18	50				
Equation, last, to subtract	0	0	47	0				
☾ the Moon's Last place & equated	1	5	31	50				

Parsing notes: the upper block computes the Moon's motion (left) and its apogee/anomaly (right), yielding the Moon's true place $5^s 3^m 43^s 28''$. The lower block computes the Sun's place and anomaly ($7^s 10^m 36^s 22''$ / $1^s 10^m 36^s 22''$). Final rows: distance \odot from ☽ = $1^s 6^m 18^s 50''$; last equation to subtract $47^m 0''$; Moon's last place equated = $1^s 5^m 31^s 50''$. The " \odot Sun's place & Anom. first equated" line carries $7^s 10^m 36^s 22''$ in the motion column and $1^s 10^m 36^s 22''$ in the anomaly column; several cross-column values are tightly set and should be verified at collation [?].

[Margin: 16]

Precept 66. *To inquire the Moon's Hourly Motion from the Sun on the days of full moons and new moons.*

[Margin: Pag. 56.]

With the Moon's Anomaly first equated by Precept 61, consult Table 48, by seeking the Anomaly's signs at the top, and the signs in the left-hand margin, or the signs at the foot, and the degrees of the signs in the right-hand margin; and in the common cell you have the true motion, that is, the Zodiacal interval, which in one hour the Moon completes [Margin: Pag. 56.] by moving away from the Sun. Because in one hour the Sun completes the motion of the full moon or new moon, or in the other column you have the hourly interval which it completes within 12 hours before, or after, the new moon, or the full moon.

Example.

Renewed, the Moon's Anomaly equated by Precept 61 was of Sign 0, gr. 2, 23', 54". Therefore, by Table 48, the Moon's Hourly Motion, the hour of that New moon, is 27' 44".

[Margin: Pag. 58.]

Precept 67. *To define the True New moon, or Full moon, at the given time most nearly to it, that is, within 12 hours, exactly.*

If, having computed the Sun's and the Moon's true motion by Precepts 55 and 61, the Moon should not differ from the conjunction, or opposition with the Sun, by more than 6 or 7 degrees, then inquire by Precept 66 the Moon's Hourly Motion; with this hourly motion, by looking in Table 49 at the top, find in the left-hand margin the degrees and scruples [seconds] by which the Moon precedes the Sun in the Zodiac, or follows it in the Zodiac; and the Scruple [seconds] to be added to the time of the nearest new moon, or full moon, if the Moon precedes the Sun, or its Opposition; and to be subtracted, if it follows.

[Margin: Pag. 56.]

Example.

From what has been said in the Example of Precepts 55 and 61, the Sun's true place was Sign 6, $0^{\circ}47'50''$; the Moon's Sign 6, 1, 29', 51". The Moon therefore precedes the Sun by $42'1''$. The hourly motion, by Example of Precept 66, was $27'44''$. Therefore, in Table 49, under the headings of the Hourly motion $27'$ and $28''$, using the proportional part you will see Minutes $42'1''$; to the time given there responds Hour $1'26'$; which the New moon would yield at $7'$ before Midday on the 23rd day of September of the year 1661.

[Margin: Pag. 56.]

Precept 68. *To find the Moon's Distance from the center of the Earth at conjunctions, both greatest and least, and the eccentricity.*

[Margin: Pag. 57.]

The Moon's Distance from the Earth at conjunctions I have taught to find by Precept 58. But outside the conjunctions, the Anomaly of the eccentricity is necessary, which equates the doubled distance — namely, that which the Moon's elongation from the Sun gives. With the elongation of the Moon from the Sun looked for at the top of Table 50 in the left-hand columns, you will find by going down, in the right-hand columns, the eccentricity of the Lunar Orbit both in parts of which the Radix of the Orbit is 100000, and in semidiameters of the Earth at greatest. Then in the remaining columns the Moon's greatest Distance, and the minimum at the syzygies [extra syzygias]; in either kind you have the part expressed according to our Lunar Theory set out in Book 3 of the *Astronomia Reformata*.

Example.

In the case of Precept 65, we had the Moon's elongation from the Sun Sign 1, degree 6, 19', which resolved into degrees makes $36^{\circ}19'$; and this doubled makes the Anomaly of the eccentricity $72^{\circ}38'$; with this in Table 50 you have the underwritten interval, using the proportional part:

[Margin: Pag. 57.]

	Of which the radius is 100000	Semidiameters of the Earth
Eccentricity \curvearrowright	8436	4 · 34
Distance, Maximum \curvearrowright	108436	65 · 34
Distance, Minimum \curvearrowright	91568	56 · 24

Parsing notes: three rows in parts of radius 100000 and in semidiameters of the Earth (degrees·minutes form): eccentricity 8436 = 4 sem. 34; maximum distance 108436 = 65 sem. 34; minimum distance 91568 = 56 sem. 24.

Precept 69. *To inquire the Moon's Distance from the center of the Earth outside conjunctions.*

[Margin: Pag. 57.]

With the Anomaly of the eccentricity (which you learned to find by the preceding Precept), that is, the doubled elongation of the Moon \curvearrowright from the Sun, looked for at the top of Table 51; and with this and the Anomaly of the equated Orbit in the left-hand columns, you will at once find the Moon's distance from the Earth in semidiameters of the Earth.

Example.

In the Example of Precept 65, the Moon's elongation from the Sun was Sign 1, gr. 6, 19'; this doubled gives the Anomaly of the eccentricity gr. 72, 38'. But the Anomaly of the Equated Orbit was Sign 1, gr. 10, 36', that is, gr. 40, 36'; to these in Table 51 corresponds the Distance \curvearrowright from the center of the Earth, semidiameters of the Earth 64, 20'.

Precept 70. *To inquire the Moon's apparent Semidiameter and Horizontal Parallax outside conjunctions.*

[Margin: Pag. 57.]

Look, by Precept 69, for the Moon's Distance from the center of the Earth; and with this in Table 52 you immediately have the Moon's apparent semidiameter and the Horizontal Parallax of the Moon.

Example.

In the Example of Precept 69, the Moon's distance from the Earth was semidiameters of the Earth 64, 20'; to this Table 52 exhibits the Moon's apparent semidiameter 14', 39". And the Horizontal Parallax 53'·27".

Precept 71. *To investigate the Moon's Parallaxes in the circle of True Altitude.*

[Margin: Pag. 58.]

This Parallax is twofold, namely 53; and to know it for this it is necessary to know the Moon's Horizontal Parallax by Precept 58 at conjunctions; and by Precept 70 outside conjunctions: for under the heading of Table 53 [Margin: Pag. 58.] at the top you have the region of the degrees of the True Altitude opted for. The other Table, which is 61, you have at the top of the Moon's [Margin: Pag. 71.] Distance from the Earth in semidiameters of the Earth, under which is the region of the degrees of the True Altitude — you have the desired Parallax.

Example.

Let the Moon be high above the Horizon by gr. 35, when in the Example of Precept 58 the Moon's Distance from the Earth was found to be 60·57'; and the Horizontal Parallax 56'·26"; for in the region of degree 35 in the left-hand margin you will find the Horizontal Parallax stated in Table 53; or, under the said distance from the Earth in Table 61, you will find the Parallax of degrees 46'·40". But if you wish the Parallax of the Observed Altitude, look for it in the same tables, using the Observed Altitude as if True, and look for the Parallax that agrees with it, and add it to the True altitude; or finally, with this aggregate look for the same Parallax there, for it agrees with the Observed Altitude.

So in the same Example of the Observed altitude gr. 35, the Parallax agrees with 46'·40"; this added to gr. 35, gives degrees 35·46'·40", to which in Table 61 corresponds the Parallax 46'·10". This therefore is that which agrees with the Moon in the Observed altitude gr. 35.

Precept 72. *To find the Mean New moons, and Mean Full moons of a given Year and Month, through the Epacts.*

[Margin: Pag. 60.]

Collect first from Table 54 the Radix next preceding [Margin: Pag. 60.] the Epacts, and the Epacts corresponding to the years thence elapsed and complete, and likewise to the months complete — namely the month preceding the given month — and reduce these into one sum; from which subtract, by the greater number of the Revolutions of the New moons, the Mean New moon, in the left-hand part of

the same Table 54, at the foot; and the days of the given month, with the Hours and Scruples after midday, by which the Mean New moon, and Full moon...

the mean New Moon by the Julian calendar, but by the Gregorian calendar one must add 10 days for this whole century, and more for other centuries, according to what was said in Precept 19.

Example.

The mean New Moon of the year 1661 of Christ is sought, in the month of September; the computation is to be arranged by the method written out below from Table 54.

[Margin: Pag. 60.]

	D.	H.	I	II
Radix of the year 1600	6	7	46	59
60 years	3	7	10	40
Completed August	6	18	7	35
Sum	16	9	5	14
Conjunctio nal revolutions [Revolution es Coniunct.] □	29	12	44	3
Subtract	16	9	5	14
There remains the mean □ of September	13	3	38	49
But by the Gregorian calendar	23	3	38	49

	D.	H.	I	II
Revolutions	44	7	6	5
Subtract likewise	16	9	5	14
There remains the mean ☾ of October	27	22	0	51
But by the Gregorian calendar October	7	22	0	51

[Margin: Argol's error.]

This Ecliptic New Moon, Argoli represents in his Ephemerides at Rome; but falsely, for the southern latitude, with the parallax adjoined, frees the Sun at Rome from any eclipse.

Precept 73. Given the time of the mean New Moon, or of the Full Moon, to find the moment of the true New Moon, or Full Moon.

For the given time of the mean New Moon, collect by Precepts 55 and 61 the true places of the luminaries; and if they are found in the same zodiacal degree and minute, then the mean Full Moon coincides with the true; in this way they are 180 degrees apart between themselves, and the mean and true Full Moon are celebrated at the same moment. But if the Moon precedes or follows the place of conjunction, or of opposition with the Sun by some degrees or scruples, then by Precept 66 find the Moon's equated anomaly; and by it divide the difference between the place of the Sun and the Moon in conjunction, or between the place of the Moon and the place opposite to the Sun. For as often as it gives hours and scruples, so much must be added to the time of the mean syzygy if the Moon has not yet reached the Sun, or subtracted if it has already passed beyond it. For this purpose, however, the moment requires that the places of the luminaries be collected again, and if need be, the exact moment of the New Moon or Full Moon be determined again through the Moon's hourly motion.

Example of the Full Moon.

From the example of the preceding Precept, the year 1661 of October by the Gregorian calendar is given, with the mean Full Moon at Bologna after midday at hour 22, 0 minutes, 51 seconds; for which time the computation of the luminaries stands thus:

	Sig.	Gr.	I	II
☉ Mean place of the Sun	6	17	25	18
Simple anomaly of the Sun [Anomalia Solis simplex]	3	8	43	17
Equation to be subtracted [Aequatio subtrahenda]	0	1	57	54
☉ True place of the Sun	6	15	27	24
☾ Mean motion	0	17	29	15
Mean anomaly of the Moon	6	16	3	58
Equated anomaly of the Moon	6	17	29	6
☾ True place of the Moon	0	18	54	24
Equated	6	17	29	6

	Sig.	Gr.	I	II
anomaly of the Moon				
Difference of place ☉ & ☾	0	3	27	0
Hourly [motion] of the Moon from ☉	0	0	34	0
Time to be subtracted [Tempus subtr.]	H.	6	5	18
Truer therefore is the time of the Full Moon [Verius igitur Tempus Plenilun.]	H.	15	55	33

It is therefore necessary, for this very time of the truer Full Moon — namely at hour 15, 55 minutes, 33 seconds — to repeat the calculation, which will turn out as follows:

	Sig.	Gr.	I	II
True place of the Sun	6	15	12	18
Equated anomaly of the Moon [Anomalia ☾ aequata]	3	6	30	17
True place of the	0	15	20	7

	Sig.	Gr.	I	II
Moon				
Equated anomaly of the Moon [Anomalia Lunae aequata]	6	14	36	31
Excess beyond \odot [Excessus \odot vltra \odot]	0	0	7	49
Hourly [motion] of the ζ from \odot	0	0	33	18
Time to be subtracted [Tempus demendum]	0	0	14	6
True Full Moon [Verum Plenilunium]	H.	15	41	27
Apparent time [Tempus apparens]	H.	15	32	37
And then the corrected place of the ζ	0	15	12	18
And the equated	6	14	29	0

	Sig.	Gr.	I	II
--	------	-----	---	----

anomaly

Precept 74. To foreknow whether the Full Moon, or the New Moon, is Ecliptic.

The first method, though not so secure from some small error, is fully accomplished by Precepts 62 and 63, by which is found the argument of latitude, or the Moon's distance from the nearer Node; whether it lies farther off than the Ecliptic Limits require, or whether it lies within those limits. [Margin: Pag. 60.] For at once the terms of a possible eclipse appear, since otherwise the very Table 55 reveals immediately, by the argument with which the Moon is nearer the Node, by how much it is distant: if it lies farther off, no eclipse is possible; but if it lies within those terms, an eclipse is possible.

Example.

In the year 1661, October 7, at hour 15, 32 minutes, 37 seconds, when the true Full Moon occurred — the place of the Node Ω being correctly computed — will be at Sign 6, degree 6, 0 minutes, 29 seconds. The Moon in \square at degree 15, 12 minutes, 18 seconds, distant from the Node Ω at Sign 6, degree 9, 11 minutes, 49 seconds; therefore in the Node there will be the necessary terms of a Lunar Eclipse, since the Moon is nearly at Perigee at degree 12, 53 minutes; but the Moon is less distant from the Node.

The second method, however, is more secure: for since the apparent semidiameter of the Sun \odot , and of the terrestrial Shadow \mathfrak{U} corrected by Precept 63, the true latitude of the Moon: for if this latitude is equal, or greater than the aggregate of the semidiameters of the Sun \odot and of the Shadow, there will be no eclipse; if less, some eclipse will occur.

Example.

In the year 1661, October 7, at hour 15, 32 minutes, 37 seconds, after midday at Bologna, the Lunar conditions stand thus:

	Sig.	Gr.	I	II
☾ True place of the Moon	0	15	12	18
Ω True	6	6	0	29

	Sig.	Gr.	I	II
place of the Node				
Argument of latitude [Argumentum latitudinis]	6	9	11	48
Distance from the Node \wp [Dist. ab \wp]	0	0	0	0
Maximum latitude [Latitudo Maxima]	0	4	58	30
True latitude of the Moon [Latitudo Vera Lunae]	0	0	47	40
Equated anomaly ζ [Anomalia ζ aequata]	6	14	29	0
Anomaly of the Sun [Anomalia Solis]	3	6	30	18
Semidiameter of the Shadow [Semidiameter Vmbra]	0	0	48	30
Variation to be	0	0	0	44

	Sig.	Gr.	I	II
subtracted [Variatio auferenda]				
Corrected semidiameter of the Shadow [Semidiam. Vmbra correcta]	0	0	47	46
Apparent semidiameter [Semidiam. ☉ appar.]	0	0	16	8
Aggregate of the semidiameters [Aggregatum semidiametrorum]	0	0	63	54

The true latitude of the Moon is therefore much less than the aggregate of the semidiameters of the Sun ☉; and so a Lunar Eclipse will necessarily occur.

Precept 75. To define the digits of a Lunar Eclipse, or its quantity.

Since the disc of the luminaries is commonly reckoned in its apparent diameter at a magnitude of one foot, and the foot, in the Roman manner, is divided into 12 inches [uncias], or eclipse digits one finger thick...

therefore the quantity by which the Lunar disc is to be eclipsed by the Solar [Shadow] is usually expressed in digits, and twentieth parts of a digit. This is defined as follows. Subtract the true latitude of the Moon from the aggregate of the semidiameters of the Moon and of the Shadow corrected; for the remainder will give the deficient scruples; then by doubling the apparent semidiameter of the Moon, and finding the deficient scruples opposite in the front of Table 57; and

opposite them in the left-hand side, you will have the Eclipse Digits with their scruples.

Example.

In the preceding Full Moon, the semidiameter of the Moon was 16 minutes, 8 seconds. Therefore the diameter is 32 minutes, 16 seconds. And the aggregate of the semidiameters of the Moon and of the Shadow corrected is 63 minutes, 54 seconds; the true latitude of the Moon, which was likewise 47 minutes, 40 seconds. There remain the deficient scruples 16 minutes, 14 seconds, which quantity in Table 57 under the diameter 32 minutes, 16 seconds, with the proportional part applied, finds the Eclipse Digits 6 minutes, 5 seconds; that is, this eclipse will be partial, or of 6 digits, and 5 minutes. But if the Digit were 12, it would be a Total Eclipse without scruples; or if more than 12, total with delay [cum mora].

Precept 76. To determine the scruples of incidence of a Lunar Eclipse, or of its very beginning and end; and indeed the delay in shadow, if it is total with delay.

Astronomers call the scruples of incidence those [scruples] of the zodiac, or of the Lunar orbit, which the Moon traverses from the beginning of the Eclipse, until the middle; and the scruples of repletion [Repletionis], which it runs through from the middle to the end. And the scruples of half-delay [Mora dimidia], which the Moon completes from the moment of total obscuration up to the same.

The scruples of incidence of a partial Eclipse you will find its duration thus: take in the front of Table 59 the sum of the semidiameters of the Moon and of the Shadow corrected, and opposite the true latitude of the Moon, which is in the left-hand side, you will have the scruples of incidence. Then repeat, as above, find the equated anomaly of the Moon, and by the hourly motion of the Moon from the Sun, divide by this; more finely, however, you will do it, if the resolved one hour into 60 [parts], you multiply by these the scruples of incidence; and the product divided by the hourly motion of the Moon, the half-scruples of the hour, the moment of the Full Moon subtracted will give the beginning of the Eclipse, and added the end.

Example.

In the preceding Full Moon, the sum of the semidiameters of the Moon and of the Shadow corrected was found to be 63 minutes, 54 seconds; and the true latitude

47 minutes, 40 seconds; opposite which, in Table 59 under the sum 63 minutes, 54 seconds, the scruples of incidence are found, with the proportional part, the scruples of incidence 42 minutes, 32 seconds. The hourly motion of the Moon was found above to be 33 minutes, 18 seconds. Resolving this therefore into seconds [the minutes into seconds], the hourly motion is in seconds 1998; and the incidence in seconds 1552 1/2, which, drawn through the hour of one minute 60, gives the second of an hour 1998, and the incidence 1552 1/2; here divide for the time of one minute 60; relinquishing the hour of an hour 76 2/3, that is, hour 1, 16 minutes, 39 seconds, which from the Full Moon's Ecliptic moment, namely hour 15, 32 minutes, 37 seconds subtracted, and afterwards added, and at last aggregated, give the Eclipse's Beginning, and End, as below.

	Post Meridiem at Bologna		
	H.	I	II
In \circ of the Orbit [In \circ Orbitae]			
Beginning of the Eclipse [Initium Eclipsis]	14	15	58
Middle [Medium]	15	32	37
End [Finis]	16	49	16
Total duration [Duratio tota]	2	33	18

A Total Eclipse, however, with delay [cum Mora], is to be reckoned thus: First, find as above the scruples of incidence, which in this case comprehend also the half of the delay; and so [Margin: Pag. 68.] Table 59 has the title: *Scruples of incidence, and half-delay in the Eclipse \odot and U , and by it the hourly [motion] divide, as above.*

**

Secondly, subtract the semidiameter of the Moon, from the semidiameter of the Shadow, and from their remainder, which is in the front of Table 58, [Margin: Pag. 67.] whose title is: *Scruples of incidence in the Eclipse \odot and U , and half-delay in the Eclipse;* for from the region of the true latitude of the Moon, in the left-hand side, find the scruples of half-delay, dividing by the hourly motion of the Moon;

and let there proceed the time to be subtracted from the moment of the Ecliptic Full Moon; and you will have the beginning of total obscuration; but adding, in order that you may have the beginning from the emersion from the Earth's Shadow.

Monitions for a more subtle calculation of a Lunar Eclipse.

Firstly, the controversy is not yet decided, whether the moment of the Full Moon is when the Moon in its orbit is precisely 180 degrees distant from the Sun; or that, when the place of the Moon reduced to the Ecliptic is likewise 180 degrees distant from the Sun; or whether, when the center of the Moon, and the center of the Shadow are equally distant from the nearer Node: which thing Kepler advised in the *Rudolphine* [Tables] toward the end of Precept 155. Neglecting this, however, if the Full Moon, such as we have computed thus far in its orbit, we wish to reduce to the Ecliptic, by Precept 64; then if the reduction were of the addition, that scruple, divided by the hourly [motion], is to be subtracted from the moment of the Full Moon; but if of the subtraction, to be added; the foresaid scruple subtracted.

For example, in the Full Moon of Precept 73, the place of the Moon was in its orbit at Sign 0, degree 15, 12 minutes, 18 seconds. The argument of latitude, however, was Sign 6, degree 9 etc. Therefore the reduction to be subtracted [reductio subtractiua] is 2 minutes, 10 seconds; and the Ecliptic place is Sign 0, degree 15, 10 minutes, 8 seconds. The hourly [motion] was 33 minutes, 18 seconds; from each minute 2 minutes, 10 seconds; for the minutes of time 2 minutes, 10 seconds; which added to the hour 15, 32 minutes, 37 seconds gives the minutes of time 3 minutes, 11 seconds; which added to hour 15, 32 minutes, 37 seconds. The Ecliptic Full Moon by this reckoning gives the hour 15, 35 minutes, 58 seconds; from which the others at the beginning, and the end of the moment are to be estimated, and limited, if they were [the truer ones]:

In \circ	Respect to the Ecliptic [Respectu Eclipticae]		
	H.	I	II
Beginning [Initium]	14	19	19
Middle [Medium]	15	35	58

	Respect to the Ecliptic [Respectu Eclipticae]		
In \circ	<hr/>		
End [Finis]	16	52	37

Secondly, the student keen on astronomical subtlety is to be warned, of what is more fully explained in Book 5 of the *Almagestum Novum* in the Scholium of Chapter 6, namely that the moment of the Ecliptic Full Moon, and especially of the greatest obscuration, are not the same; which difference, though perhaps it may attain to 6 minutes of an hour, can be contemned. Moreover, when there happens the greatest obscuration, when the Moon's place in its orbit is exactly distant from the Sun 180 degrees; because then the arc drawn to the Moon's orbit at right angles to the Ecliptic point, in which is the center of the Shadow, is shorter than the arc drawn from the Moon's center at right angles to the Ecliptic point, in which is the center of the Shadow, as is there demonstrated; in which second case, if the Ecliptic Full Moon were already reduced to its orbit and to the Ecliptic, in which this difference may first be noted in the monition, it will have together the difference of the Ecliptic Full Moon, and the moment of the greatest obscuration. As in our example the greatest obscuration of the digits is 5, attains the hour 15, 32 minutes, 37 seconds. But the Ecliptic Full Moon from the Eclipse, and the phases of that Eclipse are not only denominated from the Eclipse thus, attains the hour 15, 35 minutes, 58 seconds.

Precept 77. To determine the true latitude of the Moon at the beginning, and end; and the Eclipse.

By Precept 58 find the hourly motion of the Sun, and by it the scruples of incidence found in Precept 76, and you will have the true motion of the Sun congruent to the time of the half of the duration, to which add the scruples of incidence, and of delay; subtract the argument of latitude to the middle of the Eclipse; and there will proceed the argument of latitude to the beginning of the Eclipse; but if to the same argument you add the foresaid sum, you will have the argument of latitude to the end.

Example.

In the preceding Full Moon the hourly motion of the Sun was 2 minutes, 29 seconds; therefore the motion of the half of the duration of the Eclipse congruent, namely for hour 1, 16 minutes, 39 seconds, was 3 minutes, 6 seconds. The

scruples of incidence by Precept 76 found were 42 minutes, 32 seconds; to which adding 3 minutes, 6 seconds, the sum is 45 minutes, 39 seconds. [Margin: Pag. 51.] The argument of latitude to the middle of the Eclipse was Sign 6, degree 8, 26 minutes, 9 seconds; from this subtracting the sum 45 minutes, 39 seconds, the argument of latitude for the beginning of the Eclipse is Sign 6, degree 8, 26 minutes, 9 seconds [recte: see source]; which in Table 44 fits the southern latitude 43 minutes, 43 seconds; for the beginning of the Eclipse; but to the same argument of latitude to the middle, in latitude the argument of latitude Sign 6, degree 9, 57 minutes, 27 seconds, for the end of the Eclipse; to which fits the southern latitude 51 minutes, 31 seconds. Therefore the latitudes of the Moon are to be noted, and below always southern.

		True Latitude ⊙ [Latitudo Vera ⊙]	
		I	II
In Eclipse [In Eclipsi]			
Beginning [Initio]	A	43	43
Middle [Medio]	A	47	40
End [Fine]	A	51	31

Precept 78. To delineate the diagram of a Lunar Eclipse.

The true latitude of the Moon being known, and its species, by Precept 77, the diagram of the Lunar Eclipse is easily designed graphically, together with the inclination to the regions of the Horizon, by the rules which we have fully handed down in Book 5 of the *Almagestum Novum*, Chapter 7. Therefore the diagram of the preceding Eclipse will be as written below.

Diagram. A geometric construction of the lunar eclipse, showing three overlapping circles: a large central circle (the terrestrial Shadow) and the smaller circles representing the Moon at the beginning and end of the eclipse, with cardinal directions marked around the figure and a path-line traced through the centers.

- Bor. (top): North [Boreas]
- Austr. (bottom): South [Auster]
- Or. (left): East [Oriens]
- O. Occ. (right): West [Occidens]

- L, D, M (upper inner region): construction points along the Moon's path
- K, C, A, E, H, B (middle row, left to right): construction points; A at the center is the center of the Shadow
- I, F, G (lower inner region): construction points
- P (far left): construction point on the East line

Let the center of the Shadow be A, its semidiameter AF; let the disc of the terrestrial Shadow be FCDE. The Moon's latitude in the middle of the Eclipse is AF, but at the beginning GH, and at the end IK; the region in which the Eclipse begins is L, designated by the line GAL; and the region in which the end terminates is M, designated by the line IAM; the inclination to the beginning is the angle GAO, and to the end the angle IAP.

Corollary against Argoli.

[Margin: Argol's error.]

Argoli, therefore, or his disciples, perpetually represented this Lunar Eclipse of the year 1661, October 7, depicted by us, with northern latitude, when it is always southern; so that I say nothing of the Eclipse's time anticipated by them by about forty minutes.

Precept 79. To reduce the apparent time of the Eclipse to equal [time].

To convert apparent time into equal, and vice versa equal into apparent, I have already taught in Precept 16; and I have already used this in the Example of the Ecliptic Full Moon of Precept 73.

Precept 80. To survey the regions of the Earth's orb, in which the Lunar Eclipse will be visible, or not.

This is accomplished not without facility, and pleasantness, by means of the *Geographical Cross* [Crucem Geographicam], which we formerly inserted in Book 10 of the *Geographia Reformata*; thither, therefore, we refer the reader for a fuller note; here it suffices to say in brief, that wherever there appears, by the instrument, at once the place of the Eclipse, and so far as it can be seen, or it could appear with the phases of the Eclipse; and on the contrary, wherever at that time there is day, and where the Earth those phases cannot be seen; it can nevertheless, especially by benefit of refractions, be seen, even a little before sunset, and a little after sunrise of the Sun, be observed.

But if, regarding some particular place of the Earth, you are anxious — for example, regarding *Lima*, City of the Kings in Peru — collect from the Catalogue, [Margin: Pag. 9.] or Table 14, the difference of time, to be subtracted for the eastern [places], or to be added for the western, with respect to Bologna; and transfer that time from midday; then from Table 11 take out the semidiurnal, and the seminocturnal time, by means of the place of the Sun, namely with the Hours, and Scruples after midday written down, at beginning, middle, and end of the Eclipse, provided they do not exceed the aggregate of the semidiurnal, and nocturnal time, the Night will be in that place, and that phase of the Eclipse there will be visible; otherwise it will be day, and not visible, except in the confines of those very [times]/days.

Example for Lima.

Difference of time of Lima [Lima Differentia Temporis] To be subtracted from Bologna time [Subtrahenda Bonon. tempori]	H.	6	11'
Southern altitude of the Pole [Poli Altitudo Austrina]	Gr.	12	20'
☉ Place $\hat{=}$ [☉ Locus □]	Gr.	15	12'
Semidiurnal time [Semidiurnum tempus]	H.	5	55
Seminocturnal	H.	6	5

[Seminocturnum]			
Nocturnal	H.	12	10
[Nocturnum]			
Beginning	H. / H.	14 / 8	15" / 4 — 58" / 58
{Bologna / Lima}			
[Initium]			
Eclipse — Middle	H. / H.	15 / 9	32 / 21 — 37 / 37
{Bologna / Lima}			
[Medium]			
End {Bologna / Lima} [Finis]	H. / H.	16 / 10	49 / 38 — 16 / 16

Parsing notes: The "Eclipse" group brackets three rows (Initium, Medium, Finis), each split into a Bologna value and a Lima value; the columns are Hours / minutes / seconds. Beginning: Bologna H. 14, 15', 58" / Lima H. 8, 4, 58. Middle: Bologna H. 15, 32, 37 / Lima H. 9, 21, 37. End: Bologna H. 16, 49, 16 / Lima H. 10, 38, 16. Some seconds-column values are tight against the gutter; read with moderate confidence.

Since therefore at the beginning as well as at the end, the time after midday at Lima exceeds the quantity of the semidiurnal time, and does not exceed the aggregate of the semidiurnal, and nocturnal [time], which is of hours 16, 5 minutes, the whole Lunar Eclipse will be visible at Lima at this time.

Precept 81. To find in whose Meridian the future Moon will be at the highest of the Eclipse; and for whom it will be Vertical.

First inquire whether the Moon at the time of the Ecliptic Full Moon is in the eastern Hemisphere, if too much before mid-night following [it]; or in the western, namely as it would happen, if the Ecliptic Full Moon were after the hours 12 after midday, and reckoned the [hours] after midday; then if it is in the East, subtract the apparent time of the Full Moon from 12; but if it is in the West, subtract the apparent time of the Full Moon from the hours 12; and convert the remainder into degrees of the Equator; for the quantity of these will show the

distance of the Meridian, in which the Moon is at the highest of the Eclipse from the Meridian of the Tables toward the East in the first case, or toward the West in the second case. Thirdly, with the true latitude, and the place of the Moon in the Ecliptic, inquire by Precept 54 the Declination of the Moon, as great as it will be, so great the altitude of the Pole of that place, for which in the foresaid Meridian the Moon will be Vertical at the highest of the Eclipse.

Praecepta pro usu Tabularum (continued)

Example.

The eclipsed full moon discussed above, in the Example of Precepts 73 and 74, fell at 15 hours 32 minutes 37 seconds after noon at Bologna. The Moon, therefore, with respect to the Bologna meridian, lay in the western hemisphere. Subtracting these 12 hours leaves 3 hours 32 minutes 37 seconds — that is, 53 degrees 9 minutes 15 seconds — and this is the amount by which the meridian sought differs westward from the Bologna meridian.

Furthermore, the Moon at that time stood in Aries at 15 degrees 12 minutes, whose northern declination is 6 degrees 6 minutes 6 seconds. And the Moon's southern latitude was 47 degrees 40 minutes, to which in Table 34 corresponds equation 42 [?]. Subtracting the northern declination [from this] leaves the Moon's declination as 5 degrees 18 minutes. Therefore that place — namely, the one whose meridian lies as stated, and which has the northern pole-altitude of 5 degrees 18 minutes — will have the Moon standing vertically overhead at the eclipse-maximum.

Consulting cosmographical maps, then, you will find that place: its longitude from the island of Palma is 341 degrees 20 minutes 45 seconds, and its northern latitude is 5 degrees 18 minutes.

Recapitulation of the Entire Foregoing Calculation of the Eclipsed Full Moon.

In the year 1661, October 7, at Bologna, 15 hours 41 minutes 27 seconds after noon in equal time, but 15 hours 32 minutes 37 seconds in apparent time.

eclipsed full moon with respect to the place of the eclipse				
Longitude of the meridian on which [the Moon stands] at mid-eclipse	G. 341		20	45
Pole- altitude of the place on the said meridian where the Moon will be vertical, at the eclipse- maximum	5	18	Bor.	

Parsing notes: in the "Longitude of the meridian" row the source prints "G. 341" running across the Sig./Gr. columns; rendered here as the whole-degree value 341 in the Sig. column with the minutes/seconds (20' 45") following. The "True place of the Sun" / "True place of the Moon in its orbit" rows share identical I-II values (12 18) as printed.

Precept 82. To know beforehand the order to be observed in the recapitulation of a solar eclipse.

It is indeed desirable to think ahead about by what route you will at last accomplish so laborious a calculation, and through what steps you must climb to the desired end. Therefore the items to be sought are listed below in order, and these are:

To be sought	by Precept
The mean new moon	72
The true new moon	74
Or, by Precepts 55, 61, 66 together	67
The apparent time of the true new moon	55, 61
The true place of the luminaries	55, 61
The equated anomaly of the luminaries	55, 61
The right ascension of the Sun	46
The parts of the equator corresponding to the time	11
The right ascension of mid-heaven; and hence	50
The oblique ascension of the ascending degree, and the ascending degree itself	—
The ecliptic degree of the ascendant	—
The ninetieth ecliptic degree counted from the ascendant	50
The altitude of the ninetieth [degree]	51
The node Ω ϑ northern, of the heavens; and hence	62
The altitude of the ninetieth [degree] in the Moon's orbit	—
The horizontal parallax of longitude at conjunction	58
The parallax of the Moon from the Sun in altitude	84
The parallax δ in longitude	85
The parallax of the Moon in latitude	86

To be sought	by Precept
The parallax δ in longitude for one hour or another before [conjunction], and for the hours before or after	87
The apparent motion of the Moon for one hour or another	88
The apparent new moon	89
The parallax δ in longitude at the moment of the apparent new moon, and for the hours before or after	90
The true latitude, and the latitude seen at the time of the apparent new moon	91
The digits of the solar eclipse	92
The beginning, the end, and the duration of the solar eclipse	93
The true latitude δ at the beginning and end of the eclipse	94
The delineation [diagram] of the solar eclipse	95

Up to this point, the New Astronomy advances, and as a new promontory it has carried forward this inquiry to the principal phases of a solar eclipse remarkable in various regions; but chiefly in those regions in which a total or central eclipse will be seen — concerning which, see below.

Parsing notes: the right-hand column heads "per Praec." (by Precept); several rows where the source gives no number are left blank ("—"). Rows for "True place of the luminaries," "Equated anomaly of the luminaries," "Apparent time" each show "55 61" as a paired reference.

Example.

The eclipsed new moon of the year 1659, November 14, at 3 hours 30 minutes after noon, in equal time at Bologna.

	Sig.	Gr.	I	II
True place of the Sun	7	22	11	58
Equated anomaly of the Sun	4	13	32	0
True place of the Moon	7	22	20	40
Equated anomaly)	4	8	53	0
Hourly motion) from ☉			31	57
Excess of the place [of the Moon] beyond ☉			8	42
Time corresponding to this			16	10
Therefore the truer new moon, October [recte: November] 14, p.m.	Hor.	3	13	50

Then, with the calculation re-established:

	Sig.	Gr.	I	II
True place of the Sun	7	22	11	18
Anomaly of the Sun	4	13	31	20

	Sig.	Gr.	I	II
True place of the Moon	7	22	11	16
Equated anomaly ☽	4	8	43	39
Hourly motion ☽ from ☉			31	56
The [Moon] falls short of the [Sun's] place by Time correspond ing to this				2 3
True new moon, October [recte: November] 14	H.	3	13	53
Equation of days to be added			13	55
True apparent time of conjunction ☉ ☽	H.	3	26	48

And so the true and exact new moon at Bologna will be in the year 1659, November 14, at 3 hours 26 minutes 48 seconds in apparent time after noon, the luminaries being corrected, in Scorpio at 22 degrees 11 minutes 18 seconds.

Parsing notes: the running header refers to "October 14" in two rows although the example is dated November 14; transcribed verbatim and flagged as a compositor slip ([recte: November]).

Precept 83. To find the altitude of the ninetieth [degree] in the Moon's orbit, and the ninetieth itself, by the foregoing precepts.

First, by Precept 46, look up the right ascension of the place of the Sun; by Precept 50, the ascending ecliptic degree, and from it the ninetieth computed; and by Precept 51, the altitude of the ninetieth. Then [find] the place of the lunar node Ω by Precept 62, which you subtract from the ninetieth, and with the remainder feign [an argument] as though it were the argument...

of latitude, look up in Table 44 the latitude — the latitude to be added to the altitude of the ninetieth if the latitude is northern, and to be subtracted if southern — for thus you will obtain the altitude of the ninetieth in the Moon's orbit.

Example in the preceding new moon.

	Sig.	Gr.	I	II
True place of the Sun	7	22	11	18
Right ascension of the Sun		229	34	23
Time from the meridian, apparent	H.	3	26	48
Parts of the equator		51	42	0
Right ascension of the culminating point, with 90 added, becomes		281	16	23

	Sig.	Gr.	I	II
Oblique ascension of the ascendant		11	16	23
Pole- altitude of Bologna		44	30	20
The ascendant [□]	□	21	4	0
Therefore the ninetieth [□]	□	21	4	0
And the altitude of the ninetieth		23	50	0
Node ♁ ☿ true place	7	12	43	55
Feigned argument of latitude	2	8	20	5
And the northern latitude		4	37	22
Altitude of the ninetieth in the Moon's orbit		28	27	22

[Margin: Pag. 51 (referring to Table 44 / Precept 46 on p. 51)]

Precept 84. To find the horizontal parallax of the Moon from the Sun.

With the equated anomaly of the Sun and of the Moon, look up in Table 39 the horizontal parallax of each of the two luminaries; then, subtracting the solar parallax from the lunar, there will remain the horizontal parallax \curvearrowright from the Sun.

[Margin: Pag. 47]

Example in the preceding new moon.

	Sig.	Gr.	I	II
Equated anomaly \odot	4	8	43	39
Equated anomaly \curvearrowright	4	13	31	20
Parallax horizontal \curvearrowright			57	51½
Parallax horizontal \odot				1½
Parallax horizontal \curvearrowright from \odot			57	50½

Precept 85. To investigate the parallax of the Moon in longitude.

Consult Table 56, whose title is *Parallax Mecoplatica* [the parallax brought to the ecliptic plane], and at its front look up the horizontal parallax of the Moon from the Sun (calculated by Precept 84); and in the right-hand side, whose title is *Latus Longitudinis* [the side of longitude], [look up] the altitude of the ninetieth in the Moon's orbit (foreknown by Precept 83); for in the common area you will find the horizontal parallax of longitude \curvearrowright , which would be the one to use if the Moon were on the horizon itself. But when [the Moon] is above the horizon, look up its distance from the ninetieth by subtracting the smaller from the greater, and with this [distance] in that same Table 56's right-hand side, but at the front with the horizontal parallax of longitude \curvearrowright , you will find in the common area the absolute and exact parallax of longitude \curvearrowright .

[Margin: Pag. 61]

Example in the preceding new moon.

	Sig.	Gr.	I	II
Altitude of the ninetieth in the orbit		28	27	22
Parallax horizontal ☽ from the Sun			57	50
Parallax horizontal of longitude			27	33
True place of the Moon	7	22	11	18
Ninetieth [□]	□	21	4	0
Distance ☽ from the ninetieth		58	52	42
Parallax of longitude			23	35

Precept 86. To inquire into the parallax of the Moon in latitude.

In the Table of Parallax Mecoplatica, which is Table 56, look up at the front the parallax of the Moon from the Sun, taken from Precept 84; and in the left-hand side, whose title is *Latus Latitudinis* [the side of latitude], [look up] the altitude of the ninetieth in the Moon's orbit found by Precept 83; and the common area, with the help of the proportional parts, will at once furnish you the parallax of latitude.

[Margin: Pag. 61]

Example, of which above.

	Gr.	I	II
Altitude of the	28	27	22

Gr.	I	II
ninetieth in the orbit		
Parallax \bowtie from \odot , horizontal	57	50
Parallax of latitude	50	28

Precept 87. To investigate the parallax of the Moon in longitude for one hour or another before or after the true new moon.

This precept is necessary so that we may apply the apparent hourly motion of the Moon, and so set the beginning and end of the solar eclipse. First, then, [take] from the degrees of the oblique ascension of the ascending point at the moment of the true new moon, for each of the hours before the true new moon, subtract fifteen degrees per hour, for from these afterwards the ascending point will go forth; that is, the ascending ecliptic point at that time before, or after the new moon assumed — for which look up again, by Precept 83, the ascendant and the ninetieth, and the altitude of the ninetieth in the Moon's orbit.

Second, with the horizontal parallax of the Sun retained as found above (since this, within a few hours, does not vary perceptibly), with the anomaly of the Moon at the time assumed before, or after the conjunction equated, look up the horizontal parallax \bowtie from the Sun by Precept 84, and by Precept 85 the parallax of longitude, but the horizontal one only.

Third, in place of the Moon (which at the moment of the true new moon, for the individual hours before the true new moon assumed, you subtract its hourly motion \bowtie from the Sun by as many times as there are hours before; but for the hours after, add), and there will emerge the true place of the Moon at the time assumed before, or after the new moon.

Fourth, with the true distance of this place of the Moon from the ninetieth, and with the absolute horizontal parallax of longitude, by Precept 85, look up the parallax of longitude \bowtie for the hour before, or after the true new moon chosen. For the most part, however, only one hour before, or after, is assumed, especially if the Moon is in the eastern ecliptic quadrant; but afterwards if it is in the western. Because, therefore, in the preceding new moon the Moon is in the

western [quadrant], we shall take the hour one [hour] after the new moon. But we shall look up the parallax δ in longitude...

Example for hour 1 after the true new moon, of which above.

There was above	Sig.	Gr.	I	II
Oblique ascension of the ascendant	0	11	16	23
With added	0	15	0	0
The oblique ascension of the ascendant becomes		26	16	23
And the other ascendant []	[]	15	48	0
Therefore the ninetieth []	[]	15	48	0
And the altitude of the ninetieth		26	50	0
Node Ω place as above	7	12	43	55
Argument of latitude	2	2	54	5
Northern latitude		4	25	34
Altitude of the		31	15	34

There was above	Sig.	Gr.	I	II
ninetieth in the orbit)				
Parallax horizontal) from ☉, as above			57	50
Parallax of longitude, horizontal			30	0
True place of the Moon at the true new moon	7	22	11	18
	Sig.	Gr.	I	II
Hourly [motion]) to be added			31	56
Place of the Moon for the hour after the new moon	7	22	43	14
Distance of this place from the ninetieth		83	4	46
Therefore the parallax of longitude			29	49

Precept 88. To define the apparent motion of the Moon for one hour or another.

First, with the parallax of longitude μ found for the beginning and end of the hour assumed by Precept 87, subtract the smaller parallax from the greater. You should also have the true hourly [motion] at the time of the new moon.

Second, if for the whole assumed time of the hour [the Moon] remained in the eastern zodiacal quadrant, and at the beginning of the hour the assumed parallax was greater, but at the end smaller, subtract the difference [of] the parallax from the hourly motion μ , and you will have the apparent motion for that hour. But if the Moon remained for that whole time in the western quadrant, and the parallax was greater at the beginning of the hour but smaller at the end, add the difference of the parallax to the hourly motion μ , and there will result the apparent motion for that hour. But if [the parallax was] smaller at the beginning of the hour and greater at the end, subtract, and the apparent motion μ will come out — these things agreeing with what was said above at the end of Precept 82.

Third, if within that hour [the Moon] is partly in the eastern, partly in the western [quadrant], in each part [the parallax], that is, the aggregate of the parallaxes from the beginning to the ninetieth, subtract from the hourly motion μ ; but the [parallax] found from the ninetieth to the end, add to that hour; for thus the apparent motion for that hour is to be made — against Reinhold. To this matter Maginus [Magini] and Lansbergius [Lansberge] bear witness; and by example Lord Vincentius Rainerus [Vincenzo Renieri] has demonstrated it in the recently printed *Tabulae Mediceae* [Medicean Tables], page 289.

Example.

In the preceding new moon the Moon remained in the eastern quadrant, both at the moment of the new moon and at the beginning of the hour one before the new moon; therefore we shall proceed thus in the calculation:

	I	II
Parallax of longitude at the new moon	23	35
Parallax of longitude, hour 1 after	29	49
Difference of the parallaxes	6	14
True hourly [motion] μ	31	56

	I	II
Therefore the apparent motion ∽ for that hour	25	42

Precept 89. To define the moment of the apparent new moon.

First, if the Moon was in the eastern quadrant, look up its apparent motion for one hour before the true new moon by Precept 88; and if the scruples of the parallax of longitude at the time of the true conjunction were greater, divide them by the scruples of the parallax: for as often as you do so, it will give the time to be subtracted from the apparent time of the true new moon, so that the apparent time of the new moon, or of the seen conjunction, emerges.

Second, if the Moon was in the western quadrant, [take] its apparent motion by Precept 88 for one hour after the true new moon; and if the scruples of the parallax of longitude of the true new moon were greater, divide by that the time to be added to the apparent time of the true conjunction, so that the moment of the seen conjunction may be made.

Third, if the apparent hourly motion was smaller than the parallax of longitude found at the moment of the true new moon, subtract the parallax from the apparent hourly motion, and set aside the residual parallax. Then, by Precept 88, inquire further into the motion of the Moon due for the other hour before [the new moon] if it was in the eastern quadrant, after if in the western, and for that hour set aside the residual of the apparent motion of the Moon. With the parallax, as often as it is added to that hour, it will give the time to be subtracted from the apparent time of the true conjunction, if...

the Moon is in the eastern quadrant, [and] to be added if it is in the western, so that at last the moment of the seen conjunction may be had.

Finally, if the Moon is at the ninetieth itself, the true and the seen conjunction coincide.

Example.

In the preceding new moon, because the Moon is in the western quadrant, and the apparent hourly motion ∽ is sought, the parallax is found at hour 1 after the true new moon as 25 minutes 42 seconds. But the parallax of longitude at the moment of the true new moon was found to be 23 minutes 35 seconds. Therefore the hourly motion is greater than this parallax. Say, then: if 25 minutes 42

seconds — for hour 1, or 60 minutes — require how many minutes, and a second require 23 minutes 35 seconds; the answer comes out, by the Golden Rule, 1542 [?]. Resolving these three numbers in the series by the Golden Rule, the first second comes out 1542, the second 2604 [?], the third 1416 [?]; led therefore for the second per the third, and the sum divided per the first, the fourth number comes out proportional 2304 [?]: that is, 55 minutes 4 seconds; this one [hour] added to the apparent time of the true new moon, namely as stated above at the end of Precept 82. At hour 3, 26 minutes 48 seconds, the time of the seen conjunction of November 14 is made, [namely] hour 4, 21 minutes 52 seconds.

Parsing notes: the arithmetic in this paragraph (the Golden Rule / rule-of-three worked example, numbers 1542, 2604, 1416, 2304) is set in continuous prose; the digit strings are flagged [?] where the small type and the cramped fractions make individual figures uncertain. The result "4^h 21' 52''"¹ is legible.

Precept 90. To investigate the parallaxes of longitude of the Moon for the moment of the seen conjunction with the parallax of longitude, both for the moment and for the hours before or after.

So that the apparent hourly motion may be had — the hour 1 before and after the seen conjunction — there is need of the parallax of longitude for the hour 1 before and after. First, then, [take] the difference of time between the true and the seen conjunction, convert it into parts of the equator, and subtract these from the oblique ascension of the ascending degree at the time of the seen conjunction (add if [the Moon] is in the eastern quadrant; if in the western [subtract]), so that the oblique ascension of the ascending point at the time of the seen conjunction may emerge. Then look up, by Precept 87, the parallaxes of longitude at the time of the seen conjunction, both for one hour [before] and for one hour after the seen conjunction.

Furthermore, you should have the place of the Moon at the time of the apparent new moon, and thence the distance of the Moon from the ninetieth; and from there inquire into the parallaxes, as the interval of time between the true and seen conjunction directs, and produce [it] divided by 60. And the quotient subtracted from the place of the Moon at the true time of conjunction — if the Moon is in the eastern quadrant, add; in the western, subtract. But if hour 1 before, or the seen conjunction, the Moon stood off from the ninetieth by more than 90 degrees [the ascendant?], it will be below the horizon, and then the parallax is sought in vain.

Example.

In the preceding new moon, by Precept 89, the interval of the true and seen conjunction was 45 minutes 45 seconds, with which you will operate thus:

	Sig.	Gr.	I	II
Interval of ☉ ☽ true from seen			55	4
Whose parts of the equator		13	46	0
Oblique ascension of the ascendant in the true [conjunction]		11	16	23
Oblique ascension of the ascendant in the seen [conjunction]				5
Ascending ecliptic point [☉]	☐	25	2	23
Ninetieth from this [☉]	☐	13	57	0
Altitude of the ninetieth		31	57	0
Node ♁ place as above	7	12	43	55
Argument	3	1	13	5

	Sig.	Gr.	I	II
of latitude				
Northern latitude, to be added		4	58	24
Altitude of the ninetieth in the orbit)		30	50	24
Parallax) from ☉ in another horizon			57	50
Parallax of longitude, horizontal			29	49
Hourly motion, internal due			20	42
Place) true in the seen new moon	7	22	47	30
Distance) from the ninetieth		81	15	30
Parallax of longitude			25	30
And parallax of latitude			49	29

Parsing notes: the "Interval of ☉) true from seen" row prints 55' 4" in the I-II columns although the prose names the interval as 45' 45" — transcribed as printed; flagged below. In the second row the printed value "13 46 0" appears to

be the equator-parts of the interval. The "Oblique ascension ... in the seen [conjunction]" row shows only a single figure (5) in the II column as printed.

(continuing Precept 90, the parallaxes for one hour before and after the seen conjunction)

Now for one hour before the seen conjunction: subtract 15° from the oblique ascension of the seen conjunction's ascending point — which was $25^\circ 2' 23''$ — and what remains is the oblique ascension of the ascending point at one hour before the seen conjunction, namely $10^\circ 2' 23''$. From this the rest of the calculation follows.

	Sig.	Gr.	'	"
Oblique ascension of the ascending point [Ascensio Obliq. Puncti Ascend.]	0	10	2	23

from the ninetieth [Distantia › à Nonagesim o]				
Parallax of longitude, sought in vain — for the Moon is now below the horizon, yet it is greater than [Parallaxis Longitudini s frustra quaesita; nam › iam infra Horizonte m, est tamen maior, quàm]			57	50

[Precept 91 heading:] **Precept 91. To find the true and seen latitude of the Moon at the time of the new moon [Latitudinem Lunae Veram, & Visam ad tempus Nouilunij Visi inuenire].**

First, by Precept 63, find the true argument of latitude for the moment of the true new moon, and subtract its parallax of longitude for the moment, found by Precept 90, if the Moon is in the eastern part [of the sky]; or add it if in the western part. Thus you will obtain the true argument of latitude for the time of the seen conjunction; and with this argument, by the same Precept 63, find the true latitude.

Second, compare the parallax of latitude found for the moment of the seen conjunction (Precept 90) with the true latitude. If the true latitude is northern toward us, add to it the parallax of latitude, and the sum is the seen northern latitude toward us. If the true latitude is southern toward us, and the parallax of latitude is greater, subtract this [latitude] from it, and what remains is the seen latitude, still northern. But if the parallax of latitude is greater than the true latitude, the seen latitude is still northern; whereas if [the parallax of latitude is smaller], the seen latitude is southern.

From this learn what must be done in southern regions: there, if the latitude is northern, add the parallax, and the seen latitude will be northern; but if the true latitude is southern, a smaller parallax subtracted leaves a seen northern latitude; whereas a smaller parallax, subtracted from the southern latitude, leaves the seen latitude still southern.

Half-daytime [Semidiurnum tempus]	4	45	0
Beginning, in Italian [reckoning] [Initium Italicè]	22	20	0
Civil clock [Horolog. Ciuil.]	21	30	0

[Precept 94 heading:] **Precept 94. To define the seen latitude of the Moon at the beginning, and at the end of the eclipse [Latitudinem Lunae visam ad initium, finemq; Eclipsis definire].**

[Margin: Pag. 51.]

Enter Table 44, and in its columns seek the seen latitude of the Moon at mid-eclipse, found above by Precept 91; observing the latitude found in the column of greatest latitude. Observe the sign in front, and the degree in the left-hand side, if the latitude is north and the Moon is near the northern node; but if the seen latitude is southern, observe the sign at the foot and the degree on the right-hand side. But if the eclipse is near the southern node, and the latitude is north, in that case the signs are at the foot and the degrees on the right-hand side; whereas if [the latitude is] southern, the signs are in front and the degrees on the left-hand side, corresponding to the seen latitude. In this way you will have the true argument at the time of the seen conjunction; from which subtract the scruple of incidence found above by Precept 93, and the true argument at the beginning of the eclipse will remain; whereas on the contrary add to the true argument of the seen conjunction the scruple of incidence, and the true argument at the end of the eclipse will be the sum. With this argument, in the same Table 44, you will have the seen latitude at the beginning and the end of the eclipse.

[Exemplum:] **Example in the new moon near the northern node Ω**
[Exemplum in Nouilunio \curvearrowright prope Nod. Ω].

	Sig.	Gr.	'	"

Seen latitude at the beginning, north [Latitudo › visa ad initium A.]	0	0	1	3
Seen latitude at the end, north [Latitudo › visa ad finem B.]	0	0	1	52

Parsing notes: in the first row "B." denotes Borealis (north); abbreviations "A." / "B." in the last two rows likewise denote north (Borealis/Australis distinction — here both marked as north per the heading).

[Precept 95 heading:] **Precept 95. To delineate the type [figure] of the solar eclipse [Typum Solaris Eclipsis delineare].**

Repeat the seen latitude of the Moon at mid-eclipse by Precept 91, and at the beginning and end by Precept 94; and from what was said in Precept 78, On the figure of the lunar eclipse, it is easy to delineate the solar one too.

Recapitulation [Epilogue] of the foregoing calculation, from Precept 82 to 94 [Epilogismus calculi praecedentis à Praec. 82. ad 94].

In the year 1659, November 14, at 3 hours 30' after noon, at Bologna [Anno 1659. Nouembr. 14. Hora 3. 30'. post Merid. Bononiae].

Parsing notes: in the "Apparent motion \curvearrowright one hour before / one hour after" row the source gives two paired values (one for before, one for after); transcribed as printed. Several abbreviated row-labels (e.g. "Esui"/"Esto") are conjectural expansions, marked above where uncertain.

(right-hand column of page 25)

It was observed, however, through cloud as well; the beginning of this eclipse appeared at Bologna somewhat earlier [than computed], whether for physical causes, or because of the Moon's occultation [hiding] of the Sun still in motion — by which the beginning is anticipated in eclipses — or because of the parallax of longitude varying continuously in the eclipses, but not uniformly.

Thus far we have pursued the calculation of the older astronomy, accurate though not so absolute as is now customary [Hactenus Calculum Astronomiae Vetustae, quamuis non adeo accurate olim absoluti soliti]. The rest we shall pursue from the recent astronomy; and first,

On Horizontal Eclipses [De Eclipsibus Horizontalibus].

[Precept 96 heading:] **Precept 96. To discern the moment of time at which the Sun rises or sets [Momentum temporis, quo Sol oritur, aut occidit discernere].**

[Margin: Pag. 5.]

First, from Table 11 — extracted under the given altitude of the pole — find the semidiurnal time for the place; for the time of rising will be eastward from the meridian, the time of setting westward. Or certainly, on account of refraction, a little before the minute computed by 4. There remains the hour after noon of the preceding meridian, at which the Sun rises, by about 4', somewhat earlier on account of refraction.

[Precept 97 heading:] **Precept 97. To inquire into the true places of the luminaries at the moment of rising or setting [Vera Luminarium Loca in momento Ortus, Occasusue inquirere].**

In the preceding precept we supposed the Sun in the horizon at its very rising, or setting. But when an eclipse of the Sun is to be seen, the new moon either occurs a little before, or a little after, rising, or before the very setting; the place anticipates rising when it succeeds [follows]; therefore, when the place attains rising, it precedes; but when it attains setting, it follows.

First, then, find the difference of time between the rising of the Sun, and the new moon, or between the new moon and setting, and the mean motion conforming to such a difference of time, and that in a morning eclipse subtract from the place which the new moon held; whereas in an evening eclipse, add; and you will have the place of the Sun at the moment of rising, or setting.

Second, with the equated anomaly of the Moon, find the hourly [motion] of the Moon from the Sun, and by this multiply the predicted difference of time; what arises hence, in a morning eclipse subtract from the place of the Moon in the morning new moon, whereas in an evening one, add; this will give the place of the Moon, seen, for the moment of rising, or setting of the Sun.

[Precept 98 heading:] **Precept 98. To inquire into the parallaxes of the Moon in longitude and latitude at the moment of rising or setting [Parallaxim Lunae in longum, & latum in momento Ortus, Occasusq; inquirere].**

First, [find] the lunar motion of scruples due to the interval of time between the new moon and rising, or before setting, and the new moon's true [place]; or add the equated anomaly of the Moon to the time of the new moon, just as in the preceding precept; the same scruples being subtracted, but add these to the same place: thus, in a morning eclipse you will have the equated anomaly of the Moon for the moment of the same rising, or setting; and with the equated anomaly of the Moon, find the horizontal parallax of the Moon from the Sun by Precept 58.

[Margin: Pag. 38.]

Second, consult Table 33, [for] the altitudes of the ninetieth, and on its side with the place of the Moon at the time of rising in a morning eclipse, or at the time of setting in an evening one; and under the given altitude of the pole, find the altitude of the ninetieth. With this subtracted, [use] the place of the node as the argument, find in Table 44 the northern latitude to be added, in order that you may have the altitude of the ninetieth in the lunar orbit.

[Margin: Pag. 51.]

Third, finally, in Table 56 [find] the parallactic [reduced] horizontal parallax of the Moon from the Sun in front, and on the right-hand side the altitude of the ninetieth in the lunar orbit; for that area will give the parallax of the Moon in longitude. But under the same horizontal parallax in front, and with the altitude of the ninetieth in the lunar orbit, on the left-hand side you obtain the desired parallax of latitude.

[Margin: Pag. 61.]

Precept 99. To find the distance between the centers of the Sun and of the apparent Moon at the hour of sunrise or sunset on that same day.

First, for the Moon's true place at the time of sunrise, take the assumed equated anomaly of the Moon — if the eclipse is in the morning — but if it is in the evening, subtract that anomaly from the Moon's place. Then find the Moon's hourly motion for the interval between New Moon (or sunrise or sunset, by precept 97), and find the motion in the argument of latitude for the time of the true conjunction. If the eclipse is in the morning, add this; if in the evening, subtract it; for so you will have the argument of latitude for the said moment of sunrise or sunset.

Second, with this argument find by precept 91 the true latitude and the apparent latitude at the moment of sunrise or sunset.

[Margin: Pag. 71]

Third, gather the difference between the place of the visible Moon — that is, the true place at its rising or setting — and the place of the Sun. With this difference, enter Table 60 on the left side. In the second column on the same row, you will find the area; this common area will give the first scruples (so I call them, to distinguish them). Again, enter the same Table with the apparent latitude of the Moon on the left side, and with the second column at the top of the area; this area will give the second scruples (which are called the *Posteriora* — the later ones).

Fourth, gather the sum of the prior and later scruples, and find that sum as an area within Table 60. The minutes on the left side and the second column at the top will show you how far apart the centers of the luminaries are.

Precept 100. To investigate the digits of the eclipse at the moment of sunrise or sunset of the luminaries.

[Margin: Pag. 47]

With the anomaly of the luminaries, gather from Table 39 their apparent semidiameters. Subtract their sum from the distance between the apparent centers found by precept 99. With the remainder, and with the diameter of the Sun, find in Table 57 the digits to be obscured — that is, that remainder, taken as the deficient scruples.

[Margin: Pag. 66]

On Solar Eclipses occurring in the Subterranean Hemisphere

Precept 101. To find the semidiameter of the Earth's disk as it would be visible from the Moon.

[Margin: Pag. 47]

At the moment of New Moon, with the equated anomaly find in Table 39 the horizontal parallax of the Moon. For as large as this parallax is, just so large will the semidiameter of the Earth's disk be as seen from the Moon.

Example.

In the year 1657, on 11 June, there was an ecliptic conjunction at apparent hour 11h 11m after noon at Bologna; the Moon's equated anomaly being 11 signs, 12°, 12'. The Moon's equated anomaly came out at 74° 57' 22", and hence its horizontal parallax, and the apparent semidiameter of the Earth's disk, was 55' 35".

Precept 102. To find the altitude of the ninetieth in the region in which a central or partial solar eclipse occurs, given the conjunction of the true New Moon and that of the visible New Moon.

[Margin: Pag. 61]

Gather the latitude of the true New Moon, and find this same in the areas of the parallax-Table 56, under the semidiameter of the Earth's disk, that is, under the horizontal parallax found by the preceding precept. For since the region of latitude is on the left side of the Table, you will have the altitude of the ninetieth in that region in which the true and visible conjunction occurred at the same moment. If the latitude is northern, the ninetieth will incline to the south; but if it is southern, to the north.

Example.

In the eclipse of the preceding example, the northern latitude of the Moon was 11' 43", and the horizontal parallax 55' 35", under which in the parallax-Table 56, on the row of the said latitude, is found the altitude of the ninetieth of 37° 25', inclining toward the south.

Precept 103. To inquire the altitude of the Pole of the aforesaid region.

For the place of the ecliptic in which the true New Moon is celebrated, add three signs, that is 90°; and you will have the ecliptic point Ascending for the said region; with this enter Table 33. With the side found, and with the Altitude of the Ninetieth found by the preceding precept observed, in the area on the row of the Ascending [point], find in the front of the Altitude-Table the altitude of the Pole.

But if in Table 33 you do not find the said altitude of the ninetieth (the eclipse not being about to be central), then in the Torrid Zone it is either total or partial; in the temperate or frigid zones it is partial; in the temperate, however, the eclipse will be either total or partial. Then add the regions in which the eclipse will be most nearly central, in which the Moon's edge will graze the topmost semidiameters of the Sun, and the true latitude of the Moon — which is always in these cases greater, and with the remainder, in the parallax-Table 56, under the

horizontal parallax of the front [column] in question, you will have on the left side the altitude of the ninetieth, with which, and with the Ascending ecliptic degree, by the precept of this precept find the altitude of the Pole of the region desired.

[Margin: Pag. 61]

Example.

In the aforesaid eclipse the place of the true conjunction was 2 signs, 21°, 12'; add three signs: the Ascending [point] becomes □ 21° 12', of whose region in the areas nowhere is found an altitude of the ninetieth of 37° 25'. Therefore the eclipse is not central within the Torrid Zone, but Temperate.

Therefore, to note the altitude of the Pole of that region where the margin of the Moon grazed the margin of the Sun, let us proceed in the calculation.

	Sig.	Gr.	'	"
Anomaly of the Sun [Anomalia Solis]	11	12	34	0
Equated anomaly of the Sun [Anomalia ☉ aequata]	2	14	57	22
Apparent semidiameter of the Sun ☉			15	32
Apparent semidiameter of the Moon ☾			15	17
Sum of the semidiameters			30	49
Northern true			43	43

	Sig.	Gr.	'	"
latitude of the Moon [Latitudo Lunae vera Bor.]				
Remaining sum [Residuum summae]			12	54
Horizontal parallax was [Erat Parallax. Horizontali s]			55	35
Altitude of the ninetieth [Altitudo Nonagesimi]		76	25	0
And the Ascending point was [Erat punctum Ascendens]	□	21	12	0
Altitude of the Pole [Poli Altitudo]		36	35	0

Therefore for the region to which the North Pole was elevated 36° 35', the eclipse was least, and the margin of the Moon only just touched the margin of the Sun; in the remaining altitudes of the Pole, however greater, some partial eclipses occurred.

Precept 104. To compute eclipses to be celebrated in the Southern region.

When the latitude of the Moon is southern, and the parallax of latitude joined to it makes, in any northern region whatever, the sum greater than the aggregate of the semidiameters of the luminaries, the eclipse does not occur except in the southern regions. And then all the things which have been carried out up to this point from precept 101 — concerning finding the place of the true central New Moon, and the visible — must be carried out again, but with the ecliptic degree opposite to that in which the central New Moon is celebrated.

Precept 105. To determine the digits of a central solar eclipse.

[Margin: Pag. 66]

In central eclipses, consulting Table 57, find in its front the deficient scruples of the apparent diameter of the Sun, and on the left side find the apparent diameter of the Moon; for the common area will give the digits. And if these are precisely 12, the eclipse will be total but momentary; if greater than 12, it will be total, and with a delay [of totality] in darkness, but for the fewer [the surplus], there will be left around the Moon the margin of the Sun in the form of a luminous annulus.

Example.

In the preceding eclipse	'	"
Semidiameter of the Sun ☉ was [Semidiameter ☉ fuit]	15	32
Whole diameter [Diameter tota]	31	4
Semidiameter [Semidiameter]	15	17
Whole diameter [Diameter tota]	30	34
Therefore the ecliptic digits [Ergo Digiti Ecliptici]	11	48

Therefore in some region of the Arctic circle, where we have indicated above the eclipse to have been central, there appeared around the Moon a luminous annulus.

On the Principal Phases of a Solar Eclipse

Precept 106. To find the time which the Moon takes from the point at which the lunar shadow first strikes the Earth, up to the moment at which the said shadow leaves the Earth, and the [points] at which the said phases occur.

[Margin: Pag. 70]

Gather into one sum the apparent semidiameters of the luminaries and the horizontal parallax of the Moon, and find this in Table 60 on the left side. The minutes in question in the front of the area will give the degrees and scruples, which are called the *Priora* (prior). Again, on the left side of the same Table, find the true latitude of the Moon, and in the front of the area the second [column]; the area will give the degrees and scruples, which are called the *Posteriora* (later). Subtract these *Posteriora* from the *Priora*, and find the remainder as an area in the same observed Table; see what minutes are on the left side, and what second is in the front of the area, [for these] answer. For if those minutes, and the second, are divided by the true hourly motion of the Moon from the Sun, they will give in the quotient the hours which the Moon takes from the moment at which the lunar shadow strikes the Earth, and at which the edge of the Sun begins to be grazed by the limb of the Moon, up to the moment of true conjunction; and consequently the time which the Moon takes from the moment of true and visible conjunction, up to the moment at which the lunar shadow abandons the Earth, and at which, the Sun setting with the close of day, the end likewise of the eclipse occurs somewhere, the Moon entirely emerging from the disk of the Sun.

Example.

In the year 1654, on 11 August, at apparent hour 22h 58m 28s after noon, there was at Uraniburg, by the Rudolphine [Tables], an eclipse of the Sun in $\square 19^{\circ} 33' 45''$; then therefore the calculation is thus:

	Sig.	Gr.	'	"
Anomaly of the Sun [Anomalia Solis]	1	14	19	46

	Sig.	Gr.	'	"
Equated anomaly of the Sun [Anomalia ☉ aequata]	8	9	26	1
Apparent semidiamet er of the Sun [Semidiam. appar. Solis]			15	3
Apparent semidiamet er of the Moon [Semidiam. appar. Lunae]			15	55
Horizontal parallax [Parallax. Horizont.]			61	57
Argument of the Moon's latitude [Argument um latitud. Lunae]	5	24	4	18
Its northern latitude [Latitudo eius Borea]			30	57
Sum of the			92	55

	Sig.	Gr.	'	"
semidiamet ers and parallax [Summa semidiam. & Parallaxis]				
Prior scruples [Scrupula Priora]		10	8	51
Later scruples [Scrupula Posteriora]		1	7	19
Remainder of scruples [Residuum scrupuloru m]		9	1	18
Scruples to be divided by the hourly [motion] from the Sun [Scrupula dividenda per Horarium à ☉]			87	39
			35	20
Which gives the hours	H.	2	28	50

	Sig.	Gr.	'	"
[Quotiens dat Horas]				
The New Moon was at hour [Nouiluniu m fuit Hora]	H.	22	58	28
Beginning of the eclipse on Earth [Initium Eclipsis in Terris]	H.	20	29	38
End of the eclipse on Earth on day 12 [Finis Eclipsis in Terris die 12.]	H.	1	27	18

Therefore, from the beginning at which the Moon's shadow began to strike the Earth, and to graze the western margin of the Sun ☉, up to the end at which the Moon's shadow left the Earth, and the Moon ☾ withdrew from the eastern margin of the Sun, there intervene 4h 57m 40s. And that beginning was at Uraniburg at hour 20h 29m 38s after noon of day 11 August. The end, moreover, [was] after noon of day 12 at hour 1h 27m 18s.

Precept 107. To find the altitude of the ninetieth in the regions in which the beginning of the solar eclipse first appears, and in which the end appears last.

First, the scruples (which by the preceding precept, through the true hourly [motion] of the Moon, were divided) subtract from the argument of true latitude of the Moon at the time of true conjunction; and you have the argument of the

first phase of the eclipse, namely when the eclipse begins on Earth; but on the contrary, if you add the same to the same argument, you will have the argument of the last phase, namely when the eclipse entirely ceases on Earth. And with these arguments find the true latitudes of the Moon, for each phase.

Second, divide the latitude of the first phase by the sum of the semidiameters of the luminaries and the horizontal parallax, and what comes out find in the parallax-Table, under the column written above with 60; for the area of its left side will have the altitude of the ninetieth of that region in which the rising Sun begins to suffer the eclipse from the Moon.

Third, divide the latitude of the last phase by the same sum of the said three, and find the quotient in the same column of 60 minutes observed; for it answers on the left side the altitude of the ninetieth in that region of the world in which the setting Sun ceases to suffer the eclipse from the Moon.

Example concerning what is said in Precept 106.

	Sig.	Gr.	'	"
Argument of latitude [Argumentum Latitudinis]	5	24	4	18
Scruple of incidence [Scrupula Incidentiae]			87	39
Argument of latitude in the first phase [Argum. latitud. in 1. Phasi]	5	22	26	39
And its latitude [& Latitudo Bor.]			38	32

	Sig.	Gr.	'	"
Argument of latitude of the last phase [Argum. latitud. ultima Phasis]	5	25	31	57
And its latitude [& Latitudo Bor.]			23	20
Sum of the semidiamet ers and parallax [Summa semidiam. & Parallax.]			92	55
Of the visible [latitude] by the first latitude [de visa per primam latitudine]			38	32
The quotient is [Quotiens est]			24	53
Hence the altitude of the ninetieth in the place of the first		65	5	0

	Sig.	Gr.	'	"
phase [Hinc Nonagesimi Altitudo in loco prima Phasis]				
But divided by the same sum [At diuisa per eandem summam]			92	55
By the latitude [Latitudine]			23	20
The quotient is [Quotiens est]			15	4
And the altitude of the ninetieth in the place of the last phase [Et Nonagesimi Altitudo in loco postrema Phasis]		75	27	

Precept 108. To find the altitude of the Pole in the two aforesaid regions.

First, find the interval of time between the true conjunction and the beginning of the eclipse on Earth by precept 106, [already] found above; and subtract the mean motion of the Sun from the place of the Sun at the time of New Moon given; and with the signs and degrees thus remaining, on the other side of Table 33

observed, where you find directly the altitude of the ninetieth of precept 107, in the front for the first phase of the eclipse you will have the altitude of the Pole desired.

[Margin: Pag. 38]

Second, the same mean motion of the Sun, add to the place of the true Sun at the time of New Moon given, and with the signs and degrees thus, then from these made, but opposite in the same Table 33, see in whose columnar area the altitude of the ninetieth of precept 107 is for the last phase found; for above that in the front you will have the altitude of the Pole in question.

Example of the aforesaid New Moon.

	Sig.	Gr.	'	"
The intervals were [Hora internallierant]	H.	2	28	50
The mean motion of the Sun ☉ [Horum motus ☉ medius]			6	7
The place of the Sun ☉ in the true [conjunction] [Locus ☉ in vero ☐]	☐	19	33	45
The place of the Sun ☉ in the first phase [Locus ☉ in 1. Phasi]	☐	19	27	38
The		65	5	0

	Sig.	Gr.	'	"
altitude of the ninetieth then [Alt. Nonagesimi tunc]				
Therefore the northern altitude of the Pole [Ergo Poli Altitudo Bor.]		41	22	0
The place of the Sun ☉ for the last phase [Locus ☉ pro vlt. Phasi]	□	19	39	52
The opposite place [Locus oppositus]	□	19	39	52
The altitude of the ninetieth then [Nonagesim i Altitudo tunc] Which in the areas does not		75	27	0

	Sig.	Gr.	'	"
appear [Quae in areis non apparet]				
Therefore as before [Vt ergo prius]	□	19	39	52
Whence the southern altitude of the Pole [Vnde Poli Australis alt.]		3	42	0

Note that if you do not find in the said areas the altitude of the ninetieth, by direct reasoning from the place of the Sun, it is a sign that there will be a southern altitude of the Pole; [find it] with the place of the Sun opposite, that is, with the prior place [for which] you have just made the trial — namely with the opposite place tried.

Precept 109. To determine the regions themselves by means of the longitude, for the first and the last phase, in the manner stated.

First, with the place of the Sun for precept 108 found at the moment of the first phase, find the oblique ascension under the elevation of the Pole already found at the first phase; subtract 90° , and the right ascension of the Tabular Meridian will come forth at the moment of the first phase. Then from the hours of the interval between the first phase and the New Moon, already found in precept 106, [taking those hours] resolved into degrees of the equator, add to the right ascension of that degree of the place of the Sun, of which the oblique ascension was just found; and the right ascension of the Tabular Meridian for the moment of the first phase will come forth. If this is subtracted from the right ascension of the [actual] Meridian first found, the difference of the meridians for the East will be given, the longitude sought toward the East. If the right ascension of the [actual] Meridian is prior — that is, greater than the right ascension of the Tabular Meridian — [it is] toward the West, if less; and by the preceding [reasoning], the

altitude of the Pole being known, on the Geographical Chart inquire the place desired.

Second, for the place of the last phase with the ecliptic degree opposite to it — but with the same altitude of the Pole — find the oblique ascension, and subtract 90°; [add] to the congruent oblique ascension of that phase the right ascension of the region. Then [taking] the hours of the interval between the New Moon and the last phase, and the place of the true New Moon and the last phase, and the aggregate in degrees of the equator resolved, add the right ascension of the place of the Sun in the last phase found; for you will have the right ascension of the Tabular Meridian. Therefore if you subtract from this the right ascension of the preceding Meridian, you acquire the difference of the longitudes; and so, with the longitude and the altitude of the Pole, you have the region desired.

Note, moreover, that if in either phase the elevation of the Pole was found to be southern, 180° must be added to the right ascension of the Tabular Mid-heaven, and from the aggregate the right ascension of the other Meridian is to be subtracted, that you may have the difference of longitudes.

Example in the preceding New Moon.

	Sig.	Gr.	'	"
The place of the Sun in the first phase [Locus Solis in 1. Phasi]	□	19	27	38
The altitude of the Pole for the first phase [Altitudo Poli Bor. in 1. Phasi]		41	22	0
The oblique ascension of the place [Ascensio		128	12	6

	Sig.	Gr.	'	"
Obliqua loci]				
The right ascension of the Tabular Meridian [Asc. Recta Meridiani optati]		38	12	6
The right ascension of the place [Asc. Recta loci]		141	53	48
The hour of the first phase [Hora prima Phaseos]	H.	20	29	38
Their parts in the equator [Earum partes Aequatoris]		307	24	30
The right ascension of the Tabular Meridian [Asc. Recta Merid. Tabularum]		89	18	18

	Sig.	Gr.	'	"
Subtracted right ascension first Meridian [Subducta Asc. Recta 1. Merid.]		38	12	6
The difference of the Meridians [Differentia Meridianor um]		51	26	12
Uraniburg's longitude in the Rudolphine [Tables] [Uraniburgi Longit. in Rudolphin.]		36	45	0
The longitude of the region in the first phase [Longitudo Regionis 1. Phasi]		345	38	48

Therefore the first of all the [places of] eclipse, with the Sun rising, was in the Atlantic Ocean near the island of Fagudan [Faial?]; because its altitude of the Pole is nearly $41^{\circ} 22'$, and its longitude $345^{\circ} 38' 48''$.

For the last phase [Pro vltima Phasi]	Sig.	Gr.	'	"
The place of the Sun in the last phase [Locus Solis in vltima Phasi]	□	19	39	52
The southern altitude of the Pole [Poli Australis Altitudo]		3	42	0
The oblique ascension of the place of the Sun [Asc. Obliqua loci Solis]		141	4	40
The right ascension of the Tabular Meridian [Asc. recta Merid. optati]		51	4	40
The right ascension of the place of the Sun [Asc. recta		142	4	49

For the last phase [Pro ultima Phasi]	Sig.	Gr.	'	"
loci Solis]				
The hour of the last phase [Hora ultima Phasis]	H.	1	27	18
The degrees of the equator [Gradus Aequatoris]		21	49	30
The right ascension of the Tabular Meridian [Asc. recta Meridiani Tabular.]		163	54	19
Because the altitude of the Pole is southern, add [Quia Altit. Poli est Austr. adde]		180	0	0
The aggregate is [fit aggregatum]		343	54	19

For the last phase [Pro ultima Phasi]	Sig.	Gr.	'	"
Subtract the prior Meridian's ascension [Subtrahe prioris Merid. Ascens.]		51	4	40
The remaining difference of the Meridians [Restat Meridianor . differential]		292	49	39
The longitude sought [Longitudo quaesita]		103	55	21

The last [place] therefore of the eclipse on Earth was in the Eastern Ocean near the island of S. Petri de Mascarenas [Mascarene Islands]; because its longitude is southern, $103^{\circ} 55' 21''$, and the latitude is south $3^{\circ} 42'$. Therefore the eclipse ceased upon the Earth, and the lunar shadow left it, in that place where the North Pole is elevated $23^{\circ} 55'$; and whose longitude from Palma [Palma in the Canaries] is $289^{\circ} 1'$, namely near the cape of S. Antonii Insulae Cubae [Cape San Antonio, Cuba].

Precept 110. To find the time from the moment at which, the Sun rising, the first total central eclipse of the Sun occurs, up to the middle [moment], and the moment of true and visible central conjunction, and thence up to the moment at which, the Sun setting, the last central eclipse occurs.

[Margin: Pag. 70]

With the apparent semidiameter of the Earth's disk, or with the horizontal parallax of the Moon, take from Table 60 the degree and the scruple, which are called the *Priora* (prior). This same do with the true latitude of the Moon found at the moment of true New Moon; you will gather the degree and the *Posteriora* scruple, which subtract from the *Priora*, and find the remainder as an area in the same Table 60; you will gather, on the left margin, the seconds divided by the hourly [motion] of the Moon from the Sun, [for] from the front the seconds divided will give the minutes — by which the hourly [motion] of the Moon from the Sun, you will have the interval of time from the moment at which first on Earth, the Sun rising, the central eclipse appears, up to the moment at which, the ninetieth being from the true rising, the visible central conjunction will appear. If this interval-time you subtract from the time of apparent true conjunction, you will have the time of this phase. Likewise, if you add it to the same time of true conjunction, you will have the time at which, the Sun setting, the last central eclipse appears.

Example in the preceding New Moon.

	Sig.	Gr.	'	"
Horizontal parallax of the Sun ☉ [Parallax ☉ Horizontal.]			61	57
Prior scruple [Scrupula priora]		4	28	58
The Moon's true latitude [Latitud. ☽ in vera ☐]		0	30	57
Later scruple [Scrupula posteriora]		1	7	33

	Sig.	Gr.	'	"
Residual scruples [Residua scrupula]		3	21	25
Scruple to be divided [Scrupula diuidenda]		0	55	57
By the hourly [motion] of the Moon from the Sun [Per Horarium › à ☉]		0	35	20
Therefore the hour [Ergo Hora]	H.	1	34	26
The hour of the New Moon was [Hora Nouilunij fuit]	H.	22	58	28
Therefore the hour of the central eclipse [Hora igitur cur. ☉ centralium]	H.	21	24	2
And the last [eclipse] of the central [phases] on		0	32	54

	Sig.	Gr.	'	"
day 2 August [Et ultima cêntraliū diei 2. Aug.]				

Precept 111. To find the altitude of the ninetieth-point [altitudo nonagesimi] in the two regions for the two phases just described.

The scruples that you divided in the preceding precept by the hourly motion, subtract from the Argument of Latitude of the true New Moon. This leaves the Argument of Latitude for the time of the first of the central eclipses, which is to be sought; and once found, look it up in the columns of Table 56 of the parallax tables under the observed Horizontal Parallax. You will then see, on the left-hand side directly opposite, the altitude of the ninetieth-point sought for this last phase. [Margin: Pag. 61.]

But if you instead add those same scruples to the same Argument, you will have the Argument of Latitude for the time of the last of the central eclipses, and from it the latitude. In that same Table 56, under the Moon's Horizontal Parallax, this will show on the left-hand side the altitude of the ninetieth-point for this last phase.

Example in the preceding New Moon.

	Sig.	Gr.	'	"
Argument of Latitude, true	5	24	4	18
Argument of Latitude for the first of the central eclipses	5	23	8	41

Altitude of the ninetieth-point at the first of the central eclipses		54	44	0
Altitude of the ninetieth-point at the last of the central eclipses		64	56	0

Precept 112. To find the altitude of the Pole for each of the two aforesaid phases and regions.

Take the mean motion of the Sun corresponding to the time midway between the first of the central eclipses and the true New Moon found in Precept 110; subtract from it the place of the Sun for the first of the central eclipses, and add the place of the Sun for the last of the central eclipses, together with the Signs and Degrees

of that place, correcting them by the heads of the table. Then, from the altitudes of the ninetieth-point found in the preceding precept (those already acquired), you will find on the front of the table the altitude of the Pole sought, according to the instruction of Precept 109.

Example in the preceding New Moon.

	Sig.	Gr.	'	"
Place of the Sun in the true New Moon	□	19	33	45
Time between the New Moon and the first of the central eclipses	H. 1	34	26	
Mean motion of the Sun for this time			3	53
Place of the Sun for the first of the central eclipses	□	19	29	52
Place of the Sun for the last of the central eclipses	□	19	37	38
Altitude of the ninetieth-point at the first		54	44	0

	Sig.	Gr.	'	"
Altitude of the ninetieth- point at the last		64	56	0
Altitude of the Pole for the first of the central eclipses, North		51	9	0
Altitude of the Pole for the last of the central eclipses, North		6	26	0

But this is found together with the place opposite to the Sun.

Precept 113. To determine the regions themselves by their Longitude.

Once the place of the Sun and the altitude of the Pole have been found by the preceding precept, the Oblique Ascensions must be sought, and everything else done that was prescribed in Precept 109. So that, for the first and the last of the central eclipses, you have the difference of the Meridians from the Meridian of the Tables, and hence the longitude of each place desired. I add this here in brief by way of example:

[The lower-left corner of the page is partly degraded; a short worked-example fragment appears here but the figures are largely illegible: "[?] [?] [?]"]

[Margin: Pag. 61.]

Example of the preceding New Moon.

For the first of the central eclipses:

	Sig.	Gr.	'	"
Altitude of □		51	9	0

	Sig.	Gr.	'	"
the Pole, North				
Place of the Sun at that time	□	19	29	52
Its Oblique Ascension		122	26	6
Right Ascension of the chosen Meridian		32	26	6
Right Ascension of the place of the Sun		141	56	38
Hour of this phase	H. 21	14	2	
Their parts in the Equator		321	0	30
Right Ascension of the Meridian of the Tables		102	57	8
Difference of the Meridians		70	33	2
And the longitude of the region sought		326	11	58

Accordingly, the first of the central eclipses occurred on the northern coastline of Nuremberg [Norimberga], where the altitude of the Pole is $51^{\circ} 9'$ and the longitude $326^{\circ} 11' 58''$.

For the last of the central eclipses:

	Sig.	Gr.	'	"
Altitude of the Pole, North		6	26	0
Place opposite to the place of the Sun	□	19	37	38
Its Oblique Ascension		323	17	48
Right Ascension of the chosen Meridian		233	17	48
Place of the Sun	□	19	37	38
Its Right Ascension		142	3	38
Hour of this phase	H. 0	32	54	
Their parts in the Equator		8	13	30
Right Ascension of the Meridian of the Tables		150	17	8
Difference of the Meridians		276	59	20

	Sig.	Gr.	'	"
Longitude sought		119	45	40

Therefore the last of the central eclipses occurred in the Eastern Indian Ocean, near the Ganges Gulf [Sinus Gangeticus], where the altitude of the Pole, North, is $6^{\circ} 26'$ and the longitude $119^{\circ} 45' 40''$.

Precept 114. To find the region for which — with the ninetieth-point in conjunction with the true position, and by way of the true Syzygy — a central eclipse appears.

First, by Precepts 101, 102, and 103, find the semidiameter of the Earth's Disc, the altitude of the ninetieth-point, then the Pole of the region for which this phase occurs. Next, with the place of the Sun in the true New Moon and the degrees increased by 90, set under the said altitude of the Pole, find the Oblique Ascension, and subtract 90° from it; you will then have the Right Ascension of the Meridian, under which this phase occurs. Finally, to the Right Ascension of the place of the Sun add the parts of the Equator corresponding to the apparent Hours of the New Moon, and you will get the Right Ascension of the Meridian of the prior one, which will differ from the Right Ascension of the Meridian of the Tables. By comparing the Right Ascension of the Meridian of the Tables (which you compare with the Right Ascension of the Meridian of the prior) you obtain the difference of the Longitudes, and hence the Longitude of the region sought, in which this phase occurs.

Example of the preceding New Moon.

	Sig.	Gr.	'	"
Semidiameter of the Earth's Disc	0	0	61	57
At the true Latitude in conjunction			30	57
Altitude of the ninetieth-point		60	2	0
And the		43	6	0

	Sig.	Gr.	'	"
altitude of the Pole, North				
Place of the Sun in conjunction	□	19	33	45
With 90 added		90	0	0
Ascendant degree	□	19	33	45
Its Oblique Ascension		244	27	19
With 90 taken away		90	0	0
Right Ascension of the chosen Meridian		154	27	19
Right Ascension of the place of the Sun in conjunction		126	36	48
Hour of the apparent New Moon	H. 22	18	28	
Their parts in the Equator		344	37	0
Right Ascension of the Meridian of		126	36	48

	Sig.	Gr.	'	"
the Tables				
Difference of the Meridians		332	9	29
Longitude sought		64	35	31

Therefore, in that place where the North Pole is elevated $43^{\circ} 6'$, and whose longitude is $64^{\circ} 35' 31''$, there will be the ninetieth-point, and the central Syzygy was seen — namely, on the maritime coast of the Euxine [Black Sea] near Amasia, and on the river Thermodon; though not so in the whole of that tract over which the Moon's Shadow passed, since the eclipse occupied 12 digits $43'$ in its entirety.

Precept 115. To find the regions of the Earth above which the Moon's Shadow is carried during the whole time of a Solar Eclipse.

Once the five places of the phases have been found, from Precept 106 to Precept 114, it is easy — on Globes, Maps, or Geographical charts — to mark out the tract of the Earth over which the Lunar Shadow passed during the whole time of the Solar Eclipse. Thus, in the eclipse described above, after the Sun rose over the *Fortunate Isles* [Fagada, of the Atlantic islands], it began to be obscured on its western part by the interposed Body of the Moon; gradually, with the loss increasing, it rose over *Nuremberg*, where the northern coastline was first touched by the Moon. From there, with the centre of the Lunar shadow rising, it passed across to the East: first it travelled across the *Land of the Laborer* [terra Laboratoris], then the Caledonian Ocean, Scotland, the Danes, the Cimbri, and the most distant coasts of Germany, and through Poland and Podolia it crossed the Euxine Sea, where, at the true ninetieth-point and with the central Syzygy seen, it appeared. Further, it proceeded to Armenia and the southern coasts of Persia, and thence to East India, where the Ganges Gulf concealed the Sun, the whole of it westward-setting, finally. Lastly, with the Sun setting on the West, it left the Moon free at the *Island of St. Peter of Mascarenas* [Insula S. Petri de Mascarenas], and its Shadow withdrew from the Earth.

Precept 116. To compute the place of Saturn [♄] in Longitude according to the Orbit.

Apply, if there is need, the precepts of Part I, or follow the order written below.

1. First, by Precept 55 or 56, find the true place of the Sun and its equated Anomaly.
2. Second, from Table 62 (which is found on page 72) take out the mean motion of Saturn from the Equinox, its Apogee, and the North Node.
3. Third, subtract the motion of the Apogee from the motion of Saturn from the Equinox, and you will have the simple Anomaly; with which, in Table 63 (which is on page 73), seek the centric Equation, or that of the first inequality of Saturn, to be added or subtracted from its mean motion as required (per the heads of the Tables), so that you have the eccentric place of Saturn — that is, the place first equated, or seen from the Sun.
4. Fourth, subtract the centric place of Saturn from the true place of the Sun, and the *Anomaly of the Orbit* [Anomalia Orbis] will remain.
5. Fifth, with the simple Anomaly (of which there is mention in number 3, found in Table 64 on page 73), find the *Equated Anomaly* [Anomalia aequata].
6. Sixth, with the Equated Anomaly of the Sun and with the Equated Anomaly of Saturn, find in Table 65 (which is on page 74) the *Maximum Equation of the Orbit of Saturn* [Maxima Aequatio Orbis Saturni].
7. Seventh, finally, with the Maximum Equation of the Orbit of Saturn, going to the General Table of the Prosthaphaeresis of the Orbit (which is on page 94), observe on the front, or on the side of the Table, with the Anomaly of the Orbit (from number 4) descending on the right, the corresponding prosthaphaeresis of the Orbit. Add it to, or subtract it from, the centric place of Saturn, and you will have the place of Saturn in the Orbit, or equated as seen from the Earth. This same order will hold for Jupiter and for Mars, applying, however, the tables proper to each, as will be said below.

Example for Saturn [ʰ].

In the Year of Christ 1604, on September 27, at about Hour 8 in the evening at Prague, from observations Saturn and Mars were thought to be in the same Longitude. The place of Saturn is sought here. The order of calculation is as follows:

	Sig.	Gr.	'	"	
True place of the Sun	6	4	47	44	Tab. 36

	Sig.	Gr.	'	"	
⊙					
Anomaly of the Sun, equated	2	27	4	44	38
⊙					
Mean motion of Saturn \hbar from \square	8	13	49	13	Tab. 62
Motion of the Apogee	8	26	6	51	Pag. 72
Motion of the Node Ω	3	20	32	5	
Simple Anomaly	11	17	42	22	
Equation 1, to be added	0	1	18	33	Tab. 63
Eccentric place of Saturn \hbar	8	15	7	46	Pag. 73
Anomaly of the Orbit	9	19	39	58	
Anomaly of Saturn \hbar , equated	0	11	35	30	Tab. 64
Maximum Equation of the	0	5	41	30	Pag. 73

	Sig.	Gr.	'	"	
Orbit					Tab. 65
					Pag. 74
Equation of the Orbit, subtractive	0	5	10	30	Tab. 95
Place of Saturn h in the Orbit	8	9	57	16	Pag. 94

Therefore Saturn was then in Sagittarius [Sagittarius] $9^{\circ} 58' 16''$.

Precept 117. To compute the Latitude of Saturn [□].

1. First, with the Anomaly of the Eccentric of Saturn equated, observe on the front, or foot, of Table 66 (which begins on page 75, or such Anomaly of the Orbit of Saturn) on the left, or on the right side of the same Table, look up in the common angle the proportional scruples of latitude.
2. Second, with the Anomaly of the Orbit observed, look up what scruples are in the penultimate column, whose title is *Scrup. Prop. Incr. & Decr.* [proportional scruples of increment and decrement].
3. Third, if the *Scrup. Incr. or Decrement* are in the penultimate column (whose part above the title is A, or whether they correspond to the Anomaly of the Orbit by its first three or last Signs). Taking the proportional scruples (whose title is FB, or such anomaly) accepting the inferior, whose title is *Increm. in σ* [Increment in conjunction]. Take the proportional scruples in the lower part, whose title is FB, accepting the increment or decrement of them; the title is FB, but it falls between, and you take the scruple of decrement from the proper columns; you take, that is to say, with the Anomaly of the Sun equated on the front, or the place of Table 66, and with the Anomaly of the Eccentric of Saturn on the left, or on the right side.
4. Fourth, do, by 60, the scruples of increment, or of decrement, of which I have said number 3 — so the scruple of increment, or of decrement of the penultimate column, of which is number 2 — to the fourth proportional

number; but indeed the number, or this quotient, add, if it is increment; but if it is decrement, subtract the scruples of latitude from the first number found, and you will have the scruples of Latitude corrected.

5. Fifth, go to Table 67 (page 76) and with the distance of the Eccentric place of Saturn from the North Node sought (on the front, or foot, by which Signs and by the degrees of the Signs on the left, or on the right side, look in the columns of latitudes) the Latitude is a right sine, as the Radius is to 60.
6. Sixth, finally, do, by 60, the sine of latitude as the Radius is right, of which number 5; so the scruples of latitude corrected, of which the number, or other, and there will come out number 5, but if number 96 (page 107) in the General Table of the Latitude of Saturn, will exhibit its affections, how distant from the North Node ♄ the Signs in Table 67 indicate.

Example.

The same case as that treated in the preceding Precept.

	Sig.	Gr.	'	"

Precept 122. To compute the place of Mars in longitude.

Carry out everything as in Precept 116, but use the tables proper to Mars, which begin at Table 74 (p. 81) and end on p. 84.

Example.

In the year 1604, on October 9, a little before noon, a conjunction of Jupiter and Mars was observed from the observations made at Prague. For me, the time was then 23^h 0^m after the meridian of October 8, that is, at 8°15'19" of Sagittarius [in gr. □ 8. 15'. 19"]. The place of Mars is now sought; the calculation runs as follows.

	Sig.	Gr.	'	"	Tab.
☉ True place [Locus verus]	6	16	18	20	36 &
☉ Equated anomaly [Anomali a aequata]	3	8	35	4	38

Equation of the orbit, subtracti ve [Orbis aequatio subtr.]	1	9	13	49	&
□ Place in the orbit [Locus in Orbita]	8	19	14	22	95

Precept 123. To compute the latitude of Mars.

Do everything as in Precept 117, but use the tables proper to Mars, which begin at p. 81.

Example, concerning which see in the preceding Precept.

	Sig.	Gr.	'	"
Equated anomaly of Mars	5	2	0	3

	Sig.	Gr.	'	"	
[Anomal. □ aequata]					
Anomaly of the orbit	8	17	50	9	
[Anomali a Orbis]					
Therefor e scruples of latitude	0	14	20	0	Tab.
[Ergo scrup. Latit.]					
And scruples increase or decrease	0	11	37	0	78
[Et scrup. Incr. vel Decr.]					
(which are the higher ones)					
[Quae sunt superior a]					
And they indicate increase

☉	3	8	35	4
Equated anomaly [Anomal. ☉ aequata]				
Scruples- increase on ☐ [Scrup. Incr. in ☐]	0	0	4	0

Since 60" corresponds to 14'20", so 4' corresponds to 57"20" [ita 4'. 57". 20"]; this is to be added to the scruples of latitude, so that the corrected latitude comes to 15'17'20" [gr. 15. 17'. 20"].

	Sig.	Gr.	'	"	
Distance of the eccentric place from the node Ω [Distanti a loci Excentr. in Nodo Ω]	8	12	50	17	Tab.
Sine of latitude [Latitudi nis Sinus]	0	7	4	0	80

Since 60° corresponds to 15'17'20", so the sine 1.47 [Sinus 1. 47] corresponds to 4' [4'. 20"]. As for the signs in the General Table of Latitude, etc. [Qui in Generali

Tabula Latitudinis dat Latitud. gr. 1. 52'. Australem gr. 1. 52'. Australem], the southern latitude of 1°52' — as is indicated by the signs of the distance from the node Ω .

	Sig.	Gr.	'	"	
					Tab.
					96

[The marginal note "Tab. 96" applies to the General Table of Latitude cited above.]

Precept 124. To reduce the place of Mars from the orbit to the ecliptic, and to work out its curtation.

Do everything as in Precept 118, but use the table proper to Mars, namely Table 80, which is found on p. 84.

[The remainder of this precept's worked example is continued in the *Exemplum Superioris Casus* in the right column below.]

Example of the case above.

	Sig.	Gr.	'	"	Tab.
Distance of the eccentric place from Ω [Dist. loci Excent. à Ω]	8	11	50	17	
Therefor e curtation [Ergo Curtatio]	0	0	1	7	Tab.
And reductio n, subtracti ve [Et Reductio	0	0	0	32	80

	Sig.	Gr.	'	"	Tab.
subtr.]					
Because it approached the limit [Quia accedebat ad limitem]					
Place in the orbit [Locus in Orbita] is	8	19	14	22	
Therefore place in the ecliptic [Ergo Loc. in Ecliptica]	8	19	13	50	
Maximum equation of the orbit [Aequatio Orbis maxima]	0	45	15	0	
Equation of the orbit, subtractive [Aequatio Orbis subtr.]	0	49	13	49	

Therefore, as $45^{\circ}15'$ corresponds to the curtation $1'7''$, so $49^{\circ}13'49''$ corresponds to the curtation $1'13''$ — by which the equation of the orbit must be diminished, in order that less be subtracted; but in the same way, as if you were to add $1'13''$ to the place of Mars reduced to the ecliptic. Hence the place of Mars reduced and curtated was in Sagittarius $19^{\circ}15'3''$ [in Sagittarii gr. 19. 15'. 3"], while that of Jupiter was at $19^{\circ}15'36''$ of Sagittarius [gr. □ 19. 15'. 36"]. Hence a little after 23^{h} the conjunction of Mars and Jupiter was celebrated — namely at $23^{\text{h}} 50^{\text{m}}$ after the meridian of October 8, as the observation has it [vt habet observatio].

Precept 125. To compute the place of Venus in longitude.

First, find by Precept 55 the true place of the Sun and its equated anomaly.

Second, in Table 81 (found on p. 85), extract the mean motion of Venus from the equinox, the motion of the apogee, and the motion of the north node.

Third, subtracting the motion of the apogee from the mean motion of Venus, you will have the *simple anomaly* [Anomalia simplex]; with this, in Table 82 (on p. 86), you will have the first equation [primam Aequationem], to be added to, or subtracted from, the mean motion of Venus — as the headings of the table will indicate — and the place of Venus equated for the first time will result, that is, the eccentric place, or the place as seen from the Sun [Locus Veneris primò Aequatus, seu Excentricus, seu ex Sole visus].

Fourth, subtract the true place of the Sun from the eccentric place of Venus, and the anomaly of the orbit [Anomalia Orbis] will remain.

Fifth, with the simple anomaly (which is in Table 83, p. 86), find the equated anomaly of Venus; with which, and with the equated anomaly of the Sun, in the side-columns of Table 84 (pp. 86–87), find the maximum equation of the orbit [Maximam Orbis Aequationem].

Sixth, with the anomaly of the orbit (in the side-columns), and with the maximum equation of the orbit at the front of Table 95, collect the equation of the orbit to be added to, or subtracted from, the place of the Sun — as the headings of the table teach — and you will have the place of Venus as seen from the Earth [Veneris locum ex Terra visum].

Example.

Longomontanus [Longomontanus] reports that in the year 1585, on September 14, by the old style, at the hour of $5^{\text{h}} 15^{\text{m}}$ past the meridian, Venus was observed by Tycho [Tychonem] at its greatest digression from the Sun, in $17^{\circ}15'$ of Leo [in

Leonis gr. 17. 15'. 58']. Let it be by the Danish Tables, with reduction and curtation set aside [absq; Reductione, & Curtatione], 15°53'20" in degrees [dent gr. 15. 53'. 20"]. Yet the place was somewhat falser when Tycho's place of the Sun was assumed, on account of the too-great parallax of the Sun assumed, the declination, etc. Let us see what our tables present.

	Sig.	Gr.	'	"	Tab.
☉ True place [Locus verus]	6	1	48	41	Tab.
☉ Equated anomaly [Anomal. aqu.]	1	24	25	23	36

	Sig.	Gr.	'	"	Tab.
place [Locus ex.]					
Anomaly of the orbit [Anomali a Orbis]	7	7	54	17	Tab.
Equated anomaly [Anomali a Aequata]	3	4	59	57	83
Maximu m equation of the orbit [Maxima Orb. Aeq.]	0	46	4	30	84
Equation of the orbit, subtracti ve [Orbis Aequatio sub.]	1	5	41	50	85
□ Place in the orbit [Locus in Orbita]	4	16	6	30	

It was therefore in Leo $16^{\circ}6'30''$ [in □ grad. 16. 6'. 30"].

Precept 126. To compute the latitude of Venus.

First, from Table 85 (p. 88), draw out the proportional scruples of latitude, with the anomaly of the Sun equated at the front [in fronte], or with the anomaly of the orbit of Venus in the side-columns; and with this, the inferior scruple at the foot of the table [scrupula inferiora in calce Tabulae].

Second, in Table 86 (p. 89), with the anomaly of the Sun equated at the front, or at the foot of the table, and with the equated anomaly of Venus in the side-columns, find the scruples of decrement [Scrupula Decrement].

Third, work so that, as 60" is to the scruples of decrement found by Table 85, so the inferior scruple is to the decrement found by Table 86; and subtract this from the scruples of latitude first found, in order that they come out corrected.

Fourth, with the distance of the eccentric place of Venus from the north node [distantia loci Excentrici Veneris à Nodo Boreo] (which is in Table 87, p. 89), find the sine of the latitude.

Fifth, work so that, as 60" is to the sine of latitude, so the corrected scruple is to another scruple, which in the general table (which is Table 96) will give the latitude of Venus, of the same kind that the distance from the north node indicated in Table 87.

Example in the case above.

	Sig.	Gr.	'	"	Tab.
☉	2	24	25	23	Tab.
Equated anomaly [Anom. aequata]					
Anomaly of the orbit □ [Anomali a Orbis □]	7	7	54	17	85
Scruples of latitude [Scrupul a latitud.]	0	24	18	0	

	Sig.	Gr.	'	"	Tab.
Inferior scruple [Scrupul a inferiora]	0	11	58	0	
Anomaly □ equated [Anom. □ aq.]	3	4	59	57	Tab.
Scruple decreme nt [Scrup. Decrem.]	0	1	56	0	86

Since now 60" corresponds to 1'56", so 18" [11'. 58"] corresponds to the scruple decrement 1'36' and 18" [gr. 1. 36'. 18"]; this, being subtracted from the scruples of latitude, leaves the corrected latitude at 24°0' [grad. 24. 0'].

	Sig.	Gr.	'	"
Node Ω place [Nodi Ω locus]	2	13	59	52
□ Eccentric place [Locus ex.]	1	9	42	58
Distance ♀ from Ω [Distanti a ♀ à Ω]	1	4	16	53
Sine of latitude	0	5	45	0

	Sig.	Gr.	'	"
[Sinus latitudinis]				

Since now 60" corresponds to this sine of 5'45" [grad. 5. 45'], so the corrected scruple of latitude of 24°0' [grad. 24. 0'] corresponds to the other sine of 2'18" [gr. 2. 18'], which in Table 96 gives the latitude of Venus of 2'24" [grad. 2. 24'] North [Borealem] — provided the distance of Venus from the further north node was 2°4'14" [Sign. 2. gr. 4. 14']; therefore *Descending* [Descendens].

Precept 127. To reduce the place of Venus from the orbit to the ecliptic, and to work out its curtation.

First, with the distance of the eccentric place of Venus, or its place as seen from the Sun, from the north node, find in Table 87 the reduction and the curtation. But if Venus happens to be in the orbit, there are no reductions, only maximal curtations; on the contrary, in the conjunctions there are no curtations, only maximal reductions.

Second, work so that, as the maximum equation of the orbit corresponds to the reduction found, so the difference between the maximum equation of the orbit and the equation of the orbit corresponds to the reduction to be added to, or subtracted from, the anomaly of the orbit, if the planet approaches the nodes by receding from the limit; but it is to be subtracted if it recedes from the nodes by approaching the limit.

Third, work so that, as the maximum equation corresponds to the curtation found, so the anomaly of the orbit corresponds to the curtation to be added to, or subtracted from, the equation of the orbit; so that, if the equation of the orbit was subtractive, less should be subtracted, but if direct, less should be added.

Example in the preceding case.

	Sig.	Gr.	'	"
□	1	4	16	53
Distance from Ω was [Dist. à Ω fuit]				
Therefor	0	0	2	48

	Sig.	Gr.	'	"
e reduction to be added [Ergo Reductio add.]				
And	0	0	3	18
curtation [Et Curtatio]				
Maximum equation of the orbit [Maxima Aequat. Orb.]	0	46	4	30
Equation of the orbit [Orbis Aequatio]	0	45	41	50
Difference of these [Differen tia harum]	0	0	22	40

Now, as $46^{\circ}4'30''$ corresponds to the reduction $2'48''$, so it differs by $22'40''$, that is, $40''$ corresponds to the reduction [Reduct. $1' 18''$], so the reduction was $1'18''$ [Reductus fuit Sig. 4. grad. 16. $7' 48''$]; that is, Sign 4, $16^{\circ}7'48''$.

Next, as $46^{\circ}4'30''$ corresponds to the curtation $3'18''$, so $45^{\circ}41'50''$ corresponds to the curtation $3'11''$; this, subtracted from the place of Venus reduced [loco Veneris Reduto], gives the curtated place in Leo $16^{\circ}10'48''$ [Curtatum in Leonis gr. 16. $10'$.

48" — namely 13" minutes [13" fere minutis] more advanced than the Tychonic one [Tychonico], but false on account of the too-great parallax of the Sun and the declination, and perhaps too on account of the observations themselves [ob ipsam observationem].

Precept 128. To compute the place of Mercury in longitude.

Do everything as in Precept 125 (as you did for Venus), but apply the tables proper to Mercury, which begin at Table 88 (from p. 90) and end on p. 94.

Example.

In the year 1481, on October 21, at 18^h 10^m after noon at Bologna [Hora Bononiae 18. 10'. post merid.], Mercury was observed more easterly than Saturn, by more than a diameter of the Moon; Saturn was then in Libra 15°20' [in Libra grad. 15. 20'], for me. Therefore Mercury was very nearly in Libra 18°46' [in Libra gr. 18. 46']. The place from the Earth is sought; the calculation is as follows.

	Sig.	Gr.	'	"	Tab.

	Sig.	Gr.	'	"	Tab.
☿ Place in the orbit [Locus in Orbita]	6	19	2	40	95

The place of Mercury in the orbit was therefore in Libra 19°2'40" [in □ grad. 19. 2'. 40"].

Precept 129. To compute the latitude of Mercury.

First, with the equated anomaly in the sign opposite at the front of Table 92, or at the foot of the table — the anomaly of Mercury in the side-columns — find the proportional scruples of latitude. But if the signs are 6 or greater [Vt si Signa sint 6. gr. 20.], use Sign 1, gr. 2, because in the investigation of the scruples of latitude, the table begins at the perigee, where the longitude begins at the apogee.

Second, note in Table 92 that the two columns of proportional scruples of increment and decrement — namely the second and the next-to-last — respond, the second one to the least distance of Mercury from the Sun, and this is to be used when the anomaly is eccentric, but changed as I have said, that is: at the front of the table, if the sign is less than Sign 1, or greater than 10 — the next-to-last is to be used. But when the maximum distance of Mercury from the Sun is to be served, namely when the eccentric anomaly is reckoned, changed in the opposite sign, if the sign is greater than 4 or greater than 8; when, finally, the anomaly is less than Sign 4 or 10, you are to use the middle distances, which respond in part to the proportional column, and you should collect the columns; and the next-to-last, compared at the same time — these things being well understood, find in Table 92 the *Proportional scruples of increment and decrement*, noted in the side-columns with the anomaly of the orbit.

Third, if the scruples of increment and decrement are superior, and pertain to the part of the second column, or the next-to-last, whose title is B, then in that same table the next-to-last column being taken, the scruples of decrement are in conjunction direct with the equated anomaly of the Sun. But if the scruple [is] in-

[Continuation of Precept 129:] -crement and decrement are inferior, and pertain to the part of the second column, or the next-to-last, whose title is B, then in Table 93, with the anomaly of Mercury equated at the front, or at the foot, and with the

equated anomaly of the Sun in the side-columns, the *Scruples of decrement* are to be taken in opposition, that is, in the retrograde conjunction.

Fourth, work so that, as 60" is to the proportional scruples of decrement in ☐ direct, or retrograde, of which there is mention, so the proportional scruples of increment, or decrement, found, correspond to the scruple to be applied to the correction of the scruples of latitude, and to be added to them.

Fifth, with the distance of the eccentric place of Mercury from the north node, find in Table 94 the sine of latitude, and work so that, as 60" is to this sine, so the corrected scruple of latitude corresponds to the other sine, which in Table 96 will exhibit the latitude of its kind, such as Table 94 indicates the distance of Mercury from the north node.

Example in the preceding case.

	Sig.	Gr.	'	"	
Anomaly ☿ equated [Anomali a ☿ aequata]	7	7	46	34	
Opposite to which are [Pro qua opposita sunt]	1	17	46	34	
Anomaly of the orbit [Anomali a Orbis]	8	17	18	0	
Equated anomaly of the Sun [Anomali a Solis]	4	2	16	42	Tab.

	Sig.	Gr.	'	"	
aq.]

Scruple increase or decrease [Scrup. Incr. vel Decr.] (which are the inferior) [Quae sunt inferiora] Therefor e [the] scruples of decreme nt [Ideo scrup. Decreme nti]	0	2	17	0	
In □ retrograd e are [In □ Retrogra da sunt]	0	0	31	0	93

Tab.

Since now 60" corresponds to 31", so 17" [gr. 2. 17'] corresponds to 12" [1'. 12']; subtracting the scruples of 22'24" [gr. 22. 24'], so that the corrected scruples remain at 21°12' [gr. 21. 12'].

Then:

	Sig.	Gr.	'	"	
Node Ω place was [Nodi Ω locus erat]	1	9	20	48	
\wp Eccentric place [Locus \wp Excentric us]	3	25	10	30	
Distance \wp from node Ω [Distanti a \wp à Nodo Ω]	2	15	49	42	
Sine of latitude [Latitudi nis Sinus]	0	6	15	0	in Table 94

Since now 60" corresponds to 6'15" [gr. 6. 15'], so 21'12" [gr. 21. 12'] corresponds to the sine 2'13" [Sinum 2. 13'], which in Table 96 gives the latitude of 2°18' North [grad. 2. 18'. Borealem], as the signs indicate the distance from the node and ascending [Distantia à Nodo, & Ascendentem], on account of the approach to the north limit [ob accessum ad litem Boreum].

Precept 130. To reduce the place of Mercury from the orbit to the ecliptic, and to work out its curtation.

Do everything as for Venus in Precept 127, but use the tables proper to Mercury, namely 91 and 94.

Example in the preceding case.

	Sig.	Gr.	'	"	
Distance ☿	2	15	49	42	Tab.
Eccentric Ω [Dist. ☿ Excentric i Ω]					
Reductio n, subtracti ve [Reductio subtr.]	0	0	6	3	94
Curtatio [Curtatio]	0	0	10	3

Equation of the orbit [Aequati o Orbis]	0	18	49	50	95
Differenc e of these [Differen tia harum]	0	0	9	0	

As $18^{\circ}19'$ corresponds to the reduction $6'3''$, so the difference $9'$ corresponds to $16''$ [$9'$. ad $16''$]. Therefore the place of Mercury reduced to the ecliptic was in \square $19^{\circ}1'24''$ [in \square grad. 19. 1'. 24'']. Next, as the maximum equation of the orbit $18^{\circ}19'$ corresponds to the curtation $10'3''$, so the equation of the orbit $18^{\circ}49'50''$ corresponds to the curtation $10'$ [ad Curtationem $10'. 3''$ ad Curtationem $10'$]; this, added to the place of Mercury reduced, [gives] indeed the equation of the orbit, which was subtractive [si quidem Orbis Aequatio fuit subtractiva], so the curtated place in the ecliptic was in \square $19^{\circ}11'$ [in \square grad. 19. 11']. This observation was placed in \square at $18^{\circ}46'$ circiter [in \square grad. 18. 46'. circiter], on account of the fallacious eye-estimation [oculi aestimationis] and the Lunar day's quantity between Saturn and Mercury seen [inter ♄ & ♃ visam].

Precept 131. To find the declination and right ascension of the planets by the tables.

By the tables, I say, without the solution of spherical triangles. Therefore first inquire the longitudes by Precept (and the like), and the latitudes of the planets by the precepts handed down above; then use Precept 54 and Tables 34 and 35, made for that use.

Precept 132. To find the distance of the minor planets from the Sun, in parts of which the mean radius of the Sun's annual orbit, or the radius of the annual orbit, is 100000.

You have, from the precepts given above for each individual planet, the equated anomaly of the planet; and resolve it into degrees — for if these degrees are sought first, in the first, or second, column of Table 97 (which is found on p. 108), then over against those degrees you will have, under each individual planet, the distance of that planet itself from the Sun, in parts of which the radius of the Sun's annual orbit, or the greater semidiameter of the Solar Ellipse, or the mean of the Sun from the Earth, is 100000. But if there is need, use the proportional part, as in Saturn.

Example, from Jupiter.

Above, in the Example of Precept 116, the equated anomaly of Saturn was Signs 0, gr. 11, $35'30''$ [Signorum 0. gr. 11. $35'. 30''$]. Resolved into degrees, it remains gr. $11^{\circ}35\frac{3}{4}'$ [grad. 11. $35' \frac{3}{4}$]; for these, in Table 97, under ♄ corresponds the distance from the Sun of 1008340 parts [partium 1008340], as may be seen by the proportional part.

But in the Example of Precept 119, the equated anomaly of Jupiter was Signs 3, gr. 6 [Sign. 3. gr. 6.]; for this, gr. 96 [grad. 96], which is precisely in Table 97 under \sphericalangle , corresponds the distance 935927 parts [distantia 935927. partium], of which the radius of the Sun's annual orbit is 100000. And so for the rest.

Precept 133. To find the distance of the minor planets from the Earth in parts of the radius of the Sun's annual orbit.

If you should desire the extreme distances from the Earth — when the planet is in apogee, or perigee (that is, in aphelion, or perihelion) — those are exhibited at the foot of Table 97. The rest must be hunted out by the help of trigonometry: from the distance from the Sun given by Precept 58, and the distances of the minor planets by Precept 132, with the angle of the equated anomaly comprehended from these distances.

Precept 134. To find the distance of the planets from the Sun, or from the Earth, in semidiameters of the Earth.

We have the distance of the planet first in parts, of which the radius of the Sun's annual orbit is 100000, by Precepts 132 and 133; and multiply it by the semidiameters of the Earth, which the mean distance of the Sun from the Earth contains, according to the opinion which you please here to follow; and divide the product by 100000 — for in the quotient you will have the distance you desire, in semidiameters of the Earth.

Example in Jupiter.

In the Example of Precept 132, for \sphericalangle we had the distance of Jupiter from the Sun of 935927 parts, of which the radius of the annual orbit is 100000. Now, since by us the mean distance of the Sun from the Earth is reckoned at 7300 semidiameters of the terrestrial [orb], multiply 935927 by 7300; the product is 6832287300; and this divided by 100000 leaves the distance of Jupiter from the Sun of 68323 terrestrial semidiameters [semidiametrorum terrestrium 68323].

Precept 135. To find the longitude and latitude of the fixed stars at any given time.

Therefore first, in Table 98 (which is found on p. 109), seek the longitude and latitude of the given fixed star, given to the end of the year of Christ 1700; for the latitude indeed is there found in perpetuity. Then [seek] the intervals of years between the given year and the year, and between the year 1700,

[Continuation of Precept 135 — the fixed stars' longitude and latitude for any given time.]

seek out from Table 100 the motion of the fixed stars matching the expanded and collected years, and reduce them into a single sum. If you add this sum, when the given time falls after the year 1700, or subtract it, when the given time precedes 1700 — the result is, or there remains, the longitude of the fixed star for the given time.

Example for Regulus, in the year 456.

For the completed year 1700 of Christ, the longitude of Regulus is 25° 38' 32" of Leo [□]. Its latitude, by contrast, is perpetually north at 0° 26' 20". Now let the year 456 of Christ be given, completed; subtracting this from 1700 leaves an interval of 1244 years, to which there corresponds, from Table 100, a motion of 15° 30' 29" — for the sum stands as follows:

Motion	Gr.	I	II	III
For 1000 years	14	4	26	6
For 200 years	2	48	53	20
For 44 years	0	37	9	20
Sum	15	30	28	46

If you subtract this (because the given time precedes the epoch) from Regulus's radix longitude of 25° 38' 32", there remains for Regulus a longitude of 10° 8' 3", which agrees with that found at the end of the year 456. And the north latitude is 0° 26' 20".

Precept 136. To find the right ascension and declination of the fixed stars for a given time, with a notable advisory concerning the Pole Star [the bright star in the Lesser Bear's shoulder] and stars like it.

If the fixed star in Table 99 is not the Pole Star [the bright Humerus of the Lesser Bear], seek its right ascension in Table 99, and adjoin to that very right ascension the centennial difference belonging to it at the end of the year 1700 of Christ. This difference is to be subtracted if the given time precedes 1700, but added if it follows — for at the year 1700 the procedure is reversed: where it says "subtract" you must add, and where it says "add" you must subtract. Furthermore, each

difference is to be multiplied by the interval of time between the year 1700 and the given time, and the product divided by 100; for there comes out the difference to be added to, or subtracted from, the radix of the year 1700, as I have said.

Example for Regulus, in the year 456.

In Table 99, for the completed year 1700, the right ascension of Regulus is $148^{\circ} 4' 15''$; its centennial difference is $1^{\circ} 22' 30''$. Its declination, by contrast, is north at $13^{\circ} 25' 16''$; and its centennial difference is $28^{\circ} 30'$ [*recte* read in context below]. Now the interval of preceding time was 1244 years, which, multiplied by the right-ascension difference of $1^{\circ} 22' 30''$, yields a sum in seconds of 4950"; this makes a sum of seconds of 5157800", which, divided by 100, leaves 51578" — that is, $14^{\circ} 19' 38''$. And because the given time precedes the radix, these subtracted differences are pulled away from the right ascension of $148^{\circ} 4' 15''$ stated; subtracting the said $14^{\circ} 19' 38''$ leaves, for the year 456 of Christ, Regulus's right ascension of $133^{\circ} 44' 37''$.

But concerning the declination, the difference is not to be subtracted but added — beforehand, since the centennial difference is $28^{\circ} 30'$, that is 1710", which, multiplied through the 1244 years, makes 2327240"; dividing this by 100 leaves 23272", that is $6^{\circ} 27' 52''$; and these added to the declination of the year 1700, namely $13^{\circ} 25' 16''$, give for the year 456 of Christ Regulus's north declination of $19^{\circ} 53' 8''$.

On the bright Humerus of the Lesser Bear, for the year 456.

We showed once before, in Book 6, Problem 11, and we stressed it in Volume One of the *Astronomia Reformata*, Book 4, that the right ascension of certain stars sometimes decreases, even while their longitude increases. Supposing the obliquity of the ecliptic to be perpetually $23^{\circ} 30'$ — as we suppose — the right ascension begins to decrease in the first quadrant of the ecliptic and ceases to decrease in the second, for stars of greater latitude than $66^{\circ} 29' 40''$. But if the stars are northern, the right ascension begins to decrease in the first quadrant of the ecliptic and ceases in the second. Of such stars we have here numbered thirty-five in Table 99 — except the bright Humerus of the Lesser Bear, which, in our own time, was Cynosura [the constellation tail-tip], and nearest the Pole of the World; for this star the north latitude is no greater than $72^{\circ} 48' 40''$. Hence it follows that, from the beginning of the World, its right ascension continually decreased, the longitude continually increasing, until it should reach roughly 15° of Leo — which befalls around the year 2137 of Christ.

Therefore, since the right ascension at the year 1700 in Table 99 is given as $222^{\circ} 39' 20''$, and the centennial difference is $1^{\circ} 15'$ — that is $75''$ — which, multiplied by the 1244 years that intervene from the year 456 to 1700, makes 93300"; and this, divided by 100, leaves 933", that is $15^{\circ} 33''$ — these are not to be subtracted but added, since the right ascension is decreasing, as the page 222, 39, 20 bears out; and so the right ascension of the bright Humerus of the Lesser Bear, for the year 456 of Christ, comes out to $238^{\circ} 12' 20''$.

TABVLAE NOVALMAGESTICAE

OF THE SECOND MOTIONS [SECVNDORVM MOBILIVM]

With several Tables of the Primum Mobile necessary to them.

[Half-title / banner page. Reverse-side (verso) show-through of the preceding tables is visible but carries no independent text.]

Prima Pars Tabularum Astronomicarum spectans ad Tempus.

[The First Part of the Astronomical Tables, concerning Time.]

[Table-volume pagination restarts here at 1.]

TABVLA I. Of the Parts of the As applied. [Partium Assis applicatarum.]

Parts [Partes] — Assis	Parts — Unciae [Vnciae]	Circle [Circulo] — Degrees [Grad.]	Of a Degree, or of an Hour [Gradui, vel Horae] — Minutes [Minuta]	Of a Day [Diei] — Hours [Horae]

Bes	8	240	40	16
Dodrans	9	270	45	18
Dextans	10	300	50	20
Deunx	11	330	55	22
As (Libra)	12	360	60	24

Parsing notes: The first column gives the Roman fractional-unit name of the *as* (uncia = 1/12, sextans = 2/12, etc.); "Unciae" gives the count in twelfths.

TAB. 2. Resolution of an Hour, a Degree, or a Circle into Sexagesimal Parts [Scrupula]. [Resolutio Horae, Gradus, aut Circuli in Scrupula.]

1 Hour or 1 Degree contains [Hora 1. vel Gradus 1. continet]	Value	One whole Circle contains [Circulus unus continet]	Value
Minutes [Minuta]	60	Degrees [Gradus]	360
Seconds [Secunda]	3600	Minutes [Minuta]	21600
Thirds [Tertia]	216000	Seconds [Secunda]	1296000
Fourths [Quarta]	12960000	Thirds [Tertia]	77760000
Fifths [Quinta]	777600000	Fourths [Quarta]	4665600000
Sixths [Sexta]	46656000000	Fifths [Quinta]	279936000000

1 Hour or 1 Degree contains [Hora 1. vel Gradus 1. continet]	Value	One whole Circle contains [Circulus unus continet]	Value
Sevenths [Septima]	2799360000000	Sixths [Sexta]	1679616000000 0
Eighths [Octava]	1679616000000 00	Sevenths [Septima]	1007769600000 000
Ninths [Nona]	1007769600000 0000	Eighths [Octava]	6046617600000 0000
Tenths [Decima]	6046617600000 00000	Ninths [Nona]	3627970560000 000000
		Tenths [Decima]	2176782360000 00000000 [?]

Parsing notes: This is the successive sexagesimal expansion ($\times 60$ at each step). The final "Decima" entry in the right-hand "whole Circle" column has the most digits and is hardest to count exactly; the trailing-zero run is read as best as the resolution allows and flagged [?]. The "Decima" cell for the left column ends the left ladder; the right column carries one extra row.

TAB. 3. Conversion of Hours, and their Sexagesimal Parts, into First and Second Parts of a Day, etc. [Conversio Horarum, earumque Scrupulorum in Diei Scrupula Prima, & Secunda, &c.]

Hours [Hore] / Minutes [Minuta] / Seconds [Secunda]	Dies	I / III	II / IV	Horae / Minutes / Seconds	Dies	I / III	II / IV

18	0	45	0	48	2	0	0
19	0	47	30	49	2	2	30
20	0	50	0	50	2	5	0
21	0	52	30	51	2	7	30
22	0	55	0	52	2	10	0
23	0	57	30	53	2	12	30
24	1	0	0	54	2	15	0

Hours [Hore] / Minut es [Minu ta] / Secon ds [Secun da]	Dies	I / III	II / IV	Horae / Minut a / Secun da	Dies	I / III	II / IV
25	1	2	30	55	2	17	30
26	1	5	0	56	2	20	0
27	1	7	30	57	2	22	30
28	1	10	0	58	2	25	0
29	1	12	30	59	2	27	30
30	1	15	0	60	2	30	0

Parsing notes: The table is laid out in two half-tables side by side (entries 1–30 left, 31–60 right). The leftmost stub stacks three labels (Horae / Minuta / Secunda) and the value columns three (I/II, II/III, III/IV) — i.e. an hour resolves into Dies + first/second day-parts; a minute one rank lower; a second one rank lower again. Each numbered argument multiplies by 2½ (= 2'30") of a day-part, the regular progression confirming the readings.

TAB. 4. Conversion of the Sexagesimal Parts of a Day into Equal Hours, and into Hour-Sexagesimals [Scrupula Horaria]. [Conversio Scrupulorum Diei in Horas Aequales, & Horaria scrupula.]

Sexagesimal Parts of a Day [Scrupula Diei]: Prima / Secunda / Tertia	Horae / I / II	I / II / III	Scrupula Diei: Prima / Secunda / Tertia	Horae / I / II	I / II / III
1	0	24	31	12	24

Sexagesimal Parts
of a Day
[Scrupula
a Diei]:

Scrupula

26	10	24	56	22	24

Sexagesimal Parts of a Day [Scrupula a Diei]:			Scrupula Diei:		
Prima / Secunda / Tertia	Horae / I / II	I / II / III	Prima / Secunda / Tertia	Horae / I / II	I / II / III
27	10	48	57	22	48
28	11	12	58	23	12
29	11	36	59	23	36
30	12	0	60	24	0

Parsing notes: Again two half-tables side by side (1–30 left, 31–60 right). Each argument-step adds 24 hour-sexagesimals (the inverse of Table 3: one day-sexagesimal = 24 minutes of time). The stub stacks Prima/Secunda/Tertia day-parts against Horae + I/II hour-parts. At argument 60 the value is exactly 24 hours, confirming the column.

[Table-page number: 1]

Tabulae novalmagesticae — Part I (Time tables), continued

(Table-volume pagination: page 2 = page 3 = page 4 =)

TABLE 5. Collection of the Days of the Common and Bissextile Roman Year

[TABVLA 5. Collectio Dierum Anni Romani Communis, & Bissextilis.]

The stub-column **Bissex.** (bissextile) carries entries only in the lower portion (running counts 28–31 with the cross mark † for the leap-day positions); **Côm.** (common) is the ordinary day-of-year argument. Each of the twelve month columns gives the accumulated day-number reached at the end of that day in that month.

Parsing notes: The **Epagomenæ** column carries values only at arguments 1–5 (361–365), the five epagomenal days that close the Egyptian year; below that it is blank, as printed.

TABLE 7. Conversion of the Hours of the Primum Mobile into parts of the Equator, with the Equation to be Added for the hours of the Solar Day

[TAB. 7. Conuersio Horarum Primi Mobilis in Partes Aequatoris, cum Aequatione Addenda pro horis Diei Solaris.]

This table is printed in three side-by-side panels (each with its own argument run) so as to fit a full conversion on one page. Each panel converts an argument of the Primum Mobile into degrees and scruples of the equator (**Æquat.**: Gr. = degrees, with the sexagesimal scruples I = primes/minutes, II = seconds, III = thirds, IV = fourths), and gives the **equation to be added for the Sun** (☉, "Adde pro ☉").

Panel 1 — argument: Hours of the Primum Mobile (*Pri.Mob. Horæ; Minut.; Secund.*)

Column unit-stack as printed: argument **Horæ** (units I), **Minut.** (units II / I), **Secund.** (units III / II); equator **Æquat. Gr.** with scruples **I** (units II), **II** (units III); add-for-Sun **I** (units III), **II** (units IV).

Horæ	Æquat. Gr.	Adde ☉			
		I	II	Adde ☉ I	II
1	15	2	28	—	—
2	30	4	56	—	—
3	45	7	24	—	—
4	60	9	52	—	—
5	75	12	20	—	—
6	90	14	47	—	—
7	105	17	15	—	—
8	120	19	43	—	—
9	135	22	11	—	—
10	150	24	39	—	—

22	330	54	14	—	—
23	345	56	42	—	—
24	360	59	10	—	—

Parsing notes: In Panel 1 the "Adde pro ☉" sub-columns are blank for the whole-hour arguments (the solar equation accrues only at the finer minute/second resolution shown in Panel 2). Argument label printed as **Horæ** (hours of the Primum Mobile).

Panel 2 — argument: Minutes / Seconds of the Primum Mobile (*1.Mob. Min.; Secund.; Tert.*)

Min.	G.	Æquat. I	Æquat. II	Adde ☉	
				Adde ☉ I	II
1	0	15	0	0	2
2	0	30	0	0	5
3	0	45	0	0	7

5	1	15	0	0	12
6	1	30	0	0	15
7	1	45	0	0	17
8	2	0	0	0	20
9	2	15	0	0	22
10	2	30	0	0	25
11	2	45	0	0	27
12	3	0	0	0	30
13	3	15	0	0	32
14	3	30	0	0	35
15	3	45	0	0	37
16	4	0	0	0	39
17	4	15	0	0	42
18	4	30	0	0	44
19	4	45	0	0	47
20	5	0	0	0	49
21	5	15	0	0	52
22	5	30	0	0	54
23	5	45	0	0	57
24	6	0	0	0	59

Min.	G.	Æquat. I	Æquat. II	Adde ⊙	
				Adde ⊙ I	II
25	6	15	1	0	2
26	6	30	1	1	4
27	6	45	1	1	7
28	7	0	1	1	9
29	7	15	1	1	11
30	7	30	1	1	14

Parsing notes: Panel-2 column stack as printed: argument **Min.** (units I) / **Secund.** (units II) / **Tert.** (units III); **G.** (degrees, II); **Æquat. I** (III) and **II** (IV); **Adde ⊙ I** (III) and **II** (IV). At argument 25 the "Adde ⊙" pair rolls over to the next sexagesimal place (II = 2). Reading of the lower-right add-column digits is tight but legible.

Panel 3 — argument: Minutes / Seconds of the Primum Mobile (continued 31–60) (1.Mob. Minur.; Secund.; Tert.)

Min.	G.	Æquat. I	Æquat. II	Adde ⊙	
				Adde ⊙ I	II
31	7	45	1	1	16
32	8	0	1	1	19
33	8	15	1	1	21
34	8	30	1	1	24
35	8	45	1	1	26
36	9	0	1	1	29
37	9	15	1	1	31
38	9	30	1	1	34
39	9	45	1	1	36
40	10	0	1	1	39
41	10	15	1	1	41
42	10	30	1	1	44
43	10	45	1	1	46
44	11	0	1	1	48
45	11	15	1	1	51

Min.	G.	Æquat. I	Æquat. II	Adde ☉	
				Adde ☉ I	II
46	11	30	1	1	53
47	11	45	1	1	56
48	12	0	1	1	58
49	12	15	2	2	1
50	12	30	2	2	3
51	12	45	2	2	6
52	13	0	2	2	8
53	13	15	2	2	11
54	13	30	2	2	13
55	13	45	2	2	16
56	14	0	2	2	18
57	14	15	2	2	21
58	14	30	2	2	23
59	14	45	2	2	25
60	15	0	2	2	—

Parsing notes: At argument 60 the equator value is 15° 0' (matching argument 4 of Panel 2 scaled), consistent with 60 minutes = 1 hour-of-PrimumMobile → 15°. The final "Adde ☉ II" cell at arg 60 is blank/cut in the source (the running pattern would give ~28); flagged [?] for that single cell only.

TABLE 8. Conversion of the parts of the Equator into time of the Primum Mobile, with the Equation to be Subtracted for the times of the Solar Day

[TAB. 8. Conuersio Partium Aequatoris in Tempus Primi Mobilis, cum Aequatione Subtrahenda pro Diei Solaris Temporibus.]

Three side-by-side panels. Each converts an argument of the equator (**Æquat.**: Grad. = degrees, Min. = minutes, Secúd. = seconds) into time of the Primum Mobile (**Tép. 1.Mob.**: Hor. = hours, with scruples I, II) and gives the **equation to be subtracted for the Sun** (☉, "Subtr. pro ☉": I, II).

Panel 1 — argument: Degrees of the Equator (*Æquat. Grad.; Min.; Secúd.*)

Column stack as printed: argument **Grad.** (units I) / **Min.** (II) / **Secúd.** (II); time **Hor.** with scruples **I** (units I, II) and **II** (II); subtract-Sun **I** (III) and **II** (IV).

				I	II
270	18	0	0	2	57
280	18	40	0	3	4
290	19	20	0	3	10
300	20	0	0	3	17
310	20	40	0	3	23
320	21	20	0	3	30
330	22	0	0	3	36
340	22	40	0	3	43
350	23	20	0	3	49
360	24	0	0	3	56

Parsing notes: Panel 3 jumps from the by-degree argument of Panels 1–2 to a by-ten-degrees argument (70, 80, ... 360). At 360° the time equals 24h 0', as expected (full rotation). The "Subtr. ☉" column grows monotonically to 3' 56" at 360°. Several mid-column thirds/fourths digits in this panel are faint; the readings given follow the smooth progression and are confident, but rows 130 ("Subtr. ☉ II = 25"?) and 290 are slightly ink-light.

TABLE 9. Conversion of Hours into other Hours, reckoned from a different beginning of the Day

[TABVLA 9. Conuersionis Horarum in alias Horas, à diuerso Diei initio numeratas.]

This is a rule-table (a prose conversion grid), not a numerical table. The left stub names the **Hours to be converted** (*Horæ conuertendæ*); the right body gives **They are converted** (*Conuertuntur*) into the target reckoning by the stated rule.

Babylonian hours, or reckoned from Sunrise (*Babylonicæ, seu ab Ortu Solis, in*) are converted into —

- **Astronomical hours** (*reckoned from the preceding noon*): by adding to the Babylonian hours the half-day quantity (*semidiurnam quantitatem*) and the nocturnal quantity (*& nocturnam*).
- **European hours** (*from noon*): by subtracting from the Babylonian hours the half-day quantity, if the Babylonian hours exceed it; but if they do not exceed it, then once the subtraction is made, subtract the remainder from 12 hours — and there will remain the European hours from midnight.

- **Italian hours, or reckoned from Sunset** (*seu ab Occasu*): by adding the nocturnal quantity (*nocturnam quantitatem*).

Italian hours, or reckoned from Sunset (*Italica, seu ab Occasu Solis, in*) are converted into —

- **Astronomical hours:** by adding the half-day quantity.
- **European hours** (*from noon*): (if the Italian hours do not exceed the half-nocturnal quantity) by adding the half-day quantity (*semidiurnam*).
- **European hours** (*from midnight*): (if the Italian hours exceed the half-nocturnal quantity) by subtracting the half-nocturnal quantity (*seminocturnam*).
- **Babylonian hours:** by subtracting the nocturnal time (*tempus nocturnum*) from the Italian hours.

Astronomical hours, or from noon to noon (*Astronomica, seu à meridie ad meridiem, in*) are converted into —

- **European hours from noon** (*à meridie*): if they do not exceed 12, by adding or subtracting nothing.
- **European hours from midnight** (*à media nocte*): if the Astronomical hours exceed 12, let 12 be taken away (*demantur 12*).
- **Babylonian hours:** by adding to the Astronomical hours the half-day quantity.
- **Italian hours:** by subtracting from the Astronomical hours the half-day quantity.

European hours from midnight — which, because from midnight, coincide with the Astronomical (*Europœa à media nocte, namque à meridie coincidunt cum Astronomicis, in*) are converted into —

- **Astronomical hours:** by adding 12 European hours.
- **Babylonian hours:** by subtracting the half-nocturnal quantity from the European hours.
- **Italian hours:** by adding the half-nocturnal quantity to the European hours.

General rules (*at the foot of the table*):

Whenever the subtraction cannot be made (*Quoties subtractio fieri nequit*), add 24 to the given hours, and from the sum subtract what is required.

Whenever from the addition more than 24 results (*Quoties ex Additione fiunt plusquam 24*), cast away 24 and keep the rest.

TABLE 10. The Quantity of one Temporal Hour, corresponding to the quantity of the Artificial Day

[TABVLA 10. Quantitas Horæ unius Temporalis, Respondens quantitati Diei Artificialis.]

Six side-by-side panels share the layout. Each pairs an argument with the corresponding quantity of a single temporal (seasonal) hour. The first two panels use the argument **Minuta Diei Artific.** (minutes of the artificial day) → **Duodecima eorum pars** (their twelfth part, in I = minutes, II = seconds); the remaining four panels use the argument **Artific. Diei. H.** (hours of the artificial day) → **Duodecima pars** (its twelfth part, in I, II).

Panel A — Min. Diei Artific. → Duodecima pars (Min.; I, II)

Min.	I	II
1	0	5
2	0	10
3	0	15
4	0	20
5	0	25
6	0	30
7	0	35
8	0	40
9	0	45
10	0	50
11	0	55
12	1	0
13	1	5
14	1	10
15	1	15
16	1	20
17	1	25
18	1	30

Min.	I	II
19	1	35
20	1	40
21	1	45
22	1	50
23	1	55
24	2	0
25	2	5
26	2	10
27	2	15
28	2	20
29	2	25
30	2	30

Panel B — Min. Diei Artific. → Duodecima pars (continued 31–60)

Min.	I	II
31	2	35
32	2	40
33	2	45
34	2	50
35	2	55
36	3	0
37	3	5
38	3	10
39	3	15
40	3	20
41	3	25
42	3	30
43	3	35
44	3	40
45	3	45
46	3	50

Min.	I	II
47	3	55
48	4	0
49	4	5
50	4	10
51	4	15
52	4	20
53	4	25
54	4	30
55	4	35
56	4	40
57	4	45
58	4	50
59	4	55
60	5	0

Panel C — Artific. Diei H. → Duodecima pars (H.; I, II)

H.	I	II
1	0	5
—	10	5 50
2	0	10
—	10	10 50
3	0	15
—	10	15 50
4	0	20
—	10	20 50
5	0	25
—	10	25 50
6	0	30

Parsing notes (Panel C): This panel is printed as interleaved sub-rows: each whole-hour argument (1, 2, ...) is followed by an indented 10-line giving the value when 10 minutes are added to that hour. The interleaving and the bound digits

make the sub-rows hard to align precisely; the whole-hour values (H.1 → 0' 5", H.2 → 0' 10", ..., H.6 → 0' 30") are confident, but several of the indented 10-line second-place digits are [?]. Treat Panel C as a for the indented sub-rows.

Panel D — Artific. Diei H. → Duodecima pars (H.; I, II)

H.	I	II
7	0	35
8	0	40
9	0	45
10	0	50
11	0	55
12	1	0

Parsing notes (Panel D): As in Panel C, each whole-hour row is followed by indented 10-, 20-, 30-, 40-, 50-minute sub-rows giving intermediate twelfth-part values; those indented digits are faint and partially bound in the gutter region. The whole-hour values (H.7 → 0' 35" ... H.12 → 1' 0") are confident. Sub-row digits [?]

Panel E — Artific. Diei H. → Duodecima pars (H.; I, II)

H.	I	II
13	1	5
14	1	10
15	1	15
16	1	20
17	1	25
18	1	30

Parsing notes (Panel E): Same interleaved sub-row structure; whole-hour values confident (H.13 → 1' 5" ... H.18 → 1' 30"). Indented sub-row digits [?]

Panel F — Artific. Diei H. → Duodecima pars (H.; I, II)

H.	I	II
19	1	35
20	1	40
21	1	45

H.	I	II
22	1	50
23	1	55
24	2	0

Parsing notes (Panel F): Whole-hour values confident (H.19 → 1' 35" ... H.24 → 2' 0", i.e. a 24-hour artificial day yields a temporal hour of exactly 2' 0" of the twelfth-part scale — consistent with the linear law value/12). Indented sub-row digits faint and partly cut at the bottom-of-page / gutter; [?].**

[Foot signatures, left→right: A | B | C | D | E | F]

Tabulae novalmagesticae — Part I (Time Tables), Table 11

TAB. 11. *Semidiurni Temporis, quando Sol est in Signis Borealibus, Seminocturni autem quando Sol est in Signis Australibus ad infrascriptas Poli Altitudines.* [TABLE 11. Of the semi-diurnal time, when the Sun is in the northern signs, but of the semi-nocturnal time when the Sun is in the southern signs, for the pole altitudes written below.]

This is a single full table running across three table-volume pages (pp. 5–7 = giving the length of the semi-diurnal arc expressed in time (hours **H.** and minutes / of time) as a function of two arguments:

- **Stub (argument) columns:** at the left and right edges, the Sun's position. The left pair gives **Sign. Aust.** (southern sign) / the sign-glyph and **Gradus** (degrees within the sign) for the northern-sign case; the right pair gives **Sign. Bor.** / **Gradus** in the reciprocal (southern-sign) case. The degree argument runs 0, 3, 6, 9, 12, 15, 18, 21, 24, 27 (and 30) within each sign.
- **Column groups across the top:** the **Poli Altitudo** (pole altitude / terrestrial latitude) in whole degrees, each split into **H.** (hours) and / (minutes) sub-columns.

Each pair of entries is the half-length of the day (or night) at that latitude for that solar position, in equinoctial hours and minutes. Values near 6h 0' correspond to the equinoctial situation; they increase with latitude and with the Sun's distance from the equator.

The decorative sign-glyphs in the stub: ♈ Aries, ♉ Taurus, ♊ Gemini (northern, ascending) paired against ♎ Libra, ♏ Scorpio, ♐ Sagittarius (southern); and at the far right the reciprocal glyphs ♍ Virgo, ♌ Leo, etc., marking where the same numeric body serves the complementary case.

Table 11 — Panel 1 (table-volume p. 5 = PDF p. 457, upper half): Pole altitudes 6°–37°

[Left stub: **Sign. Aust. / Sign. Bor., Polus, Gradus.** Right stub: **Sign. Bor. / Sign. Aust., Polus, Gradus.**]

Sign sequence in the left stub for this panel: ♎ (Libra group) with ♈ Aries; then ♉/♊ Taurus; then ♊/♈ Gemini. Right-stub reciprocals: ♍, ♌, etc.

Parsing notes: □/□ solstitial limit at the foot, right stub. Foot signature **F**; right margin catchword **Poli** (catching "Poli Altitudines" of the next page). At degree 15, the 49°-column prints "7 19", identical to the 47°-column "7 19" in the same row;

the across-column progression (7 15 → "7 19" → "7 19") is non-monotone — one of the two (most likely the 47°-column entry) is a suspected compositor repeat. Transcribed as printed in both cells.

Table 11 — Panel 3 (table-volume p. 6 = PDF p. 458, upper half): Pole altitudes 50°–59°

Parsing notes: latitude 60°–68°. Past the Arctic Circle (66⅔°) the Sun no longer sets near the solstice, so the lower-right cells run blank (—) where continuous day begins; the appendix below handles those cases. The 66⅔° column reaches "12 0" (a full half-day) at the last row. The blanks (—) in the 67° and 68° columns are genuine blank cells in the source (layout feature, not illegibility). The □/□ boundary row at "0" is the Taurus/Gemini junction.

Table 11 — Panel 5 (table-volume p. 7 = PDF p. 459, upper half): Pole altitudes 69°–80°

[Header: **Poli Altitudines**. Left stub: **Polus / Grad.**; right stub **Polus / Grad.**]

Parsing notes: latitude 81°–89°, with the pole (90°) collapsing to a single column. Near the pole, even small solar declinations yield perpetual day; almost all cells blank. Right-stub glyph at foot □ / □ marks the reciprocal sign-limit. The "90" stub holds only the □0 entry.

Appendix to Table 11 (table-volume p. 7 = PDF p. 459, lower half)

[Display heading:]

Appendix TAB. 11. pro Maxima Die, ubi Polus elevatur plus Gradibus 66⅔, ex Sphæra Clavii cap. 4. non considerantis Refractiones, pro quibus vide nostram Geographiam Reformatam. [Appendix to Table 11, for the longest day, where the pole is elevated more than 66⅔ degrees, from the *Sphere* of [Christopher] Clavius,

chapter 4, which does not take account of refractions — for which see our *Reformed Geography*.]

This appendix gives, for high latitudes (pole elevations beyond the Arctic Circle, where the day becomes continuous), the **Arcus semper apparens** (the arc of the ecliptic / sky always above the horizon — i.e. the band of perpetual day) and the **Dies continuus** (the duration of continuous day), as functions of **Elevatio Poli** (pole elevation in degrees).

- **Elevatio Poli** (Gr. = degrees): the latitude argument.
- **Arcus semper apparens** (Gr. degrees, M. minutes of arc): the always-visible arc.
- **Dies continuus** (D. days, H. hours, M. minutes): the length of the continuous day.

Elevatio Poli (Gr.)	Arcus semper apparens (Gr.)	Arcus (M.)	Dies continuus (D.)	Dies (H.)	Dies (M.)

85	154	42	161	5	23
86	159	50	166	11	23
87	164	52	171	21	47
88	169	58	176	5	29
89	174	58	181	21	58
90	180	0	187	6	39

Parsing notes: the table is printed in two side-by-side halves (rows 67–78 on the left, 79–90 on the right); I have stacked them into one sequence by **Elevatio Poli**. The **Dies continuus** "H." column at Elevatio 81 reads "31" which exceeds 24 — flagged as impossible (likely a compositor error or a misread of the day-count carry); transcribed as printed. The **Dies continuus** "D." column jumps 90 → 104 between rows 74 and 75 (a 14-day jump where neighbours step by ~5–10); transcribed as printed (suspected source error). The reference is to Clavius, *In Sphaeram Ioannis de Sacro Bosco Commentarius*, ch. 4.

[A faint offset/show-through of a table from the facing leaf is visible at the lower right margin — not part of this page's content.]

TABLE 12. The Equation of Time at the Sun's apogee [in ☉ apogeo], according to Tycho [Brahe], with the obliquity of the ecliptic posited at 23° 30' 20"

[TAB. 12. Aequat. Temporis in ☉ apogeo, Tychonicè, ad mentem ejus positâ Obl. Ecl. gr. 23. 30'. 20".]

[Heading rubric over the body: **Subtract from the Apparent. Add to the Equal time.** (*Subtr. Appar. Adde Æqu. temp.*)]

The argument column at the left ("Gr." = degrees) is the Sun's place; the upper paired-sign banner runs ☐ & ☐ | ☐ & ☐ | ☐ & ☐ | ☐. The four data groups give the

equation in minutes/seconds/etc. (" " """) and a final "Gr." column descending 30→0.

Gr.	(□	'	"	""	(□	'	"	(□	'	"	(□	'	"	Gr.

29	8	12	2	8	54	51	0	21	41	1
30	8	23	8	8	45	29	0	0	0	0

[Footer rubric: **Gr.** (left) | **Add to the Apparent, Subtract from the Equal.** (*Adde Apparenti Subtrahe Æquali.*) | **Gr.** (right)]

Parsing notes: This is a four-quadrant equation-of-time table; the ascending argument (0→30) reads the upper sign-pairs, the descending argument (30→0) reads the lower rubric. Several blank cells (where the ascending and descending series meet) left empty as printed. Row 10's first group reads "2 15 49" where a smooth progression would expect □ 3 15; flagged below as a likely compositor error.

[Lower-left sub-table on table-page 8:]

Residuum [Remainder] of TABLE 12.

[The argument column "Ano-maliæ" (anomaly), in "Gr.", runs 0→30; the table gives corrections of the Sun's equation of time ("Anomal. Solis Coæqu.") under headings I, II,... for the several signs, with descending "Anomalæ" at the right.]

[Footer rubric: **V. Subtr.** | **IV. Subtr.** | **III. Subtr.** — **XI. Add.** | **X. Add.** | **IX. Add.**
| **Anomal. Solis Coæqu. Signa** (the signs of the equated solar anomaly).]

Parsing notes: This compact residuum/interpolation sub-table is badly cramped in the gutter; the three-column digit grouping is the best reading achievable at this resolution. The third group ("III/IX") jumps from a leading "5 32 50" downward, and the second digit-pair is hard to separate from the first — several cells flagged uncertain. Whole sub-table

Parsing notes: This twelve-column civil-day equation table is exceptionally dense, with sign-column boundaries that the original prints without rule-lines between every pair, so adjacent sign-columns' digit pairs run together. Cells marked "S." / "A." are the printed switch-points where the correction changes from Subtract to Add (or vice versa) mid-column (e.g. "0. S. 19" at □/row 19; "0 A. 8" at □/row 29). Many interior digit-pairs are ambiguous at this resolution and the per-cell groupings should be regarded as provisional; whole table

[Lower-right sub-table on table-page 8:]

Another [Altera] provisional TABLE of the Equation of Civil or Natural Days, serving exactly for the Year of Christ 1736; for [converting] Common [Apparent] into Equal [Mean Time].

[Altera TAB. Temporaria Aequationis Dierum Civilium, & servient exactè Anno Christi 1736. pro Comm. App. in Aeq.]

Same structure as the table above (argument "Loci ☉," "Gr." 0→30; twelve zodiacal sign columns, each Add./Subtr. in minutes & seconds).

[Footer rubric, spanning both right-column sub-tables: **If [the correction] is to be applied to the Apparent [time] [Si Aequale vertendum sit in Apparens], do the opposite of the title** (*Fac contrarium Tituli*).]

Parsing notes: Both right-column sub-tables (TAB. 13 and its *Altera*) are the densest on the page — twelve sign-columns of minute/second pairs printed without separating rules. The digit groupings within each row should be treated as provisional; the original frequently runs the trailing column of one sign into the leading column of the next. The "S." / "A." in-column markers flag where a given sign's correction crosses from Subtract to Add. Both sub-tables No sexagesimal value clearly exceeds 59 in the seconds positions that could be confidently isolated, but column alignment is too uncertain to certify the absence of impossibles.

TABLE 14. CATALOGUE OF THE MORE NOTABLE PLACES.

[TAB. 14. CATALOGVS LOCORVM INSIGNIORVM.]

With the Difference of Time to be Added to, or Subtracted from, the Time of the Bologna Italic meridian, and the Altitude of the North Pole [latitude], where no "A." is added [the difference is to be subtracted, "sub."]. Taken from Book 9 of our *Geographia Reformata*, in which it is treated much more fully.

[Cum Differentia Temporis Addenda, aut Subtrahenda Tempori Meridiani Bononiensis Italici, & Altitudine Poli Borealis, ubi non additur A. sumptus ex Lib. 9. Nostrae Geographiae Reformatae, in quo habetur multò amplius.]

Column headings: **Nomina Locorum** (Names of Places — Latin name, then a vernacular/modern form in italics); **Differentia Temporis** (Difference of Time: H. = hours, ' = minutes, " = seconds; "ad." = add, "sub." = subtract); **Altitudo Poli** (Altitude of the Pole = latitude: G. = degrees ' "). The page is set in two parallel halves; the entries below run the left half first, then the right half.

[Left half of table-page 9:]

Parsing notes: Place-name catalogue. Each entry gives the Latin place-name, an italic vernacular form, the time-difference (H ' " with ad./sub./A.), and the latitude (G ' "). The "A." after a latitude (e.g. *Angola, Caput S. Augustini, Caput Bonæ Spei*) marks Southern (Austral) latitude. Several time-difference and latitude minute/second values in the gutter were hard to resolve; transcribed as best read.

[TABLE 14, continued — CATALOGUE OF THE MORE NOTABLE PLACES. Same column structure (Names of Places; Difference of Time H ' " ad./sub.; Altitude of the Pole G ' ").]

Parsing notes: Catalogue continues. As on the previous page, each entry pairs a Latin place-name with an italic vernacular form; the time-difference is H ' " with ad./sub.; the latitude is G ' ". A handful of gutter-side minute/second values were difficult to read (e.g. *Complurum* latitude shows "4 28" where □ 40 28 would be expected for Alcalá de Henares; *Comorinum* latitude shows a sun-symbol glyph "☉" for a digit). Note the editorial gloss at *Ferraria Italiæ* — "*Auctoris Patria*" (the Author's homeland), i.e. Riccioli's native city, Ferrara.

TAB. 14 — *Catalogus Locorum Insigniorum* (Catalogue of the More Notable Places), continued

Gazetteer from the Geographia Reformata. Each entry pairs a Latin place-name with its italic vernacular form, the time-difference from the Bologna Italic meridian (H. ' " , with ad. = adding / sub. = subtracting), and the latitude (G. ' " = degrees, minutes, seconds of the elevation of the pole).

Column headers throughout: **Nomina Locorum** (Names of Places) | **Differentia Temporis** (Difference of Time): H. ' " | **Altitudo Poli** (Elevation of the Pole): G. ' " .

Parsing notes: Two compound entries spread their italic vernacular onto a continuation line in the stub ("Nanchinum Sinarum. / Nanking ad" and "Nanquinum Chinæ vel"). The "Nanchinum" row's *ad.* column-marker fell on the continuation line in the source; I have placed it in the row's *ad./sub.* column. Catchword at foot: "Nea-" (→ *Neapolis*). "Lingones Lägres · *Lin* [?]" — the vernacular form is truncated/abbreviated in the source.

Samar- kanda vetus. · <i>Samar- kand & noua</i>	4	6	0	ad.	45	0	0
[Sama- rkand- a, secon- d line]	4	3	4	ad.	39	37	23

Parsing notes: The "Pequinum"/"Quinsai" and "Samarkanda vetus / & noua" entries each give two rows of figures (old/new or alternate positions); I have transcribed both numeric lines, the second on a [...second line] row. "Plescouia Russiæ" — the minutes/seconds of the time-difference fell on the continuation line in the source and are not legibly resolvable as printed (the *ad.* marker is on the second line); marked [-]. Catchword at foot: "San-" (→ *Sancianum*).

Parsing notes: This page ends the gazetteer (TAB. 14). Two entries appear for Syracuse with slightly different latitude seconds ("Siracusæ · *Siracusa*" at 37° 3' 57" and "Sytacusæ · *Siracusa*" at 37° 3' 37") — transcribed as printed; the duplication and the differing seconds (57" vs 37") are a source feature, not a misread. "Uraniburgum Daniæ" is Tycho Brahe's [Tycho Brahe] observatory island of Hven/Uraniborg.

Closing note (boxed, at foot of table-page 13):

Many places, even notable ones, we have omitted, because right now there is scarcely time for them — places for which an astronomical calculation must be carried out, or which we are unwilling to transfer to this place. But since the longitude of **BOLOGNA** is established, from what we have demonstrated in our *Geographia Reformata*, at 34° 30' from the **PALMA** of the Fortunate Isles, the longitude of other places can easily be gathered from this Catalogue, by means of the difference of Time converted through Table 7 above (where it is divided into its parts), and the scruples [seconds] of the Equator, with 34° 30' added where the note reads *ad.*, or subtracted where the note reads *sub.*

TAB. 17. Of the Centesimal (Hundred-) Years, Common or Bissextile in the Gregorian Form, with the Excess of Days over the Julian Days [Annorum Centesim. Communium, vel Bissextilium in forma Anni Gregoriani, cum Dierum excessu supra Dies Iulianos]

In the leftmost two sub-columns, **B** marks a centesimal year that remains bissextile (leap) in the Gregorian reckoning, and **C** marks one that becomes common (non-leap). "Dies" is the cumulative excess of Gregorian over Julian days.

	Anni	Dies		Anni	Dies
B	1600	10	C	4100	29

	Anni	Dies	Anni	Dies
C	3800	27		
C	3900	28		
B	4000	28		

Note (spanning beneath Tables 15–17): It is assumed that the intercalation was made in the years [indicated], and thereafter always as Julius Caesar had ordered — leaving out of account here the Year of Confusion and the error of the ancients in intercalating. [*Supponitur intercalatio facta Annis ante, & porro semper prout iusserat Iulius Caesar, dissimulato hoc Anno Confusionis, & errore Priscorum in intercalando.*]

TAB. 18. Of the Cycles of the Sun [Cyclorum Solis]

This table lists multiples (years) belonging to the 28-year solar cycle. Read down each column in turn.

28	1008	1960	2968
56	1036	1988	2996
84	1064	2016	3024
112	1092	2044	3052
140	1120	2072	3080
168	1148	2100	3108
196	1176	2128	3136
224	1204	2156	3164
252	1232	2184	3192
280	1260	2212	3220
308	1288	2240	3248
336	1316	2268	3276
364	1344	2296	3304
392	1372	2324	3332
410	1400	2352	3360
448	1428	2380	3388
476	1456	2408	3416
504	1484	2436	3444

532	1512	2464	3472
560	1540	2492	3500
588	1568	2520	3528
616	1596	2548	3556
644	1624	2576	3584
672	1652	2604	3612
700	1680	2632	3640
728	1708	2660	3668
756	1736	2688	3696
784	1764	2716	3724
812	1792	2744	3752
840	1820	2772	3780
868	1848	2800	3808
896	1876	2828	3836
924	1904	2856	3864
952	1932	2884	3892
980		2912	3920
		2940	3948

Parsing notes: the final two rows of the last two columns read "2912 / 3920 / Cycli sunt 175" and "2940 / 3948". The second column ends at 1932; column 1 ends at 980.

TAB. 19. Of the Weekday Table [Hebdomatica Feriarum]

The column headers carry both Roman ferial numbers (I–VII) and the Greek weekday names (with their planetary symbols beneath): I Κυριακή (Lord's Day / Sunday, ☉ Sun); II Δευτέρα (Monday, ☾ Moon); III Τρίτη (Tuesday, ♂ Mars); IV Τετράς (Wednesday, ☿ Mercury); V Πέμπτη (Thursday, ♃ Jupiter); VI Παρασκευή (Friday, ♀ Venus); VII Σάββατον (Saturday, ♄ Saturn).

I — Κυριακ ή ☉	II — Δευτέρ α ☽	III — Τρίτη ☿	IV — Τετράς ♃	V — Πέμπτη ♃	VI — Παρασκ ευή ☿	VII — Σάββατ ον ♄
Iunius (June)	Septem ber	April.				
4	Decem b.	5	6	7	8	Martius (March)
9	10	11	12	Maius (May)	13	14
15	16	Iulius (July)	17	18	19	20
Febr. seq. (the followi ng Februa ry)	21	22	23	24	August. (August)	25
26	27	28	Octob. (Octobe r)	Ianu. seq. (the followi ng January)		Nouem b. (Novem ber)

TAB. 20. Of the Weekday in the Arabic Vague Year [Feriarium in Anno Arabico vago Hegirae]

The body shows, for each ferial column (I–VII), the running day-count and the months of the Arabic (Hegira) year that begin on that weekday. The rightmost column is the "Cyclus Arabicus" (Arabic cycle).

I	II	III	IV	V	VI	VII	Ciclus Arabic us
	180		150		120	0	

I	II	III	IV	V	VI	VII	Ciclus Arabic us
90		60		30			210 — 0
	2			1		Much arram . 3	410 — 0
5	Sepha r	Rabie I 7	4	Rab- ie II 9	6	8	630 — 0 840 — 0 1050 — 0
	10		12		Giuma -di I. II		1260 — 0
13	Regeb	15			14		1470 — 0
Giuma -di II	18		Sabab en	17		16	1680 — 0
21			20		Rama dhen	19	Scheu al
Dulka- dati		23		25		22	24
29	Dulha- cati	28	30 curr.		27		

Parsing notes: this is a crowded grid; month-names (Mucharram, Sephar, Rabie I, Rabie II, Giumadi I, Giumadi II, Regeb, Sababen, Ramadhen, Scheual, Dulkadati, Dulhacati) are interleaved with day-numbers across the ferial columns, and the right-hand "Ciclus Arabicus" runs 210, 410, 630, 840, 1050, 1260, 1470, 1680, 1890, 2100 each paired with 0. The "30 curr." (= 30 *currens*, "30 running/current") is at the foot of column IV. Cell alignment is approximate; some day-numbers sit between columns in the source.

TAB. 21. Of the Collected Years, and the Months of Various Nations [Annorum Collectorum, & Mensium Diversarum Nationum]

The left block tabulates "Roman Julian Years" (Romanorum Iulianorum Anni) against the cumulative "Collected Days of the Common Months" (Dies Collecti Mensium Com.) and the bissextile count (Bissex.). The right blocks give the month-names of several nations: Macedonian & Antiochene months (Menses Macedonum, & Antiochen.); the less-settled Athenian months (Athenien[s]ium Menses inconstantes); the Greek month-appellations with their zodiacal signs (Graecorum Mensium aliae appellationes); and the Syrian & Jewish months (Syrorum, & Iudaeorum menses).

Note beneath: The months of the Syrians, Jews, and Macedonians — certain of them begin from the seventh of the Julian months; the Athenian and Greek months for the greater part of themselves run concurrent with the Julian months noted opposite. [*Syrorum, Iudaeorum, ac Macedonum Menses, quidam ineunt à septimis diebus Iulianorum Mensium Athenienses, & Graecorum Menses potiori sui parte concurrunt cum Iulianis Mensibus è regione notatis.*]

Of the Egyptians, & Persians [Aegyptiorum, & Persarum]; and the 30-day Months, with their beginnings [Menses 30. dierum, & horum initia in ...]

This composite block: at left, the collected years and days of the Egyptians; the days of the Egyptian and Persian collected months; then the 30-day months of the Egyptians, Persians, modern Alexandrians (Alexandrini Hodierni), Copts & Abyssinians (Coptitarum, & Abissin.); and at right the start in the Julian bissextile / common year (Anno Iulian. Bissextil. — Comm.).

		Epago menç 365	Asphan dar 365	Elnisi	Pagome n	August. 24 — 24

Note (Persian column): "Vuahak significat additionem dierum 5" — *Vuahak* signifies the addition of 5 days. (At Pharmuthi/Apanma the entry "245 cum Vuahak" includes the 5 epagomenal days.)

Parsing notes: the Egyptian month-names (Thoth, Paophi, Athyr, Choeac, Tybi, Mechir, Phamenoth, Pharmuthi, Pachon, Paÿni, Epephi, Messori, Epagomenae) and Persian month-names (Pharuardin, Artipehest, Chordat, Tyrma, Mertat, Sacheriur, Mecherma, Apanma, Aderma, Dima, Pellnan, Asfori, Asphandar) each

carry running day-totals; the "Anno Iulian." right column gives the Julian-calendar start for both bissextile and common years.

The Collected Days of the Arabic Hegira Years [Arabicorum Hegirae Annorum dies collecti]; Collected Days of the Arabic Months [Arabicorum Mensium Dies collecti]; the Month begun in Year 1 of the Hegira [Menses inibat Anno 1. Hegirae]; the Armenian 30-day Months [Armenorum Menses Dierum 30]; their beginning in the Julian [Ineunt in Iuliano]

Marginal note (right of the Hegira-year block): "Anno Chr. 622" — i.e., Year 1 of the Hegira corresponds to A.D. 622.

Parsing notes: the Hegira-year/day pairs run in three sub-columns (years 1–15, 16–30, then multiples of 30 up to 300). The "Menses iniebat Anno 1. Hegirae" column gives each Arabic month's cumulative day and its Julian-calendar starting date in Year 1 of the Hegira. The Armenian months (Nauazard, Hori, Sahmi, Dre Thri, Kagots, Aracz, Mahegi, Areki, Ahgi-Abeli, Marini, Marcacz, Herodicz, Aieliacz, with "intercalar." for the epagomenal) and their Julian starts complete the row.

TAB. 22. Synopsis of the Notable Epochs, with the Year before or after the Common Epoch of Christ noted in the left margin [Synopsis Epocharum Insigniorum, ineuntium Anno ante, vel post Epocham vulgarem Christi in sinistro margine, notato]

This is a chronological synopsis (two-column running text on the page, here transcribed as a table keyed to the marginal "Years before Christ" / "Years of Christ" values). Each entry describes the radix/beginning of a notable era.

Anni ante Christum (Years before Christ)	Epoch / Entry
5509	MUNDUS (The World): its beginning on the 1st of September [<i>Cal. Septembris</i>], according to the Greeks, under the Patriarch of Constantinople; but they reckon their fifteen-

Anni ante Christum (Years
before Christ)

Epoch / Entry

4713

year Indictions from another beginning.

IULIANA Periodus (The Julian Period): taken over from the Greeks by Joseph Scaliger [Iosepho Scaligero], which consists of 4980 [*recte*: 7980 — printed "7980" in error as "4980"? See note] years; for it is produced [by multiplying] 28 (Cycles of the Sun) by 19 (Lunar Cycle) — Lunar Cycles are 532, and these times 19 produce the Cycle of Indictions, 7980. In this very year [4713 B.C.] occurred the first year of any one of these Cycles. Hence, in what year of the first Christian Epoch the year of the Julian Period was 4714; and the Cycle of the Sun was 10, the Lunar 2, the Roman Indiction 4.

776

OLYMPIADIS primae Annus primus (First Year of the First Olympiad): in which Coroebus of Elis [Coroebus Elidensis] was first set down in the Catalogue of the Olympiads — Iphitus having restored the interrupted Olympic games. The Athenians, however, began these years from a new-moon nearer the summer solstice, namely from some day of June or July, or otherwise. This was year 3938 of the Julian Period. The Cycle of

Anni ante Christum (Years
before Christ)

Epoch / Entry

753

the Sun 18, of the Moon 5, the
Indiction 8.

**ROMA URBS Condita (The City
of Rome Founded):** the *Palilia*,
or 21st of April, thus [reckoned]
by this Marcus Varro, the
foremost of critics, censors, and
likewise of most learned men,
[and] of the magistrates
themselves in the secular games.
Let the founding [*Esto condita*]
be put at the year 752 before the
Christian Epoch, according to
Cato, Taruntius, the Capitoline
Fasti, and a few others. But
moreover the year 753 [is] of the
aforesaid 6th Olympiad. The
third year, not yet completed,
[is] of Julian Period 3961. The
Cycle of the Sun 13, of the Moon
9, the Indiction 1.

747

NABONASSARI (Nabonassar):
the year begins astronomically
at midday of the 26th of
February, whence the first
month Thoth in the Egyptian
Year, constant at 365 days, set
out; the completed beginning of
which falls in the year 1460 —
this is the *Magnus Annus*
Canicularis (Great Canicular
Year), or the *Periodus Sothiaca*
(Sothic Period); and in the year
1461 it returns to the same day
of the same Julian month. This
was year 3967 of the Julian

Anni ante Christum (Years
before Christ)

Epoch / Entry

	Period, ferial 4 [feria 4]. The Cycle of the Sun 19, of the Moon 15, the Indiction 7. The founding of the City [running] in the 6th year.
529	CAMBYSES I, son of Cyrus [Cambyses I. Cyri filius], began to reign in the Nabonassar year 219, who entered Egypt [in] 219. (1 January.)
433	METON: from the 26th of June began his nineteen-year Cycle, although together with the summer solstice of Euctemon, and he set up that Cycle to be observed in the year 432 before Christ, [on] the 27th of June.
330	CALIPPICAE Periodus (The Calippic Period): constant at 76 years, beginning from the summer solstice — by Greek reckoning, but by Egyptian on the 15th of November — entered in the Nabonassar year 419. The first year of the Calippic Period began in the year 254 before Christ, & the <i>Tertia</i> (Third) in the year 178.
324	ALEXANDRI Magni mors (The Death of Alexander the Great): in the year 4390 of the Julian Period, & 424 of Nabonassar completed, & beginning [year] 425, at midday of the 12th of November. The Egyptians reckon Alexander's

Anni ante Christum (Years
before Christ)

312

[era] together with Ptolemy and Theon, & together with these al-Battānī [Albategnius] indeed reckons from there — the Alexandrian & Egyptian [eras] being Nabonassarian. Let Alexander's death be the preceding May, between April and June.

SELEUCIDARUM Aera (The Era of the Seleucids): it begins, or is called the Greek [era] of Contracts [*Graecorum dicta, seu Contractuum*], or that of Alexander Dhū'l-Qarnayn [Alexandri Dhilkarnayn] — that is, of the kingdom of Alexander divided into the two Great Horns [*in duo Magna Cornua*] of Seleucus, namely ... [text continues]

Anni ante Christum
(top, continuation)

Epoch / Entry (right column)

... begins to reign in Asia Minor; & of Ptolemy in Egypt. This Epoch the History of the Maccabees [*Historia Machabeorum*] employs in Judaic matters (Bk. 1), & it sets out from the 1st of Nisan, or the start of spring. But Bk. 2, in Greek matters, takes it up from autumn, or the Ides of October; & by this usage they are Antiochene; nay rather, the

Anni ante Christum

Epoch / Entry (right column)

	Arabs after Christ [reckon] it, but from the Kalends of October of the Julian Year. But the Chaldeans entered upon it in the following year from the Kalends of October.
311	DIONYSII Mathematici (Dionysius the Mathematician): the years among Ptolemy begin from the 27th of June.
285	[entry at 285 — see note]
45	IULIANORUM Annorum (The Julian Years): that is, ordained by Julius Caesar after the confusion of the years; the first of these is from the Kalends of January, ferial 6 [feria 6], according to the Augustan correction extended back retrospectively.
38	AUGUSTI Aera Hispanica (The Spanish Era of Augustus): begun from the Kalends of January, & in use in the Councils.

Christi Anni (Years of Christ)

Epoch / Entry

(heading)

The first year in the Roman Calendar begins from the Circumcision of the Lord, or from the Kalends of January, & in the Ecclesiastical [reckoning] indeed from midnight of the night preceding, [agreeing] with the ancient Romans, & with the

Christi Anni (Years of Christ)

Epoch / Entry

Prutenic Tables. But in our [present] Tables, & in the Medicean, & in the Maginus [tables], it begins at the last midday of the preceding December; whereas in the Rudolphine, Danish [Danicis], Tyconic, & Philolaic [Tables] [it begins] at the very first midday of January. But civilly some [reckon] from the Nativity, others from the Annunciation, & otherwise — concerning which more in our *Chronologia Reformata*.

(Christ, year 1)

The first **CHRISTIAN Epoch** [*CHRISTIANAE Epochae*] year is of the Julian Period 4714. The Cycle of the Sun 10, the Lunar 2, the Roman Indiction 10. & the same was of the Julian Years 46; & from the Kalends of January to the 21st of April, it ran concurrent with the Varronian year of the City founded, 753; but afterwards indeed with 754. Moreover, before the new-moon nearest the summer solstice it ran concurrent with the 194th Olympiad, year 4; but thereafter with the 195th Olympiad. Finally, however, with the 13th of August, in the midday year [Meridiem die] — & up to the 13th of August it was concurrent with the Nabonassarian year 748; & with Alexander 324; thereafter with the

Christi Anni (Years of Christ)	Epoch / Entry
	Nabonassarian year 749, & Alexander's 325.
28	VICTORIS Capuani (Victor of Capua): the Paschal Cycle begins from the October of this year.
81	DOMITIANI (Domitian): year 1 [begins] on the 13th of September.
96	NERVAE (Nerva): year 1 from the 19th of September, as in our <i>Chronologia Reformata</i> .
98	TRAIANI (Trajan): year 1 [begins] on the 10th of January.
117	ADRIANI (Hadrian): year 1 [begins] on the Ides of July, at the midday of the following 25th.
137	ANTONINI (Antoninus): year 1 on the 10th of July, [at] the following 11th.
222	HIPPOLYTI (Hippolytus): the Paschal Cycle begins on the Kalends of January.
238	CENSORINUS: in this year he writes to Q. Cerellius the golden booklet <i>On the Natal Day</i> [<i>De Die Natali</i>], which he illustrates by notable epochs — & that the Julian [year] 283 was from the Kalends of January, whence he had derived the Consulate of Ulpian, & of Pontianus; from the Olympiad it was the year M.XCIV (1094) [text continues] — the beginning of the summer

Christi Anni (Years of Christ)	Epoch / Entry
	of this year from the Agon Olympicus; the beginning 991, the beginning at the <i>Palilia</i> of this year, that is from the 21st of April; & the Nabonassarian year 986, the beginning of this ... [continues, cut at page foot]

Parsing notes: TAB. 22 is set as a continuous two-column synopsis on table-volume page 16, not a ruled grid; the left margin of each column carries the "Years before Christ" / "Years of Christ" radix-value for the entry. I have keyed each entry to its marginal year. The page is dense and several entries run on or are cut at the page foot; the entry at marginal year 285 (between Dionysius/311 and the Julian/45 block) has no caption visible at this resolution and is flagged below.

TAB. 22 (continued) — Chronological synopsis of epochs (conclusion)

This is the conclusion of the two-column running synopsis of epochs begun in the previous batch. Each entry is keyed by a Year of Christ in the left stub. The Censorinus entry (AD 238) carried over from the prior page; this page resumes within the entry surrounding it and continues through the close of the table.

Left column:

Year of Christ	Entry
(continued)	...on the day preceding the 6th Kalends of July [Iulias], that is, from the midday of 25 June, whence he adds that the Year of Alexander the Great [Alexandri Magni] had begun 562; for the corrected codices have it thus: it was the year 4451 of the Julian Period [Iulianae Periodi].
	Of DIOCLETIAN [DIOCLETIANI]: Year 1, from 29 August, with Solar Cycle [Cyclo

☉] 13, Moon [Lunae] 19, Indiction [Indictione] 2. From here begin the Paschal Cycles of Dionysius of Alexandria [Cycli Paschales Dionysij Alexandrini], and the Era of Martyrs [Aera Martyrum], likewise of the Egyptians [Elkopti, *seu Coptorum*], and also of the Abyssinians [Abassinorum] — though the Alexandrian Church chose, for the head of the Era of Martyrs, the Kalends of April of the year 285, which was then the head of the Paschal month.

312

The INDICATIONS [INDICTIONES] of Constantine [Constantini] begin to be used in the Imperial courts from 25 September; but the Greeks, that is the Greek emperors and the Church of Constantinople, from the Kalends of September. As for the Roman Church and its Pontiffs, from the Kalends of January, year 313; and Ignatius, Patriarch of Antioch, from the Kalends of May, or Artemisius, likewise of the year 313.

552

The Era of the ARMENIANS [ARMENORVM] begins here, from August, with Persian months — of which months 11 are full [Persici], but the intercalation is purely Roman.

622

Of the HEGIRA [HEGIRAE], that is the Muslim flight from

Year of Christ	Entry
	Mecca [Mahometicae fugae ex Mecca]. Here the first repetition of the Lunar [months] [Lunarium] begins, beginning on 16 July, Feria 6, Solar Cycle 23, Moon 15, Roman Indiction 10.

Right column:

Year of Christ	Entry
(continued)	...it being year 5335 of the Julian Period [Periodi Iulianae], the year 1370 of Nabonassar [Nabonassari] still running; but reckoned from its initiated day, 21 March. Following this Era of the Muslims [Aera Mahometani], the Arabs and Turks — though this is the Arab sect — which the Alphonsine [tables] [Alphonsini] follow, set the beginning of the Hegira at 15 July. Choeak [Chœac] 27, Feria 5.
632	Of YEZDEGERD [IESDAGIRDIS], King of the Persians [Persarum Regis], on 16 June; whence the Persian Era [Persica Aera] is reckoned, varying by year [vagos], and repeating in the manner of the Egyptian years.
800	CHARLEMAGNE [CAROLVS Magnus] begins as emperor [Imperator].
1079	The GELALAEAN [GELALAEA] Epoch of the Persians

Year of Christ

Entry

1453

[Persarum], restored by year through the equinox observed on 14 March.

CONSTANTINOPLE CAPTURED [CONSTANTINOPOLIS Capta], Feria 2, at Pentecost, by Muhammad the Ottoman [Mahumede Othomanico] on 29 May; whence the beginning of the Ottoman Empire [Imperij Othomanici].

1582

The GREGORIAN [GREGORIANA] correction of the calendar [Kalendarij correctio], absolute, promulgated, and accepted by the greatest part of the Christian world [Orbis Christiani]; of which the days 5 October were made 15. It was the year 6295 of the Julian Period [Iulianae Periodi].

The remaining Epochs, and the fuller treatment and confirmation of those preceding, see in our *Chronologia Reformata* [Chronology Reformed], if God grant it to come to light — into whose hands are both the Temporal Years [Anni Temporales] and the ETERNAL [Years]; to Him be Glory unto the ages of ages. Amen.

TAB. 23. — *Nabonassaris Anni Incipientes Anno ante, vel post Epocham CHRISTI, dieq; Mensis Iuliani, aut Gregoriani infranotato.*

TABLE 23. The Years of Nabonassar beginning in the year before or after the Epoch of CHRIST, and on the day of the Julian or Gregorian month noted below.

This table is laid out in three vertical panels across the page (each a self-contained block of columns), plus a running text block at the lower right and at the lower left a fourth small block that continues the leftmost panel. I transcribe each panel in turn. Column meanings: "Years of Nabonassar" [Anni Nabonassari]; "Years before / Epoch of Christ" [Anni ante Christum / Epochae Christi] — "B." prefixing a year marks a Bissextile (leap) year; "Beginning of the month Thoth" [Initium Mensis Thoth] giving the Julian-calendar date on which the Egyptian month Thoth (and hence the Nabonassar year) opens; in the rightmost panel the Thoth-opening is given in both Old Style [Veteri] (Julian) and Gregorian [Gregor.] reckonings.

Panel 1 (left)

Anni Nabonassari	Anni ante Christū	Initium Mensis Thoth
1	747	Febr. 26
2	746	26
3	B. 745	25
4	744	25
5	743	25
6	742	25
7	B. 741	poster. 24
8	740	rior 24
9	739	24
10	738	24
11	B. 737	prior 24
12	736	24
99	649	Febr. 2
100	648	Febr. 1
103	645	Febr. 1

Anni Nabonassari	Anni ante Christū	Initium Mensis Thoth
104	644	Ian. 31
223	B. 525	Ian. 2
224	524	Ian. 1
227	B. 521	Ian. 1
228	idē 521	Dec. 31
229	520	31
230	519	31
231	518	31
232	B. 517	30
348	B. 401	Dec. 2
351	398	Dec. 1
	2053	Oct. 1
	2056	
352	397	Nou. 2
468	281	Nou. 1
471	278	Nou. 1
472	B. 277	Oct. 31
592	B. 157	Oct. 1
595	154	Oct. 1
596	B. 153	Sept. 30
712	B. 37	Sept. 1
715	34	Sept. 1
	2330	[—]
	2331	[—]
716	B. 33	Aug. 31
744	B. 5	24
745	4	24
746	3	24
747	2	24
748	B. 1	23

Parsing notes (Panel 1): the "poster." / "rior" / "prior" annotations beside the day-24 entries flag whether the Thoth opening falls on the earlier ("prior") or later ("posterior") of two candidate days within a leap-cycle; "idē" (= idem, "the same") at year 228 marks repetition of the preceding "B. 521" argument. The orphan rows with "ante Christum" values 2053/2056 and 2330/2331 (no Nabonassar number) belong to a parallel Julian-Period reckoning interleaved in the same panel — transcribed in place.

Panel 1 — lower continuation block (lower left)

Nabonass.	Anni Christi	Initium Thoth
749	1	Aug. 23
750	2	23
751	3	22
752	B. 4	22
836	B. 88	Aug. 1
839	91	Aug. 1
840	92	Iulij 31
960	B. 212	Iul. 1
963	215	Iul. 1
984	216	Iunij 30
985	B. 236	Iun. 25
986	‡ 237	25
987	238	25
988	239	Iun. 25
1080	B. 240	Iun. 24
1083	332	Iun. 1
1084	335	Iun. 1
1204	B. 336	Maij 31
1207	456	Maij 1
1208	459	Maij 31
	B. 460	April. 30

Parsing note: the "‡" symbol (a cross) beside year 237 is a marginal mark in the source, transcribed in place; the surrounding Iunij/Maij progression is preserved as printed.

Panel 2 (center)

Anni Nabonass.	Epochae Christi	Initium Mensis Thoth
B. 576	April. 1	
579	April. 1	
B. 580	Mart. 31	
B. 700	Mart. 1	
703	Mart. 1	
B. 704	Febr. 28	
719	Febr. 25	
B. 720	poster. 24	
721	24	
722	24	
723	24	
B. 724	prior. 24	
725	23	
813	Febr. 1	
B. 816	Febr. 1	
817	Ian. 31	
837	Ian. 1	
B. 940	Ian. 1	
idē 940	Dec. 31	
B. 1060	Dec. 1	
1063	Dec. 1	
B. 1064	Nou. 30	
B. 1180	Nou. 1	
1183	Nou. 1	
B. 1184	Oct. 31	
B. 1304	Oct. 1	
1307	Oct. 1	

Parsing note (Panel 2): the stub here carries the Nabonassar argument with "B." (Bissextile) prefixes and a single "idē 940" (= idem) repetition; the "Epochae Christi"

column gives the Christ-epoch year, and the third column the Julian Thoth-opening date. The header label "Anni / Nabonass." stands over this panel's stub, then "Epochae / Christi", then "Initium Mensis / Thoth".

Panel 2 — lower continuation (Veteri / Gregor. dates)

Below the center panel a sub-block adds, for each Christ-epoch year, the Thoth-opening in Old Style [Veteri] and the corresponding Gregorian [Gregor.] date.

Epochae Christi	Stylo Veteri	Gregor.
1583	Iul. 24	Aug. 3
B. 1584	Iul. 23	Aug. 2
B. 1588	Iul. 22	Aug. 1

Epochae Christi	Stylo Veteri	Gregor.
B. 2000	April. 10	April. 23
B. 2036	April. 1	April. 14

*Parsing notes (Panel 2 lower): "Stylo / Veteri" = "in the Old Style"; "Gregor." = Gregorian. Several Gregorian entries that lag their Old-Style date (e.g. 1700 → Iul. 5; 1968 → April. 31; 1972 → April. 30) reflect the diverging Old-Style/New-Style gap and the leap-century suppression — transcribed verbatim. **Note the printed "April. 31" at year 1968: April has only 30 days, so a date "April. 31" is impossible — flagged below.**

Panel 3 (right)

Anni Nabonassari	Epochae Christi	Initium Thoth stylo Veteri	Initium Thoth stylo Gregor.
2789	B. 2040	Mart. 31	April. 13

*Parsing notes (Panel 3): the right panel reaches into far-future projected years (Christ-epoch 2040–2400, Nabonassar 2737–3150). The "poster." / "prior" annotations at years 2180/2184 again flag the later/earlier candidate day. **The Nabonassar value "2737" against Christ-epoch 2088 breaks the otherwise-ascending Nabonassar progression (2789 → 2737 → 2841): the sequence dips then resumes — flagged as a possible compositor transposition.** Several leftmost Nabonassar values in this panel may be misreads given the tight engraving; see uncertain readings.*

Lower-right running text block

Since 1460 Julian years make up 1461 Egyptian years — and by this Period the Years of the Great Canicular [Cycle] [Anni Magni Canicularis], that is the Sothic [seu Sothiaci], are completed — the beginning of Thoth returns to the same day of the Julian year. For this reason, reckoned from the year before Christ 757, when the beginning of Thoth fell on the same day of the Julian month in February [Februarij], 24, there was no change up to the very Bissextile year, but from the year 1 after the Bissextile, and so up to the year before Christ 521, when the Nabonassar year becomes double [duplex Nabonassari Annus incipit]: for from there arises the change in that very Year, up to the Year of Christ 724, when again the beginning of Thoth reverts to February [Februarij] 24, the earlier [priorem].

Thereafter again the change is always made on the first day after the Bissextile, and so up to the Year of Christ 940, when once more the double Nabonassar year begins. [C] Hence further, from the change in that very Year, and so onward up to the Year of Christ 1184, when the beginning of Thoth a third time reverts to February [Februarij] 24, the earlier [priors]. Then, however, the change is made in the year first after the Bissextile, and so up to the Year of Christ 2400, when a third time the double Nabonassar year begins, [C] and there will be need to make a change of day in that very Bissextile year — but will the World endure so long?

God knows. [Deus novit.]

THE SECOND PART OF THE SELECTED TABLES, FROM THE PRIMUM MOBILE.
 [SECVNDA PARS TABVLARVM EX PRIMO MOBILI SELECTARVM.]

TAB. 24. — *Conversio Graduum Signorum in Gradus Zodiaci.*

TABLE 24. Conversion of the Degrees of the Signs into Degrees of the Zodiac.

A 30-row × 12-column grid: the stub (1–30) gives the degree within a sign; each of the twelve columns is headed by a zodiac sign-glyph and a Roman numeral (I–XII) for the sign's order, and gives the cumulative degree of the ecliptic (zodiacal longitude) for that degree of that sign. The column sub-heading "G." / "Gr." = degrees [Gradus].

Column heads (sign order I–XII): I ☉ Aries · II ♉ Taurus · III ♊ Gemini · IV ♋ Cancer · V ♌ Leo · VI ♍ Virgo · VII ♎ Libra · VIII ♏ Scorpio · IX ♐ Sagittarius · X ♑ Capricorn · XI ♒ Aquarius · XII ♓ Pisces.

TAB. 25. — *Gradus Zodiaci, & Signorum diametraliter oppositi.*

TABLE 25. The Degrees of the Zodiac, and of the Signs, diametrically opposite.

A grid pairing each degree (stub 1–30, "Gr. cō." = degrees in common) with the diametrically opposite zodiacal longitude. The column heads run in opposite-sign pairs: ♈/♏, ♉/♍, ♊/♎, ♋/♑, ♌/♒, ♍/♓ — each column giving the longitude 180° away. "Gr." = degrees.

Column heads: ♈ Aries | ♏ Libra | ♉ Taurus | ♍ Scorpio | ♊ Gemini | ♎ Sagittarius | ♋ Cancer | ♑ Capricorn | ♌ Leo | ♒ Aquarius | ♍ Virgo | ♓ Pisces.

TAB. 26. — *Decl. ☉, & Ec+lipt. ad Obliq. Gr. 23. 30'. 20".*

TABLE 26. The Declination of the Sun [Declinatio Solis], and of the Ecliptic, at an Obliquity of 23°30'20".

The Sun's declination [declinatio] as a function of ecliptic longitude, computed at obliquity 23°30'20". The stub at left and right (0–30) is the degree within a quadrant-sign; three paired columns each cover a sign-pair, giving degrees, minutes, and seconds [Gr. ' "]. The headers run: □ Bor. / □ Austr. (Aries northern / Libra

southern); ν Bor. / \mathcal{M} Austr. (Taurus N / Scorpio S); \mathbb{I} Bor. / ν Austr. (Gemini N / Sagittarius S). The foot-labels (reading the column upward, for the complementary signs) are: \square Bor. / \square Austr.; \square Bor. / \square Austr.; \square Bor. / \square Austr. "Bor." = northern [Borealis]; "Austr." = southern [Australis].

(stub)	\square Bor. / \square Austr. (Gr. ' ")	\square Bor. / \square Austr. (Gr. ' ")	\square Bor. / \square Austr. (Gr. ' ")	(stub)

30	11 30 20	20 12 23	23 30 20	0
(foot)	□ Bor. / □ Austr.	□ Bor. / □ Austr.	□ Bor. / □ Austr.	(foot)

Parsing notes (TAB. 26): three sign-pair declination blocks, each "Gr. ' "" (degrees / minutes / seconds). The stub is bidirectional — the left stub (0→30) reads the top sign-pair downward; the right stub (30→0) reads the foot sign-pair upward, the standard mirror layout for a declination table. The terminal value 23 30 20 at row 30 of the third block equals the stated obliquity, confirming alignment. A few mid-table seconds (e.g. row 14 first block "5 39 59" where the smooth progression would suggest ~5 32) sit slightly off the monotone trend and are flagged as possible misreads/compositor slips below.

TAB. 27. — *Angulus Orientalis Eclipt. & Meridiani ad Obliquitatem Eclipt. Gr. 23. 30' ½.*

TABLE 27. The Eastern Angle of the Ecliptic and of the Meridian, at an Obliquity of the Ecliptic of 23°30'½.

The angle the ecliptic makes with the eastern horizon (and with the meridian) as a function of longitude, at obliquity 23°30'30". Stub 0–30 at left and right; three sign-pair columns, each "Gr. '" (degrees, minutes). Headers: □ Boreal / □ Austr.; □ Bor. / □ Austr.; □ Bor. / □ Austr. Foot-labels (read upward): □ Austr. / □ Bor.; □ Austr. / □ Bor.; □ Austr. / □ Bor.

(stub)	□ Boreal / □ Austr. (Gr. ')	□ Bor. / □ Austr. (Gr. ')	□ Bor. / □ Austr. (Gr. ')	(stub)
0	66 30	69 22	77 43	30

27	68 50	76 41	88 42	3
28	68 59	77 1	89 8	2
29	69 11	77 22	89 34	1
30	69 22	77 43	90 0	0
(foot)	□ Austr. / □ Bor.	□ Austr. / □ Bor.	□ Austr. / □ Bor.	(foot)

Parsing notes (TAB. 27): three sign-pair blocks, each "Gr. '" (degrees, minutes). Terminal value 90 0 at row 30 of the third block (ecliptic perpendicular to the horizon at the solstitial point) confirms alignment. Several minutes-column entries are clearly compositor slips or my misreads of tight engraving and are flagged below: row 7 second block "70 81" (81 > 59, impossible as a minutes value), row 1 second block "69 8" sits below row 0 "69 22" breaking the rising progression, row 3 second block "69 8" repeats and breaks monotone, row 25 third block "87 5" dips below row 24 "87 24" and row 26 "88 17", and row 2 second block "69 45" likewise sits above its neighbors. These are transcribed as printed/read and flagged.

TABULA 28. Right Ascension of the Sun at the Obliquity 23° 30' 20"

[TAB. 28. Ascensio Recta ☉ ad Obliquitatem Grad. 23. 30'. 20".]

This table gives the right ascension [*ascensio recta*] of the Sun for each degree of the first six zodiacal signs. The argument (stub) column is the degree (Gr.) within each sign (1–30); each sign-block gives degrees (Gr. = °), minutes ('), and seconds (") of right ascension. The six sign-headings across the top are: ♈ (Aries), ♉ (Taurus), ♊ (Gemini), ♋ (Cancer), ♌ (Leo), ♍ (Virgo).

Upper half — signs ♈ ♉ ♊ ♋ ♌ ♍

Header row: Sign. then the six zodiacal glyphs; sub-header Gr. (argument) and, for each sign, Gr. | ' | " (= °, minutes, seconds of right ascension).

Parsing notes: The ♏ column foot value 180°0'0" at Gr. 30 closes the first semicircle of right ascension, as expected.

Residuum Tabulae 28 — signs ♎ ♏ ♐ ♑ ♒ ♓ [*Residuum Tabulae 28.*]

This is the lower half of Table 28, giving the right ascension for the second six signs: ♎ (Libra), ♏ (Scorpio), ♐ (Sagittarius), ♑ (Capricorn), ♒ (Aquarius), ♓ (Pisces).

Parsing notes: □ column foot value 360°0'0" at Gr. 30 closes the full circle of right ascension, as expected. At Gr. 7 of □, the printed minutes "28" breaks the otherwise smooth descent (neighbors read 51, 15); transcribed as printed and flagged below. The □"-column value at Gr. 1 reads "56" matching the □/□ pattern.

TABULA 29. Of the Ascensional Differences, at the Obliquity of the Ecliptic 23° 30'

[TAB. 29. Differentiarum Ascensionalium: ad Obliq. Eclipt. Grad. 23. 30'.]

Sub-heading (banner under the title): **"The Altitude of the Pole, if the declination of the star be taken in the side [margin]; or the Declination of the star, if the Altitude of the Pole be taken in the side."** [*Altitudo Poli, si in latere sumatur Declinatio Sideris; vel Declinatio Sideris, si in latere sumatur Alt. Poli.*]

[Margin, left side, running vertically: **"The Declination of the star, or the Altitude of the Pole, &c."** — *Declinatio Sideris, aut Altitudo Poli, &c.*]

This is a double-entry table of the ascensional difference [*differentia ascensionalis*]. The top header gives integer columns **1** through **10** (degrees of pole-altitude or declination); each column is sub-divided G. | ' | " (degrees, minutes, seconds of ascensional difference). The leftmost stub column (here labeled implicitly by a marginal index 1–60, the small inner digits) is the argument running 1–60 downward; the rightmost narrow column gives the complementary argument running 89 down to 30 (the co-argument for the bottom/right reading). The foot row repeats the column indices **89, 88, 87 ... 80** (the complementary top-arguments), with H. and Resid. markers at the foot.

Note: This page is extremely dense (10 data columns × 3 sub-columns × 60 rows, plus two marginal index columns). Inner seconds-digits are at the resolution limit in several rows; values flagged [?] are at the legibility floor and are noted as

Foot of columns (complementary top-argument indices): **89** | **88** | **87** | **86** | **85** | **84** | **83** | **82** | **81** | **80**. Foot markers: **H.** (center) and **Resid.** (right).

Parsing notes: This table is read in both directions (the marginal label gives "Altitude of Pole ... or Declination of star ... taken in the side"), so the left argument runs 1→60 and the right co-argument runs 89→30, with the bottom indices (89→80) being the complementary top-arguments for the reverse reading. Several seconds-digits in the high-degree columns (8, 9, 10) are at the resolution limit; the ones I could not resolve cleanly are listed in the QA report. At Gr. 44 of column 6 the printed value reads "6 48 35" where the smooth progression of that row/column would suggest ~5 48; transcribed as printed and flagged. At Gr. 60 of column 8 the printed value reads "24 5 20" where the column trend would suggest ~13 31; the leading "24" is an apparent compositor slip — transcribed as printed and flagged.

[Foot marker: H.] [Foot marker: Resid.]

Residuum of Table 29. The Difference of Ascensions (continued — columns 1–10, arguments 61–90)

[Resid. Tab. 29. Differentia Ascensionalium.]

[Margin, left side, running vertically: "**The Declination, in the side [front], is taken; or the Altitude of the Pole, in the side, &c.; or the Declination of the star, &c.**" — *Declinatio in fronte sumatur Altr. Poli; vel Altit. Poli in fronte sumatur Declinatio ... &c.*] (marginal label partly abraded; gloss approximate)

This is the continuation (residue) of Table 29 for columns **1–10** at arguments 61–90, completing the lower-argument portion. The right narrow column gives the complementary argument 29 down to 0; the foot row repeats top-indices **89 ... 80**.

Foot of columns: 89 | 88 | 87 | 86 | 85 | 84 | 83 | 82 | 81 | 80.

Note within the table (lower-right block, replacing the empty cells): *[Latin: "Vbi desunt numeri areales, signum est aggregatum ex numero frontali, & marginis sinistri excedere quadrantem, quod intelligendum est de sequentibus quoque; spatiis areis vacuis in residuis partibus Tabulae, mox secuturis. Vel certe superflue ibi quaeruntur cum in alia huius parte reperiri possint."]*

Translation: **"Where the areal numbers are missing, it is a sign that the sum of the front-number and the left-margin number exceeds a quadrant [90°] — which is to be understood of the following ones too, namely the empty areal cells in the remaining parts of the Table that come next. Or else they are sought there to no purpose, since they can be found in another part of this Table."**

Parsing notes: The lower-left triangle of empty cells reflects sums exceeding 90° (the ascensional difference reaches its 90° limit, printed as "90 0 0" along the staircase), per the explanatory note. I have marked the unfilled cells with –. At arg 79, column 9, the value reads "65 6 44" then the next row's column-8 reaches "90 0 0"; these staircase values approaching the 90° limit are transcribed as printed.

Residue of Table 29. The Difference of Ascensions (continued — columns 11–25)

[Residuum Tab. 29. Differentiarum Ascensionalium.]

Sub-heading (banner): **"The Altitude of the Pole, if in the left side the Declination be taken; or the Declination, if in the left side the Altitude of the Pole be taken."** *[Altitudo Poli si in latere sinistro sumatur Declinatio; vel Declinatio si in latere sinistro Alt. Poli.]*

[Margin, left side, running vertically: **"The Declination, in the side [front], is taken — Altitude of the Pole; or the Altitude of the Pole, in the side, &c.; the Declination, in the front, is taken, the Altitude of the Pole, &c."** — *Declinatio, in fronte sumitur Alt. Poli; vel Altit. Poli in fronte sumatur Declinatio, &c.*] *(marginal label partly abraded; gloss approximate)*

This second lower block extends Table 29 to pole-altitude/declination columns 11–25, with the left argument 1→30 and the right complementary argument 88→61 (small inner digits). Each column is sub-divided g. | ' | ". This block is extremely fine; values at the resolution limit are flagged and noted as

0 7 1 8 4 2 0 0 0 9 1 8 2 2 9 3 9 4 1 4 4 5 7 9

Foot of columns: 79 | 78 | 77 | 76 | 75 | 74 | 73 | 72 | 71 | 70 | 69 | 68 | 67 | 66 | 65. Foot marker: **Resid.** (right).

Parsing notes: This second residue block carries only two sub-columns per pole-altitude index in the engraved layout (G. and ' ; the seconds column is omitted at this scale of the table — the values here are degrees-and-minutes of ascensional difference). Several minutes-cells in the high-index columns (22–25) are at the legibility floor: in particular the column-22 value at arg 2 reads "1 13" and column-23 at arg 2 reads "1 6" where the smooth progression would suggest sub-degree values (~0 53 / ~0 55); transcribed as printed and flagged as probable misreads / compositor slips. Column 25 at arg 2 reads "1 6" and at arg 10 reads "4 41" (vs. an expected ~4 47 by progression) — flagged. These are at the resolution limit and

[Foot marker: Resid.]

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae

Part II (the Primum Mobile tables), continued — Tables 29 (residue), 30, 31

TABLE 29 (continued) — Residue of Table 29, the Ascensional Differences

Heading (verbatim): *Residuum TAB. 29. Differentiarum Ascensionalium.* — "Residue of Table 29, the Ascensional Differences."

Sub-heading (verbatim): *Altitudo Poli, si in sinistro latere sumatur Declinatio; vel Declinatio, si in eodem latere sumatur Alt. Poli.* — "Pole-altitude, if the declination is taken on the left side; or declination, if the pole-altitude is taken on the same side."

Left margin label (verbatim): *Declinatio, si in fronte sumatur Alt. Poli; vel Alt. Poli, si in fronte sumatur Declinatio.* — "Declination, if the pole-altitude is taken at the top; or pole-altitude, if the declination is taken at the top."

The column-head arguments run 11–25 (the pole-altitude / declination columns); the left stub argument runs downward 31→79 and the right stub upward 59→11. Each cell gives degrees (G.) and minutes (').

Inset note (verbatim): *Residuum Tabulae incipientis utrinque, à gradu 27. quare in sequenti pagina.* — "The residue of the table begins on both sides at degree 27; for which see the following page."

Foot column-labels (verbatim, left→right): 79 78 77 76 75 74 73 72 71 70 69 68 67 66 65 — (these are the complementary pole-altitude arguments for reading the table from the bottom).

Parsing notes: The right margin gives the upward-running complementary stub (59→11). High-index cells are blank (the table is triangular: the "90 0" perpetual-day staircase steps in from the upper right). Cell at arg 54, col 13 reads "51 54" as printed, where the smooth progression would suggest ~"31 54" — flagged. Cell at arg 59, col 17 reads "32 44" where smooth progression suggests ~"30 44" — flagged.

TABLE 29 (continued) — Residue of the Table of the Ascensional Differences (second block, pole-altitudes 26–40)

Heading (verbatim): *Residuum Tabulæ Different. Ascensionalium.* — "Residue of the Table of the Ascensional Differences."

Sub-heading (verbatim): *Altitudo Poli, aut Declinatio ut supra.* — "Pole-altitude, or declination, as above."

Left margin label (verbatim): *Declin. vel Alt. Poli.* — "Declination or pole-altitude."

Column-head arguments 26–40; left stub 31→40; right stub 59→50.

Foot column-labels (verbatim, left→right): 64 63 62 61 60 59 58 57 56 55 54 53 52 51 50.

Catchword / signature line:

Parsing notes: clean second residue block. Right margin gives the complementary stub 59→50.

TABLE 29 (continued) — Residue of the Table of the Ascensional Differences (third block, pole-altitudes 26–40, args 41–64)

Heading (verbatim): *Residuum Tab. Differentiarum Ascensionalium.* — "Residue of the Table of the Ascensional Differences."

Sub-heading (verbatim): *Altitudo Poli, si in latere sinistro sumas Declinationem; vel Declinatio si in latere eodem sumas Alt. Poli.* — "Pole-altitude, if you take the declination on the left side; or declination, if you take the pole-altitude on the same side."

Column-head arguments 26–40; left stub 41→64; right stub 49→26.

Foot column-labels (verbatim, left→right): 64 63 62 61 60 59 58 57 56 55 54 53 52 51 50.

Parsing notes: triangular table; the "90 0" perpetual-day staircase steps in from the upper right. Several cells in the high-index region show probable compositor errors (e.g., arg 50 col 37 "63 65" and arg 52 col 35 "63 65" — minutes >59; arg 59 col 27 "57 62" — minutes >59). Flagged below.

TABLE 29 (continued) — Residue of the Table of the Ascensional Differences (final fragment, pole-altitudes 27–33 and 41–45)

Heading (verbatim): *Resid. Tab. Differentiarum Ascensionalium.* — "Residue of the Table of the Ascensional Differences."

Sub-heading (verbatim): *Altitudo Poli, si in latere sinistro sumas Declinationem; vel Declinatio si ibi altitudo Poli.* — "Pole-altitude, if you take the declination on the left side; or declination, if the pole-altitude is there."

Left margin label (verbatim): *Declin. &c.* — "Declination, etc."

This middle band carries two sub-panels. The left panel (column arguments 27–33, stub 27→30) and the right panel (column arguments 41–45, stub 41→49).

Left panel — columns 27–33:

Arg	27 G.	28 G.	29 G.	30 G.	31 G.	32 G.	33 G.	Arg
↓	'	'	'	'	'	'	'	↑
27	15 5	15 45	16 24	17 6	17 50	18 34	19 20	63

Arg ↓	27 G. '	28 G. '	29 G. '	30 G. '	31 G. '	32 G. '	33 G. '	Arg ↑
28	15 43	16 25	17 8	17 53	18 33	19 24	20 12	62
29	16 24	17 8	17 54	18 40	19 27	20 16	21 6	61
30	17 6	17 53	18 40	19 28	20 18	21 9	22 1	60

Foot column-labels (verbatim, left→right): 63 62 61 60 59 58 57.

Right panel — columns 41–45:

Arg ↓	41 G. '	42 G. '	43 G. '	44 G. '	45 G. '	Arg ↑
41	39 5	51 31	54 9	57 5	60 23	49
42	51 57	54 9	57 5	60 24	64 13	48
43	54 9	57 5	60 24	64 14	68 49	47
44	57 5	60 24	64 14	68 13	74 57	46
45	60 24	64 13	68 49	74 57	90 0	45
46	64 10	68 49	74 56	90 0		44
47	68 48	74 75	90 0			43
48	74 54	90 0				42
49	90 0					41

Foot column-labels (verbatim, left→right): 49 48 47 46 45.

Parsing notes: the left panel cells are slightly degraded but legible; the right panel is the highest pole-altitude corner of the residue. Cell at arg 41 col 41 reads "39 5" where the column trend suggests ~"49 5" — flagged. Cell at arg 47 col 42 reads "74 75" (minutes >59) — flagged.

TABLE 30 — Difference of the Oblique Ascension at the Cardinal Points of the Ecliptic, for Pole-Altitude 44° 30' 20"

Display heading (verbatim): *TAB. 30. Differ. Ascensionalis Punctor. Eclipt. ad Alt. Poli Gr. 44. 30'. 20".* — "Table 30. The ascensional difference of the points of the ecliptic, for pole-altitude 44° 30' 20"."

The table is arranged in three double-columns, one for each pair of signs sharing a value: Aries / Libra (☉ Boreal / ☉ Austral), Taurus / Scorpio (♉ Boreal / ♏ Austral), and Gemini / Sagittarius (♊ Boreal / ♐ Austral). The bottom labels give the

complementary signs: Virgo / Pisces (☿ Bor. / ♃ Aust.), Leo / Aquarius (♌ Bor. / ♎ Aust.), Cancer / Capricorn (♋ Bor. / ♏ Aust.). The argument (Gr. = degrees of the sign) runs 0→30 down the left stub, 30→0 up the right.

Column-head signs (verbatim):

- First pair: ☿ Bor. / ♃ Austr. (Aries Boreal / Libra Austral)
- Second pair: ♌ Bor. / ♎ Austr. (Taurus Boreal / Scorpio Austral)
- Third pair: ♋ Bor. / ♏ Austr. (Gemini Boreal / Sagittarius Austral)

Each entry gives degrees (Gr.), minutes (′), seconds (″).

Gr. ↓	☿/♌ Gr. ′ ″	♋/♎ Gr. ′ ″	♌/♏ Gr. ′ ″	Gr. ↑
0	0 0 0	11 32 19	21 12 30	30

17	6 36 36	17 26 39	24 29 30	13
18	7 0 46	17 45 38	24 36 38	12
19	7 23 45	18 4 28	24 41 59	11
20	7 46 42	18 22 58	24 50 9	10
21	8 9 40	18 41 22	24 54 50	9

Gr. ↓	♈/♈ Gr. ' "	♉/♉ Gr. ' "	♊/♊ Gr. ' "	Gr. ↑
22	8 32 27	18 59 7	24 59 47	8
23	8 55 26	19 17 6	25 4 5	7
24	9 17 27	19 34 35	25 7 56	6
25	9 40 35	19 51 47	25 11 0	5
26	10 3 6	20 8 35	25 13 45	4
27	10 25 34	20 25 5	25 15 5	3
28	10 47 54	20 41 15	25 16 0	2
29	11 10 27	20 57 0	25 18 10	1
30	11 32 19	21 12 30	25 18 30	0

Bottom column-labels (verbatim):

- First pair: ♈ B. / ♈ A. (Virgo Boreal / Pisces Austral)
- Second pair: ♉ B. / ♉ A. (Leo Boreal / Aquarius Austral)
- Third pair: ♊ B. / ♊ A. (Cancer Boreal / Capricorn Austral)

Catchword (verbatim):

Parsing notes: signs are read by their zodiac glyphs as printed; the doubling (Boreal/Austral, top/bottom) is the standard four-fold symmetry of the ascensional difference. Cell at arg 4, col ♈/♈ reads "12 50 12" where the smooth progression would suggest ~"13 0 12" — flagged. Cell at arg 9, col ♈/♈ reads "3 31 20"; arg 10 reads "3 51 50" where the step suggests ~"3 54 50" — flagged.

TABLE 31 — Oblique Ascension for Pole-Altitude 44° 30' 20" and Obliquity of the Ecliptic 23° 30' 20"

Display heading (verbatim): *TAB. 31. Ascensionis Obliquæ ad Altit. Poli Gr. 44. 30'. 20". & Obliq. Eclipt. 23. 30'. 20". — "Table 31. Of the oblique ascension, for pole-altitude 44° 30' 20" and obliquity of the ecliptic 23° 30' 20"."*

The table gives the oblique ascension (in degrees, minutes, seconds) against the degree of each zodiac sign. The first half (this top panel) covers Aries (♈), Taurus (♉), Cancer (♊), Leo (♌), Virgo (♍); the argument (Gr.) runs 1♈ 30♈ Gemini (♊) the left stub.

Column-head signs (verbatim): ♈ | ♉ | ♊ | ♌ | ♍ | ♎

Catchword (verbatim):

Parsing notes: clean ascension table. The Libra value at argument 30 (219° 26' 16") and the Pisces value at argument 30 (360° 0' 0") close the full circle. Cell at arg 22, col □ reads "249 33 18" where the column trend suggests ~"248 33 18" — flagged.

Cell at arg 28, col → reads "322 48 31" wh
suggests ~"321 48 31" — flagged. Cell at arg 29, col □ reads "322 36 33" — below
the preceding row, breaking the monotone progression — flagged.

Tabulae novalmagesticae — Table 32 (table-pages 26–28)

TABULA 32 — Oblique Ascension for varying pole altitudes (2° – 24°)

TAB. 32. *Ascensio Obliqua graduum Signor. Borealiū in Horizontib. Borealib. Australiū in Horiz. Australib. quam subtrahe gradib. 360. fietq; Asc. Obliqua Signor. Austral. in Horiz. Boreal. & Signor. Boreal. in Horiz. Austral.*

[Translation of title: **The Oblique Ascension of the degrees of the Northern Signs in the Northern Horizons [and of] the Southern [Signs] in the Southern Horizon; subtract this from 360 degrees, and there will result the Oblique Ascension of the Southern Signs in the Northern Horizon and of the Northern Signs in the Southern Horizon.**]

Banner across all column-groups: **Altitudines Poli** [Pole Altitudes].

Each pole-altitude (2, 4, 6, 8, 10, 12, 14, 16, 18, 20, 22, 24) heads a paired sub-column: **Gr.** (degrees) and ' (minutes). The leftmost and rightmost stub columns (**G.**) give the argument: the degree (0–30) within each zodiacal sign. The left stub on this page (p. 26) runs from sign ♈ (Aries) and ♉ (Taurus); the right stub counts the complementary degrees. Entries are oblique ascension in degrees and minutes.

This single table spans table-pages 26–28. The three page-segments are transcribed in sequence below.

Parsing notes: This is a full-page citation-grade table with twelve pole-altitude column-pairs plus left and right argument stubs. Columns are tightly set; minute-values approaching the gutter and several digits on each page show ink-bleed and were read at the limit of resolution. Cells read with low confidence are flagged [?]. Sexagesimal minutes that read ≥ 60 are flagged as impossibles (see QA report). The argument runs in two half-page blocks per page (each headed by a zodiac glyph), with the right-hand stub counting down complementarily (30→0).

Segment 1 — table-page 26

Left-stub upper block headed ♈ (Aries); lower block headed ♉ (Taurus). Right stub headed **G.** counting down; lower-right marked ♈ / **X** region (the complementary

descending count). Column header row: G. 2/2 | 2 | 4 | 6 | 8 | 10 | 12 | 14 | 16 | 18 | 20 | 22 | 24 | G. each pole-altitude split Gr./.

Upper block (argument sign □ Aries, degrees 0–30):

[Foot of page: signature "B2"; centre signature "I"; right-foot folio number "26".]

[Table continues on next page.]

Table-page 31

Pole-altitude headers: **26, 28, 30, 32, 34, 36, 38, 40, 41, 42, 43, 44**. This page tabulates the residue of the signs (sign □ Leo block in the upper portion; sign □ Virgo marker mid-page), completing the oblique ascension to 180°0' for every pole-altitude at the foot.

Upper block (sign □ Leo; argument 0–30; right-argument 30 [□ marker at foot]–0)

[Foot of page: centre signature "I 2"; right-foot folio number "45".]

Parsing notes: This is a dense citation-grade oblique-ascension table; columns are tightly set and many minute-values are faint or ink-worn. A fresh cell-by-cell further re-transcription () was applied to this batch: it resolved the handful of degree/minute cells the first pass had flagged (e.g. p. 481 upper arg 14 pole 36 "8 50"; p. 482 upper arg 12 pole 30 "56 49", arg 12 pole 44 "47 11", arg 14 pole 43 "49 53", arg 16 pole 36 "57 3", arg 19 pole 41 "56 21") but, reading conservatively, flagged a much larger residue of worn single-digit minute/degree glyphs [?]. **This is a DPI-floor batch:** the residual [?] cells (~120, up from the first pass's ~18 because the first pass under-flagged) are worn glyphs that cannot be resolved with confidence at this scan resolution and are higher-DPI — they have NOT been guessed. The worn glyph is in nearly every case a single minute digit drawn from {0, 3, 5, 6, 8, 9}. The Gr. (degree) column entries legitimately exceed 60 (they run up to 180°), so only the ' (minute) sub-columns are subject to the >59 impossibility check; no minute cell reaches 60. Two suspected SOURCE (compositor) errors are transcribed as printed and flagged below, not corrected: p. 481 lower block arg 22 pole 38 prints "36 28" (a degree slip where the column requires ~35); and p. 481 upper block arg 20 pole 43 prints "10 49", duplicating the adjacent pole-44 value (a column-slip / repeated set, where ~11 04 is expected). The compositor's implicit degree-carry layout (whole degree set once and not reprinted on an unchanged following row) is reconstructed in context, not an illegibility.

Riccioli, *Astronomiae Reformatae Tomi Duo* — Tomus II, *Tabulae novalmagesticae*

These three pages continue **TAB. 32 — the oblique ascension (*ascensio obliqua*) for variable pole-altitudes** [Almagestum Novum / Tabulae novalmagesticae]. Each page carries pole-altitude column headers **45° through 56°**, each split into a degrees sub-column (**Gr.**) and a minutes sub-column ('). The left stub (**G.** with a zodiac sign-symbol below) gives the argument: degrees 0–30 within the running sign. The right stub gives the complementary count (30 down to 0) and carries the complementary sign-symbol. Sign-symbols printed in the stubs mark where one sign ends and the next begins.

The argument continues from the prior batch (which closed the Aries→Virgo block at 180°0'). This batch presents the **Libra→Pisces** residue across the same 45°–56° pole-altitude block.

TAB. 32 (continued) — Oblique ascension, pole-altitudes 45°–56°
 (table-page 32, PDF p. 484)

[Stub head: G. over the sign symbol (♏); right stub head over Aries-opposite symbol. The page opens within the sign Libra (♏) and runs through the following signs.]

[Foot of page 34: printed folio "57" at lower right; signature/catchword region at foot illegible. This completes the 45°–56° pole-altitude block of TAB. 32 — the full semicircle closes at 180°0' across all twelve pole columns. The next tables (Part III: nonagesimal altitude, Sun's mean motions, etc.) follow in subsequent batches.]

Parsing notes: All three pages share an identical layout: 12 pole-altitude column-pairs (45°–56°), each split Gr. /'; left stub = argument degree (0–30) under a zodiac sign-symbol; right stub = complementary degree (30→0) with the complementary sign-symbol. The complementary right-stub count is rendered here as the trailing "(← 30)" column. Sign-symbols in the original are engraved glyphs in the stub cells at sign boundaries; identified here by zodiacal position (the progression Libra → Scorpio → Sagittarius → Capricorn → Aquarius → Pisces continues the Aries→Virgo block from batch 161 and closes the circle at 180°0'). The minute columns are dense; where a digit was ambiguous I cross-checked against the

column's monotone progression. A few faint cells (noted below) are best-readings. The header repeats "Gr." over each pole; I have prefixed each with the pole-degree for table clarity, but the engraved header is simply the pole-degree number atop a "Gr. | '" pair.

Tabulae novalmagesticae — TAB. 32 (continued)

The oblique ascension for variable pole-altitudes (the high-latitude columns, 57°–67°).

These three pages continue TAB. 32 — the table of oblique ascension reckoned for the elevation of the pole — carrying it through the pole-altitude columns from 57° up to 67° (including the intermediate column 66½°). Each pole-altitude block is given in degrees (*Gr.*) and minutes ('). The leftmost stub column gives the argument: the running count of degrees within each zodiacal sign, with the zodiac signs marked at the head of each thirty-degree block. The rightmost column gives the complementary argument (counting down from 30) and the complementary sign.

The "TAB. 33." catchword at the foot of the third page (table-page 37) signals that TAB. 33 begins on the following leaf; it has not yet started within this batch.

Table-page 35 — pole altitudes 57°–67°, signs Aries (♈)→ Gemini (♊) start

Column heads, left to right: argument (degrees within the sign); pole-altitude blocks 57, 58, 59, 60, 61, 62, 63, 64, 65, 66½, 67, each in **Gr.** (degrees) and ' (minutes); complementary-argument column at right.

The stub for the first 30-degree block is headed ♈ (**Aries**); the second block (rows 0–30 again) is headed ♉ (**Taurus**) at left, with the right-hand sign marker ♏ (**Scorpio**) / the descending count.

[Margin: the right-hand index column runs 30, 29, 28 ... down to 0, marking the complement of the argument.]

Parsing notes: page 35 covers the first sign-block (☊ Aries, argument 0–30) and the second (♉ Taurus, argument 0–30). In the 66½° column every entry reads 0 0 in this argument range (the oblique ascension is effectively suppressed at this high pole-altitude near the start of the table). Several 66½° / 65° cells in rows 6–8 and 16 are blank in the source (marked —), as is consistent with the table's truncation at high latitude. The descending complement column at far right gives the supplement (☊ 357°–360°) for the Libra/Scorpio reflection.

Table-page 36 — pole altitudes 57°–67°, signs Gemini (♊) ☊ Cancer (♋)

Column heads identical: argument; pole-altitude blocks 57, 58, 59, 60, 61, 62, 63, 64, 65, 66½, 67 in **Gr.** /'; complementary argument at right.

The first 30-degree block is headed ☊ (**Gemini**) at left; the second is headed ☊ (**Cancer**). In the 66½° and 67° columns at high latitude the entries break off, and the source prints the words "**Non oc-ci-dit.**" ("does not set") spread down the column cells — the marginal note that, for these declinations at this pole-elevation, the point is circumpolar and never sets.

Parsing notes: page 36 covers the ♊ (Gemini, arg. 0–30) block and the ♋ (Cancer, arg. 0–30) block. The 67° column in the Gemini block (rows 19–30) and again in the Cancer block (rows 1–11) is replaced by the printed legend "**Non occidit.**" ("does not set") set vertically across the cells — these high-declination points are circumpolar at the 67° pole-elevation and do not rise/set. In the Cancer block the 66½° column resumes finite values from row 1 (2'11" etc.). Several rightmost-complement cells were tightly set; the descending index column (30→0) is given at right. The two-figure right-hand entries in the Cancer block (e.g. "16 1", "23", "41") are the residual 67° values printed where the legend ends.

Table-page 37 — pole altitudes 57°–67°, signs Leo (♌) Virgo (♍)

Column heads identical: argument; pole-altitude blocks **57, 58, 59, 60, 61, 62, 63, 64, 65, 66½, 67** in **Gr.** /'; argument index at far right (here counting 30→0, with the sign markers ♌ Leo and ♍ Virgo at the heads of the two blocks).

Parsing notes: dense small numerals throughout. The middle of this page (the □–□ blocks, signs around 88°–89°) is where the nonagesimal altitude approaches and crosses its maximum (the zenith, 90°), so values rise to ~89° and then turn back; a handful of near-90° crest cells remain hard to resolve cleanly and are flagged [?] The earlier whole-page [?] flags in the upper Aries/Taurus blocks were resolved by the verified re-transcription (e.g. the Poli. 2 column at rows 15/18 now reads cleanly 65 10 / 65 30). The □-block row 15 / Poli. 5 cell prints 80 20, which breaks the monotone descent across the row — retained as printed as a suspected engraving error (footnoted later).

TAB. 33 — Page 39: poles 15–28

Continuation of TAB. 33. Altitude of the Nonagesimal of the Ecliptic, reckoned from the Ascendant. (*Residuum TAB. 33. Altitudo Nonagesimi ab Ascendente numerati.*)

Column headers: **Poli.** 15–28, each in **Gr.** / '. Left stub: **Sig. G.**; right stub: **Alt.** — **G. Si.**

Parsing notes: the □ and □ blocks at the foot of this page sit at the maximum-altitude region (nonagesimal near the zenith, 89°–90°), where the printed figures are crowded and several remain smudged after further re-transcription; these are flagged [?]. The verified re-transcription resolved the earlier whole-block uncertainty (the □-block descending columns now read as clean monotone sequences, e.g. the Poli. 15 column 82 40 / 82 20 / 82 0 ...), leaving only the genuine near-crest cells (chiefly the Poli. 22–24 region of the □/□ blocks) still [?].

TAB. 33 — Page 40: poles 29–41

Continuation of TAB. 33. Altitude of the Nonagesimal of the Ecliptic, reckoned from the Ascendant. (*Residuum TAB. 33. Altitudo Nonagesimi ab Ascendente numerati.*)

Column headers: **Poli.** 29–41, each in **Gr.** / '. Left stub: **Sig. G.**; right stub: **Alt. — G. Si.** (Note: this page carries 13 pole-columns, 29 through 41.)

Parsing notes: this page (poles 29–41) is the most legible of the three for the bulk of the table, since here the nonagesimal altitudes stay well below the zenith and the columns descend in a clean monotone progression across the row (each column ~1° lower than the one to its left). The verified further re-transcription confirmed the bulk of the page and resolved most of the earlier flags; the residual [?] cells are the locally damaged/over-inked □-block degree rows at the foot of the page (rows 6 and 9, Poli. 35–41) and a handful of faint cells. The minute-columns are internally consistent (no values >59 observed). Suspected source/compositor repeats retained as printed: □ rows 9 & 12 / Poli. 33 both print 33 49; □ row 6 / Poli. 40 prints 29 18 against a smooth ~29 11; the □-block row 6 degree-figures are locally one degree high and over-inked (footnoted later).

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae

TAB. 33 (continued) — Residuum: *Altitudo Nonagesimi ab Ascendente numerati*

[Residue of TAB. 33 — The altitude of the nonagesimal point counted from the ascending point]

This page continues the table of the nonagesimal altitude. The columns are headed by the pole-altitude (*Poli*, i.e. the latitude of the place) from 42 to 54. The left-hand stub gives the argument (the ascendant) by sign (Sig.) and degree (Gr.); the right-hand stub (Al t.) gives the complementary argument read upward, by degree and sign (G. Si.). Each cell gives degrees and minutes (Gr. ').

Parsing notes: This is a square interpolation table; the right-hand stub repeats the argument read in the reverse sense (signs □ □ □ □ □ descending), and only appears at sign-boundary rows. Several values were read at the limit of legibility in the densely-printed interior columns; I have transcribed the most consistent reading and flagged the single doubtful cell. The cell at □ 0 / col. 48 reads "20 2" but the units digit is ink-merged; flagged [?].

Continuation of the residue of TAB. 33, for pole-altitudes 55 through 67.

Parsing notes: At the high-pole end of this table (the rightmost columns, poles 64–67) the nonagesimal altitude approaches and crosses zero in the relevant range; near the foot of column 66 the source prints the words "**Consul-**" / "**vacat**" (i.e. *consule / vacat* — "consult [the text]" / "[this cell is] empty/void"), indicating that for those high latitudes and arguments the entry is not tabulated. These verbal cells are transcribed in place of numbers. This page is densely printed and several interior cells are at the edge of legibility; readings flagged where doubtful. The values in the right-hand high-pole columns are small (single-digit degrees) and so the printing is cramped; some units digits are uncertain.

TAB. 34 — *Prosthaphaeresis Declinationis*

[The prosthaphaeresis of declination]

This table is in two halves. The upper half is headed:

Declinationi Signor. Bor. Adde; Australium Subtrahe. [To the declination of the northern signs *add*; for the southern, *subtract*.] sub-banner: **Latitudo Borealis.** [Northern latitude.]

The lower half is headed:

Declinat. Signor. Boreal. Subtrahe; Australium Adde. [For the declination of the northern signs *subtract*; for the southern, *add*.] sub-banner: **Latitudo Australis.** [Southern latitude.]

The argument columns are headed by latitude (1, 3, 5, 7, 9 degrees), each giving Gr. '. The left stub (G.) gives the degree within the sign, with the entering signs marked at top (☾ ☽ at left, with ☽ and the rest descending); the right stub (G.) gives the complementary degree (30...3) with exit-signs (☽ ☾, etc.).

Upper half — Latitudo Borealis:

Sign	G.	1 Gr.'	3 Gr.'	5 Gr.'	7 Gr.'	9 Gr.'	G.	(exit)
☽ ☽	0	0 55	2 45	4 35	6 25	8 14	30

Parsing notes: The two halves are arithmetically identical except for the sign of the correction (the headers tell whether to add or subtract), as expected for a symmetric prosthaphaeresis-of-declination table; I have transcribed both in full as printed rather than collapsing them.

TAB. 35 — *Prosthaphaeresis Ascensionis Rectae*

[The prosthaphaeresis of right ascension]

This table is likewise in two halves, with a third (sub-)banner at the foot of each half. The upper half:

Asc. Rectae Signor. Boreal. *Subtrahe*; Australium *Adde*. [For the right ascension of the northern signs *subtract*; for the southern, *add*.] sub-banner: **Latitudo Borealis pro Signis Boreis.** [Northern latitude, for the northern signs.] foot-banner: **Latitudo Australis pro Signis Australib.** [Southern latitude, for the southern signs.]

The lower half:

Asc. Rectae Signor. Boreal. *Adde*; Australium *Subtrahe*. [For the right ascension of the northern signs *add*; for the southern, *subtract*.] sub-banner: **Latitudo Australis pro Signis Boreis.** [Southern latitude, for the northern signs.] foot-banner: **Latitudo Borea pro Signis Australib.** [Northern latitude, for the southern signs.]

Argument columns: latitude 1, 3, 5, 7, 9 degrees (Gr. '). Stub as in TAB. 34.

Upper half — Latitudo Borealis pro Signis Boreis:

(Foot-banner of upper half: **Latitudo Australis pro Signis Australib.**)

Lower half — Latitudo Australis pro Signis Boreis:

(Foot-banner of lower half: **Latitudo Borea pro Signis Australib.**)

Parsing notes: TAB. 35 is a prosthaphaeresis-of-right-ascension table; both halves run to zero at 30° (the equinoctial/solstitial points), as expected. Several interior cells in the lower half (the south-latitude/north-sign block) are at the limit of legibility because of foxing in the lower-right of the page; transcribed best-reading. The lower half's columns 3 and 5 around □ argument show a few values where the digits are cramped — the monotone decline to zero is preserved.

Tabulae novalmagesticae — Part III (the Sun's and Moon's motions)

Part Three of the Tables, on the Motions of the Sun and Moon.

TABULA 36. The Sun's Equal (Mean) Motion.

[Verbatim title: *TABVLA 36. Solis Motus Aequalis, seu Medius.*]

This page is laid out as two facing master-blocks. The left block gives the **Epochs (Radices)** — the Sun's mean longitude and the longitude of the Sun's apogee, both reckoned from Aries (♈), for a series of years before and after Christ (in the Julian, then Gregorian, reckoning). The right block gives the **expanded and collected Julian years** (*Anni Iuliani Expansi, & Collecti*). Columns throughout are Sig. / Gr. / ' / " (signs / degrees / minutes / seconds). "B." in a year column marks a bissextile (leap) year.

Left block — Epochs (Radices)

[Column heading: *Epochæ, seu Radices.* — over: *Longit. ☉ ab ♈* (the Sun's longitude from Aries) and *Longit. Apogei ☉ ab ♈* (the longitude of the Sun's apogee from Aries).]

The stub column gives the year; the segment labels in the left margin run, from top to bottom: **(years before Christ)**, then **At Christ** [*B^e Christi* — the radix at

Christ], then **Old Julian style** [*Stylo veteri Iuliano*], then **New Gregorian style** [*Stylo novo Gregoriano*].

Parsing notes: The "before Christ" / "at Christ" / Old-Julian / New-Gregorian segment labels appear vertically in the left stub margin; I have inserted them as italic row-headers at each segment boundary. In the New-Gregorian section the Sun's-longitude degrees revert to ~9–10° (the Gregorian calendar reform), whereas the Old-Julian section had climbed past 22°; this is a genuine feature of the dual-style radices, not a misread. The 1581/1582/1584/B.1600 block sits between the round-century Julian rows and the Gregorian rows as the calendar-transition radices.

Right block — Expanded and Collected Julian years

[Column heading: *Anni Iuliani Expansi, & Collecti*. — over: *Longit. ☉ ab √* and *Longit. Apogei ☉ ab √*. "B." marks bissextile years.]

Parsing notes: This right-hand block continues onto the next page (table-page 45). The Sun's-longitude column oscillates around $11^s 29^o / 0^s 0^o$ because one tropical year carries the Sun nearly but not exactly back to its starting point; the small annual surplus (the leap-year reset at each "B." row) is the expected behavior of an expanded-years table and is not an error.

SOLIS MOTUS ÆQUALIS — continued (table-page 45)

Expanded and Collected Julian years (continuation)

[Column heading: *Anni Iuliani Expansi, & Collecti*. — *Longit.* ☉ *ab* ♃ and *Log. Apog.* ☉ *ab* ♃. The lower part of the stub shifts to *Anni Collecti* (collected years) in hundreds, marked "B."]

Parsing notes: The lower-stub block jumps from single years (...99) to *Anni Collecti* in centuries; the printed century labels (100, 200, 300, 500, B.600 ... B.4000) are transcribed exactly as set — note the row order/labels are irregular as printed (a "200" appears at the segment head followed by "100"), which appears to be a compositor sequencing quirk rather than my misread (see anomaly a). The B.2000 Apogee-second cell reads "64" (flagged below as a numerical impossible).

TABULA: Common and Bissextile Months

[Heading: *Menses Communes Bissextiles*. — over: *Lóg.* ☉ *ab init.* ♀ (the Sun's longitude from the beginning of Aries) for *Menses Completi* (completed months), in two parallel sets.]

57	2	20	27	17
58	2	22	55	8
59	2	25	22	59
60	2	27	50	50

Parsing notes: Row 48 (Gr. 1, ' 55, " 16, ''' 40) breaks the smooth ~2'28"-per-step progression — the minutes should read ≈58 (continuing 53→55→58→0...). Flagged below (anomaly b); likely a compositor error in the source. Row 47 ''=48 and row 48 ''=16 with the degrees-column failing to roll to 2° suggest a transposition in the printing.

TAB. 37. PARALLAXES OF THE SUN (*PARALLAXIVM SOLIS*)

[Verbatim heading: *TAB. 37. PARALLAXIVM SOLIS.* — "Table 37. Of the Parallaxes of the Sun."]

The argument (stub) is altitude (*Altitud.*) in degrees (Gr.); the three value-pairs give the Sun's parallax [parallaxis Solis] at apogee (☉ *Apogeo*), at mean distance (☉ *In med. dist.* — *in media distantia*), and at perigee (☉ *Perigee*), each in ' and ''.

Altitud e (Gr.)	Apogee '	Apogee "	Mean dist. ' "	Mean dist. " "	Perigee '	Perigee "
0	27	28	28	18	29	8
5	25	10	26	10	27	8
10	23	20	24	20	25	20
15	21	30	22	30	23	30
20	19	40	20	40	21	30
25	17	50	18	50	19	40
30	16	0	17	0	17	50

Altitude (Gr.)	Apogee '	Apogee ''	Mean dist. '	Mean dist. ''	Perigee '	Perigee ''
35	14	40	15	30	16	0
40	12	30	13	30	13	30
45	10	0	11	20	11	40
50	9	30	9	40	10	0
55	7	40	7	50	8	20
60	6	0	6	10	7	0
65	5	0	5	10	6	0
70	4	0	4	10	4	30
75	3	0	3	8	3	20
80	2	0	2	6	2	6
85	1	0	1	2	1	6
90	0	0	0	0	0	0

Parsing notes: At altitude 90° (the zenith) all parallaxes go to 0'0", as expected. The fine '"/' pairs at low altitude are small and partly ink-bled; the values 0°: Apogee 27'28", mean 28'18", perigee 29'8" are read with moderate confidence.

[Footnote/key below the parallax table — the zodiac-sign correspondence for the altitude argument:] *I. II. — XI. XII.; III. IV. — IX. X.; V. VI. — VII. VIII. over Anomaliae Signa* ("the signs of anomaly") — i.e. the table-argument signs pair (I & II with XI & XII), (III & IV with IX & X), (V & VI with VII & VIII).

TAB. 38. The Equations of the Sun (*Aequationum Solis*) — table-page 46

[Verbatim heading: *TAB. 38. Aequationum Solis Excentricitate tota partium 3480. sed Bisiecta 1740. qualium Radius 100000.* — "Table 38. Of the equations of the Sun, the whole eccentricity being 3480 parts, but the bisected (halved) eccentricity 1740, of which kind the radius is 100000."]

The table is given twice: first **In Forma Circulari** ("in the circular form"), then **In Forma Elliptica** ("in the elliptical form"). The argument is the anomaly (*Anomalia*) — read down the left stub in signs (*Signa*) and degrees (*Gradus*) 0–30 and up the right stub in the complementary signs. Each sign-column gives the equation in G. (degrees) /' /'', headed by its Roman ordinal and the instruction

Subtrahe (subtract) in the upper half and *Adde* (add) in the lower half, with intervening *Diff.* (difference) columns.

In Forma Circulari

[Headers: *Anom. Signa / Gradus* (left); six value-blocks — *O. Subtrahe* (with *Differentia*), *I. Subtrahe* (Diff.), *II. Subtrahe* (Diff.), *III. Subtrahe* (Diff.), *IV. Subtrahe* (Diff.), *V. Subtrahe* (Diff.); *Anom. Sig. G.* (right).]

[Bottom-of-block sign labels (read upward for the right-hand argument): *XI. Adde.* — *X. Adde.* — *IX. Adde.* — *VIII. Adde.* — *VII. Adde.* — *VI. Adde.*]

Parsing notes: This circular-form sub-table is extremely dense (six equation-blocks each with degree/" plus a Diff. column). The equation is symmetric about anomaly 90° (sign III, 0°), where it peaks near 1°59'41"; the column-V values at the right margin mirror the column-O values, consistent with the *Subtrahe* (top) / *Adde* (bottom) symmetry of a solar equation. Several Diff. and " cells in the inner columns are small-type and ink-affected; readings carry moderate confidence. Row 12 column-IV minutes read "38" where the smooth descent suggests □ 29 — possible misread or compositor slip (flagged anomaly c).

In Forma Elliptica

[Headers: *Gr.* (left); six value-blocks — *O. Subtr.*, *I. Subtr.*, *II. Subtr.*, *III. Subtr.*, *IV. Subtr.*, *V. Subtr.*, each *G./"/*; *An. Sig. Gr.* (right).]

[Bottom-of-block sign labels: *XI. Adde.* — *X. Adde.* — *IX. Adde.* — *VIII. Adde.* — *VII. Adde.* — *VI. Adde.*]

[Reference note at foot: *TAB. 39.* pointing to the next table.]

Parsing notes: The elliptical-form table mirrors the circular form's symmetry: the equation peaks near 1°59'38" around anomaly 90° (sign III, 0°) and runs to 0°0' at the ends. This page has no separate Diff. columns (unlike the circular form). Several "-cells in the inner columns are small-type/ink-affected; readings carry moderate confidence. Column-V row 5 and row 6 both read 49'18" — a likely duplicated/dittographed value where one should differ (flagged anomaly d).

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae, Part III (continued)

Table-page 47

TAB. 39 — The distances of the Moon and Sun, horizontal parallaxes, hourly motions, and semidiameters at apogee, mean distance, and perigee

[TAB. 39. *Luni-Solaris Distantiarum, Parallax. Horiz. Horarij, & Semidiametrorum in \odot , \square & \oslash* — Table of the Moon-Sun distances, horizontal parallax, hourly motions, and semidiameters at conjunction (\odot), quadrature (\square), and opposition (\oslash).]

The argument (anomaly) runs down both edges of the table: degrees 0–180 in the left column descending in steps of 5, and degrees 360–180 in the right column (descending from 360 at the top to 180 at the bottom).

Column groups: **Distance from the center of the Earth** — *Ad Radium* (to the radius, parts of 100000) and *In Semidiam. Terrae* (in semidiameters of the Earth: 1st hypothesis, 2nd hypothesis); **Horizontal Parallax** ($^{\circ}$, $'$, $''$); **True hourly motion** (*Horarius mot. Verus*: $^{\circ}$, $'$, $''$); **Apparent semidiameter** (*Semidiam. apparentes*: $'$, $''$); **Apogee of the shadow** (\odot *Apo. Vmbrae* in 12ths, $'$); **Variation of the half-diameter** (*Variat. \odot Vmbrae demed.* $''$); **Axis of the Earth's shadow** (*Axis Vmbrae Terrae*: 1st hyp., 2nd hyp.).

Argument: **Apparent altitude** (*Altitud. appar.*, in degrees, left stub). Three seasonal blocks, each subdivided for the Sun (☉), an unmarked column, and the fixed stars (* *Fixae*): **Summer** (*Aestiva*), **Equinoctial** (*Aequinoctalis*), **Winter** (*Hyberna*). Entries are minutes (') and seconds (") of refraction.

[At foot:] *De Emendatione Tychonicarum, vide dicta Lib. 1. Astronom. Reformatae Cap. 14. & 15.* — On the correction of Tycho's [refractions], see what is said in Book 1 of the *Astronomia Reformata*, Chapters 14 and 15.

Parsing notes: TAB. 40 is a very densely packed three-season × three-source refraction table; the inner column splits (⊙ / unmarked / *, each ' ') are extremely tight. Many low-altitude rows mix single- and double-digit entries in adjacent narrow columns, so alignment of the higher-altitude rows (where most cells fall to 0) is approximate. Several cells in the bottom rows (24°–26°) are blank or 0 in the original and have been transcribed as read; this block for column-alignment verification.

Table-page 48

TABULA 41 — The Moon's equal, or mean, motion, and of the node (♁)

[TABVLA 41. *Lunae Motus Aequalis, seu Medius, & Nodi ♁.*]

This opening presents the **epochs/radices** and the **expanded and collected years** for the Moon's mean motion in longitude (*Longit. ab* ☿ — longitude from Aries), its **anomaly** (*Anomalia*), and the **motion of the node** (*Nodi ♁ mot.*). Each entry is given in signs, degrees, minutes, seconds (Sig. G. ' ").

Left half — EPOCHS, OR RADICES (EPOCHAE, SEV RADICES)

Argument: years **before Christ** (*Anni ante Christum*), then **of Christ** (*Christi*), counted by Gregorian reckoning (*Stylo Gregoriano / Stylo Iuliano* — Gregorian / Julian style as noted in the stub).

Parsing notes: The stub-block marked *Stylo Gregoriano / Stylo Iuliano* governs the lower set (years 1600–2300, the second 1600 onward); the upper set runs ante-Christum then Christi by hundreds. I have kept the printed second "1600" row as it appears (the table repeats 1600 to mark the Gregorian/Julian transition).

Left lower block — EXPANDED AND COLLECTED YEARS (ANNI EXPANSI, ET COLLECTI)

[Margin (between the two right blocks, vertical):] *Omnes hi sunt Bissextiles* — All of these are leap years (marking the years 64–96, multiples of 4).

Parsing notes: The right column's lower section (years 64 through 6000) lists every 4th year (all bissextile/leap years) and then round centuries/thousands. The Anomalia entry for year 64 reads "7 2 27" with a gap where a digit-group appears dropped in the original (likely "7 2 ?? 27" or a tight three-group); transcribed as printed and flagged.

Table-page 49

Parsing notes: For *HORAE ET SCRVPVLA*, the heading establishes a place-value scheme — the same numeric blocks serve hours (degrees ' '), minutes of time (" "), and seconds of time (" "" ""); only one set of figures is printed and the reader shifts the place-value per the *Hora* / *Min.* / *Sec.* row labels at the head. The

Longitude block reaches $\sim 32^{\circ}56'$ over 60 hours, the Anomalia $\sim 32^{\circ}39'$, the Node $\sim 7'57''$ — all smoothly monotone, confirming the readings. The unmarked extra order-columns (3rd/4th place) in the original are folded into the labelled blocks above.

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae, Part III (continued)

TABVLA 42 — *Aequationum Lunae in Copulis, seu in ϕ , ϕ° .*
 (Table of the equations of the Moon in the conjunctions/oppositions, i.e. at ϕ and ϕ°)

(Table-page 50, top. The argument is the anomaly [anomalia], read down on the left (G. = degrees) and up on the right. Six paired equation columns follow, each giving degrees / minutes / seconds [G. / ' / "], headed by Roman numerals with the instruction Subtr. [subtract] at the head and Adde [add] at the foot. The header reads "O. Subtr." for the first block, then "I. Subtr." ... "V. Subtr."; the foot labels run "XI. Adde", "X. Adde", "IX. Adde", "VIII. Adde", "VII. Adde", "VI. Adde". These index the sign of the argument [Sig.]: subtract for signs 0–5, add for signs 6–11.)

Parsing notes: argument runs 0–30 down the left (Anom. G.) and 30–0 up the right (Anom. Gr.). Each block heading carries the sign index and the instruction (Subtract at top for signs 0–5; Add at bottom for signs 6–11). A handful of seconds digits in the lower rows are tight in the gutter-side columns; the readings given are my best resolution.

TAB. 43 — *Aequatio Nodi, & Latitudo Maxima Lunae.* (Equation of the node, and the maximum latitude of the Moon)

(Table-page 50, bottom. Display instruction at the head: SVBTRAHE [Subtract]; at the foot: ADDE [Add]. Left and right edge stubs read "Distantia vera ☉ a ☽" (the true distance of the Sun from the node ☽). Argument is degrees (Gr.) 0–30. Three sign-blocks across, each with paired columns "Æquat. ☽" (equation of the node,

G''') and "Lat. Max." (maximum latitude, *G'''*). The block headers read "Sign. 0 vel 6", "Sign. 1 vel 7", "Sign. 2 vel 8"; the foot headers read "Sign. 11 vel 5", "Sign. 10 vel 4", "Sign. 9 vel 3".)

Parsing notes: head instruction SVBTRAHE, foot instruction ADDE. Top sign-block headers (Sign. 0/6, 1/7, 2/8) pair with foot headers (Sign. 11/5, 10/4, 9/3). Argument 0–30 down (left stub) and 30–0 up (right stub). Some seconds in the middle sign-block were tight; readings are best resolution.

TABVLA 44 — *LATITVDINIS LVNAE*. (Of the latitude of the Moon)

(Table-page 51. A two-panel page; the table is split into an upper and a lower half, each covering all 12 signs of the argument across paired column-groups, with "Signa Argumenti" running headers top and bottom of each panel, and "Arg. Latit." stubs at left and right (Gr. 0–30 down, 30–0 up). The sub-header reads "Latitudinis Maxima Termini" (limits of the maximum latitude). Each column-group is a value of the maximum-latitude limit; the group headers carry "G. 4 58", "5 0", "5 5", "5 10", "5 15", "5 18" — i.e. the maximum-latitude argument expressed in G'. The panel headers index which signs are northern (Bor. = boreal/north) or austral (Austr. = southern).)

TABVLA 44 — upper panel

	X. Latit. Austr.				IV. Latit. Bor.		

Parsing notes (TAB. 44): six maximum-latitude argument columns (4°58' through 5°18'), each in G'''. Argument runs 0–30 down (left stub) and 30–0 up (right stub). The sign-block north/south labels are panel headers, not column heads. Several seconds digits in the densest inner columns were tight; readings are best resolution. This table continues onto the next page as TAB. 44 *Residuum*.

TABVLA 44 — *Residuum*. (continuation)

(Table-page 52, top. Same structure: "Signa Argum." headers, "Arg. Latit." stubs (Gr. 0–30 down, 30–0 up), "Latitudinis Maximae Termini" sub-header, and the six maximum-latitude argument column-groups headed "G. 5 58", "5 0", "5 5", "5 10", "5 15", "5 18". Top header: "II. Latitudo Bor. ... VIII. Latit. Austr." Bottom header: "IX. Latit. Austr. ... III. Latit. Bor.")

	IX. Latit. Austr.				III. Latit. Bor.		

Parsing notes (TAB. 44 Residuum): the first column-group header reads "G. 5 58" — note the leading degree-figure "5" where the prior page's parallel column read "4 58"; transcribed as printed (this is the maximum-latitude argument and the inconsistency is flagged below). Argument runs 0–30 down and 30–0 up. Values approach the maximum-latitude limit (□ 5°17'30") at argument 30. Some seconds in the inner columns were tight; best resolution given.

TAB. 45 — *Reductio loci veri ad Eclipticam.* (Reduction of the true place to the ecliptic)

(Table-page 52, lower-left. Stubs "Argum." (Gr. 0–30 down, 30–0 up). Three sign-blocks headed "Sig. 0 / 6", "1 / 7", "2 / 8" with the instruction Subtrahe [subtract] across the top; foot instruction Adde [add] with foot headers "11 / 5", "10 / 4", "9 / 3". Each block is a paired '/' column. Left-edge vertical note: "0 Latit. Bor. Descend. / 6 Latit. Austr. Ascend." — "for sign 0, north latitude descending; for sign 6, south latitude ascending.")

Argum. G.	Sig.0/6 '/'	Sig.1/7 '/'	Sig.2/8 '/'	Argum. G.

29	5 58	6 11	0 15	1
30	6 6	6 6	0 0	0
	Sig.11/5	Sig.10/4	Sig.9/3	

Parsing notes (TAB. 45): values are '/' only (the degree place being 0 throughout, omitted in the header). Foot instruction "Adde"; head "Subtrahe". Argument 0–30 down, 30–0 up.

TAB. 46 — *Eclipsium Critica*. (Criticism / examination of eclipses)

(Table-page 52, lower-right. Columns: "Argum. Latitud." (Sig. / G.), "Latitudo Vera ☽" (true latitude of the Moon, G/''), "Accusverus inter cætera" [more precisely Arcus verus inter cetera — the true arc among the rest] (G/''), "Arc. intermomenta" [Arcus inter momenta — arc between the moments] (/''), "Tempus addendū" [Tempus addendum — time to be added] (/''), and a right-edge "Argum. Latitud." (Sig. / G.). The right-edge vertical note: "Sign. 5 Latit. Austr. Descend. / Sign. 11 Latit. Bor. Ascend." The argument runs in 18 rows; the printed Sig./G. column gives the latitude argument.)

Argu m.Lati t. Sig.	Argu m.Lati t. G.	Latitu do Vera ☽ G/'')	Arcus verus inter cetera G/'')	Arcus inter mome nta '/'	Temp us adden dum /'	Argu m.Lati t. G.	Argu m.Lati t. Sign.

Argu m.Lati t. Sig.	Argu m.Lati t. G.	Latitu do Vera ⋃ G/'/'	Arcus verus inter cetera G/'/'	Arcus inter mome nta '/'	Temp us adden dum /'/'	Argu m.Lati t. G.	Argu m.Lati t. Sign.
	12	1 2 18	1 2 13	2 52	5 14	18	
	13	1 7 24	1 7 18	3 6	5 39	17	
	14	1 12 29	1 12 22	3 19	6 3	16	
	15	1 17 33	1 17 25	3 32	6 27	15	
	16	1 22 36	1 22 27	3 44	6 49	14	
	17	1 27 37	1 27 28	3 56	7 11	13	
	18	1 32 36	1 32 26	4 7	7 33	12	

Parsing notes (TAB. 46): the Sig. columns at left and right edges carry only the vertical sign-notes (5 Latit. Austr. Descend. / 11 Latit. Bor. Ascend.), the numeric argument running in the G. columns 1–18 down and 29–12 up. The third data column's printed header reads "Accusverus inter cāetera" — read as *Arcus verus inter cetera*; rendered above. The "Tempus addendū" head expands to *Tempus addendum*. Lower rows (19–30) are not printed on this page — the table continues; catchword "TAB. 47" points to the next table-page.

Astronomia Reformata — Tomus II, *Tabulae novalmagesticae*, Part III (batch 169)

This batch is **TAB. 47** of the *Tabulae novalmagesticae* — the table of the **Final Equation, compounded from the Evection of the Centre and the Variation** (*Aequatio Ultima composita ex Euectione Centri, & Variatione*). It is a large composite table that runs across these (and following) pages. The argument structure is:

- The **horizontal argument** is the *Distance of the Moon from the Sun, or its opposition to the quadrature* [□] (i.e. elongation), tabulated in steps of **3**

degrees under the column blocks headed 3, 6, 9, 12, 15, 18, 21, 24, 27, 30.

- The **vertical argument** (stub, both left and right margins) is the **First Equated Anomaly** (*Anomalia primò Aequata*), given as Sig. (sign) and G. (degree), running 0°–30° within each sign-block 0 through 11.
- The page is divided into half-page panels, each headed by a **SIGNUM/SIGNA ... DISTANTIAE** banner indicating which sign of distance the panel covers, together with the directional rubric (*Subtr.* = subtract, *Adde* = add) and the ascending/descending rule printed below each panel.
- Each tabulated cell is a value in **degrees (G.) and minutes (')**; the symbol A. printed before a value marks where the running total crosses a whole degree (a carry/turnover marker as printed in the source). The astronomical glyphs in the banners are: ☉ (Sun), ☾/☾ (Moon), ☐ (quadrature), ☿ (conjunction), ☽ (opposition, printed 8-like glyph).

Because of the extreme density of these full-folio numeric panels and the small type, individual digits carry a non-trivial misread risk; the whole of TAB. 47 across pp. 53–55 is flagged as a (see report). Values are transcribed as printed; the A. carry-markers are preserved verbatim. Where a glyph could not be resolved it is marked [?].

PDF p. 505 (table-page 53) — TAB. 47, panels for Signum ☉ 0 and Signa 5

TAB. 47. The Final Equation, compounded from the Evection of the Centre and the Variation (*Aequatio Ultima composita ex Euectione Centri, & Variatione*)

Upper panel — SIGNUM 0. DISTANTIAE ☾ A ☉, VEL EIUS ☽ AD ☐ (Sign 0 of the Distance of the Moon from the Sun, or its opposition to the quadrature)

Directional rubric: each distance-column is headed **Subtr.** (subtract). Stub at both margins = the First Equated Anomaly (Sig. G.). Each cell = G. (degrees) ' (minutes).

Foot banner of lower panel: **SIGNA III. DIST.** ♪ A ⊙ ♪ A □ AD ♂, VEL ♂♂. —
Below: *Supra Scalam Subtrahitur Ascendendo, infra Descendendo.* ("Above the scale it is subtracted going up, below going down.")

Margin labels (both panels): **Anomalia primò Aequata** (First Equated Anomaly), left and right.

Page signature (foot center): **M 2.** — Catchword (foot right): **TA-** (i.e. *TABULA* — continuing onto the next page).

Parsing notes: TAB. 47 is laid out as a *double-entry* table read in two directions: the head banner gives the sign-of-distance for entry from the top with the upper Anomaly stub, while the foot banner gives the complementary sign (e.g. Sign 0 ↔ Signa 5; Sign I ↔ Signa IV; Signa II ↔ Signa III) for entry from the bottom with the inverted Anomaly stub, and the Gr. ladder at the foot of each column inverts the degree-of-distance argument (30 ↓ 0). The Subtr./Adde cell-bands and the ascending/descending rule below each panel govern the sign of the correction. The "G." (degree) sub-column of each block frequently carries 0 implicitly down a run of cells (the source leaves it blank, the value carrying from the row above); blank G-cells in the transcription reflect this. The A. prefix marks a degree-carry within the minute column. Several minute-cells in the dense interior of these panels could not be resolved with full confidence at this resolution; values are given as best read and the whole table flagged as a No sexagesimal-impossible (>59') values were found that were not attributable to a misread of the G./' column boundary (see Numerical impossibles).

TABVLA 48. — *The Moon's hourly motion from Sun to Sun in conjunction and opposition, or the motion 12 hours before or after them*

Signs of the Moon's equated Anomaly [Signa Anomaliæ ᵀ coæquatae] (top band, signs 0–5)

The argument runs down the left "Anomal." column (degrees, in 3°-steps). For each sign there are two columns: **Hor. in** ♂ & ♀ (hourly motion at conjunction and opposition) and **Horat. ultra** (hourly motion beyond). Units are minutes (') and seconds (").

	35	0	32	17	7	22	42	44	34	21	2	15	

Bottom band: Signs 11, 10, 9, 8, 7, 6 (read upward from the foot) — **Signs of the Moon's equated Anomaly** [Signa Anomalix̄e ḡ coæquatæ]. The same paired columns serve the complementary signs; the right-hand argument column (Anomál. Gr.) runs 30→0 to give the entry for the upper half.

Parsing notes: This is a double-entry table for the Moon's hourly motion. The top header gives signs 0–5 (left-to-right); the bottom header gives signs 11–6 (the same body rows serve both, with the left "Anomal." column 0→30 read top-down for signs 0–5 and the right "Anomál." column 30→0 read for signs 11–6). Row 12° / sign 3 "ultra" reads "31 25" — identical to the 9° entry above it, breaking the

smooth ~31'15"→31'35" progression of that column; suspected compositor repeat, transcribed as printed (footnoted later). Cell values verified by further re-transcription; the earlier ambiguous "ultra" readings in the high-anomaly rows are now resolved.

**TABVLA 49. — *Verification of the conjunctions and oppositions of the luminaries* [Verificatio ☿, & ☾
Luminarium]**

The Moon's horary minutes from Sun to Sun in conjunction and opposition
[Minuta Horarii ☽ à ☉ in ☿, & ☾]

The top header gives the degrees of motion (**Grad.**) 27–35. Beneath: **H.** (hours), **I** (minutes), and below that **I / II / III** (minutes / seconds / thirds). The left stub gives **M.** (minutes of motion) running 1–60. Each block of columns supplies hours, minutes, seconds, and thirds for the given degree.

Parsing notes: A four-figure sexagesimal table (Hours, minutes ', seconds ", thirds ""), so the per-cell triplets read as H ' "" (with hours = 0 until the values exceed an hour). The blank rows between groups of 5/10 in the source are spacing only. The stub jumps from 30 to 35, 40, 45, 50, 55, 60. Col 30 (M.=30) is the reference column (I = stub-arg, II = 0 throughout), confirming column alignment. Row 9 / col 31 verified as "0 17 25" (the earlier "0 19 21" was a misread); row 40 / col 35 verified as "1 8 33". No seconds-position value exceeds 59.

Parsing notes: Five sexagesimal/decimal column-pairs. The apogee "Qualium R.100000" column equals 100000 + eccentricity, and the perigee column equals 100000 - eccentricity; this internal check confirms the readings. **Row 120:** eccentricity corrected to "11509" (the first-pass "10509" was a leading-digit 1→0 misread); with 11509 the eccentricity column is monotone — 10944 (110) → 11509 (120) → 12243 (130).¹ The earlier readings "11243/111243" (row 130) and "11029/113029" (row 180) were first-pass misreads; verified as "12243/112243" and "13029/113029" respectively. Row 90 eccentricity corrected to "9685" (the distance 109685 is the printed value; the first-pass "9681" was internally inconsistent). Apogee-semidiameter column rows 0–30 corrected from "65 xx" to "63 xx" (systematic first-pass 3→5 misread; the column is monotone 63→68). Row 30 perigee verified as "94618".

TAB. 51. — *The distance of the Moon from the centre of the Earth, outside conjunction and opposition* [Distantia Lunæ à Centro Terræ extra ☿, & ☽]

Anomaly of eccentricity, or double elongation of the Moon from the Sun [Anomalia Excentricitatis, seu duplicata Elongatio ☽ à ☉] — top argument 0–180 (in 20°-steps), with the complementary argument 360–180 below it. Body entries are **Semidiameters of the Earth** [Semidiametri Terræ], in semidiameters (Sem.) and minutes (').

¹ TAB. 50, row 120 (Gr. 120/240), apogee "Qualium R.100000" cell: the printed value is **110509**. With the corrected eccentricity 11509, the apogee should arithmetically read 111509 (= 100000 + 11509), so the printed 110509 is a one-digit compositor slip (a dropped 1). The printed cell is **retained verbatim** here, flagged for editorial footnote rather than silently "fixed."

Parsing notes: Body cells are Sem. ' (semidiameters and minutes of the Earth's semidiameter). The complementary-argument row (360→180) at the foot mirrors the head. This is a densely-set block; the earlier first-pass had several flagged cells now resolved by further re-transcription. Row 90° cols 140/160 verified as "60 0" — the minute figure reads 0 where neighbours run 60–61 (plausible at the apogee/perigee symmetry node, transcribed as printed). Rows 130° and 150° right-hand columns (160/180) both show "55 55" / "54 37", which duplicate across the two rows — suspected compositor line-repeat, transcribed as printed (footnoted later). The cell (20°, col 180), formerly flagged [?], is recovered as "67 55", consistent with the column head and the monotone neighbour rows.

Parsing notes: The "Distant. D " stub is in Earth-semidiameters and half-minutes (52 0, 52 30, 53 0 ...). The apparent-semidiameter and horizontal-parallax columns are each minutes $'$ and seconds $''$, both descending monotonically as distance grows — a clean consistency check. The earlier first-pass values at 54 0 (parallax "63 39"), 58 0 ("59 19"), 58 30 ("58 49"), 61 30 (sd "15 20"), 66 0 (sd "14 19") are corrected to the verified readings shown.

TABVLA 53. — *The true parallaxes of the Moon in the circle of altitude [Parallaxium ☽ in Circulo Altitudinis Vera]*

Horizontal Parallax in Minutes [Parallaxis Horizontalis Minuta] — column heads 50–64

The left stub is **True altitude** [Altitudo vera], in degrees (G.), 1–60. Each column heading (50, 51 ... 64) is a value of the horizontal parallax in minutes; the body cells give the parallax in altitude as minutes ' and seconds ''.

Parsing notes: This is the very large lunar-parallax-in-altitude table — 15 horizontal-parallax columns (50–64 minutes), argument = true altitude 1–60°. Body cells are minutes ' and seconds ". The further re-transcription resolved the great majority of the first-pass [?] flags and the spurious >59 second-values (which were degraded misreads of the smooth column progression, not compositor errors); each column descends monotonically with altitude, which serves as the consistency check. The argument 50–64 across the top equals the *I*-column of the row-1 entries minus one (e.g. col-50 row-1 = 49'59"), confirming column alignment. The remaining [?] cells are individual second-glyphs that stay genuinely illegible at this resolution — concentrated in the dense lower-right quadrant (cols 60–64, rows 20–60) and the worst row 20; these are not high-resolution-recoverable in this pass and the lower-right quadrant of the table remains a higher-resolution. The right-hand columns (63, 64) lose their rightmost data near rows 41–60 into the gutter/trim; where a column's pair is blank in the source the row is left short rather than padded.

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae (batch 171)

Table-page 59

This page completes TABLE 53 (begun in the prior batch). The upper block continues the **minutes of horizontal parallax** [Minuta Parallaxis Horizontalis] from 50' through 64' across the top, with the **true altitude** [Altitudo vera, in degrees G.] as the argument down the left, here running from 61° to 89°. Each parallax column gives a pair (' "). The three lower blocks extend the table to horizontal parallaxes 65', 66', 67', with the true-altitude argument restarting at 1° and running to 90° across the three panels.

Upper block — Minutes of horizontal parallax 50'–64' (true altitude 61°–89°)

Each cell is (' "). Columns are the horizontal parallax in minutes: 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64.

Parsing notes: All cells resolved on further re-transcription; no residual [?]. The double-entry cells show (") pairs. Row 77, col 53 prints "11 56", which breaks the otherwise smooth descent of that column (neighbours "11 52" and "12 20") — transcribed as printed; suspected compositor error, footnoted later.

Lower block — Minutes of horizontal parallax 65', 66', 67' (true altitude 1°–90°)

Three side-by-side panels, each headed *M. Parallaxis Horizontalis* with columns 65, 66, 67; the true-altitude argument (G.) runs 1–30 (left panel), 31–60 (middle panel), 61–90 (right panel). Each cell is (").

Parsing notes: All cells resolved on further re-transcription; no residual [?]. In the middle panel (col 67), rows 34/35 read "55 11" / "55 32" — the pair appears transposed/miscomposed against the smooth descent of neighbouring rows; transcribed as printed, suspected source error, footnoted later.

Table-page 60

Quarta Pars Tabularum Reliquarum pro Eclipsibus.

(The Fourth Part of the Remaining Tables, for Eclipses.)

[PART IV banner — the eclipse-calculation tables.]

TABLE 54 — *Epactarum pro Noviluniis, ac Pleniluniis Mediis* (Of the Epacts, for the Mean New and Full Moons)

The table gives the **epacts** [epactae] — accumulated quantities expressed in Days, Hours, minutes, seconds (D. H. ' ") — used to reduce to the mean new/full moon. The left section is the *Epochae Epactarum* (Epochs of the Epacts): completed years counted **before Christ**, headed *Ante Christum* and noted "completed years counting upward in ascending order, but in the calculation proceeding downward" [*Anni completi ascendendo; sed ineuntes in calculo descendenti*]; then the **Radix** at the year of Christ; then the *Anni completi* (completed years) of the Christian era by centuries. The right section gives the epact increment for individual completed years 1–100, then by hundreds and thousands. Years marked **B.** are bissextile (leap) years.

Left section — Epochs of the Epacts

[*Ante Christum* — Before Christ:]

Anni (years B.C.)	D.	H.	'	"
6000	11	12	54	15
5000	27	4	6	37

11000	24	7	35	39
12000	10	10	3	58

Parsing notes: All cells resolved on further re-transcription; no residual [?]. The "Anni" sub-headers *D. H. ' "* repeat at the head of each of the three right-hand panels; merged here into two markdown tables (years 1–60, then 61 through 12000). The earlier-flagged "60" at year 3000 and the degraded foot rows (3000, 9000) all resolved on close re-reading: year 3000 reads "17 8 53 1" (not "60"), and no seconds value in this table exceeds 59 — there is no numerical impossible.

TABLE 55 — *Termini Eclipsium. Distantia a Nodo ☉* (Limits of Eclipses. Distance from the Node)

[Lower-right panel of the page.] Distance from the ascending node ☉ at which eclipses are possible, for lunar [Lunarium] and solar [Solarium] eclipses, each given at apogee [☾ Apog.] and perigee [Perigæa].

	Lunarium ☾ Apog. G. '	Lunarium Perigæa G. '	Solarium ☾ Apog. G. '	Solarium Perigæa G. '
Sole Apog.	10 48	12 2	15 58	17 14
Sole Perig.	10 40	11 53	16 5	17 20

Parsing notes: "Sole Apog." / "Sole Perig." form the stub (Sun at apogee / at perigee). Columns are paired G. ' (degrees, minutes). No value exceeds 59'.

Table-page 61

TABLE 56 — *Parallaxeon Mesoplaticae* (Of the Mesoplatic Parallaxes)

[*Parallaxeon Mesoplaticae* — the "mesoplatic" (mid-latitude) parallax. The Greek-derived term μεσοπλατική here denotes the parallax reckoned for an intermediate position. Title as printed: *Parallaxeon Mecoplaticae*.]

The argument down the left is the **latitude** [Latitudo, *Latitud. latus.*, in degrees G.], running 0°–90°; the matching value on the right edge is the *Nonagesimi Altitudo* (altitude of the nonagesimal), running 90° down to 0° as a complement, labelled *Longitud. latus.* at top and *Nonagesimi Altitudo* down the right margin. Across the top are the **minutes of horizontal parallax** [Minuta Parallaxeos Horizontalis], columns 1 through 13. Each cell is (" ").

Parsing notes: All cells resolved on further re-transcription; no residual [?]. The right-margin argument (*Nonagesimi Altitudo / Longitud. latus.*) is the complement (90 - latitude) and runs 90→0. The descending diagonal structure (parallax decreasing as latitude→90°) serves as the consistency check. Several cells break the otherwise smooth monotone progression and are transcribed as printed (suspected compositor errors, footnoted later): row 16 col 4 ("4 58"); row 10 col 11 ("11 45"); row 81 col 13 ("2 24"); and rows 89 & 90 col 7 (both "0 9", where the row pattern expects "0 7"). Row 90 duplicates the seconds of row 89 across cols 2–13 (the bottom boundary row mirrors the row above) — transcribed verbatim. No minute or second value exceeds 59. N PARAL-

Astronomia Reformata — Tomus II, Tabulae novalmagesticae, Part IV (the eclipse tables)

Note on this batch: The prior batch's handoff anticipated TAB. 57 here, but the three pages of this batch are all continuation pages of **TAB. 56** (the mesoplatic parallaxes), each headed *Residuum TAB. 56. Parallaxis Mecoplatica* ("Remainder of TAB. 56, the mesoplatic parallax"). TAB. 56 spans many columns of the horizontal parallax; this batch covers the argument-of-horizontal-parallax columns **14' through 52'**. Each page is a full pipe-table with latitude as the left/right argument and the minutes of horizontal parallax across the top. A glossary divergence note is recorded in the batch report.

Remainder of TAB. 56 — The Mesoplatic Parallax (continued)

[The Parallaxes of Longitude and Latitude]

Each of the three tables below is captioned "**Residuum TAB. 56. Parallaxeon Mecoplaticæ**" ("Remainder of TAB. 56, of the mesoplatic parallaxes"), with the body of values listed under the banner "**Minuta Parallaxeos Horizontalis**" ("the minutes of horizontal parallax"). The leftmost column is **Latitud. latus** ("latitude of the side," i.e. the latitude argument in degrees, G.), running 0° down to 90°; the rightmost column repeats the latitude argument as **Longitud. latus** running 90° up to 0° (read against the *Nonagesimi Altitudo*, the altitude of the nonagesimal, noted in the right margin). For each minute-of-horizontal-parallax heading (14, 15, 16 ...), two sub-columns give minutes (') and seconds (").

horizontal-parallax columns 14'–26'

[Margin (right): Nonagesimi Altitudo (the altitude of the nonagesimal)]

Parsing notes: At row 24 the 21' and 22' columns read "21 36" and "22 50" — these break the otherwise smooth diagonal progression and appear to be compositor errors (see Numerical impossibles). Row 79 in the source has no entry printed in the 26' column (left blank). At row 80 the 25' entry "4 31" and 26' entry "4 10" break the column's monotone descent (flagged). Some seconds values were hard to resolve against the gutter on the left columns.

horizontal-parallax columns 27'–39'

[Margin (right): Nonagesimi Altitudo (the altitude of the nonagesimal)]

[Margin (left, foot): PARAL- (continuation marker)]

[Margin (left, foot): PARAL-]

[Margin (right, foot): PARAL-]

Parsing notes: Rows 10 and 12 (and partly 14, 16, 18) in the 40' column print the leading minute as "19"/"18" where the column trend requires "39"/"38" — these are clear compositor errors (a dropped/misformed leading "3"); transcribed as printed and flagged. Row 20 onward the 40' column resumes "37 ..." correctly. Row 18 at column 45' reads "42 58" against an expected ~42:5x progression — flagged. Row 79 at columns 46' ("8 58") repeats the seconds of the following pair (likely compositor error). The 60° row gives the clean baseline (parallax = the heading value, seconds = 0). Several leading "3"/"4" digits in the left columns sat close to the gutter and were resolved by column-monotonicity.

PARALLAXES OF LONGITUDE AND LATITUDE [PARALLAXES LONGITVD. ET LATITVD.]

Residuum of TAB. 56. The Mecoplastic Parallax [*Residuum TAB. 56. Parallaxeos Mecoplasticae*]

Parsing notes: This is a very dense full-page table with 28 numeric sub-columns; some interior digits are ink-bled or pinched between rule-lines. Verified by a focused cell-by-cell re-transcription, which resolved the great majority of the originally flagged interior cells. Residual low-confidence cells remain flagged [?]: the isolated single-digit reading at Latit. 16 / col 56" (read 5, trend suggests ~50), and the faint ink-bled lower-right block at Latit. 80–81 across cols 64'/65'/66'. ; the block for a cropped single-column pass isolating the right-end strip (cols 64'–66', rows 78–83) at native resolution without the tile seam.] The Latit. 60°

row is the baseline (the seconds-values run 0, 30, 0, 30... in a clean pattern, confirming alignment). The 90° row is all zeros, the expected lower boundary. Right margin reads vertically "Nonagesimi Altitudo" [the nonagesimal altitude]. Suspected source (composer) errors transcribed verbatim, not flagged [?]: Latit. 42 / col 53' = 19(breaks the monotone descent where neighbours read ~40); Latit. 28 / col 66" = 61` (a true sexagesimal impossible, >59 seconds — see Numerical impossibles); and several non-monotone single cells in the 62'–66' block (Latit. 60–61 rows).

DIGITS OF ECLIPSE [DIGITI ECLIPTICI]

TABLE 57. OF THE DIGITS OF ECLIPSE [TABVLA 57. DIGITORVM ECLIPTICORVM.]

; the body columns are headed across the top "Scruples of the Diameter of the Sun, or of the Moon" [*Scrupula Diametri Solis, aut Lunae*], running from 30 through 36 by half-steps (30, 30½, 31, 31½, 32, 32½, 33, 33½, 34, 34½, 35, 35½, 36). Each value-column is split into digits and minutes [*Digit.* ʹ]. The catchword at the foot reads "SCRV." A decorative printer's ornament (foliate band) sits at the foot of the table.]

Top heading over the value-columns: **Scruples of the Diameter of the Sun, or of the Moon** [*Scrupula Diametri Solis, aut Lunae*]

Parsing notes: TAB. 58 and its Residuum together carry 16 argument columns (21'–36'), each split into minutes (') and seconds ("). Both half-tables are triangular: the body fills from the top and each successive column extends one or more rows further down before reaching its terminal "0 0" entry, so the lower-left cells are genuinely empty (rendered as blank cells here — NOT [?]; faint show-through digits visible in those empty cells are bleed from the page beneath and are not data). The seconds (") values stay within 0–59 throughout (no sexagesimal impossibles). Verified by further. The lower half-table's tail prints irregular row labels (... 28, 29, 30, then 32, 34, 36 by 2-steps); the final two rows have no printed stub value (cropped/illegible at the foot of the page) — provisional row identities (37)/(38) are given in parentheses and flagged [?] to preserve column alignment. One residual low-confidence seconds reading remains at Latit. 30 / col 35' (read 2, possibly 12), flagged [?].

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae

Part IV — The Eclipse Tables (continued)

TABVLA 59. The scruples of incidence and half-duration in a lunar eclipse [TABVLA 59. *Scrupula Incidentiae, & Semimora in Eclipsi Lunæ*].

The sum of the semidiameters of the Moon ☽ and of the shadow [umbra] [Summa Semidiametrorum ☽, & Vmbræ].

This is a double-entry table. The argument (stub) column at left is the *true latitude* [Latitudo Vera ☽] of the Moon, running 0–59; the left margin is further annotated, by ranges, "true latitude ☽" [Latitudo vera ☽] repeated. The body is divided into columns headed by the sum of the semidiameters in minutes — 52', 53', 54', 55', 56', 57', 58', 59', 60' — each subdivided into *I* (minutes) and *II* (seconds), giving the scruples of incidence / half-duration in minutes (*I*) and seconds (*II*). Blank body cells (where the printed source leaves a gap, the latitude exceeding the semidiameter sum) are shown empty.

Parsing notes: A triangular double-entry table; the upper-left of the body is blank (latitude < semidiameter-sum region prints empty) and the lower-left columns terminate in "0 0" entries before going blank. The 52' column shows only one body value ("54 0" at lat. 0 in column-head row); from lat. 1 onward the 52' pair is blank in the printed source. Several lower cells are faint from ink wear; values flagged [?] in the report where uncertain. Catchword: "SCRV." (i.e. *Scrupula*, the continuation table).

**The remaining scruples of incidence and half-duration in a lunar eclipse
[Reliqua Scrupula Incidentiæ, & Semimora in Eclipsi Lunæ].**

**The remaining sum of the semidiameters of the Moon ☽ and of the shadow
[Reliqua Summa Semidiametrorum ☽, & Vmbræ].**

Continuation of TAB. 59. Same structure; the argument (stub) is the true latitude ☽ (0–67); columns are the semidiameter sums 61' through 68', each subdivided into *I* (minutes) and *II* (seconds).

Parsing notes: Triangular continuation; lower-left columns terminate in "0 0" then blank. Some interior digits are worn or ink-bled (notably rows 12–14 and 28–30 in the 63' and 64' columns) and are transcribed as the most probable reading; values where I am genuinely uncertain are noted in the report. Catchword "DI-" (i.e. *Distantia*, pointing to TAB. 60).

TABVLA 60. The distance of the centers of both luminaries [TABVLA 60. *Distantia Centrorum vtriusq; Luminaris*].

This is a double-entry table giving, for an argument of *Scruples* [*Scrup.*] (0–99, in the stub column) and a parallax/elongation increment heading (0', 10', 20', 30', 40', 50', 60'), the distance of the centers expressed in degrees (*G.*, i.e. *Gradus*), minutes (*I*), and seconds (*II*).

Parsing notes: The stub steps by 1 in the top group (0–4), then by 2 thereafter (rows are grouped 4 at a time with rule-bands). The columns are grouped G./I/II per parallax-increment heading. Row "3" of the stub (between 2 and 4) is absent in the printed source — the top block prints 0, 1, 2, 4 (no row 3). Faint cells at row 46 (0' column "2 19 2" — likely a worn "2 29 2") and at the 60' column row 46 ("2 33 46" where monotone suggests "2 35 46") are transcribed as printed and flagged below. Catchword "PARAL." (i.e. *Parallaxis*) at foot, pointing to the next table.

TAB. 61. The parallaxes of the Moon in the circle of true altitude, given the distance from the center of the Earth [Parallaxes Lunae in Circulo Altitudinis Verae, sub data distantia à centro Terrae]

This is a four-panel parallax table. The argument is the apparent altitude (Alt./Gr., 0°–89°, read down the stub). The column-groups give the Moon's parallax in altitude (minutes ' and seconds ") for each value of the Moon's distance from the Earth's center, expressed in Earth-radii [Distantia ∽ à centro Terrae in semidiametris Terrae]. The two left-hand quadrants cover distances 52–61 radii for altitudes 0°–60°; the two right-hand quadrants cover the same distances for altitudes 60°–89°.

Left half — header: "Distantia 〕 à centro Terrae in semidiametris
Terrae." — Altitudes 0°–60°

Distance columns 52–61 radii. Each distance gives minutes (') and seconds (").

Parsing notes: This left half is exceptionally dense; many '/' pairs sit on shared rule-lines and several seconds-digits are ink-merged. On further re-transcription

every cell resolved to printed glyphs (no residual [?]). The column-wise monotone descent (parallax decreasing with altitude and with increasing distance) was used as a consistency check. Three internally-inconsistent groups were confirmed as printed and are kept as suspected source (compositor) errors: row 43 col 59 = 44 24 and row 44 col 59 = 43 24 (both interrupt the smooth decline of column 59); row 56 col 58 = 33 5 and col 59 = 34 3 (col 59 exceeds col 58, which is impossible — parallax must decrease with greater distance); row 57 col 54 = 34 53 (breaks its row's monotone decrease). All transcribed exactly as printed.

Right half — header: "Distantia 〕 in semidiam. Terrae." — Altitudes 60°–89°

Distance columns 52–56 radii (top sub-panel) and 57–61 radii (bottom sub-panel).

86	4	17	4	14	4	14	4	4	4	0
87	3	13	3	10	3	13	3	3	3	0
88	2	8	2	6	2	12	2	2	2	0
89	1	4	1	3	1	11	1	1	1	0

Parsing notes (right half): All cells resolved on further re-transcription (no residual [?]). In the lower block (distances 57–61), column 59 rows 87–89 (3 13, 2 12, 1 11) each exceed the neighboring column-58 value and break the smooth descent; row 86 col 59 (4 14) equals the col-58 value. These four are kept as printed — suspected source (compositor) errors where a stray trailing digit appears to have been set in the unit-second place; the expected pattern (□ 3 1, 2 1, 1 1, 4 4) matches the col 60/61 progression. Transcribed exactly as printed.

TABULA 62. The mean motions of Saturn [Mediorum Motuum Saturni ♄]

This page opens **PART V, the planetary tables**, beginning with Saturn. It is a composite of several sub-tables giving Saturn's mean motions in longitude from Aries [Long. ab ♈], in the motion of the apogee [Apogaei], and of the ascending node [Nodi Bor. = Nodus Borealis], each expressed in signs, degrees, minutes, seconds (Sig. G. ' "). The radices are referred to the Bologna meridian (see the footnote below).

Left top: EPOCHAE, seu RADICES MOTVVM (the epochs, or radices of the motions) — argument "Anni Capleti [completi] ante Christum" (complete years before Christ)

The left-hand year-axis is labelled "Sr. veter." (the old style [Stilo veteri]) for the rows down to 1600, and "Stylo Gregoriano." (Gregorian style) for the rows from 1600 onward — hence the doubled 1600 entry. The two distinct 1600 lines (6 28 24 14 ... and 6 28 4 10 ...) are a genuine source feature: the Julian/Gregorian split at the 1582/1600 calendar reform (Old-Style vs. Gregorian radices). They are kept and flagged so reconciliation does not read the pair as a duplicate-row artifact.

Left bottom: ANNI EXPANSI, & COLLECTI (the expanded and collected years) — argument "Anni" 1–20

B. 20	8	4	41	29	0	38	3	0	8	38		

The rows marked "B." are the bissextile (leap) years.

Foot-note (below the left columns): The radices here affixed are for the Bologna meridian [Meridiano Bononiensi], at midday of the last December preceding. The years — except for year 1 of Christ, which is the entering year — are complete years, reckoned both upward (before Christ) and downward (after Christ) [Radices affixae sunt Meridiano Bononiensi, in meridie ultimi Decembris praecedentis. Anni praeter 1. Christi, qui est iniens, sunt completi, tam sursum numerando ante Christum, quam deorsum post Christum].

Right top: ANNI COLLECTI (the collected years) — argument "Anni" 40–6000

Parsing notes: This is the densest page of the batch — a fine-print composite of seven sub-tables packed onto one folio. On further re-transcription all cells resolved to printed glyphs (no residual [?]). The DIES block resolves to a longitude column (G. ') with a "minutes" sub-column accumulating across the month and a single-second "Apog. "" column (0–2). The HORAE block is a separate two-column argument (' ") running only 1–12 hours; the first-pass "60 | 2 | 30 [?]" row at the foot was an artifact of interleaving the two argument-axes and is not present in the source — HORAE terminates at 12. The doubled 1600 radices row is a real calendar-reform layout feature (Julian vs. Gregorian), not a duplicate. Monotone progression was used as a column check throughout.

TABULA 63. The first equation of the simple inequality of Saturn [Aequatio Prima Inaequalitatis Saturni]

A double-entry equation table. The argument is the simple anomaly [Anomalia simplex] in degrees (Gr. 0–30, repeated in the right-hand stub running upward). The column-groups are headed by the signs of the simple anomaly [Signa Anomaliae simplicis], 0 through V at the top (with **SVBTRAHE** — "subtract" — as the operative instruction) and XI through VI at the foot. Each sign-column gives the equation in degrees, minutes, seconds (G. ' ").

The foot of the upper table carries the instruction **ADDE** ("add") for the ascending (XI–VI) arguments, complementing the **SVBTRAHE** at the head.

Parsing notes (TAB. 63): On further re-transcription all cells resolved to printed glyphs (no residual [?]). Column V row 16 reads 1 53 0: within column V the value rises then falls (row 15 1 50 10, row 16 1 53 0, row 17 1 45 47) where a smooth decrease (□ 1 47) is expected. This is kept as printed — a suspected source (compositor) mis-set.

TAB. 64. The equated anomaly of Saturn, corresponding to the simple anomaly [Anomalia Aequata Saturni, respondens Anomaliae simplici]

A double-entry table giving the equated anomaly. The argument is again the simple anomaly in degrees (Gr. 0–30 down the left stub, repeated upward on the right). Sign-columns 0–V across the head, XI–VI across the foot, each in signs/degrees/minutes/seconds (Sig. G. ' ").

Parsing notes: TAB. 63 and TAB. 64 share the page in stacked register. The argument runs down the left stub and back up the right; the sign-columns are mirrored head-to-foot (0...V at top, XI...VI at bottom) in the standard double-entry equation layout. On further re-transcription all cells resolved to printed glyphs (no residual [?]). The Sig.G. (signs-and-degrees) cells were split on the column rule-lines; the Sig. figure increments at each 30° crossing (e.g. col II row 2→3 jumps Sig 1→2; col V row 1→2 jumps Sig 4→5). The final cell (row 30, col V) prints 5 30 0 0 — Sig. 5, 30°, equal to 6 signs (a full-circle reset); transcribed as printed. Column IV row 17 reads 4 14 34 38: the minutes 34 break the smooth minute-progression of column IV (row 16 42 6, row 18 47 8), where 44–45 is expected. This is kept as printed — a suspected single-digit source (compositor) mis-set (34 for 44).

Riccioli, *Astronomiae Reformatae Tomi Duo — Tabulae novalmagesticae*, Part V (the planetary tables)

EQUATIONS OF SATURN [AEQUATIONES SATURNI]

TABLE 65. Of the maximum equations, or of the annual parallaxes of the orbit, for Saturn [*TABULA 65. Maximarum Aequationum, seu Parallaxium Orbis annuae pro Saturno*]

[Margin (left, running vertically): Anomaly of the equated orbit of Saturn — *Anomalia Aequata Saturni*] [Margin (right, running vertically): Anomaly of the equated orbit of Saturn — *Anomalia Aequata Saturni*]

This is a double-entry equation table. The **top heading** reads: *Signa, & quindeni Gradus Anomaliae Solis Aequatae* ("Signs, and the fifteen-step Degrees of the equated anomaly of the Sun"); the **foot heading** mirrors it: *Signa, & seni Gradus Anomaliae Solis Aequatae* ("Signs, and the six-step Degrees of the equated anomaly of the Sun"). The sign-columns run **0–V** across the top and **XI–VI** across the foot. Each sign holds two sub-columns of degrees-of-argument (headed 0 / 15 / 30 etc. at top, mirrored at foot), and each cell gives the equation in degrees (G.) and minutes (').

The left argument column (Sig. G. / An. h) steps the equated anomaly of Saturn in degrees down the page; the right argument column mirrors it. The body values are degrees and minutes; the leading 5 and 6 are the whole-degree part. The

LATITUDES OF SATURN [LATITUDINES SATURNI]

TABLE 66. Proportional minutes of the latitude of Saturn [TABULA 66. *Scrupula Proportionalia Latitudinis Saturni*]

This page carries the table in two stacked panels, the upper for **Signs O and I**, the lower (a *Residuum*) for **Signs II and III**. The common heading is *Anomalia Aequata Excentrici Saturni* ("Equated anomaly of the eccentric of Saturn"); the side margins read *Anomalia Orbis Saturni* ("Anomaly of the orbit of Saturn").

[Margin (left & right, vertical): Anomaly of the orbit of Saturn — *Anomalia Orbis Saturni*]

Upper panel — Signs O and I

Column heading band: **Sign O** at degrees 0 / 15 / 30; **Sign I** at degrees 0 / 15 / 30; then the increment columns. Each sign-degree block holds **Scrupula**

proportionalia (proportional minutes, in G. ') and **Decr. in** \varnothing (decrement at opposition). The right-hand block holds: **Incr. in** \varnothing (increment at conjunction, '), **Scrup. proport. Increm. & Decrem.** (proportional minutes of increment & decrement, G. '), and the right **Anom. orbis** \square argument.

Foot sign-row (mirrored): **XI** (G. 30 G. 15) — **X** (G. 0 G. 30 G. 15) — common foot heading: *Anomalia Aequata Excentrici Saturni*. The rightmost foot-sign label under the (G.) 0 column is printed IV, out of sequence with the IX/X/XI series — a suspected misset or worn sort; transcribed as printed.

Lower panel — *Residuum* TAB. 66, Signs II and III

[Heading: *Residuum* TAB. 66. *Scrupula Proportionalia Latitudinis Saturni* — Remainder of TAB. 66, proportional minutes of the latitude of Saturn] [Common heading: *Anomalia Aequata Excentrici Saturni*]

Column band: **Sign II** at Gr. 0 / Gr. 15 / Gr. 30; **Sign III** at Gr. 15 / Gr. 30; then the increment columns.

Foot sign-row (mirrored): **IX** (G.30 G.15) — **VIII** (G.0 G.30 G.15) — common foot heading: *Anomalia Aequata Ex centrici Saturni*.

Parsing notes: TAB. 66 has many narrow paired columns (proportional minutes G.' next to a single-digit decrement). Alignment of the Decr. in □ single-digit column against its Scrupula proportionalia pair was the chief difficulty in the first pass. A further cell-by-cell re-transcription () verified the body values for both panels; the residual uncertainties on these two panels are resolved.

LATITUDES OF SATURN [LATITUDINES SATURNI]

Residuum TAB. 66 — Signs IV and V

[Heading: *Residuum TAB. 66. Scrupula Proportionalia Latitudinis Saturni* — Remainder of TAB. 66, proportional minutes of the latitude of Saturn] [Common heading: *Anomalia Aequata Excentrici Saturni*] [Margin (left & right, vertical): Anomaly of the orbit of Saturn — *Anomalia Orbis Saturni*]

Column band: **Sign IV** at Gr.0 / Gr.15 / Gr.30; **Sign V** at Gr.15 / Gr.30; then the increment columns.

Foot sign-row (mirrored): VII (G. 30 G. 15) — Sign — VI (G. 30 G. 15 G. 0) — Sign.

Parsing notes: same column layout as the upper TAB. 66 panels. A further cell-by-cell re-transcription () verified the body values; one genuinely faint cell remains

flagged (Sig4 G12, V Gr15 = 57 0[?], with the leading "57" supported by the column trend). The value 59 50 at Sig5 G30 in the V Gr15 column breaks the otherwise monotone increase of that column (Sig5 G24 = 59 49; the parallel V Gr30 column reaches 60 0; expected \square 59 54–59 56) — a suspected compositor digit error; transcribed as printed and flagged [?]. The minute value 60 0 in the final V Gr30 cell is the table's maximum (= 1°0'), consistent with the column reaching its end-point, not a sexagesimal overflow within the body proper.

TABLE 67. Of the latitude, reduction, and curtation of Saturn

TABLE 67. Of the latitude, reduction, and curtation of Saturn [TABULA 67. Latitudinis, Reductionis, & Curtationis Saturni]

[Top heading: *Signa Distantiae Saturni à Nodo Boreali* — Signs of the distance of Saturn from the northern node Ω] [Foot heading: *Signa Distantiae Saturni à Nodo Boreali*]

The argument column (Gr. Dist. à Ω — degrees of distance from the node) runs 0–30 down the left, mirrored on the right. The table holds three blocks, each headed by a distance-in-signs banner (top, with the foot mirror beneath): **0 north & 6 south** [0 Bor. & 6 Austr.], **1 north & 7 south** [1 Bor. & 7 Austr.], **2 north & 8 south** [2 Bor. & 8 Austr.]. Each block gives **Latitude** [*Latitudo*] (G. '), **Reduction** [*Reductio*] (' '), and **Curtation** [*Curtatio*] ('').

Foot sign-row (mirrored): **5 north & 11 south** [5 Bor. & 11 Austr.] — **4 north & 10 south** [4 Bor. & 10 Austr.] — **3 north & 9 south** [3 Bor. & 9 Austr.].

Parsing notes: In TAB. 67 the third block's **Curtation** column (2 Bor. & 8 Austr.) is printed but engraved entirely blank in the source (no values); transcribed as empty cells (not [?]). The Reduction column of the third block decreases

monotonically as the argument increases (1'27" → 0'0"), consistent with the mirrored read direction. A further cell-by-cell re-transcription () verified the seconds-figures in the Reduction columns; no residual [?] remains in this table.

TABULA 68. The Mean Motions of Jupiter (TABVLA 68. MEDIORVM MOTVVM IOVIS ♃)

This page comprises several sub-tables of Jupiter's mean motion, each tabulating Longitude from ♈ (Aries) [Longit. ab ♈], Apogee [Apogæi], and Northern Node [Nodi Bor.] in Signs, Degrees, minutes, seconds (Sig. G. ' ").

EPOCHÆ, or RADICES MOTVVM — Epochs, or Radices of the Motions (Years Completed before Christ — Anni Completi ante Christum)

(Stub markers at left of this block: *Stylo veteri* — Old Style — through 1600; *Stylo Gregoriano* — Gregorian Style — from 1700 onward.)

Parsing notes: The before/after-Christ blocks share the three column-triads. The stub for the post-Christum block opens with "Christm" (= the Christ epoch) then 100...2300. Old-Style/Gregoriano-Style bracket markers sit in the left margin of the longitude block.

Decemb.	30	20	32	30	25	30	1	22	1	22

Parsing notes: For Martij and Aprilis the Communis longitude figures (7 28 54 / 9 58 32) versus Bissextilis (7 13 53 / 10 3 31) — transcribed as printed; the Martij common-year minutes/seconds read 28'54" where the bissextile reads 13'53", an apparent reset crossing into the next degree, transcribed verbatim. The Decemb. Nodi reads 1'22" (the leading-minute figure carried down through the column); transcribed as printed.

DIES — Days (1–32) and HORÆ — Hours (right block)

Dies	Long.			Apog.	Horæ	Long.	
	G.	'	"			ab □'	"

17	1	24	48	3	17	3	32
18	1	29	47	4	18	3	44
19	1	34	46	4	19	3	57
20	1	39	45	4	20	4	9
21	1	44	45	4	21	4	22
22	1	49	44	5	22	4	34
23	1	54	43	5	23	4	47
24	1	59	43	5	24	4	59
25	2	4	42	6	25	5	12
26	2	9	41	6	26	5	24
27	2	14	40	6	27	5	37
28	2	19	39	6	28	5	49
29	2	24	39	7	29	6	2
30	2	29	38	7	30	6	14
31	2	34	36	7	40	8	19
32	2	39	36	7	60	12	18

Parsing notes: The Horæ block stub for the last two rows reads "40" and "60" where one would expect continued hour-counting — likely the table shifts to a different argument (the "40" and "60" appear to be a fractional/minute sub-argument); transcribed as printed. The Apogee column for Dies is a single seconds-column ("").

[Margin, foot of table:] *Radices affixæ sunt Meridiano Bononiensi, in meridie ultimo Decembris præcedentis. Anni præter 1. Christi, qui est iniens, sunt Completi, tam numerando sursum ante Christum, quàm deorsum post Christum.* — The radices are fixed to the Bologna meridian, at noon of the last [day] of the preceding December. The years — apart from the year 1 of Christ, which is the year then beginning — are completed years, whether counted upward before Christ or downward after Christ.

TABULA 69. The Equation of Jupiter's First Inequality (TABVLA 69. Æquatio Primæ Inæqualitatis Iovis)

Top half: argument is the Simple Anomaly [Anomalia simplex], in Signs of the Simple Anomaly [Signa Anomaliæ simplicis]. Top sign-row: 0, I, II, III, IV, V; the instruction **SVBTRAHE** (Subtract) governs the upper half. Bottom (mirrored) sign-row: XI, X, IX, VIII, VII, VI; instruction **ADDE** (Add). Each sign-column gives Degrees, minutes, seconds (G. ' ") of the equation. Stubs at both edges: Anom. simpl. Gr. (degrees of simple anomaly), running 0–30 (left, descending argument) / 30–0 (right).

Parsing notes: Upper half SVBTRAHE; lower half ADDE. The bottom row repeats the column heads as the mirrored sign block (XI/X/IX/VIII/VII/VI). Right-edge stub descends 30→0. Row 16 col IV reads "4 2 5" and row 20 col IV "3 44 44" as printed. Row 24 col IV reads "3 36 1": the IV degree-minute column otherwise descends

monotonically (row 23: 3·30·48; row 25: 3·21·10), so the "36" interrupts the descent and is likely a compositor transposition for "3 26 1"; transcribed as printed and flagged.

TAB. 70. Jupiter's Equated Anomaly, corresponding to the Simple Anomaly (TAB. 70. Anomalia Æquata Iovis, respondens Anomaliæ simplici)

Bottom half of p. 530. Argument: Simple Anomaly [Anomalia simplex] in Signs (Signa Anomaliæ simplicis), top sign-row 0, I, II, III, IV, V; foot sign-row XI, X, IX, VIII, VII, VI. Each sign-column: Sig. G. ' " of the equated anomaly. Stubs both edges 0–30 / 30–0.

Parsing notes: This is a wide Sig./G./" table (each sign-column carries a Sig. sub-field). The values run monotone within each column; a few minute/second cells in columns III–IV are faint near rows 18–20. The mirrored foot sign-row reads XI/X/IX/VIII/VII/VI.

[Side-stub, both margins:] *Anomalia Æquata Iovis* — Jupiter's Equated Anomaly.

[Foot sub-heading repeated:] *Signa, & quindenii Gradus Anomalix Solis Æquatæ.* — Signs, and each fifteenth degree of the Equated Solar Anomaly.

Parsing notes: This is a double-entry table: top argument = Equated Solar Anomaly by sign and by 15° sub-step; side argument = Jupiter's Equated Anomaly by sign and 3°. Cells give degrees and minutes (most entries 10° or 11° plus minutes); to save column width the "10"/"11" degree figure is printed only on the first row of each block and at the 15° / 30° rows, the intervening rows showing minutes alone — I have transcribed degree-figures where printed and left minutes alone where the source omits the repeated degree. Row "1—30" col II(15°) reads "10 50" and col III(0°) "10 46" (carrying the smooth column progression). The final side-block prints rows at 6/12/18/24/30 (omitting some 3° steps), transcribed as printed. Row "0—3" col IV(15°) reads "21" where the column otherwise runs 23→23→24 — an isolated dip, possible compositor slip; transcribed as printed and flagged.

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae, Part V (Planetary Tables)

THE LATITUDES OF JUPITER

TABULA 72. The Proportional Minutes of Jupiter's Latitude

TABVLA 72. *Scrupulorum Proportionalium Latitudinis Iouis.* (Table 72. The proportional minutes of Jupiter's latitude.)

Column banner: **Signs, and every fifteen degrees of Jupiter's equated anomaly of the eccentric** (*Signa, & quindenii Gradus Anomaliae Aequatae Excentrici Iouis*).

The argument is the **Common Anomaly** (*Anom. Comut.*) running down the left stub (and mirrored on the right stub, descending). The body is a double-entry grid: top arguments are signs 0–V (left-to-right) over the upper half and signs XI–VI (the foot row) for the lower-reading; each sign column is subdivided into the 15° and 30° sub-columns, each giving degrees (G.) and minutes (').

The full table is reproduced below. Left stub = Common Anomaly (Sig. G. = sign, degree). The upper foot-row of degree markers reads 30 / 15 / 30 / 15 / 30 / 15 / 30 / 15 / 30 / 15; the lower sign banner reads XI / X / IX / VIII / VII / VI.

Foot degree-row: 30 / 15 / 30 / 15 / 30 / 15 / 30 / 15 / 30 / 15 / 30 / 15 / 30 / 15

Foot sign banner: XI · X · IX · VIII · VII · VI

Left margin (vertical): *Anomalia Aequata Commutationis Iouis* (the equated anomaly of Jupiter's commutation).

Parsing notes: This is a double-entry proportional-minutes grid; values approach 60' (= a full proportional unit) at the lower-right corner, consistent with the smooth monotone rise across the page. After further re-transcription most interior cells were resolved; three residual cells remain flagged [?] where a digit could not be confirmed against the column progression (Sig.I row 6 V 15° 41 58; Sig.II row 12 I 15° 44 42 and II 30° 44 44; Sig.IV row 18 IV 15° 55 46). The 44 42 / 44

44 / 55 46 cells break the otherwise-smooth descent/ascent and are suspected source/compositor anomalies, transcribed as printed.

Residuum TAB. 72 (lower-left block) — Remainder of Table 72

Residuum TAB. 72. (Remainder of Table 72.)

Argument: Common Anomaly (*Anom. Comut.*, Sig. G.). Columns: the increment in minutes (*Incrementum in '*), the decrement in minutes (*Decrementum in '*); then a second argument-block — the minutes of the proportional increment & decrement (*Scrup. proport. incr. & decr.*, Gr.) with its own Common Anomaly (*Anom. aeq. Co.*, G. Sig.). The "Scrup. proport." block packs a degree figure and a minute figure into a paired column.

V · 30	13	26	60	0	0 · 6

Parsing notes: The right-hand "Scrup. proport." block packs a degree figure (Gr.) and a minute figure (') into a paired column; the degree figure descends 60→0 then folds back upward across the "B."-marked midpoint, consistent with a proportional-scruple table. "A." (row 0·0) and "B." (row III·6) are interlinear directionality marks printed beside the scruple figure and transcribed as printed. further re-transcription resolved most of the previously-ambiguous paired entries; two cells remain flagged [?] (row 0·24 Scrup-Gr 55 and ' 44, faint impression; row II·30 Scrup-Gr 9, faint vs surrounding teens).

TAB. 73. Jupiter's Latitude, Reduction, and Curtation

TAB. 73. *Latitudinis, Reductionis, & Curtationis Iouis.* (Table 73. Of Jupiter's latitude, reduction, and curtation.)

Banner: **Signs of Jupiter's Distance from the North Node** (*Signa Distantiae Iouis à Nodo Boreali*).

Argument: Difference (*Diff.*, descending left stub, Gr.) and a mirrored *Diff.* on the right. Each sign-distance block (0 North / 6 South; 1 North / 7 South; 2 North / 8

South) carries three sub-columns: Latitude (*Latit.*, G.''), Reduction (*Red.*, ''), Curtation (*Curt.*, '').

Diff. (Gr.) 0 Bor. / 6 Austr. — Latit. (G.'') Red. (") Curt. (") 1 Bor. / 7 Austr. —

Foot sign banner: **Sig. 5 Bor. 11 Austr. · 4 Bor. 10 Austr. · 3 Bor. 9 Austr.** (i.e. for the lower readings, Signs 5/11, 4/10, 3/9 of distance from the North Node).

Parsing notes: The leftmost and rightmost narrow "Diff." columns are blank in the body (differences printed only at the block edges); left empty where the source shows no figure. Latitude is degrees-minutes-seconds; Reduction and Curtation are single seconds columns. further re-transcription resolved most of the formerly-ambiguous cells; residual [?] remain at row 11 (group-2 Latit-" 29 faint; group-3 Curt-" 1 faint) and row 24 (group-2 Latit-" 28 faint). Row 27 group-2 Latit-'

prints 32, interrupting the descent near the foot — suspected source error or misread, transcribed as printed and flagged.

THE MEAN MOTIONS OF MARS

TABULA 74. The Mean Motions of Mars (♂)

TABVLA 74. MEDIORVM MOTVVM MARTIS □. (Table 74. Of the mean motions of Mars.)

Sub-table A — EPOCHS, or RADICES (left column)

EPOCHAE, seu RADICES. Argument: complete years before/after Christ (*Anni Completi ante / post Christum*). Columns: Longitude from Aries (*Longit. ab* □, Sig. G. ' '); Apogee (*Apogaei*, Sig. G. ' '); North Node (*Nodi Bor.*, Sig. G. ' ').

2300	0 9 56 51	5 14 32 21	1 24 57 35

Left-margin year-bracket labels: *Sr. veteri* (Old Style era, the upper block, to 1600) and *Sr. nouo* (New Style era, the lower block, from 1600 onward).

Parsing notes: The two "1600" rows reflect the Old Style → New Style era split (the calendar reform); both are printed and retained verbatim. Seconds columns all ≤ 59. This is a citation-grade radices table; further re-transcription confirmed the cells, with one residual [?] at row 2200 (Nodi-" 12, faint impression).

Sub-table — COLLECTED JULIAN YEARS (upper-right)

ANNI IULIANI COLLECTI. Motion (*Motus*): Long. from Aries; Apogee; North Node.

Anni	Long. ab □ (Sig. G. ' ")	Apogaei (Sig. G. ' ")	Nodi Bor. (Sig. G. ' ")
40	3 6 39 50	0 0 52 32	0 0 32 0

32	16 46 23	8	60	78 36

Parsing notes: The HORAE stub jumps from 1–30 to selected multiples (40, 60). The Hor-' entries at 40 h (52) and 60 h (78) exceed 59, but these are cumulative arc-minute totals of mean motion (78' = 1°18'), correct in context — NOT sexagesimal-overflow errors. further re-transcription confirmed the DIES/HORAE cells; one residual [?] remains at Dies 29 (Lon-" 5, faint).

Sub-table — EXPANDED & COLLECTED JULIAN YEARS (lower-left)

ANNI IVLIANI EXPANSI, & COLLECTI. Motion (*Motus*): Long. from Aries; Apogee; North Node. The "B." prefix marks bissextile (leap) years.

Anni	Long. ab □ (Sig. G. ' ")	Apogaei (")	Nodi Bor. (")
1	6 11 17 8	1 19	0 48
2	0 22 34 16	2 38	1 36

(foot)	Adde XI	Adde X	Adde IX	Adde VIII	Adde VII	Adde VI	G.

Foot banner: **Signs of the simple, or mean, anomaly** (*Anomaliae simplicis, seu Mediae Signa*).

Parsing notes: The 0-sign column begins at 0 0 0 and the V-sign column ends at 0 0 0, as expected for an equation table symmetric about apogee/perigee. Top headers add the directive "Subtr." (subtract), foot headers "Adde" (add). Seconds columns ≤ 59 throughout. further re-transcription resolved the formerly-flagged cells, all now recovered. Row 5 sign V 5 0 12 is the correct terminus of the V-column's descent (5 53 16 / 42 54 / 32 25 / 21 49 / 11 44 \rightarrow 0 12); the earlier "compositor column-slip" suspicion was a transcription artifact in rows 1–4 (now corrected) and is withdrawn.

TAB. 76. Mars's Equated Anomaly, corresponding to the Simple Anomaly

TAB. 76. *Anomalia Aequata Martis, respondens Anomaliae simplici.* (Table 76. Mars's equated anomaly, answering to the simple anomaly.)

Banner: **Signs of the simple, or mean, anomaly** (*Anomaliae simplicis, seu Mediae Signa*).

Argument: simple anomaly in degrees (*Anom. simpl. Gr.*, descending left stub; mirrored right). Top sign-headers 0–V, foot sign-headers XI–VI. Each entry gives Sig. G. ' " (the first column is a combined sign+degree figure, then minutes and seconds).

Anom. simpl. (Gr.)	0 (Sig. G. ' ")	I (Sig. G. ' ")	II (Sig. G. ' ")	III (Sig. G. ' ")	IV (Sig. G. ' ")	V (Sig. G. ' ")	Anom. simpl. (Gr.)

(foot)	XI	X	IX	VIII	VII	VI	G.

Foot banner: **Signs of the simple anomaly** (*Anomaliae simplicis Signa*).

Parsing notes: The first column of each sign is a combined sign+degree figure (e.g. 0 27, 1 25, 2 24, 3 25, 4 27), then minutes and seconds. The table runs continuously: each sign's bottom row (Gr 30) equals the next sign's top row (Gr 0). The equated-anomaly columns advance monotonically to 6 0 0 0 (a full

revolution) at the V-column, row 30. further re-transcription cut the flagged cells substantially; rows 10, 15, and 17 sign V are now recovered. Residual [?] remain in the ink-crowded lower-right and a few faint cells: row 2 sign V (" , gutter-faint) and row 26 sign II (" , gutter-faint). Row 26 sign II reads 2 20 ... (degree 20, not 21); sign III is the genuine 3 21 14 4. The earlier "compositor doubling" of the 21 14 4 triplet was a transcription artifact (sign-II degree misread 21 for 20) and is withdrawn.

TABLE 77. Of the maximum equations, or parallaxes of the annual orbit, for Mars [TABVLA 77. Maximarum Aequationum, seu Parallaxium Orbis Annui pro Marte]

This is a double-entry table. The argument is the **equated anomaly of the Sun, complete** [Signa Anomaliae Solis Aequatae Completa], read from the top for signs O–VI and from the bottom (foot row) for signs XII–VI. The left and right stub columns give the **equated anomaly of Mars** [Anomalia Aequata Martis] in signs (Sig.) and degrees (G.). Each sign-column is divided into degrees (Gr.) and minutes ('). Values are in degrees and minutes.

[Margin, left side: Anomalia Aequata Martis] [Margin, right side: Anomalia Aequata Martis]

Header: Signs of the equated anomaly of the Sun, complete.

	0	7	4	7	6	6	1	6	9	5	7	5	4	5	6		

Foot header (read upward): Signs of the equated anomaly of the Sun, complete [Signa Anomaliae Solis Aequatae Completa]. Foot sign-row (left to right under the body columns): XII | XI | X | IX | VIII | VII | VI.

Parsing notes: Sign-columns O–VI run across the top; the mirrored sign-row XII–VI is printed at the foot, so each cell serves two arguments. Two interior cells in column O appear to be compositor transpositions of the minutes digit (row 2°/4°: "39 17" where the smooth progression and the 39 49 → 40 5 sequence imply ≈39 57; row 2°/18°: "40 17" where 40 7 → 40 30 implies ≈40 57); flagged inline with [recte:]. Row 3°/22° column III reads "43 50" but the row's other columns (43 47 / 43 40 / 43 19) and the descending pattern imply ~42 50; column IV "43 22" likewise implies ~42 22; both flagged. See Numerical impossibles.

TABLE 78. Of the proportional minutes of the latitude of Mars [TABVLA 78. Scrupulorum Proportionalium Latitudinis Martis]

Double-entry table. Outer stub columns: **the common, or mean, anomaly of the orbit** [Anomal. orb. seu comun.] in signs (Sig.) and degrees (G.), with the leftmost paired "Scrup. propt. increm. & decem." (proportional minutes, increment & decrement) column. The body argument across the top is the **equated anomaly of the eccentric of Mars, complete** [Signa Completa Anomaliae Aequatae Excentrici Martis], signs O–VI, each in degrees (Gr.) and minutes ('). The far-right

Foot sign-row (read upward): XII | XI | X | IX | VIII | VII | VI. Foot header: Signs of the equated anomaly of the eccentric of Mars, complete [Signa Completa Anomaliae Aequatae Excentrici Martis].

Parsing notes: This table is heavily ruled, many narrow cells, and some interior body cells are partly broken up by ink bleed and the gutter at left. Where a degree value and its minute value could not be confidently separated, the entry is given as read; several rows show only partial/run-together digits and are flagged [?] in the QA report. The "A." and "B." marks in the proportional-minutes columns are register/segment letters in the source, transcribed verbatim. This is a dense citation-grade page and is marked a

TABLE 79. Of the decrements of the proportional minutes of the latitude of Mars [TAB. 79. Decrementi Scrupul. Proportion. Latit. □]

Double-entry. Stub: **the equated anomaly of the eccentric** [An. exc. aequ.] in signs (Si.) and degrees (G.) at left; mirrored at right. Body argument across the top: **the equated anomaly of the Sun, complete** [Signa Anomaliae Solis Aequatae Completa], signs O–VI, each ' and ''.

Foot sign-row (read upward): XII | XI | X | IX | VIII | VII | VI. Foot header: Signs of the equated anomaly of the Sun, complete [Signa Completa Anomaliae Solis Aequatae].

Parsing notes: This sub-table is the most degraded region of the page — very small '/' cells with ink bleed at the gutter side. Many cells in signs III–VI show run-together or transposed digits; several are flagged [?] or [recte:] where the column's monotone progression makes the intended value clear. Marked a

TABLE 80. Of the latitude, reduction, and curtation of Mars [TAB. 80. Latitudinis, Reductionis, & Curtationis □]

Argument: **the distance from the northern node** [Signa Distantiae à Nodo Boreali], top and foot, in degrees (Distant. Gr.). Three triple-column blocks across the top, headed by the latitude band: "6 Bor. 6 Austr.", "7 Bor. 5 Austr.", "8 Bor. 4 Austr." (i.e. each block valid for a Boreal and an Austral value of the inclination), each block giving Latitude (Latit., G. / '), Reduction (Red., '), Curtation (Curt., '). The right stub repeats the distance.

Distant. Gr. 6Bor/6Austr Latit.G. Lat ' Red." Curt." 7Bor/5Austr Latit.G. Lat ' Red." Curt." 8Bor/4Austr Latit.G. Lat ' Red." Curt." Distant.

3 | 40 | 47 | 35 | 6 | 22 | 47 | 7 | 21 | 0 | 70 | 0 |

Foot latitude-band labels (right to left): 5 Bor. 11 Austr. | 4 Bor. 10 Austr. | 3 Bor. 9 Austr. Foot header: Signs of the distance from the northern node [Signa Distantiae à Nodo Boreali].

Parsing notes: TAB. 80 is laid out in three triple-column blocks (Latit. G', Red. ", Curt. ") per latitude pairing. The column rules are fine and the right two blocks suffer ink bleed and gutter compression, so several Latitude-degree/minute and Reduction/Curtation cells run together; values are given as read and uncertain ones flagged. The "61"/"62"/"63"... figures in the second block read as Reduction-seconds running into the next column in places and could not always be cleanly separated; this block The header bands "6 Bor. 6 Austr." etc. denote which Boreal/Austral inclination the column serves.

TABLE 81. Of the mean motions of Venus ♀ [TABVLA 81. MEDIORVM MOTVVM VENERIS □]

A multi-panel mean-motion table. The left half gives the **epochs, or radices of the motions** [EPOCHÆ, seu RADICES MOTVVM] for years completed before and after Christ, plus the expanded and collected Julian years. The right half gives the collected Julian years, the months of the common and bissextile year, the days, and the hours. Each motion block has three sub-columns: **Longitude from Aries** [Longit. ab □], **Apogee** [Apogæi], **Northern Node** [Nodi Bor.], in signs/degrees/minutes/seconds (Sig. G. ' ").

Left panel — EPOCHS, or RADICES OF THE MOTIONS [EPOCHÆ, seu RADICES MOTVVM]

Stub: **Years completed before Christ** [Anni Cópleti ante Christú], then after Christ.

Parsing notes: TAB. 81 is the densest page in the batch — six panels (epochs, expanded/collected Julian years, collected centuries, months common/bissextile, days, hours) packed into one folio leaf. The four-digit motion entries (Sig./G./"/) are mostly clear; uncertainty concentrates in the apogee- and node-second sub-columns of the epoch panel near the gutter, and in the Days panel's degree column where a few cells run together (the day-15 row appears to drop a digit). The two 1600 rows (old style "Sr. nouú" / old style) are both genuine in the source — a calendar-reform feature, not a duplication error. The Hours panel's last two rows are labelled "60" (= 60 minutes / a full hour carry) rather than a 33rd–34th hour. Values flagged [recte:] where a column's smooth arithmetic progression makes the compositor's intended value clear; bare [?] where I cannot resolve the glyph.

Tabulae novalmagesticae — Part V (the planetary tables): Venus's equations and latitudes

(*Tomus II, Tabulae novalmagesticae, Part V. Table-volume pages 86–88 = Venus's equation and latitude tables, TAB. 82–85.*)

TABVLA 82. *Aequationum Primae Inaequalitatis Veneris.* — Table 82. The equations of the first inequality of Venus.

[Margin/sub-heading: **Signa Anomaliae simplicis, seu Mediae** — Signs of the simple, or mean, anomaly]

The upper argument (left stub) runs **Anom. simpl. G.** (simple anomaly, degrees) 0–30 descending its own count; each sign-panel (0–V) has minutes (') and seconds (") sub-columns, all under **Subtr.** (subtract). The lower argument (right stub) is **Anom. simpl. G.** counting 30→0. Below the body the complementary instruction reads **Adde XI / Adde X / Adde VIII / Adde VIII / Adde VII / Adde VI** (Add ...) beneath the respective panels, with the foot-label **Signa Anomaliae simplicis** (signs of the simple anomaly).

30	27	0	47	10	54	36	47	34	27	20	0	0	0	

Foot of body (complementary "Adde" labels beneath panels 0–V): **Adde XI | Adde X | Adde IX | Adde VIII | Adde VII | Adde VI** — (Add XI, Add X, Add IX, Add VIII, Add VII, Add VI), with foot-label **Signa Anomaliae simplicis** (signs of the simple anomaly).

Parsing notes: This is a standard equation table whose columns each rise then fall (the equation peaks near the middle of the cycle), so straightforward monotone-progression checks do not apply. All cells resolved on re-transcription. Row 24, panel II " prints "4" where the column's progression (rows 23→25 read 14, 4, 15) would expect a value near "9/19" — a suspected source compositor slip, transcribed as printed. Panel headers read "0 Subtr., I Subtr., II Subtr., III Subtr., IV Subtr., V Subtr." across the top.

TAB. 83. *Anomalia Aequata Veneris, respondens Anomaliae simplici.* — Table 83. The equated anomaly of Venus, corresponding to the simple anomaly.

[Sub-heading: **Signa Anomaliae simplicis** — Signs of the simple anomaly]

Left stub **Anom. Gr.** 0–30 descending its count; six sign-panels (0–V) each carrying **Sig. G.** | ' | " (signs, degrees, minutes, seconds). Right stub **Anom. Gr.** 30→0. Foot row of panel-numbers **XI X IX VIII VII VI**, foot-label **Signa Anomaliae simplicis**; right-margin note **Signa Distantiae à Nodo boreali** (signs of distance from the northern node) appears faintly at the foot. Catchword **AEQVA-**.

Foot row (panel numbers beneath 0–V): **XI** | **X** | **IX** | **VIII** | **VII** | **VI**; foot-label **Signa Anomaliae simplicis** (signs of the simple anomaly). Catchword: **AEQVA-** (→ AEQVATIONES, continuing Venus's equation tables on the next opening).

Parsing notes: Very dense full-page table with six three-sub-column panels (Sig.G./"/") plus two stub columns. The leading **Sig.G.** column repeats the sign number for each panel; the second sub-column carries the running degree and the third the minutes/seconds. All cells resolved on re-transcription. Row 22, panel I" prints "50" where the smoothly falling " progression around it would expect a lower value — a suspected source compositor slip, transcribed as printed. The bottom-right corner (row 30, panel V) wraps to the descending-stub corner "6 | 0 | 0". The right-margin foot note **Signa Distantiae à Nodo boreali** is partly faint; gloss confident.

TABVLA 84. *Maximarum Aequationum, seu Parallaxeon Orbis annui Veneris.* — Table 84. The maximum equations, or parallaxes of the annual orbit of Venus.

[Sub-heading: **Signa Anomaliae Veneris Aequatae Completa** — Complete signs of the equated anomaly of Venus]

Left margin (rotated): **Anomalia Solis Aequata** — equated anomaly of the Sun.
 Right margin (rotated): **Anomalia Solis Aequata** — equated anomaly of the Sun.
 The body is grouped in blocks of six argument-rows. Stub at left **Sig. | G.** (signs; degrees in steps of 3: 0, 3, 6, 9, 12, 15, then 18, 21, 24, 27, 30...). Seven argument panels labelled **0, I, II, III, IV, V, VI**, each with **G. | ' (degrees, minutes)**; the right edge repeats **G. | Sig.** as the complementary descending argument. The whole-degree figure (44/45/46/47) is printed once at the head of each sub-group and carries down implicitly to the rows beneath where the degree cell is blank; the carried-down degree is supplied in parentheses below. Foot panel-numbers **XII XI X IX VIII VII VI**; foot-label **Anomaliae Veneris Aequatae Signa Completa** (complete signs of the equated anomaly of Venus). Signature **Q 2**. Catchword **LATI-** (→ LATITUDINES).

Foot row (panel numbers across the seven panels): **XII | XI | X | IX | VIII | VII | VI**; foot-label **Anomaliae Veneris Aequatae Signa Completa** (complete signs of the equated anomaly of Venus). Signature **Q 2**. Catchword: **LATI-** (→ LATITUDINES, Venus's latitude tables).

Parsing notes: Argument runs in 3-degree steps within each sign (0, 3, 6, ..., 30), so the stub column shows Sig. then G. in steps of 3; only the first row of each sign-block carries the Sig. number explicitly. The degrees columns (G.) hold steady near 44–47 across the table while the minutes climb and fall — this is the maximum-equation curve, so monotone checks apply only within local runs. The whole-degree figure is printed once at each sub-group head and carries down implicitly; the implicit (carried) degree is shown in parentheses, which resolves the earlier degree-column [?] flags as a layout omission rather than illegibility. The block-II minutes cell at Sig.4/G.6 is illegible/blank in the source where the surrounding degree run continues (shown –). The block-0 minutes run at Sig.4/G.6 –12 prints "35, 34, 56" where the smooth trend reads ~29–39; the "56" is wildly out of line and "35 > 34" is a local inversion — suspected compositor errors,

transcribed as printed. The right-edge complementary stub (G./Sig.) descends; only the changing Sig. value is printed (12, 11, 10, 9, 8, 7, 6).

TABVLA 85. *Scrupulorum Proportionalium Latitudinis Veneris.* — Table 85. The proportional minutes of the latitude of Venus.

[Sub-heading: **Signa Completa Anomaliae Solis Aequatae** — Complete signs of the equated anomaly of the Sun]

Left margin (rotated): **Anomalia Orbis Veneris** — anomaly of the orbit of Venus. Right margin (rotated): **Anomalia Orbis Veneris** — anomaly of the orbit of Venus. Stub at left **Sig. | G.** in blocks of six rows. Seven argument panels **0, I, II, III, IV, V, VI**, each **G. | '**, then a rightmost **Scrup. decr.** (decreasing minutes) panel carrying the note **Scrupula proportionalia Decrementi in retrogradatione** (proportional minutes of decrement in retrogradation) over its own **G. | '** sub-columns; final right stub **G. | Sig.** Foot panel-numbers **XII XI X IX VIII VII VI**; foot-label **Signa Completa Anomaliae Solis Aequatae**. Catchword **LATI-**.

Foot row (panel numbers across the seven panels): **XII | XI | X | IX | VIII | VII | VI**; foot-label **Signa Completa Anomaliae Solis Aequatae** (complete signs of the equated anomaly of the Sun). Catchword: **LATI-** (→ **LATITUDINES**, continuing Venus's latitude tables on the next opening).

Parsing notes: Wide ten-panel table (seven argument panels 0–VI of G./, plus a rightmost **Scrup. decr.** [scrupula decrescientia] panel carrying the rubric **Scrupula proportionalia Decrementi in retrogradatione** — proportional minutes of decrement in retrogradation — which begins printing numeric values only from row "Sig.3/G.18" downward, the upper cells of that panel being occupied by the spelled-out rubric). The argument steps vary: 12-degree intervals in the first signs, then tightening to 3-degree and finally 1-degree steps in the upper signs (rows Sig.4/G.5 through Sig.6/G.0), where the latitude rises steeply toward conjunction. All cells resolved on re-transcription. Several cells in the dense lower rows break the smooth column progression and are suspected source compositor errors, transcribed as printed: panel 0 at Sig.5/G.26 (prints "51 | 13", interrupting the rising 50 54 → 51 41 run); the disordered VI column near the foot (Sig.5/G.7–G.9 reading 35 28, 35 58, 37 39, internally non-monotone); panel IV at Sig.5/G.27 ("58 | 0", out of trend); and panel I at Sig.2/G.30 ("12 | 4" against neighbouring "12 5"). The final row's VI/decr. entry "60 | 0" is a whole-degree limit marking the cycle close, not a minutes overflow. The rightmost descending stub (G./Sig.) is preserved; only the changing Sig. is printed (12, 11, 10, 9, 8, 7, 6).

Tabulae novalmagesticae — Part V (the planetary tables), continued

LATITUDES OF VENUS [LATITVDINES VENERIS]

*(Table-volume page 89 = *

TABLE 86. The Proportional Minutes of the Decrement of the Latitude of Venus [*Scrupulorum Proportionalium Decrementi Latitudinis Veneris*]

Top margin (column band): **Complete Signs of the Equated Anomaly of the Sun** [*Signa Completa Anomaliae Solis Aequatae*]. Bottom margin (column band, read from the foot, right-to-left): **Complete Signs of the Equated Anomaly of the Sun** [*Signa Completa Anomaliae Solis Aequatae*].

The outer stub on each side is the **Anomaly of Venus** [*Anomal. Aeq. □*], given as Sig./Gr. (signs and degrees). The six interior double-columns are headed with the sign-count of the Sun's equated anomaly (0, I, II, III, IV, V across the top; reading from the foot they continue XII, XI, X, IX, VIII, VII, VI). Each interior column gives

Gr./' (degrees and minutes) — these are the proportional-minute values. The left stub reads top-to-bottom; the right stub reads bottom-to-top.

		I				II	I								

Parsing notes: This is a folio-wide proportional-minutes table. The left and right outer stubs are the two halves of Venus's anomaly argument (left runs Sig. 0–5 top-down at 6° steps; the right outer column runs Gr. then Sig. bottom-up, 12 down to 6). Within each interior sign-column the Gr. value is printed only when it changes; blank Gr. cells repeat the value above. A few of the very small interior minute digits in the upper rows are faint; the values given are my best reading.

TABLE 87. The Latitude, Reduction, and Curtation of Venus
[Latitudinis, Reductionis, & Curtationis Veneris]

(Table-volume page 89 = lower panel)

Top margin (column band): **Signs of the Distance of Venus from the Northern Node** [*Signa Distantiae Veneris à Nodo Boreali*]. Bottom margin (column band, read from foot, right-to-left): **Signs of the Distance of Venus from the Northern Node** [*Signa Distantiae Veneris à Nodo Boreali*].

The outer stubs (both sides) are the **Distance from the Node** [*Dist. à Ω*] in degrees (*Gr.*); the left runs 0–30 top-down, the right runs 30–0 bottom-up. The interior holds two paired sign-groups. The first group is headed at top **0 Boreal / VI Austral** [*O Boreal. / VI Austral.*] and at foot **V Boreal / XI Austral** [*V Boreal. / XI Austral.*], with sub-columns Latitude (*Gr.'*), Reduction (*'"*), Curtation (*'"*). The second group is headed **I Boreal / VII Austral** [*I Boreal. / VII Austral.*] (foot: **IV Boreal / X Austral**) and the third **II Boreal / VIII Austral** [*II Boreal. / VIII Austral.*] (foot: **III Boreal / IX Austral**), each likewise with Latitude, Reduction, Curtation.

Parsing notes: A triple-argument latitude/reduction/curtation table. Each of the three interior groups carries three sub-fields (Latitude Gr./, Reduction '"/, Curtation '"/). I have aligned the Latitude as Gr.+' , Reduction as '+"/, and Curtation as '+"/ per the printed sub-headers. The left outer stub (Dist. from Node, 0–30 down) and right outer stub (30–0 up) frame the body. A handful of the "-column digits in the densest rows (rows 11–17) are faint; values are my best reading.

MEAN MOTIONS OF MERCURY [MOTVS MERCVRII]

*(Table-volume page 90 = *

TABLE 88. The Mean Motions of Mercury ☿ [*Mediorum Motuum Mercurii* ☿]

This is a folio-wide epoch-and-motion page divided into several stacked panels. Headers throughout: **Longitude from ♈ (Aries)** [*Longit. ab ♈*], **Apogee** [*Apogaei*], **Northern Nodes** [*Nodi Bor.*], each given as Sig./Gr./'"/.

Panel 1 (left): EPOCHS, or ROOTS OF THE MOTIONS [EPOCHAE, seu RADICES MOTVVM]

Stub: Complete Years before / after Christ [Anni Completi ante / post Christum].

Parsing notes: This Epochs panel runs "Years before Christ" (top, 6000 down to 100), then **Christi** (the radix), then "Years after Christ" (100 up to 2300). The 1300 row is marked *St. veteris* (Old Style) and there are paired 1600 rows marked *St. novo* (New Style) — the Gregorian-reform doubling. A few terminal-second cells (rows 6000, 300) show a dash where the print is blank/illegible; flagged. Several "-column digits in the longitude block are faint.

Panel 2 (lower-left): JULIAN YEARS EXPANDED & COLLECTED [ANNI IVLIANI EXPANSI, & COLLECTI]

Stub: **Motion / Years** [*Motus / Anni*]. (B. = bissextile/leap year.) Headers: Longit. ab □ (Sig./Gr./""); Apogaei (""); Nodi Bor. ("").

24	4	5	32
(extra) 60	9	15	50

Marginal note (foot of left-bottom block) [*Radices affixae sunt Meridiano Bononiensi, in meridie ultimo Decembris praecedentis. Anni sunt Completi, sive numeres sursum ante Christum, sive deorsum post Christum.*]: [Margin: "The roots are fixed to the Bologna meridian, at noon on the last day of the preceding December. The years are complete, whether you count upward (before Christ) or downward (after Christ)."]

Parsing notes: This page packs six panels around the central rule. I have transcribed them as six separate pipe-tables. The Hours panel carries a stray "60 — 9 15 50" entry at its foot (an hourly-rate extension row); transcribed as printed. Several "-digits in the dense Epochs longitude column are faint; flagged in the QA report.

EQUATIONS OF MERCURY [AEQVATIONES MERCVRII]

*(Table-volume page 91 = *

TABLE 89. The Equations of the First Inequality of Mercury [*Aequationum Primae Inaequalitatis Mercurij*]

Top margin (column band): **Signs of the Simple Anomaly of the Eccentric of Mercury** [*Signa Anomaliae simplicis Excentrici Mercurij*]. Bottom margin (column band): **Signs of the Simple Anomaly of the Eccentric of Mercury** [*Signa Anomaliae simplicis Excentrici Mercurij*].

Outer stubs: **Simple Anomaly** [*Anom. simpl.*] in degrees (*Gr.*); left 0–30 down, right 30–0 up. The six interior double-columns are headed at top **0 / I / II / III / IV / V Subtract** [*O Subtr. ... V Subtr.*] and at foot **Add XI / Add X / Add IX / Add VIII / Add VII / Add VI** [*Adde XI ... Adde VI*]. Each interior column gives *Gr./'"/*.

Parsing notes: An equated-anomaly table for Mercury — six interior sign-groups each Sig./Gr./"', framed by the mirror argument (0–30 down on the left, 30–0 up on the right) with the top/foot sign-banners (0–V / XI–VI). The values are highly

dense; a number of the "-column digits in the central rows are faint and represent my best reading.

[Margin (lower-left, sideways): "LATI-" — bleed-through / page-locator fragment]

THE EQUATIONS OF MERCURY

TABLE 91. Of the maximum equations, or of the parallaxes of Mercury's orbit.

Completed signs of the equated solar anomaly.

Top sign-banner (completed signs of the equated solar anomaly): **0 | I | II | III | IV | V | VI**

Foot sign-banner (completed signs of the equated eccentric anomaly of Mercury):
XII | XI | X | IX | VIII | VII | VI

Completed signs of the equated eccentric anomaly of Mercury.

Parsing notes: TABLE 92 is extremely dense (twenty body columns plus two argument columns and the conjunction-decrement column). It sits at the scan's DPI floor: the increment/decrement reversal sub-blocks (Sig.3 g3–g15 and the

Sig.4/Sig.5 middle sign-blocks) are physically faint and ink-spread across the gutter, so the residual [?] flags here are genuine illegibility, not mere misalignment. The further table-reprocess confirmed this zone could not be resolved at the available resolution; the residual [?] cells are retained verbatim and TABLE 92's reversal sub-blocks remain a review-within for a higher-resolution pass. The "A." (max, =60) at top and "B." (min, =0) at the proportional-minutes turning point are printed as in the source.

THE LATITUDES OF MERCURY (continued)

TABLE 93. Of the decrement of the proportional minutes [scruples] of Mercury's latitude in retrograde conjunction; when the anomaly of the orbit corresponds to the lower minutes [scruples] of the next-to-last column of the preceding table.

Completed signs of the equated eccentric anomaly of Mercury.

Block footers (reading upward): **V Boreal. XI Austral. | IV Boreal. X Austral. | III Boreal. IX Austral.**

Signs of Mercury's distance from the ascending [boreal] node.

Parsing notes: TABLE 87 — the Reductio and Curtation sub-columns of Blocks 2 and 3 are tightly set against the gutter; the further table-reprocess resolved the bulk of the earlier minute/second [?] flags against the smooth column progressions. The B2 Latitudo-G degree column was reported as column-slip-prone in the reprocess (its leading 5/1 digits confuse), but the batch readings (5°-series, physically consistent with the latitude growing with node distance) are retained as printed; the reprocess's alternate degree readings were not adopted where they broke the column's internal consistency. The Latitudo G. column in

Block 1 jumps from 0 to 1 around distance 9°, as expected for the latitude growing with node distance. Residual [?]: B3 Red." at Dist.23 (9[?]) and B2 Red.' at Dist.26 (50[?]) remain faint at the DPI floor.

Astronomiae Reformatae — Tomus II, *Tabulae novalmagesticae*, Part V (batch 183, PDF pp. 547–549)

All three pages of this batch belong to a single multi-page table: **TABVLA 95, the orbital prostaphaereses** [*Prostaphaeresis Orbis*] for the five planets (Saturn ♄, Jupiter ♃, Mars ♂, Venus ♀, Mercury ☿). The table is the *maximum* (composite) equation as a function of the planet's distance (the argument). The pages are paginated 95, 96, 99 in the source (a printed pagination jump between p. 96 and p. 99 — flagged in the report).

The table is read in two directions: the heading **ADDE** ("ADD") applies when entering from the top with the argument increasing downward, and the foot label **SVBTRAHE** ("SUBTRACT") applies when entering from the bottom with the argument increasing upward. The outer **G.** columns (left and right) give the degree of the argument; the **S** marks at the four corners denote the entry sense (top vs. foot). Each interior column is headed by its argument-degree value (5, 6, 7, ... 18) and is divided into sub-columns **Gr. ' "** (degrees, minutes, seconds of the equation).

TABVLA 95. *Prostaphaeresis Orbis* ♄, ♃, ♂, ♀, ☿, à Clariss. Dn. de S. Legier, Aucion. excogitata, & exactè computata. ("TABLE 95. The orbital prostaphaeresis of Saturn, Jupiter, Mars, Venus, and Mercury, devised by the most distinguished Monsieur de Saint-Légier of Avignon, and exactly computed.")

Sub-heading: *Æquatio maxima, seu composita* — "The maximum, or composite, equation." Top label: **ADDE** ("ADD").

The argument column headers run **5, 6, 7, 8, 9, 10, 11, 12, 17, 18** (degrees), with the left stub **G.** giving the argument degree 1–30 (in groups of five), and a right stub **G.** counting 29 → 1. Each cell is ° ' " of the equation; the leading degree digit (0–5) is given once per cell.

Parsing note: this is a very dense full-page sexagesimal table; values are transcribed as read. Where a glyph could not be resolved with confidence it is marked [?].

Foot label: **SVBTRAHE** ("SUBTRACT"). Signature: **R 2**.

Page number **96** top left.

TABVLA 95. *Prostaphaeresis Orbis* ♃, ♄, ♂, ♀, ♁. (continuation of Table 95 — same five planets).

Sub-heading: *Æquatio maxima, seu composita* — "The maximum, or composite, equation." Top label: **ADDE** ("ADD"). Argument-degree column headers: **5, 6, 7, 8, 9, 10, 11, 12, 17, 18**. Left stub continues the argument count; right stub counts downward.

Parsing note: this page is more faded than p. 547, with several columns lightly inked at the right edge near the gutter; doubtful glyphs are flagged [?]. The left-stub group markers (2, 3, 4 in the margin) denote the running sign/group of the argument as on the facing page.

Garbled band P2-A — flagged for focused re-transcription review.

The descending sub-blocks of this page (the rows re-numbered 1→30 from "| 1 | 4 59 17 ..." onward) carry a one-column drift and duplicated col-17°/18° pairs; the cells are NOT reliable as transcribed and have NOT been reconstructed here. Re-transcribe this band (all columns) against the source page in a dedicated review. (Confirmed single-cell corrections from the recovery pass have been applied in place.)

Foot label: **SVBTRAHE** ("SUBTRACT").

Page number **99** top right.

Pagination jumps from 96 to **99** — two folio numbers (97, 98) skipped in the printed pagination. The table content is continuous (Table 95 still running), so this is a compositor's page-numbering error, not a gap in content. Flagged in the report.

TABVLA 95. *Prostaphaeresis Orbis* ℏ, ϰ, ♂, ♀, ϣ. (continuation of Table 95).

Sub-heading: *Æquatio maxima, seu composita* — "The maximum, or composite, equation." Top label: **ADDE** ("ADD"). Argument-degree column headers: **5, 6, 7, 8, 9, 10, 11, 12, 17, 18**. Left stub continues the argument count; right stub counts downward.

Parsing note: dense and partly faded as on the preceding pages; doubtful glyphs flagged [?]. Several cells in the upper-left of this page show the equation falling back below the maximum (the table's descending branch).

Garbled band P3-A — flagged for focused re-transcription review.
 Cols 9°–12° of stub-rows 18–20 (the rows "| 18 | ... | 19 | ... | 20 | ..." in the middle block) carry a column-shift, including the impossible value "13 16 36"; these cells are NOT reliable as transcribed and have NOT been reconstructed here. Re-transcribe this band (cols 9°–12°) against the source page in a dedicated review. (Confirmed single-cell corrections from the recovery pass have been applied in place.)

Foot label: **SVBTRAHE** ("SUBTRACT").

Astronomiae Reformatae Tomus II — *Tabulae novalmagesticae*, Part V

TABVLA 95 (continued): The orbital prosthaphaeresis of all five planets (Saturn, Jupiter, Mars, Venus, Mercury) — degree-arguments 19–28

These three pages (table-volume folios "98," "99," "100" = continue TABVLA 95, the *prosthaphaeresis orbis* (orbital prosthaphaeresis) of the five planets compiled by [Saint-Léger] of Avignon. The prior batch carried the same table for the head-argument degree-blocks 5–18; this batch carries the complementary degree-blocks **19 through 28**, with the same dual-direction layout: read top-down with the **ADDE** ("ADD") header for one half of the argument, bottom-up with the **SVBTRAHE** ("SUBTRACT") foot label for the other.

The page banner on every page reads **PROSTAPHÆRESES ORBIS** ("Orbital prosthaphaereses"). The display heading reads:

TABVLA 95. The orbital prosthaphaeresis of ♄, ♃, ♂, ♀, & ☿ [*Prosthaphaeresis Orbis ♄, ♃, ♂, ♀, & ☿* — i.e. Saturn, Jupiter, Mars, Venus, and Mercury]

Sub-heading: **The maximum, or composite, equation** [*Æquatio maxima, seu composita*].

Layout of each table: the leftmost **G. / S** column gives the argument (degrees, read top-to-bottom with the ADD interpretation); the rightmost **G. / S** column gives the complementary argument (read bottom-to-top with the SUBTRACT interpretation). Each degree-block (headed by its degree number, 19–28) contains three sub-columns: **G.** (degrees of equation), **'** (minutes), **"** (seconds). The figure boundaries in this dense citation-grade engraving are at the limit of the scan's legibility; values flagged [?] are transcribed as best read.

Table-page "98" — TAB. 95, argument-blocks 19–28, argument rows 1–30 (top half, marginal index "0" at left / "I" mid / "2" foot; right margin "12 ... 10")

Each cell below is the equation-value in **degrees ' "** under the named degree-block. Left stub = argument (top-down, ADD); right stub = complementary argument (bottom-up, SUBTRACT).

Page banner: PROSTAPHÆRESES ORBIS. — **Header:** ADDE — **Foot:** SVBTRAHE — **Catchword:** PRO-

Foot row (column re-statement): G. 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28
| G.

Parsing notes: This is the upper of the two half-page argument cycles on table-page "98." The engraving sets two stacked 1–30 argument cycles per page; the marginal letters (0 / I / 2 at left, 12 / 11 / 10 at right) are the conventional running index of the prosthaphæresis argument. Several seconds-digits in the gutter-side columns (19–21) are at the edge of legibility; 0 49 3[?] at arg-3, col-22 is the only value I could not fully resolve.

Table-page "99" — TAB. 95, argument-blocks 19–28 (lower half of the cycle, marginal index "2 ... 4" at left, "10 ... 8" at right)

Foot row (column re-statement): G. 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 | G.

Parsing notes: This page brings the equation toward its maxima — note the values approaching the full degree-block value (e.g. 18 59 49, 19 59 49, 21 0 0, 23 0 0, 24 0 0, 25 0 0, 26 0 0) along the diagonal where the maximum equation for each degree-block is reached. The arg-21 / col-25 cell prints 22 22 55 where the smooth progression of the column would suggest 21 22 55; transcribed as printed and flagged as a numerical impossible (broken monotone — see report). The arg-12 / col-27 cell prints 27 7 16 where the column elsewhere reads ~25; flagged likewise. One seconds-digit at arg-18 / col-26 (25 44 4[?]) is at the edge of legibility.

Table-page "100" — TAB. 95, argument-blocks 19–28 (descending branch, marginal index "4 ... 6" at left, "8 ... 6" at right)

This page carries the descending half of the prosthaphaeresis (values now decreasing as the argument passes its maximum), still read top-down under **ADDE** / bottom-up under **SVBTRAHE**.

Foot row (column re-statement): G. 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28
| G. — **Catchword:** PRO-

Parsing notes: **Table-page "100" is the most degraded page of the batch.** The lower-left quadrant (the descending branch, marginal index "5"/"6," arguments 18–30 of the second cycle) suffers heavy ink-bleed and gutter compression, and many cells could be read only partially. Throughout the descending branch the engraver frequently abbreviates the leading degree-figure (printing only the changed minutes/seconds with a dash or repeated degree implied from the cell above); where the degree-figure is dropped in the source I have rendered the cell as printed (sometimes only ' ') and marked the omission with an em-dash – for the implied degree-block value. Numerous cells in the bottom three argument-rows of the second cycle break the otherwise-smooth descending monotone —

these are flagged collectively as a rather than itemized, because the degradation makes it impossible to tell engraver error from misread on a cell-by-cell basis. **This whole page (table-folio "100," and especially its lower-left descending branch,**

THE ORBITAL PROSTHAPHAERESES [PROSTAPHÆRESES ORBIS]

TABLE 95. The orbital prosthaphaeresis [Prosthaphaeresis Orbis] of Saturn ♄, Jupiter ♃, Mars ♂, Venus ♀, and Mercury ☿.

[Margin/sub-title: *Æquatio maxima, seu composita* — The maximum, or composite, equation]

ADD [ADDE] (reading the top argument *G.* downward, signs *S* at left)

This is a double-entry argument table. The top-of-page argument runs in two halves down the page (the left "S/G." stub gives the degree argument, the right "G./S." stub the complementary argument); each major column heading (29, 30, 34, 35, 36, 37, 38, 39, 40, 41 degrees) carries paired sub-columns of degrees-and-minutes-and-seconds of the equation (printed as *G. / ' / "*, where the leading whole-degree figure is 0 unless shown). The banner at the page foot reads **SUBTRACT** [SVBTRAHE]; the catchword is **PRO-** (continuing *PROSTAPHÆRESES* on the next page).

Because the body of this table is a dense grid of sexagesimal equation values with no intervening prose, it is transcribed below as a single pipe-table per source page, preserving the left and right argument stubs verbatim. Where the leading whole-degree digit is blank in the source it represents 0.

Page "101" — first half (signs/argument block, rows 1–30, sub-cycle "O / I" at left; "I / II" at right)

Columns: each heading 29...41 is one composite column carrying degrees-minutes-seconds. The first sub-block (left margin "O", right margin "II") rows 1–30:

Parsing notes (p.554 first half): the left stub column degrades from "26/27/28/29/30" to a misprinted/over-inked "16/17/18/19" sequence in the lower block — transcribed as printed; these are the second-decade rows (26–30). Several seconds-cells in rows 22–23 of the 38–41° columns are ink-bled and ambiguous (e.g. the "36 56 54" at row 23/38° is almost certainly a misread of a value near 29 39, and the 41° row-23 value is [?]).

Page "102" — second half (left band "3", rows 1–30)

Parsing notes (p.554 second half): left stub again degrades mid-column from "21/22/23/24/25" to over-inked "12/13/14/15"; these are the rows 21–25 of the second decade, transcribed as printed. At row 29/29° the value reaches "29 0 0" and at row 30/30° "30 0 0" — the maxima where the argument equals the column-degree, as expected for the descending branch.

; right-stub S / G.: 29, 30, 34, 35, 36, 37, 38, 39, 40, 41.]

TABLE 95 (continued). The orbital prosthaphaeresis of Saturn ♄, Jupiter ♃, Mars ♂, Venus ♀, and Mercury ☿.

[Sub-title: *Æquatio maxima, seu composita* — The maximum, or composite, equation] — **ADD** [ADDE]

Page "103" — first half (left band "4", rows 1–30)

Parsing notes (p.555 first half): this block is the apex of the descending branch. Where the leading whole-degree figure repeats unchanged from the row above, the source leaves it blank; transcribed as "—" in those cells (the degree carries

from the preceding row, e.g. "—48 55" = "28 48 55"). Several near-maximum cells where the equation crosses its peak (e.g. "0 0 0" at row 4/34°, and the "39 0 0", "40 0 0", "41 0 0" turning-points) are the points where each column's argument equals its heading-degree. A handful of badly ink-bled cells in rows 17–18 of the 38–39° columns are ambiguous and may be misread.

Page "103" — second half (left band "5", rows 1–30, closing to band "6")

; right-stub S / G.: 29, 30, 34, 35, 36, 37, 38, 39, 40, 41. Signature: **S 2.**]

Parsing notes (p.555 second half): this is the closing descending branch of TABLE 95 — the equation falls smoothly toward 0 0 0 at row 30/29° (where argument = column-degree on the far side of the cycle). The leading degree digit is again suppressed where it repeats from the row above. The final row (30) reads 0 0 0 for the 29° column and the remaining columns close at their own zero in the continuation; cells shown "—" are blank in the source at the very foot. Numerous near-zero cells are clean. A few mid-block seconds in the 38–40° columns (rows 4, 9) are ink-bled (e.g. "33 8 33" at row 4/38° and "31 4 12" at row 9/40° break the otherwise smooth monotone descent and are likely compositor or scan artifacts — flagged below).

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae, Part V

TABVLA 95 (continued) — The orbital prosthaphaereses of Saturn, Jupiter, Mars, Venus, and Mercury

These three pages (table-volume pages 104–106) continue **TABVLA 95**, *Prosthaphaeresis Orbis* ♄, ♃, ♂, ♀, & ☿ ("The orbital prosthaphaeresis of Saturn, Jupiter, Mars, Venus, and Mercury"), carrying the argument-degree column-groups **Gr. 42 through Gr. 48**. The running banner across the top of each page reads **PROSTAPHAERESES ORBIS** ("Orbital prosthaphaereses"). The sub-heading line reads *Æquatio maxima, seu composita* ("The maximum, or compound, equation") on the left and **ADDE** ("ADD") as the operative instruction for the upper (descending-argument) half; the foot of each page carries **SVBTRAHE** ("SUBTRACT") for the lower half.

Each column-group is headed by the whole-degree argument value (42, 43, ... 48) and a degree-marker, and is subdivided into **Gr. | ' | "** (degrees | minutes | seconds). The outermost left and right columns are the argument stub columns **S / G.** (Signs / Degrees), counting the minute-argument 1–30 downward on the left and the complementary 29→0 upward on the right. On page 104 the far-right panel carries the *Sinus omnium gr. maxima aequationis* ("Sine of the greatest equation for every degree") values.

Layout note on implicit carried-down degrees: within each column-group the compositor prints the whole-degree figure only on the row where it changes; on the following rows the degree column is left blank and the *same degree carries down* until a new one is printed. In the tables below, a carried-down degree that

is not re-printed in the source is supplied **in parentheses** so each cell (deg) min sec is complete. Parenthesized degrees are NOT illegible — they are simply not re-printed in the source. This layout feature accounted for the large majority of the first-pass [?] flags (now resolved); [?] is retained only on the small number of cells whose minute/second glyphs are themselves degraded at the scan resolution.

[Title line: TABVLA 95. *Prosthaphaeresis Orbis* †, ‡, §, ¶, & †.] [Sub-heading: *Æquatio maxima, seu composita* — ADDE.]

Left stub block marker: **S** ... (signs/degrees argument); the two outer Sign-markers printed in the left margin read **0** (top block) and **11** (lower block), with **I** likewise at the descending mid-table marker. Right outer markers read **12, 11, 10**.

Parsing notes (page 104): the right-hand *Sinus* panel is printed in a narrow column with irregular row spacing, and the argument labels are printed slightly offset from their sinus rows; the list is non-contiguous (it skips arguments 1–4, 22–25, 31–33), and the labels are transcribed as printed. The values at arguments 13 and 14 (122973, 117435) break the smooth monotone decrease of the sine column (157064 at gr. 12 → expected $\approx 147k / \approx 138k \rightarrow 112218$ at gr. 15); these are almost certainly compositor digit-transposition errors and are transcribed as printed — see Numerical impossibles. The main table's left/right stub blocks switch between ascending (1–25) and the continuation numbering (16–30, then 1–30) exactly as printed; this reflects the table's sign-block layout, not a transcription error.

[Title line: TABVLA 95. *Prosthaphaeresis Orbis* ♃, ♁, ♂, ♀, & ♄.] [Sub-heading: *Æquatio maxima, seu composita* — ADDE.]

Left outer Sign-markers: **2, 3**; right outer markers: **10, 9, 8**. (The three rightmost column-groups on this page are ruled but blank — the table runs only through Gr. 48; no values are printed in the empty right panels.)

Foot stub: **S** | G. 42 | 0 | 43 | 0 | 44 | 0 | 45 | 0 | 46 | 0 | 47 | 0 | 48 | 0 | G. **S**
[Foot instruction: **SVBTRAHE.**]

Parsing notes (page 105): the three column-groups to the right of the Gr. 48 block are ruled but contain no printed values (the table closes at 48 degrees of argument). The row at left-stub 15 in the Gr. 45 group reads exactly **30 0 0** — a clean round value at mid-table, consistent with the table's symmetric construction (the 30°-of-arc crossing). Page 105 is clean throughout; no residual illegible cells.

[Title line: TABVLA 95. *Prosthaphaeresis Orbis* ᵿ, ʌ, σ, Ϙ, & ϙ.] [Sub-heading: *Æquatio maxima, seu composita* — ADDE.]

Left outer Sign-markers: **4, 5**; right outer markers: **8, 7, 6**. On this page the printing of the left column-groups (Gr. 42, Gr. 43, especially the degree component) is faint and intermittent — in many rows the whole-degree figure is not re-printed (it carries down from the row where it last changed), so only the minute and second components show. Per the layout note above, the carried-down degree is supplied **in parentheses** so each cell (deg) min sec is complete; only a handful of cells whose minute/second glyphs are themselves degraded retain [?]. The three rightmost column-groups are again ruled but blank.

Foot stub: **S** | G. 42 | 0 | 43 | 0 | 44 | 0 | 45 | 0 | 46 | 0 | 47 | 0 | 48 | 0 | G. **S**
[Foot instruction: **SVBTRAHE.**]

Parsing notes (page 106): this is the most degraded page of the batch. The Gr. 42 and Gr. 43 column-groups on the upper-left are faint, and in many rows the whole-degree figure was not re-printed by the compositor (the table only re-prints the degree when it changes), so the leading "41" / "42" / "43" carries down implicitly; these carried degrees are supplied in parentheses, e.g. (42) 25 33. Re-transcription resolved the great majority of the first-pass [?] flags as this carry-down layout feature rather than illegibility. Only a small set of cells whose minute/second glyphs are themselves ink-degraded retain [?]: see notes PN-5 through PN-9 below (and PN-2/PN-3 elsewhere on this page). The descending lower half of the table closes at the final row (left-stub 30 / right-stub 0) with all groups at **0 0 0**, exactly as expected for the end of the prosthaphaeresis argument — confirming TABVLA 95 finishes here at 48° of argument and 90° of anomaly. Rows 12–18 of the upper block show the table's maximum-equation crossing, where successive groups read the round maxima for each whole-degree argument (**42 0 0 / 43 0 0 / 44 0 0 / 45 0 0 / 46 0 0 / 47 0 0 / 48 0 0** in turn down the diagonal) — these clean round values are a feature of the table construction, not transcription artifacts.

Residual illegible cells on page 106 (genuine DPI-floor ink-loss, NOT the layout feature; best readings given above):

- PN-2 (Gr. 45, upper-block arg 11): (44) 51 31 — the seconds 31 is faint; reading tentative.
- PN-3 (Gr. 42, upper-block arg 19): 41 34 5 — final seconds digit faint (could be 5 or 8).

- PN-5 (Gr. 45, lower-block arg 1): 40 45 [?] — degree and minutes printed but the seconds field is partly lost; third position unresolved.
- PN-6 (Gr. 45, lower-block arg 7): 37 33 38 — value sits below the local trend and glyphs are faint; possible misread and/or trend-break.
- PN-7 (Gr. 48, lower-block arg 9): 40 57 [?] — seconds field lost at right edge / gutter.
- PN-8 (Gr. 48, lower-block arg 15): 34 6 42 — faint; minutes uncertain.
- PN-9 (Gr. 45, lower-block arg 29): 1 24 42 — leading degree reads 1 but the column trend wants 2; faint.

Suspected source errors on page 106 (monotone-breaks / out-of-order values, transcribed as printed — NOT smoothed; for editorial footnoting):

- SE-2 (Gr. 44, upper-block arg 3): 42 8 30 sits far below its neighbours (42 18 5 above, 43 16 49 below) and breaks the rising trend; the degree is almost certainly mis-set or a figure dropped. As printed.
- SE-3 (Gr. 42, upper-block arg 13): 41 59 30 is a small dip after 42 0 0 (arg 12) — consistent with the table's turning point near the Gr. 42 maximum (~42°0'), so plausibly correct turning-point behaviour rather than an error; noted for verification.
- SE-4 (Gr. 47, upper-block arg 27): (46) 5 5 breaks the descent (46 17 49 above at arg 25, 45 34 5 below at arg 28) and the degree carry is ambiguous (46 vs 45). Suspected mis-set. As printed.
- SE-5 (Gr. 42, upper-block arg 30): 38 10 20 drops steeply from 38 56 35 (arg 29); flagged though it may be a genuine steep gradient near the SVBTRAHE fold. As printed.
- SE-6 (Gr. 43, lower-block arg 9): 34 55 50 is out of order — it exceeds arg 8 (34 47 51) where the column is descending; almost certainly should be ~33 5x. Suspected compositor digit error. As printed.

Astronomiae Reformatae Tomus II — Tabulae novalmagesticae, Part V

TABVLA 96 (table-page 107)

TABVLA 96. The General Latitude of the Five Planets (*Generalis Latitudinis Quinque Planetarum*).

Sub-heading: **Degrees of the circle up to 10** (*Gradus Circuli usque ad 10*).

The argument (stub) is **Scrupula Graduum** ["minutes of degrees," read vertically down the left margin], running 0–60. Each whole-degree column (headed 0, 1, 2, ... 9) gives a pair of values **G. | '** (degrees | minutes). Per the foot note, these are sines.

Foot note: *Numeri per Columnas distributi sunt sinus Graduum, & Scrupulorum tales qualium Radius sit 60.* — "The numbers distributed through the columns are the sines of the degrees and minutes, of the kind for which the radius is taken as 60."

Parsing notes: This is a finely ruled small-figure sine table on radius 60; the block whose final row (stub 60) equals the next block's first row (stub 0) — a continuity check that confirms cell alignment. Verified cell-by-cell in further reprocess (): all first-pass [?] cells in the lower-right block (degree-columns 4–9, argument rows 43–56) were resolved on fresh close reading; no residual [?] remains in this table. Suspected SOURCE compositor slips, transcribed exactly as printed and left for footnoting: row 47 col 3 = 3 | 58 (skips 3 | 57); rows 52–53 col 4 both = 5 | 6 (doubled where the run wants 5|5 then 5|6). No minute value exceeds 59; the 4–9

degree columns roll over (e.g. 9 G. → 10 G. at argument 36) consistent with the sine progression.

TABVLA 97 (table-page 108)

TABVLA 97. The Distance of the Planets from the Sun, in parts of which the radius of the Sun's Annual Orbit is 100000 (*Distantia Planetarum à Sole in partibus, qualium Radius Orbis Annui Solis est 100000*).

The argument (stub, read down the left margin: **Anomalía Æquata Planetarum**, "the equated anomaly of the planets") is given as two columns, **Gr.** ascending and **Gr.** descending (complementary arguments). The five data columns are headed with the planetary symbols, here rendered: ♄ (Saturn), ♃ (Jupiter), ♂ (Mars), ♀ (Venus), ☿ (Mercury).

180	180	899103	497154	138274	71823	30480

Foot heading (sub-table banner): **Distantia à Terra in partibus qualium Radius Orbis Annui 100000.** — "The distance from the Earth, in parts of which the radius of the Annual Orbit is 100000."

	Planeta (state)	♄ Saturn	♃ Jupiter	♂ Mars	♀ Venus	☿ Mercury
Sole Apogeo (Sun at apogee)	Aphelio	111103	649629	268164	174713	148430
Sole Apogeo	Perihelio (perihelion)	797362	395413	36534	30136	71260
Sole Perigeo (Sun at perigee)	Aphelio	100755	646149	264684	171233	144950
Sole Perigeo	Perihelio	800843	398893	50014	26656	67780

Parsing notes: Wide six-column distance table in small figures with vertical rule-lines. Verified cell-by-cell in further reprocess (): all first-pass [?] cells were resolved on fresh close reading; no residual [?] remains in this table. The Saturn (♄) column descends monotonically from 1009293 at 0° to 899103 at 180°. Suspected SOURCE errors, transcribed exactly as printed and left for footnoting: (1) (2) in the sub-table, the two Mars (♂) perihelion values — Sole Apogeo / Perihelio = 36534 and Sole Perigeo / Perihelio = 50014 — place the apogee-row perihelion distance *below* the perigee-row value, the reverse of the other planet columns; both figures are clearly printed, flagged as internally curious. Note the planetary-symbol column heads are engraved sigils; rendered here by standard names.

TABVLA 98 (table-page 109)

TABVLA 98.

OR THE UNIVERSAL CATALOGUE OF FIXED STARS, COMPLETE TO THE YEAR OF CHRIST 1700.

(*SEV CATALOGVS FIXARVM VNIVERSALIS AD ANNVM CHRISTI MDCC. COMPLETVM.*)

Sub-heading: *Et ad Quatuor Classes, Gradusue Certitudinis Reductarum, huc ex Libro Quarto transcripta.* — "And reduced to Four Classes, or Degrees of Certainty, transcribed here from Book Four."

Prefatory note (the four classes of certainty):

The **First Class** (*Prima Classis*) contains the stars most often observed by us together with Father Francesco Maria Grimaldi [Francesco Maria Grimaldi], whose longitude and latitude — following Book IV — we reckon as certain in the first degree; to these we have added the Pleiades, observed by Don Vincenzo Muto [Vincenzo Muto / Vincentius Mutus] and by Michele Fiorentino Langreno [Michael Florentius van Langren].

The **Second Class** (*Secunda Classis*) holds the remaining stars observed by Tycho [Tycho Brahe], or by Kepler [Kepler], as they stand in the Rudolphine Catalogue [the *Tabulae Rudolphinae*], yet with their numbers corrected wherever a discrepancy between our own [observations] and those of the first class requires it; the stars of this same constellation, or those nearby, we place in the second degree of certainty.

The **Third Class** (*Tertia Classis*) embraces the remaining stars observed neither by us, nor by Tycho, but by Hipparchus [Hipparchus] and Ptolemy [Ptolemy] — though they bear upon those constellations, or neighboring ones, of which some fixed stars have been observed by us, or by Tycho — their numbers being corrected so far as the difference between Ptolemy's [values] and our own, or Tycho's, requires. And we have placed these in the third degree of certainty, not excluding a manifest error of 10 minutes. So Kepler says: *that they were corrected by him from the surrounding numbers, by Tycho's example.*

The **Fourth Class** (*Quarta Classis*) extends to the stars observed neither by Hipparchus, nor by Ptolemy (so far as we know), nor by Tycho, nor by those who observed from them — and by the pilots [*Naucleri*, navigators]. Their longitude we have merely reduced to the end of the year 1700, adding to the Rudolphine

longitude the motion of 100 years, which for us is 1° 24' 27". The latitude, however, we transcribed wholly unchanged from the Rudolphine Catalogue. We have reckoned these to be in the 4th degree of certainty; and, having regard to the radius (or to the astronomical staff [*Baculus Astronomicus*], which the navigators use), we have found ourselves liable to an error of some several minutes, and we do not judge them more certain than the Ptolemaic [values], until they shall have been observed by another, and in a more accurate manner.

PARS PRIMA — De Stellis Fixis Signorum XII. Zodiaci. ("Part One — On the Fixed Stars of the Twelve Signs of the Zodiac.")

The catalogue is set in two side-by-side columns of stars. Each entry gives: **Nomina Fixarum** (names of the fixed stars), **Longitudo** (Sig. = sign, Gr. = degrees, ' = minutes, " = seconds), **Latitudo** (Gr. degrees, ' minutes, " seconds, with B = Borealis/north or A = Australis/south), and **Magnitudo** (magnitude). Sign symbols: ♈ Aries, ♉ Taurus, ♊ Gemini.

Parsing notes: The star catalogue is set in very small type with the Longitudo/Latitudo split across narrow Sig./Gr./" sub-columns and a final B (Borealis = north) or A (Australis = south) flag immediately before the Magnitudo. Sign symbols are engraved zodiacal sigils — ♈ (Aries), ♉ (Taurus), ♊ (Gemini); each ambiguous glyph was resolved by the degree value and constellation, consistent with the precessed 1700 positions. Class sub-headings (*1. Classis, 2. Classis, 3. Classis*) are interleaved italic rubrics within each constellation, transcribed as label-rows. The right column begins with the nine named Pleiades (Alcyone, Electra, Taygeta, Merope, Maia, Asterope, Celaeno, Atlas, Pleione) carried over to the second-class body stars of Taurus. Verified cell-by-cell in further reprocess (): residual [?] reduced to a single cell — the final row ("In talo pedis sequentis"), whose latitude N/S letter (A/B) and magnitude digit are ink-lost in the trimmed bottom corner (degrees/minutes/seconds 12 | 1 | 50 legible). No sexagesimal value exceeds 59' or 59"; no zodiac-degree value exceeds 30° within a sign.

TABVLA 98 — Universal Catalogue of Fixed Stars to AD 1700 (continued)

The catalogue continues through the zodiacal constellations (PARS PRIMA). Each page is laid out in two star-columns. Every star row carries: the descriptive Latin name/position phrase (*Nomina Fixarum*), the zodiacal sign sigil, Longitudo (Sig./Gr./"/), Latitudo (Gr./"/) with the **B (Borealis = north) / A (Australis = south)** flag, and Magnitudo. Per-constellation *Classis* rubrics (1.–4. Classis = the four certainty-classes) are preserved as label-rows. Descriptive phrases are transcribed verbatim in Latin, with an English rendering in brackets where it aids the reader.

The column structure for every table below is:

- **Nomina Fixarum** — the star's descriptive name/position (verbatim Latin)
- **Sign** — zodiacal sign sigil
- **Long. Gr. / ' / "** — Longitude: degrees within the sign, minutes, seconds
- **Lat. Gr. / ' / "** — Latitude: degrees, minutes, seconds
- **B/A** — Borealis (north) / Australis (south)
- **Mag.** — Magnitudo

Left column — Taurus (continued)

[Note appended to Aquarius:]

Adverte Keplerum, & Lõgomontanũ posuisse humeri dextri longitudine in \square gr. 27. 49' $\frac{1}{2}$ vel gr. 27. 48'. Anno 1600. cum Tycho posuerit gr. 27. 9 $\frac{1}{2}$. quare excessit \bar{u} errore 40' minutum.

[Note that Kepler and Longomontanus placed the longitude of the right shoulder at \square 27° 49' $\frac{1}{2}$ — or 27° 48' — for the year 1600, whereas Tycho placed it at 27° 9' $\frac{1}{2}$; hence the discrepancy amounts to an error of 40 minutes.]

Notes on this batch

- **Sign sigils:** The catalogue continues the ecliptic-longitude ordering. Many descriptive phrases use a sign sigil one ahead of the constellation whose stars are being catalogued (e.g. Taurus body-stars listed with ♉/♉ longitudes, Gemini stars with ♊, Leo stars spanning ♌/♌, etc.), because the stars' *longitudes* fall in the next sign — this is normal precession-era reduction to AD 1700 and is transcribed as printed.
- **Greek/Arabic star names:** *Regulus, Antares, Spica, Scheat, Fomahant* (= Fomalhaut), *Vindemiatrix, Propus* transcribed verbatim. *Asellus Boreus/Australis, Praesepe* (the Manger) likewise.
- **Source authorities cited inline:** *Ex Keplero de noua Stella* (Scorpius, 2. Classis); *ex Clauio* [Clavius] (Scorpius, 3. Classis); *vel Kepl. / vel Ptolem.* alternate readings (Sagittarius); *Tychonis alter codex* (Leo region); the Kepler/Longomontanus/Tycho discrepancy note (Aquarius). All preserved.
- Several Latin words are abbreviated with macron/tilde in the source (e.g. *duarũ, frõtis, sinistræ man?, ãpe, Lõgomontanũ*); transcribed with the tilde where it aids fidelity and glossed in brackets.

TABVLA 98 — Universal Catalogue of Fixed Stars to AD 1700 (continued)

This batch concludes PARS PRIMA (the conclusion of Pisces) and begins PARS SECVNDA, the northern extra-zodiacal constellations. Each star row carries: the descriptive Latin name/position phrase (with bracketed English gloss), the

zodiacal sign sigil, Longitudo (Gr./'"), Latitudo (Gr./'") with its B (Borealis = north) / A (Australis = south) flag, and Magnitudo. The *Classis* rubrics (1.–4. Classis) and constellation headings stand as label-rows.

Printed p. 113

Pisces [☿ Fishes] — conclusion (left column)

This first block continues the constellation Pisces. The Longitudo column here carries the sign sigil ☿ (Aries) for most entries — the precessional reduction to AD 1700 runs the longitude one sign ahead of the constellation figure, as throughout PARS PRIMA.

Riccioli, *Astronomiae Reformatae Tomi Duo* — TABVLA 98, PARS SECVNDA / PARS TERTIA

Universal Catalogue of Fixed Stars to AD 1700 (TABVLA 98), continued. These pages complete **PARS SECVNDA** — *Astra Borealia extra Zodiacum* (the northern extra-zodiacal constellations) and open **PARS TERTIA** — *Astra Australia* (the southern constellations). Each page is laid out as two side-by-side catalogue blocks (a left and a right column-group), each carrying the same six fields: the descriptive Latin name/position of the star (with an English gloss), the zodiacal sign sigil, Longitude (Gr./'" within the sign), Latitude (Gr./'"), the latitude-direction flag — **B (Borealis = north)** through PARS SECVNDA, switching to **A (Australis = south)** in PARS TERTIA — and Magnitude. The northern blocks all carry the B flag (the header reads *Latitudo B.*); the southern blocks carry *Latit. A.*

The descriptive position-phrases are transcribed verbatim from the Latin, with a bracketed English gloss given once per constellation block where the phrasing recurs; sign sigils are rendered as the standard symbols.

Riccioli, *Astronomiae Reformatae Tomi Duo* — Tomus II

TABVLA 98 — Universal Catalogue of Fixed Stars to AD 1700, PARS TERTIA (*Astra Australia*)

Each catalogue page is laid out in two side-by-side blocks of entries. The columns in every block are: **Nomina Fixarum** (Names of the fixed stars — the descriptive Latin position-phrase, transcribed verbatim with an English gloss); **Longitudo**

(Sig./Gr./''' — zodiacal sign sigil, then degrees, minutes, seconds); **Latitudo A.** (Gr./''' — degrees, minutes, seconds, all carrying the **A = Australis / south** direction flag for these southern figures unless a row is explicitly marked otherwise); **Magnitudo.** The *Classis* rubrics (1.–4. *Classis* = the four certainty-classes) and constellation headings are preserved as label-rows.

Sign sigils used on these pages: ☉ Taurus, ♊ Gemini, ♋ Cancer, ♌ Leo, ♍ Virgo, ♎ Libra, ♏ Scorpio, ♐ Sagittarius, ♑ Capricorn, ♒ Aquarius, ♓ Pisces.

Page 119 — left block (Eridanus continued; Lepus; Canis Maior)

[Eridanus / the River, continued — 2. *Classis*]

QA / batch report

TABVLA 98 — Universal Catalogue of Fixed Stars to AD 1700, PARS TERTIA (*Astra Australia*), continued and concluding

This page (folio 122) is set in two columns. The left-hand column continues **Pavo** (begun in the prior batch), then runs through **Apus / Avis Indica**, **Apis / Musca**, **Chamaeleon**, and **Triangulum Australe**. The right-hand column carries **Piscis Volans / Passer**, **Dorado / Xiphias**, **Toucan (Anser Americanus)**, and **Hydrus**,

after which the catalogue closes with a summary tally of stars (prose, transcribed below). All southern figures carry the A (Australis) latitude flag.

Left column

Closing summary of the catalogue (prose, end of TABVLA 98 / PARS TERTIA)

The catalogue concludes with a tabulated tally set in prose at the foot of the right-hand column:

Thus, then, the constellations of the Zodiac are 12; the northern ones, moreover, are 23; and the southern ones are 27 — all together they come to 62.

Tally	Count
In Zodiaci Astris sunt Stellæ primæ Magnitudinis [Among the Zodiacal stars there are stars of the first magnitude]	6
Secundæ Magnitudinis [of the second magnitude]	9
In Borealibus Astris sunt Stellæ Magnitud. Primæ [Among the northern stars there are stars of the first magnitude]	3
Secundæ Magnitudinis [of the second magnitude]	22

Tally	Count
In Australibus Astris sunt Stellæ Primæ Magnitud. sunt [Among the southern stars there are stars of the first magnitude]	5
Secundæ Magnitudinis [of the second magnitude]	28
Ergo omnes Stellæ Primæ Magnitudinis sunt [Therefore all the stars of the first magnitude are]	14
Secundæ autem [the second, moreover]	59

TABVLA 99 — Right Ascension and Declination of the Fixed Stars

TABVLA 99. The Right Ascension and Declination of one hundred Fixed Stars to the completed Year of Christ 1700.

This new table abandons the ecliptic coordinates (Longitudo/Latitudo) of TABVLA 98 and instead gives, for one hundred selected bright stars, their **Right Ascension (Ascensio Recta)** and **Declination** for the year 1700, each in degrees, minutes, and seconds, together with the **secular change (Differentia Annorum 100)** in right ascension and in declination. The final declination-difference column carries a **B/A** flag (Borealis/Australis); for that column **B** marks a northern and **A** a southern declination-change. Stars are listed alphabetically by constellation.

Column structure: Name | Right Ascension (Anno 1700): Gr. /' /" | Declination (Anno 1700): Gr. /' /" | Difference of Right Ascension (per 100 years): Gr. /' | Difference of Declination (per 100 years): ' + B/A flag.

[Foot of table, left column: *Anni 61* — i.e., the second argument block continues from "Years 61."]

Parsing notes: The left block (Anni 1–60) has no separate "Gr." (degrees) heading; its column I carries the integer degrees through 50 (the precession motion at ~50".4 per year, reaching ~50°40' over 60 years), with columns II and III for minutes and seconds. The right block carries an explicit **Gr.** column, then **I, II, III** for minutes, seconds, thirds. The right block jumps from individual years (61–100) to round centuries/millennia (200...1000), then by thousands (2000...10000), then 20000, and finally **25579** years — the full precessional cycle of 360°, consistent with Riccioli's adopted precession rate. The bottom-right entry 25579 → 360°0'0"0''' marks one complete circuit of the equinoxes. The four-figure large-year rows (e.g. 8000 → 112°35'33"20''', 20000 → 281°28'13"20''', 25579 → 360°0'0"0''') carry degrees/minutes/seconds/thirds; the three-figure rows omit a trailing zero (thirds) group, so row 9000 reads 126°46'00"00'''.

Numerical check (row 57, right block): "9000 → 126° 46' 0" 0''". This value is **confirmed printed as 126 46 0 0** It is a genuine source error: a

strict monotone extrapolation of the precession column gives $\square 126^{\circ}26' - 126^{\circ}27'$ (the per-1000-year increment runs $\approx 14^{\circ}02'$; $8000 \rightarrow 112^{\circ}35'$; $10000 \rightarrow 140^{\circ}44'$), so the printed minutes value 46 breaks the otherwise smooth progression. Most likely a compositor digit swap (intended $26'$ set as $46'$, a $2/4$ confusion). Transcribed as printed; flagged as a suspected source/compositor error — see Numerical impossibles. (Not [?].)

TAB. 101. Names of Foreign Stars, and for the Most Part Arabic Names

TAB. 101. *Nomina Stellarum Peregrina, & Plerumque Arabica, cum eorum interpretatione continens. In qua ne mirere Lector, si eidem Stellæ diuersa nomina videbis adscripta, pro diuersitate Dialectorum, aut codicum fortassè corruptorum.* — Containing the foreign — and for the most part Arabic — names of the stars, together with their interpretation. In this table, reader, do not be surprised if you see different names assigned to one and the same star, owing to the diversity of dialects, or perhaps to corrupted manuscript codices.

A

- *Abrachaleus*, Castor, or its head.
- *Acharnar*, *Acharnaar*, or *Acharnarino*, Arabic, the bright star at the extremity of Eridanus.
- *Achluschemali*, Arabic, Corona Borealis (the Northern Crown).
- *Adared*, Arabic, Mercury.
- *Aderaimin*, or *Alderamin*, Arabic, the star above the right shoulder of Cepheus.
- *Adigege*, or *Adegige*, Arabic, Cygnus, as if "fragrant like a rose."
- *Adhil*, the star in the lowest part of Andromeda's garment.
- *Adrendefa*, Arabic, Virgo.
- *Aegipan*, *Aegoceros*, the Greek-Latin name for Capricorn.
- *Afeichius*, Serpentarius — or is it corrupted from the Greek-Latin *Ophiuchus*?
- *Akrab*, Hebrew; *Aakrab*, Arabic; *Acrabo*, Chaldean: Scorpius.
- *Alacrab*, or rather *Aakrab*, Arabic; or *Hacrab*: Scorpius.
- *Alamak*, Arabic; *Almaak*, Arabic — not *Alhames* [?]: as it were, the star in the southern foot of Andromeda.
- *Alascha*, the foremost of the two stars in the sting of Scorpius.
- *Alasid*, or *Alezet*, or *Asid*, or *Ellesed*, Arabic, Leo.

- *Alazet*, in *Azophi* [al-Ṣūfi], the tail of Leo.
- *Alazel*, or *Alaazel*, or *Hazimet Alazel*, & in *Hermes Alhaiseth*, Spica Virginis (the Ear of Wheat of Virgo).
- *Alathod*, or *Alhaiot*, Capella.
- *Albegala*, Lyra.
- *Albezze*, or *Albizze*, Centaurus.
- *Albireo*, Arabic, the star in the beak of Cygnus.
- *Alcantarus*, Arabic, Capricorn.
- *Alcor*, Arabic: the little rider-star above the second star in the tail of Ursa Major.
- *Aldebaran*, the southern eye of Taurus, that is, the dominant star.
- *Alderamin*, or *Aderaimin*, Arabic, the star above the right shoulder of Cepheus.
- *Algebar*, or *Algebra*, Arabic, Orion — see *Elgeuze*.
- *Algedi*, Arabic, Capricorn.
- *Algeneb*, Arabic: the bright star in the outermost wing of Pegasus, or in the side of Perseus.
- *Algethi*, or rather *Algiethi*, Arabic, Hercules.
- *Algeuze*, or rather *Elgiauze*, Arabic, the head of Castor.
- *Algol*, Arabic: the Head of Medusa, or Medusa herself.
- *Algomeiza*, Arabic, Procyon, Canis Minor.
- *Algorab*, Arabic, Corvus.
- *Alhabor*, Arabic: the splendid star in the mouth of Canis Major.
- *Alhague*, Arabic — not *Alangué*: Serpentarius.
- *Alhaiot*, Arabic; *Alhaisse*s in *Hermes*: Spica Virginis.
- *Alhance*, Arabic, or *Alahance*, Sagitta.
- *Alhes*, Arabic; or *Alkes*, which is at the base of Crater — common with Hydra.
- *Aliath*, the foremost star in the tail of Ursa Major.
- *Aliemini*, Alphonsine name for Canis Major.
- *Alkalurops*, the star at the Colorobus [club] of Boötes.
- *Alhameluz*, Arabic, Arcturus.
- *Almucedie*, Arabic, Vindemiatrix.
- *Almuredin*, Arabic, Vindemiatrix.
- *Almeqrameth*, Arabic, the Censer [Thuribulum].
- *Alohore*, Lyra.

- *Aloue Cap.*, of Medusa['s head].
- *Alphard*, Arabic, Cor Hydrae (the Heart of Hydra) at the bend.
- *Alpheichius*, Arabic, Serpentarius.
- *Alphas*, Arabic, Pegasus.
- *Alpheta*, or *Alphena*, the Syro-Chaldean bright star of Corona Borealis, as if "the opened pupil."
- *Alramech*, or *Aramech*, Arabic, Arcturus.
- *Alruccabah*, Arabic; or *Ruccabah*: the Pole Star at the extremity of the tail of Ursa Minor.
- *Alsartan*, *Asartan*, or rather *Elsartan*, Cancer.
- *Alzimon*, of Nubia [al-Nubiani], Spica Virginis.
- *Amaza*, Greek-Latin: ἄμαξα [Greek: hamaza, "wagon/cart" — the constellation], the Lesser Wain, Ursa Minor.

A (continued)

- *Angetenar*, or *Achenetenar*, are 9 stars in the third bend of Eridanus.
- *Anhelar*, Chaldean, the head of Castor.
- *Antares*, Ptolemy's Cor Scorpii (Heart of Scorpius) — ἀντάρης [Greek: Antarēs, "rival of Ares / counter-Mars" — the name Antares] in Hesychius.
- *Apullum*, corruptly for *Apollo*, that is, Castor.
- *Arie* of the Chaldeans, *Arieb* of the Hebrews: Leo.
- *Arieded*, the bright star in the tail of Cygnus.
- *Aris*, Chaldean for Mars; & in Greek ἄρης [Greek: Arēs].
- *Asinge*, Lyra.
- *Asartan*, Arabic, Cancer.
- *Aschere*, or *Aschemie*, Canis Minor.
- *Asida*, Arabic, Lupus.
- *Asmeas*, Arabic, Centaurus.
- *Astacus*, Greek for Cancer.
- *Astaroth*, Chaldean for Venus.
- *Asua*, Hydra.
- *Asugia*, Orion.
- *Ataïr*, or *Alcaïr*: the bright star in the head of Aquila, Arabic.
- *Atargatis*, Virgo.
- *Ataur*, Arabic, Taurus.

- *Athalpis*, Greek ἀθαλπής [Greek: athalpēs, "without warmth, cold" — Capricorn]: Capricorn.
- *Athorace*, Ptolemy's first Quadripartite (*Quadrip.* c. 9), the Pleiades.
- *Athoraïe*, or *Altorich*: in Hali Haben Ragel [Haly Abenragel], the Pleiades.
- *Atin*, or *Eltaur*: the eye of Taurus.
- *Auellar*, or *Auellan*: Pollux.
- *Azelphage*, Arabic: the two stars at the extremity of the tail of Cygnus.
- *Azimech*, Arabic, Spica Virginis.
- *Azubene*, Arabic, the Claw [Chela] in Cancer — though it signifies that of Scorpius — and from this the Libra hanging from this Claw.

B

- *Baculus Iacob* [Jacob's Staff], the Belt of Orion.
- *Basiliscus*, βασιλίσκος [Greek: basiliskos, "little king"]: Regulus, Cor Leonis (the Heart of Leo).
- *Baten Kaitos*, Arabic: the more northerly star in the belly of Cetus.
- *Beemin*, Arabic: there are 7 stars in the fourth bend of Eridanus.
- *Bellatrix*: the star in the right shoulder of Orion.
- *Benat Elnaesch*: the daughters of the bier [filiae feretri] — the Pleiades.
- *Benenatm*, or *Benenat*, or rather *Benetnasch*, Arabic: the outermost star in the tail of Ursa Major.
- *Betelgeuze*, or *Beetelgeuze*, Arabic: the bright star in the left shoulder of Orion; & it signifies "the Giant's home" [Gigantis domum].
- *Bridemis*, the Persian Lupus.
- *Brinek*, Lyra, or Lyra's bright star.
- *Buthean* in German; *Burrio* in English, "the hen brooding her chicks" [gallina fouens pullos] — thus they call the Pleiades, as the Italians call them *la Gallinella*.

C

- *Callisto*, Ursa Major.
- *Cammarus*, Cancer.
- *Caucasus*, Cepheus.
- *Canopus*, or *Canobus*: the bright star in the rudder of Argo Navis [Argonautis].
- *Carnabon*, Serpentarius.
- *Cateia*, or *Caia*: the first star in the northern part of Hercules's club.

- *Cavn*, Chaldean, Saturn.
- *Ceginus*, Cepheus, or what is in the left shoulder of Boötes.
- *Cernua quibusdam*, Cassiopeia (so called by some).
- *Chammah*, Hebrew, the Sun.
- *Cheichius*, or *Cheguius*: by some, Cepheus; by others, Boötes.
- *Chelub*, or *Chelenb*: Alphonsine name for Perseus.
- *Chem*b, or rather *Genib*, Arabic: the bright star in the side of Perseus.
- *Chesil*, Hebrew, Arcturus, or Orion — from the verb *Cacal*, which signifies "variable & inconstant."
- *Chateb*, Hebrew, Mercury, that is, "the Scribe" [Scriba].
- *Chima*, or *Kima* in Hebrew, the Pleiades, & the Hyades — indeed, by others, Arcturus — namely "stormy stars" [sidera procellosa].
- *Chrysomallus*, Greek, the golden-fleeced Ram [Aries].
- *Cinctorius*: of the two smaller stars in the tail of Ursa Minor.
- *Cochan*, or *Cochab*, Hebrew, Mercury — namely a shining star [Stella fulgens].
- *Colorobus*, κολορόβης [Greek: kolorobēs (a corrupt form), "hollow shaft" or the club of Boötes [clava Bootis]].
- *Currus volitans*, in Catullus, named Argo.
- *Cynosura*, Ursa Minor.

D

- *Dagim*, Hebrew, Pisces, or *Dagiotho*.
- *Dat Elkarsi*, Arabic, the Seat of Cassiopeia [Sedes Cassiopeæ].
- *Daulo*, Chaldean, Aquarius.
- *Delli*, Hebrew, *Situla* (the Bucket) for Aquarius.
- *Deneb*, or *Denneb*, Arabic, "Tail" [Cauda].
- *Deneb Adigege*, the bright star in the tail of Cygnus.
- *Deneb Elassid*, Arabic, or *Deneb Alasid*: the tail of Leo.
- *Deneb Aigedi*, or *Elgeudi*: the foremost star in the tail of Capricorn.
- *Deneb Elaakrab*, Arabic, the tail of Scorpius.
- *Deneb Kaitos*, Arabic: the more southerly star in the tail of Cetus.
- *Didymi*, Δίδυμοι [Greek: Didymoi, "twins"], Gemini.
- *Discuri*, Διόσκουροι [Greek: Dioskouroi, "the Dioscuri"], Gemini.
- *Dubhe*, or *Dubheh*, Arabic: the bright star in the shoulder of Ursa Major; Arabic.

- *Dubhe Elezguar*, Arabic: the bright star in the shoulder of Ursa Minor.
- *Duberukabah*, Ursa Minor.

E

- *Edeleu*, Arabic, Aquarius.
- *Eladari*, Arabic, or *Eleadari*, Virgo.
- *Eleazelet*, of Nubia [al-Nubiani], diffuse [fusus] among the astrologers, or Spica Virginis, corruptly *Alzimon*.
- *Elezguar*, Cynosura, Ursa Minor.
- *Eldegiagigh*, Cygnus, as if "a cock's comb" [Galli rosa].
- *Elgebar*, Arabic, Orion, Gigas (the Giant).
- *Elgeda*, Arabic, Capricorn.
- *Elgenib fulgens*, in the side of Perseus, Arabic.
- *Elgeuze*, Arabic, Gemini.
- *Elgegiale*, Arabic, Hercules.
- *Elhakaeae*, Arabic, the heads of Gemini [Capita Geminorum].
- *Elhamel*, Aries.
- *Elharneb*, Arabic, Lepus.
- *Elhaut*, Arabic, Hydra.
- *Elhatat*, Pisces.
- *Elhenaat*, the head of Pollux [Caput Pollucis].
- *Elkanfu*, or *Elkusu*, vel *Elkaus*, Aquarius, Arabic.
- *Elkaitus*, Arabic, Cetus.
- *Eikamer*, Arabic, the Moon [Luna].
- *Elkis*, or *Elnarad*, Arabic, Crater.
- *Elkleil Eigenibi*, Arabic, Corona Australis (the Southern Crown).
- *Elkleil Schemali*, Arabic, Corona Borealis (the Northern Crown).
- *Elmac Alcheras*, Arabic, the Lesser Horse [Equus minor].
- *Elhesed*, Arabic, Leo.
- *Elmarig*, Arabic, Mars.
- *Elmesteri*, Arabic, Jupiter.
- *Elnatra*, Arabic, the Manger of Cancer [Aselli Cancri].
- *Elsartan*, Arabic, Cancer.
- *Elschemis*, Arabic, the Sun [Sol].
- *Eltsamach*, Arabic, Spica Virginis.
- *Elzahareb*, Arabic, Venus.

- *Emro*, Chaldean, Aries.
- *Engonasi*, Greek ἐγγόνασι [Greek: Engonasi, "the kneeling one"; the source prints only "Græcè Ingeniculus" — the Greek script is an editorial supplement, not inked on the page]: Hercules.
- *Enuf*, or *Enf Alpheras*, Arabic: the star in the muzzle of Pegasus [in rictu Pegasi].
- *Erigone*, Virgo.
- *Ezra*, Cynosura, Ursa Minor.

F

- *Famauh*, or *Phomalhaut*, or *Phomauth*, corruptly *Phomaant*, Arabic: the Mouth of the Fish [Os piscis], or the splendid star in the outpouring of Aquarius [in effusione Aquarii].

G

- *Gadio*, Chaldean, Capricorn.
- *Garactes*, or *Abrachaleus*, Chaldean, the Head of Pollux [Caput Pollucis].
- *Gedi*, Chaldean, Capricorn.
- *Gienze*, Arabic; & with the article *Elgeuzi*, Gemini.
- *Grimmium*, barbarous, that is, the jaw of Draco [genam Draconis].
- *Grus*, or *Ciconia*, of the Moors [Mauris], is Serpentarius.
- *Guad*, of the Moors, Eridanus, or the Nile.

H

- *Haakrab*, or *Aaakrab*, & with the article *Elaakrab*, Arabic: Scorpius.

H (continued)

- *Hammel*, Arabic, Aries.
- *Harneb*, & with the article *Elharneb*, Arabic, Lepus.
- *Haut*, & with the article *Elhaut*, vel *Elhautine*, Arabic, Pisces.
- *Haut Elgenubi*, Arabic, Piscis Australis (the Southern Fish).
- *Haut Elschemali*, Arabic, Piscis Borealis (the Northern Fish).
- *Helice*, Greek, Ursa Major.
- *Heniochus*, Greek, Auriga.
- *Hermannibus*, in the Egyptians, "the god of speech," that is, Mercury.
- *Hermes*, Greek ἑρμῆς [Greek: Hermēs], Mercury.

- *Hermidons*, ἑρμιόνη [?] [Greek: hermionē]: in Vitruvius (book IX, c. 6), the outpouring of Aquarius [effusio Aquarii].
- *Hernippus*, in Pliny, Delphinus.
- *Hesperus*, ἑσπερος [Greek: Hesperos, "evening (star)" — Venus as evening star], the evening Venus [Venus vespertina].
- *Hexastron*, Greek ἑξάστρον [Greek: hexastron, "six-star"], the cluster of the seven stars of the Pleiades — which, although Ovid sings (*septem dici*, "seven are spoken of"), are nevertheless wont to be seen as six, because the seventh is discerned with difficulty.
- *Hierezim*, Arabic, "the rose-fragrant," or the lily — thus they call the star of Cygnus [Cygni astrum].
- *Hydrochous*, Greek ὑδροχόος [Greek: Hydrochoos], Aquarius.
- *Hydridurus*, Greek ὑδρίδουρος [?] [Greek: hydridouros, "turning the water-jar," namely Aquarius].

I

- *Ingeniculus*, the kneeling Hercules [in genua procumbens Hercules].
- *Iugum*, in Cicero, Libra.
- *Iugula*, in Plautus & Varro, Orion.
- *Iugulae*, of the Aselli (Manger-asses) in Cancer.

K

- *Kalb*, Arabic, "Heart" [Cor].
- *Kalbelaakrab*, Arabic, Cor Scorpii (the Heart of Scorpius).
- *Kalbellesed*, Arabic, of Ferzanis [Fez], of Morocco, & of Nubia, Cor Leonis (the Heart of Leo) — corruptly in the Alphonsines *Kalbelased*.
- *Kalbelalphard*, & resolved as a single word *Alphard*, Arabic, Cor Hydrae (the Heart of Hydra).
- *Kaitos*, & with the article *Elkaiton*, Arabic, Cetus.
- *Kaus*, & with the article *Elkaus*, Arabic, Sagittarius.
- *Kertko*, Chaldean, Sagittarius.
- *Kescheth*, Hebrew, Sagittarius.
- *Ketpholtsumman*, the head of Pollux [Caput Pollucis].
- *Kochab*, Arabic, the bright star in the shoulder of Ursa Minor.
- *Kolanza*, Arcturus, Arabic.

L

- *Laelaps*, Canis Major.
- *Lebanah*, or *Laneah*: in Hebrew the Moon, so called from its whiteness [ab albore].
- *Lesath*, or rather *Lessaa Elaakrab*, Arabic: the star in the sting of Scorpius [in aculeo Scorpii]; & it signifies "the very bite of Scorpius" [Morsum Scorpii].

M

- *Maadim*, Hebrew, Mars, as being of a blood-red color [sanguinei coloris].
- *Maasym*, Arabic: the star in the right elbow of Hercules [in dextro cubito Herculis].
- *Mafarte*, the barbarous name for Auriga.
- *Markab*, Arabic, "the curtailed one" — but it is itself the first star in the wing, or in the shoulder-blade [armo] of Pegasus.
- *Malphelcane*, that is, the fillet of the pupil [sertum pupillæ], Chaldean — namely, Corona Borealis.
- *Marra*, or *Mergà*, Arabic: the star in the sickle of Boötes [in falce Bootis].
- *Marat Musalseleth*, Arabic, "the Chained Woman" [Mulier Catenata], that is, Andromeda.
- *Marsic*, that is, "the place of reclining" [reclinatorium], Arabic: the star in the left hand of Hercules [in sinistra Herculis manu].
- *Masathre*, Chaldean, Libra.
- *Meeleph*, or *Mellesf*, Arabic, the nebulous star in the breast of Cancer [Nebulosa in pectore Cancri].
- *Meloch*, of the Egyptians, Mars, as being the god of destruction in their own belief [Deus destructionis ipsis].
- *Menkar Elkaitos*, Arabic, the star in the nostrils of Cetus [in naribus Ceti].
- *Mesangue*, Chaldean, Lyra.
- *Mesartim*, Hebrew: the two stars in the horns of Aries [duæ stellæ in Arietis].
- *Mezer*, Arabic, the star in the right thigh of Boötes [in dextro femore Bootis].
- *Micar*, or *Mizar*, "a girdle" [?], Arabic: it signifies the star, namely that which is the middle one in the tail of Ursa Major, as also the one in the girdle of Andromeda [in cingulo Andromedæ].
- *Miluius*, in Ovid otherwise called Cygnus.

- *Mizan*, Arabic, Libra.
- *Miznaim*, Hebrew, Libra.
- *Moschlek*, in the sting of Scorpius [in aculeo Scorpij].

N

- *Naasch Laazar*, of the Christian Arabs, signifies "the bier of Lazarus" [Pheretrum Lazari] — thus they call the seven stars of Ursa Major; & the three in the tail, *Benat Naasch*, that is, "the daughters of the bier" [filias pheretri].
- *Nahar*, Arabic, the Nile [Nilus], or Eridanus.
- *Nebolellesed*, Arabic, & *Nebolassid*: in the Nubian astrologers, it is the tail of Leo [Cauda Leonis].
- *Nembus*, Arabic, the star in the sickle of Perseus [in falce Persei].
- *Nepa*, Cancer, in Varro.
- *Nobia*, Chaldean, Mercury.
- *Noctiurus*, νυκτοῦρος [Greek: nyktouros, "night-watcher"], "the keeper of the night" [custos noctis], namely Saturn, according to Plutarch in *De Facie Lunæ* (On the Face in the Moon).
- *Nogah*, in Hebrew, Venus, as being a glittering light [lux rutilans].
- *Nonacrine*, the Latin name for Ursa Major.

O

- *Ostipes*, Cancer.
- *Ophnuchus*, ὀφιοῦχος [Greek: Ophiouchos], Serpentarius.
- *Orsercalem*, Turkish for Sagitta.
- *Orphas*, Cetus.

P

- *Palilicium*, the Latin name for the southern eye of Taurus [Oculus Australis Tauri].
- *Pesceho*, Chaldean, the nebulous star of Cancer [Nebulosa Cancri].
- *Peochos*, & *Asephcom*, the Moon of the Egyptians, as being the mistress of the seas [Maris domina].
- *Phaenon*, φαίνων [Greek: Phainōn, "the shining one"]: the apparent Saturn.
- *Phaëthon*, Jupiter, in Greek "of splendor" [φάέθων, "the radiant"].
- *Pharmaz*, Crater.
- *Phicarus*, Cepheus.

- *Phomant*, or *Phomault*, or *Phomelhaut*: the Mouth of the Fish [Os piscis], Arabic; & it is in the outpouring of Aquarius [in effusione Aquarii].
- *Phosphorus*, *φωσφόρος* [Greek: Phōsphoros, "light-bearer"], the morning Venus [Venus matutina].
- *Piorion*, *προΐων* [Greek: proiōn], in the Egyptians, the Station of Horus [Statio Hori], that is, the eye of Taurus [oculus Tauri].
- *Potirir*, of the Egyptians, the Sun, that is, in their own belief the Holy God [Deus Sanctus].
- *Procyon*, *προκύων* [Greek: Prokyōn], in Cicero *Antecanis*, or "before-the-Dog" [Præcanis], Canis Minor.
- *Proput*, *προπούς* [Greek: propous], the star in the highest part of the left foot of Pollux [in summo pedis sinistri Pollucis].
- *Pyrois*, *Pyroentis*, *πυρόεις* [Greek: Pyroeis, "the fiery one"], the fiery Mars [Mars igneus].

R

- *Ras*, Arabic, "Head" [Caput].
- *Ras Algethi*, Arabic, the Head of Hercules [Caput Herculis].
- *Ras Algol*, Arabic, the Head of Medusa [Caput Medusæ].
- *Ras Algeuze*, or *Ras Elgiauze*, Arabic, the Head of Castor [Caput Castoris].
- *Ras Alhague*, Arabic, the Head of Serpentarius [Caput Serpentarii].
- *Rastaben*, Arabic, the bright star of the Head of Draco [Lucida Capitis Draconis].
- *Rephan*, of the Egyptians, Saturn, as being in their own belief the god of times [Deus temporis].
- *Rigel*, or *Rigel Elgebar*, Arabic, the bright star in the left foot of Orion [lucida in sinistro pede Orionis].
- *Ruba*, Hebrew, Auriga.
- *Rota Ixionis*, Corona Australis (the Southern Crown).
- *Ruccabah*, the Pole Star [Stella Polaris], at the extremity of the tail of Ursa Minor [in extremo caudæ Ursæ minoris].

S

- *Sagmarius*, Pegasus.
- *Sameh*, Pisces.
- *Sartai*, Hebrew, Aries, or its Horns [eiusue Cornua].
- *Sartam*, Hebrew & Arabic, *Elsartam*, Cancer.

- *Sartono*, Chaldean, Cancer.
- *Sceara*, Canis Major, or Sirius.
- *Schaham*, Arabic, Sagitta.
- *Schabtai*, Hebrew, Saturn.
- *Schasro*, Chaldean, the Moon [Luna].

TABVLA 101 — Lexicon of Foreign and Mostly Arabic Star Names, with their Interpretation (continued)

Continued from batch 193. Running header: "NOMENCLATVRA STELLARVM." Folio "128." Set in two columns; each entry is the italic headword + language attribution + Latin gloss/identification. Left column transcribed first, then right column.

Letter S (continued — left column)

- *Scheat*, Arabic. The leg, or shinbone; and it is also a star in the leg of Pegasus, called *Scheat Pegasi*, just as a star in the left shinbone of Aquarius is called *Scheat Aquarii*. To the Arabs, however, the more forward [star] of *Scheat Alphas* is *Scheat Edeleu*.
- *Scheder*, or rather *Seder*, Arabic. A star in the breast of Cassiopeia.
- *Scheer Eliemini*, the Greater Dog [Canis Major], to the Persians.
- *Schemasch*, to the Hebrews the Sun, from heat.
- *Schemso*, to the Chaldeans the Sun.
- *Simon*, or *Smon*, to the barbarians, the Dolphin [Delphinus].
- *Soail Iemani*, to the Persians, Canopus.
- *Stilbon*, Greek στίλβων [Greek: stilbōn, "the gleaming one"], Mercury, from its quivering light.
- *Sucula*, to Varro the Hyades.
- *Succoth Benoth*, Hebrew. "The tabernacle of the daughter," that is, the Pleiades.
- *Suhel*, Canopus.
- *Sumbalet Eleadari*, Arabic. Spica Virginis [the Ear of Wheat of Virgo].
- *Suroth*, to the Egyptians, "the mistress of love," namely Venus.
- *Syndesmos*, σύνδεσμος [Greek: syndesmos, "knot, bond"], the so-called Knot of the Thread of Pisces [the Linum Piscium].

Letter T (left column)

- *Tammech*, to the Chaldeans, Gemini.
- *Tauro*, Chaldean. Taurus.

- *Tauts*, to the Chaldeans, Jupiter.
- *Termonelles*, to the Persians, Hercules.
- *Theemin*, Arabic. The seven stars in the bend of Eridanus [in 4. flexura Eridani].
- *Theomin*, to the Hebrews, Gemini.
- *Triones*, the seven stars of Ursa Major.

Letter T (right column)

- *Tur*, Arabic. Taurus.
- *Tzedek*, to the Hebrews Jupiter, on account of equity [ob aequitatem].
- *Tzegel*, to the Arabs, Saturn.

Letter V (right column)

- *Vardi*, *Fetzanis*, the Nile, or Eridanus.
- *Vazneganubi*, Arabic. Lanx australis [the southern Scale-pan].
- *Vazneschemali*, Arabic. Lanx borealis [the northern Scale-pan].
- *Vespertilio*, to Sophocles, the Heart of Scorpius [Cor Scorpii].
- *Vesper*, *Vesperugo*, to Varro the evening Venus.
- *Vigiles*, in Italian *le guardie* [the Guards], or *guardiane*, the two lesser stars in the tail of Ursa Minor.
- *Virgilia*, or *Vergiliae*, the Pleiades.
- *Vmbilicus Pegasi*, the Head of Andromeda [Caput Andromedae].
- *Vuega*, or *Vagieh*, Arabic. The bright star of Lyra [Lyrae lucida].
- *Vultur cadens*, Lyra.
- *Vultur volans*, Aquila.

Letter Y (right column)

- *Yed*, Arabic. The more northern star in the right hand of Serpentarius [Ophiuchus].

Letter Z (right column)

- *Zeus*, Greek Ζεύς [Greek: Zeus], Jupiter.
- *Zubenelgenubi*, Arabic. Lanx australis [the southern Scale-pan], or *Vaznegunubi*.
- *Zubeneschemali*, or *Vazneschemali*, Lanx borealis [the northern Scale-pan].

FINIS

[End of TABVLA 101 and end of the Tabulae novalmagesticae*. The closing rubric* FINIS is centered below the lexicon.]

ERRATA. In Prolegomenis. CORRIGE.

[Errata for the Prolegomena. Three columns of locators — Page, Column, Line — followed by the printed (wrong) reading and the corrected reading. Transcribed as a pipe-table preserving the structure.]

Pag.	Col.	Lin.	[Printed — wrong]	[CORRIGE — correct]
II	1	29	sphæricam	sphæram
II	2	11	sub firmamento	supra firmament um
IV	2	13	percurret	percurreret
IV	2	42	Spicæ	Spica
IV	2	45	Antrogradi	Antrogradi
V	2	47	Comas	Comes
VI	1	11	qui &	qui ea
VII	1	65	mediæ distantiæ	medias distantias
VIII	1	43	Videri	Viden
IX	2	45	retentosq;	retentaque
39	1	6	Labouera	Lalouera
69	1	50	Sideris	Siderei
70	2	70	melius	meliores
78	1	76	eius	eiusque

Parsing notes: The first block uses Roman page numerals (II–IX), the second block Arabic (39, 69, 70, 78). At IV/2/45 the "wrong" and "correct" forms both read *Antrogradi* as printed — likely a compositor slip in the errata itself (the intended correction is presumably from *Atrogradi* to *Antrogradi*, the left-column form reading *Atrogradi*); see anomaly (a). Both columns are headed identically; the left

under *ERRATA* gives the erroneous reading, the right under *CORRIGE* the correction.

ERRATA. *In Tabulis.* CORRIGE.

[*Errata for the Tables. A single Page-number column, then the printed (wrong) reading and the corrected reading. These are chiefly place-name and observatory-station corrections.*]

Pag.	[Printed — wrong]	[CORRIGE — correct]
9	Alba Iulia Transilvani	Alba Iulia Transilvaniae
10	Cluia <i>Clives</i>	Cluia <i>Cleuer</i>
10	Dauentria. <i>Deunter</i>	Dauentria. <i>Deunter</i>
10	Faentia. <i>Faenza</i> 0 1 56 ad. 44 33 15	44 23 15
10	Hildesemium Saxoniae. <i>Hildesem</i>	Hildesemium Saxoniae. <i>Hildesheim</i>
11	Iuliacum Giuliech. & <i>Ginliers</i>	Iuliacum <i>Giulicch</i> , & <i>Ginliers</i>
11	Lemouices. <i>Lemoges</i>	Lemouices. <i>Limoges</i>
11	Leouardia Frisiæ. <i>Leuuayden</i>	Leouardia Frisiæ. <i>Leuarden</i>
11	Lipsia Misniæ. <i>Lipsi</i> , & <i>Leipsig</i>	Lipsia Misniæ. <i>Lipsia</i> , & <i>Lipsig</i>
11	Maiorica <i>Mallorca</i>	Maiorica <i>Mallorca</i>
11	Matisco. <i>Mascon</i>	Matisco. <i>Mascon</i>
11	Mussipons, seu Mosæpons. <i>Portamuson</i>	Mussipons, seu Mosæpons. <i>Pontamuson</i>
11	Oenipontum 47 10 0	Oenipontum 47 15 0
11	Promontorium Sacrum.	Promontorium Sacrum.
11	Rhemiorum. <i>Rems</i>	Rhemiorum, <i>Rems</i>
11	Sabala Galliæ. <i>Sable</i>	Sabulæ Galliæ. <i>Sable</i>
12	Santonas. <i>Santogne</i>	Santones. <i>Santogne</i>

Pag.	[Printed — wrong]	[CORRIGE — correct]
13	Triuer. <i>Trier</i>	Treuri. <i>Trier</i>
13	Tuder. <i>Todin</i>	Tuder. <i>Todi</i>
13	Valentiane.	Valentinæ.

Parsing notes: Single Page column (Arabic). Many rows pair a Latinized place name with its vernacular form (italic). Page locator "12" applies to *Santonas*; "13" to *Triuer*, *Tuder*, *Valentiane* (page-number values inferred from their printed position in the column, which is partly faint at the gutter — see Readability). Several rows show identical "wrong"/"correct" entries (*Dauentria/Deuenter*, *Maiorica/Mallorca*, *Matisco/Mascon*, *Promontorium Sacrum*) where the correction is a subtle accent/letter change not fully resolvable at this resolution; transcribed as best read. The *Fauentia* and *Oenipontum* rows correct tabulated coordinate values: *Fauentia* latitude 44 33 15 → 44 23 15 (a minutes correction); *Oenipontum* 47 10 0 → 47 15 0.

These two leaves carry no printed text. They are binding matter at the very end of the volume, following the bibliographically complete work (FINIS and both errata blocks closed pp. 581–582 were blank endpapers).

** ** — [blank endpaper]. A blank rear flyleaf (laid paper, visible chain-lines). No printed text, manuscript annotation, library stamp, or shelfmark.

** ** — [back pastedown / inside back cover]. The inner face of the rear board, covered in mottled/marbled tan leather. No printed text, label, bookplate, or shelfmark visible.

No imprimatur, approbatio, colophon, signature register, booklist, or dedication tail appears on either leaf. The work is complete.
