Translator Version beta

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: "What do I need this new instrument for?" — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBrit HaShalem* (1797)

A note on the work

A mature reckoning with the heavens as the telescope was revealing them — a sequel to the vast *Almagestum Novum* (1651), built on further years of observation at Bologna with the collaborator Grimaldi, with fresh measurements and corrected parameters at center stage. Across two volumes it treats the Sun, eclipses, the Moon, the fixed stars, and each of the planets in turn, then reduces it all to working tables. It carries some of the earliest sustained telescopic accounts of Saturn's changing shape before its rings were understood, of the bands and spots crossing Jupiter, and of the apparent sizes of the stars — wielded as evidence that the Earth stands still. A vivid window onto astronomy at the dawn of the telescopic age.

A note on the translation process

This translation was produced with the [translation-pipeline](#). See the linked repository for details on the process.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Acknowledgements

Translated with the assistance of Claude. The translator thanks the [Anthropic](#) team for making this work possible.

This batch covers the front-of-volume material at the very start of the digitization. No printed text is present; the three leaves are the binding cover and two blank flyleaves carrying only modern librarian/shelfmark annotations in pencil.

**** Front cover of the binding. Mottled tan/brown leather (tree-calf marbled pattern), with raised bands visible along the spine edge at left. No lettering, title, or tooling is legible on the cover. No informational content.

**** Blank flyleaf (light tan laid paper), pasted to the front board at left. The only marking is a modern pencil annotation in the upper-left corner:

[Margin: "1529 (Rar)" — modern librarian's pencil note, upper-left corner. The figures and parenthetical reading are uncertain; "Rar" presumably abbreviates *Rarum* / rare-books designation.] [?]

**** Blank flyleaf (light tan laid paper). The only marking is a modern pencil shelfmark in the upper-right corner:

[Margin: "Rar 9471: 3 fol." — modern library shelfmark in pencil, upper-right corner. The numerals are uncertain; reads approximately "Rar 9471: 3 fol." ("Rarum 9471, 3°, folio").] [?]

[Blank folio: — verso of the title leaf. No text is printed on this surface; only the mirror-image show-through of the title page on the recto is visible. Top margin carries a modern pencil shelfmark "2922" [?] (with a further pencil mark to its right [?]).]

[Margin: pencil shelfmark "2922" [?]]

Mirror-bleed of the title page (read through the leaf, reversed), recorded as legible:

- "...REFOR..." — i.e. [*Astronomiae*] *Reformatae*
- "Serenissimi" [Of the Most Serene]
- "FERDINAND..." [Ferdinand] — i.e. Ferdinand Maria, Elector of Bavaria
- "BAVARIAE ET..." [of Bavaria and...]
- "DVCL..." [to the Duke...]
- a central engraved armorial device/coat of arms (the dedicatee's arms)
- at the foot: "BONONIAE M.DC.LXV" [At Bologna, 1665]
- "Ex Typographia Haered..." [From the printing house of the heirs of...] — the printer's imprint

[Blank folio: — flyleaf with no printed text on its surface. Faint mirror-image show-through of the title page is visible ("FORMATAE", "Serenissimi", "...CAIANI ETC" reversed). Top margin carries a modern pencil shelfmark [?.]

[Margin: pencil shelfmark [?.]]

Engraved dedicatory title leaf (recto)

This is the engraved title page proper, with red-and-black letterpress text above an engraved armorial cartouche.

ASTRONOMIA REFORMATA [The Reformed Astronomy]

AD [To]

Serenissimum D. [the Most Serene Lord]

FERDINANDVM MARIAM [Ferdinand Maria]

BAVARIÆ ETC. DVCEM. [Duke of Bavaria, etc.]

Diagram. An engraved armorial cartouche occupying the lower two-thirds of the title page: the coat of arms of the House of Wittelsbach (Bavaria). At the top, winged putti (cherubs) flank and support an electoral/ducal crown, while two further putti at the upper corners blow long trumpets. The central escutcheon is an ornate baroque shield: it displays the characteristic Bavarian lozengy (fusily) bend of alternating diagonal bands, quartered with a rampant lion. A smaller inescutcheon at the center bears an orb or globe device. The shield is framed by elaborate scrollwork (rollwork) with grotesque caryatid female figures at either side, and a festoon of fruit and flowers below, terminating in a mascaron (grotesque mask) at the base. The engraver's signature appears at the lower right of the plate, reading approximately "G. B. Tinti Fe[*cit*]" [?] (i.e., "G. B. Tinti made [this]").

- Top center (crown): electoral/ducal crown of Bavaria, supported by a winged putto
- Upper corners: two trumpeting putti
- Central shield: Bavarian fusily (lozengy) bend with rampant lion (Wittelsbach arms)
- Center inescutcheon: orb/globe device
- Flanks: grotesque caryatid figures within scrollwork
- Base: mascaron and festoon of fruit/flowers
- Lower right of plate: engraver's signature "G. B. Tinti Fe[*cit*]" [?]

BONONIÆ, MDCLXV. [At Bologna, 1665.]

Ex Typographia Hæredis Victorij Benatij. [From the printing house of the Heir of Vittorio Benacci.]

SVPERIORVM PERMISSV. [By permission of the superiors.]

[Margin: blue oval library stamp at upper right; round library stamp at lower center]

Verso of the engraved title leaf

The page surface is blank; what is visible is the mirror-reversed show-through of the engraved title page on the recto — the same red-and-black title text (*ASTRONOMIA REFORMATATA / AD / Serenissimum D. / FERDINANDVM MARIAM / BAVARIÆ ETC. / DVCEM.*) and the armorial cartouche, all printed in reverse from the bleed-through, together with the *BONONIÆ. MDCLXV.* imprint and the printer's line.

[Margin: modern pencil shelfmark at upper left, "1973 (Rar.)" [?]] [Margin: faint pencil mark at lower right]

Printed letterpress title page (Tomus I)

ASTRONOMIÆ REFORMATÆ TOMI DVO, [The Reformed Astronomy, in Two Tomes,]

QVORVM PRIOR OBSERVATIONES, HYPOTHESES, ET FVNDAMENTA TABVLARVM. [Of which the first contains the observations, the hypotheses, and the foundations of the tables.]

Posterior præcepta pro vsu Tabularum Astronomicarum, Et ipsas Tabulas Astronomicas CII. continet. [The second contains the rules for the use of the astronomical tables, and the astronomical tables themselves, 102 in number.]

PRIORIS TOMI IN DECEM LIBROS DIVISI, Argumenta Pagina sequenti exponuntur. [The contents of the first Tome, divided into ten Books, are set out on the following page.]

AVCTORE P. IOANNE BAPTISTA RICCILO SOCIETATIS IESV. FERRARIENSI. [By the author, Fr. Giovanni Battista Riccioli [Riccioli] of the Society of Jesus, of Ferrara.]

BONONIÆ, MDCLXV. [At Bologna, 1665.]

Ex Typographia Hæredis Victorij Benatij. [From the printing house of the Heir of Vittorio Benacci.]

SVPERIORVM PERMISSV. [By permission of the superiors.]

[Margin: faint mirror show-through of a facing page of letterpress text visible behind the title; not legible as continuous text.]

Verso of the Tomus I title page (blank; show-through)

This page is the blank verso of the letterpress Tomus I title page. It carries no printed text of its own. The lettering visible on it is mirror-reversed show-through bleeding through from the recto — the title-page text already transcribed in batch 003 ("ASTRONOMIÆ REFORMATÆ TOMI DVO ... BONONIÆ, MDCLXV. Ex Typographia Hæredis Victorij Benatij. SVPERIORVM PERMISSV."). No new content.

Dedicatory Epistle — opening

To the Most Serene and Most Powerful Prince and Lord, Lord Ferdinand Maria [Ferdinand Maria], Arch-Steward [Archidapifer] of the Holy Roman Empire, Elector of Both Bavarias and of the Upper Palatinate, Duke, Landgrave of Leuchtenberg.

F. S. [*Felicitas. Salus.* — "Good fortune and well-being"; or the author's subscription formula]

[Historiated initial: a large woodcut capital F, set in a decorated square block, opens the epistle.]

May it be with favorable and auspicious omen, Most Serene Prince, that the science of astronomy — *Reformed*, as best I could manage, by my hand — now comes forth from the press at this very time, born as it were from the womb. For just as the Sun has entered Leo, so this work, by its natal star, has drawn as its lot the royal sign of the heavens. Yet by a far happier design it seeks for itself help and protection under the illustrious name of Your Highness; for in Your royal coat of arms the globe of the world, gleaming with the star of the Cross and set between twin Lions above and below, is guarded more securely than by Atlas and upheld more strongly than by Hercules. For it has been, and is, the peculiar mark of this Most Serene House — by a twofold virtue, of orthodox Faith and of unblemished Loyalty — on the one hand to protect and guard the Catholic Church and the Supreme Pontiffs, and on the other to defend and preserve the Roman Empire and the Emperors; and to join political pru-

Dedicatory Epistle — continued

-dence with sincere Religion, Equity toward men with Piety toward God, Justice with severity, Magnanimity with Clemency, the arts of War with the pursuit of Peace, Wisdom with Fortitude, Arms with Letters; and — what is the very property of Leo — splendor of Wealth combined with the most generous munificence in showering its bounty upon learned and good men.

It is remarkable that the wisest priests of Egypt, to signify the overflowing of the Nile, chose to employ as their hieroglyphic the Lion — the sign diametrically opposite — rather than Aquarius itself. For what affinity, I ask, appears between that most blazing sign, with its fiery heat and the dry burning that scorches the very bowels of the earth, indeed sears its face, and that vast abundance of waters which the Nile pours forth at the height of its season? Yet here lies a mystery, whether of Nature's more hidden workings or of the secret providence of the Deity: that the subterranean lakes of Ethiopia and Egypt, stirred up by the "barking" of the Dog-Star and by the roaring of the celestial Lion, swell and boil over from those vast caverns, so that the Nile then rises and overflows — at the very time when other rivers shrink, and the Nile triumphs in its abundance of waters, while the rest run dry or stand parched. Moreover, if one considers the nature of the Nile and the temperament of the Lion, a great likeness between the two will hold good. Other rivers, the moment their banks are broken or overtopped, burst out with tyrannical violence and a mass of waves, and lay waste fields and farmers alike, devastating everything in their path —

through every field, with their stalls, they drag the herds along [camposque per omnes / Cum stabulis armenta trahunt]

— bringing on barrenness, dearth of grain, and all the evils that follow. The Nile, by contrast:

Fertile in its flooding, never fails to bring forth fruit [Fertilis exundans, nunquam non frugifer exit]

It conquers its banks only to enrich the fields; it floods only to make them fruitful; and the more violently it does so, the more bountiful it proves. By its neighbors it is then most of all hoped for, the higher it swells in pride — so much so that they fear lest it should not swell, lament if it should not overflow, and reckon it a shipwreck of their fields whenever they are not overwhelmed by the mass of its waters.

The Lion likewise, of all wild beasts the least savage, is as terrible toward those who scorn his majesty as he is gentle toward the submissive — milder toward women and infants, kindlier toward those who do him good, more generous toward the hungry, with whom he shares the food he has more than once divided, content himself with a modest portion. He knows how to serve holy or religious men no less than how to rage against others. Nor is any wild beast more easily tamed than the Lion — especially if he keeps company with princes, deeming it unworthy of the King of beasts not to lay aside his ferocity in the royal court, and not to put on a human gentleness in the presence of men robed in purple.

Ages of old saw it: under Hanno of Carthage [Hanno the Carthaginian]; under Augustus and under Domitian, lions so tame that fawns and hares played within their very jaws, fearing nothing there, while the lions themselves were the more afraid lest they should harm in even the slightest way creatures so defenseless. A more recent age too has seen it, under John of Austria [John of Austria], under Maximilian, and under Rudolf II [Rudolf II]: lions walking harmlessly through the palace and waiting upon their masters; and at the castle of Eitelberg [Eitelberg], lions of Otto Henry, Count Palatine [Otto Henry, Count Palatine], playing with puppies and sleeping untroubled at their side.

To what end, you will ask, this digression about the Nile and about Lions? Why, so that through the Lions blazing so brilliantly in Your most noble coat of arms I might urge that there are signified those Heroic virtues which I recounted above — the very virtues which Your HIGHNESS has dra-

[The dedicatory epistle to Ferdinand Maria continues from the prior batch; the opening words of p. 13 complete a sentence broken off on p. 12: "...the very virtues which Your HIGHNESS has dra-[hau-]"]

—drawn upon, and which Your Ancestors transmitted down into You in unbroken succession all the way from Charlemagne [Carolo Magno] through the illustrious line of their descendants. Among these Ancestors, one who won immortal remembrance and raised his head high was Otto the Great [Otho Magnus] — tall indeed in body, but greater in spirit, and destined to rise higher still, had not Heaven, in that very year 1180 when he was chosen Duke in Bavaria, begrudged him to the earth. Yet in his stead his son, Ludwig [Ludovicus], Duke of Bavaria, Septemvir, Count Palatine, and founder of Straubing [Straubinga], earned distinction for his loyalty toward Frederick II [Fridericum II], and won praises for his Religion and his Piety toward Innocent IV [Innocentium IV], so that he merited high tribute as a glory of both Empire and

Church. His grandson, Ludwig II [Ludovicus II], surnamed the Severe, with the gravity of his character contending against his fairness, ceded Lower Bavaria to his brother Henry [Henrico]. From this line came that distinguished offspring, Ludwig III [Ludovicus III], who in the year 1314 was chosen King of the Romans and soon after Emperor — so great a man that the age could not decide what was more to be admired in him: his kindness toward his peoples, or his love of letters and of learned men, or his zeal for the Orthodox Faith and his unceasing devotion to defending the Church of God. His great-great-grandson, Albert [Albertus], surnamed the Pious — but no less the Magnanimous — refused the proffered Kingdom of Bohemia, having tested within himself a Kingdom ampler and nobler, and proving true that saying of Horace [Horatianum illud]:

The more you rule by mastering a greedy Spirit, than if you should join Libya to far-off Gades, with either Carthaginian in servitude to one man alone.

Therefore from this stock was born the second Albert [Albertus], called the Wise, who, emulating the Piety of his Father no less than the most religious devotion of his wife Kunigunde, raised up very many Churches in Munich [Monachij], that by these — as if by citadels — he might storm Heaven, not by giant-like daring but by humble devotion. Why then should he not have begotten one like himself, William [Guillelmum], in whom so great an ardor for the Catholic Religion shone forth? And this William in turn was that very Albert V [Albertum V], who, also bearing the surname "the Wise," showed himself the wiser the more keenly he championed the Orthodox Faith. From him was sprung Your grandsire William [Guillelmus Ferdinandus], most zealous for the Catholic Religion, who in the year 1597, so that out of the storms of this World he might withdraw into harbor, and thence more safely into Heaven, abdicated the Dukedom of both Bavarias to be free for himself — nay rather, to be free for God alone. Afterward, from Renata [Renata] — that most illustrious Heroine — he had received Your Father, the best of men, Maximilian [Maximilianum]; and concerning him it is more fitting to keep silent than, in too cramped a compass and beneath his deserts, to wish to comprehend in a single tribute either his skill in arms, or his cultivation of peace, or his love of justice and of equity, or his most religious piety, or the rest of those endowments on account of which Germany acclaimed him Father of his Country.

Of all these, most Serene Ferdinand Maria [Serenissime Ferdinande Maria], You willed that the prerogatives be Yours by hereditary right and by voluntary possession: above all, Prudence in the choosing of counsels, Equity in judgments, the most amiable Humanity in governing Your subjects, a steadfast Zeal in

defending the Orthodox Faith, and resoluteness in repelling the enemies of the Faith and of the Empire. From this it came about that Your Cohorts withstood, repulsed, routed, and put to flight the forces of the Turks — superior in number, not in valor — with a memorable slaughter of the foe and to Your own praise.

[p. 14 — *the close of the dedicatory epistle and its subscription. The whole leaf is heavily ghosted by show-through from the printed verso/recto, but the recto text is legible.*]

But just how much our Society [Societas nostra] owes to You, to Your most illustrious Father, and to Your grandsire — how great the Munificence it has enjoyed from that quarter, and the protection surpassing all glory that it has rejoiced in, and rejoices in to this very day — no words can express, no monuments can attest; nor can it be discharged against so great a mass of debt, however great Your Magnanimity may be — because to do so would itself be a fresh benefaction and an immense new debt, under which one could never cease to labor for its repayment, even unto eternity. It remains only that the Greatness of Your HIGHNESS [Celsitudinis Tuae] deign neither to scorn the smallness of my Work, nor the slenderness of my talent, nor to refuse to admit me among Your most devoted clients.

Of Your Most Serene Electoral Highness

[*set lower right:*]

The most humble and obedient Servant,

Giovanni Battista Riccioli [Io. Baptista Ricciolus], of the Society of Jesus.

INDEX OF THE BOOKS.

BOOK ONE.

In which are the observations of the Sun, and the foundations of the Solar hypotheses.

BOOK TWO.

In which are select observations of Eclipses of the Moon and of the Sun, for establishing the lunisolar motions and the Moon's first inequality, and for delimiting the apparent Diameters of the Luminaries.

BOOK THREE.

In which are the observations of the Moon apart from Eclipses, treating of the Moon's monthly inequality, its variation, and its libration.

BOOK FOUR.

In which select observations of the Fixed Stars are examined, drawn from the ancients and from more recent astronomers; and from these, Tables are constructed and presented up to the Year of Christ 1700.

BOOK FIVE.

In which are the observations of the Planet Saturn, and the hypothesis of its motions.

BOOK SIX.

In which are the observations of the Planet Jupiter, and the hypothesis of its motions.

BOOK SEVEN.

In which are the observations of the Planet Mars, and the hypothesis of its motions.

BOOK EIGHT.

In which are the observations of the Planet Venus, and the hypothesis of its motions.

[Index Librorum, conclusion]

BOOK NINE.

In which are the observations of the planet Mercury, and the hypothesis of its motions.

BOOK TEN.

In which are the supplementary matters [paralipomena] concerning observations bearing on the fixed stars and the minor planets — namely, on their apparent diameters, their figure, their phases [Fasciis], their spots [Maculis], their rotation

[Vertigine], their satellites [Comitibus], the motions of those satellites, and their distances from the Sun and from the Earth.

Faculty [license] of the Reverend Father Girolamo Claramonti [Hieronymus Claramontius] of the Society of Jesus, Provincial in the Province of Venice.

Since two priests of our same Society of Jesus, expert in theology and in mathematics, have reviewed the *Astronomia Reformata* of Father Giovanni Battista Riccioli [Io. Baptista Ricciolus], a priest of our Society, and have approved that it may be published — we too, having obtained the faculty granted to us by the Most Reverend Father Goswin Nickel [Gosuinus Nikchel] of the Society of Jesus, our Superior General, concede that it be committed to the press, if so it shall seem fitting to those to whom this pertains. In witness whereof we have given these letters, subscribed by our own hand and secured with our seal. At Bologna [Bononia], the 28th day of October, 1658.

Girolamo Claramonti [Hieronymus Claramontius].

Place * of the Seal [Locus Sigilli].

Examined by [Vidit] the Lord Carlo Gorani [Carolus Goranus], Penitentiary, on behalf of the Most Eminent and Most Reverend Lord Archbishop of Bologna and Prince.

Examined by [Vidit], out of his singular goodwill toward the Author, the Most Reverend Father Inquisitor of Bologna himself, Friar Guglielmo Foschi [Gulielmus Fochus], and the faculty of printing was confirmed by his Most Reverend Successor.

Let it be printed [Imprimatur].

Friar Giovanni Vincenzo Paolini di Gatteo [Ioannes Vincentius Paulinus de Gatexio], Master Inquisitor General of Bologna.

INDEX OF THE BOOKS AND CHAPTERS AFTER THE PROLEGOMENA — to the *Astronomia Reformata*

BOOK ONE — On the Sun.

CHAP.

1. On the methods of observing the equinoxes, solstices, and the maximum declination of the Sun, with the least possible error [fallacia]. — p. 1

2. On the instruments most suitable for finely observing the Sun and any star's meridian altitudes; and especially on the celebrated gnomon of Bologna and others like it. — 3
 3. Observations of the equinoxes, or near the equinoxes, from 162 years before Christ down to the year of Christ 1656. — 7
 4. On the quantity of the equinoctial year, and on the diurnal and the annual motion of the Sun. — 14
 5. Observations of the solstices. — 16
 6. Observations of the obliquity of the ecliptic, or of the maximum declination. — 18
 7. Observations made with quadrants and semicircles. — 22
 8. Selected observations of the Sun's meridian altitudes apart from the equinoxes and solstices. — 23
 9. On the motion of the Sun's apogee. — 29
 10. On the eccentricity of the Sun, and the inequality of the diurnal motions. —
 11. On the eccentricity, equation, and intervals of the Sun, to be investigated within the elliptical geometry [in *Ellipsi Geometricè investigandis*]. — 33
 12. Selected observations of the Sun's apparent diameter, in which a remarkable source of error, into which certain other astronomers had fallen, has very recently been detected. — 37
 13. On the Sun's parallax and its distance from the Earth. — 41
 14. On the astronomical refractions, their comparison, and their use together with the parallaxes; and a new inquiry into the parallaxes through the refractions. — 42
 15. On the Sun's refractions. — 57
 16. On establishing the epochs of the Sun's motion. — 61
 17. A new theory of the Sun's motions is proposed. — 62
 18. The theory of the Sun's spiral motion is indicated. — 65
 19. Conclusions concerning the certainty acquired so far, or to be hoped for hereafter, regarding the Sun's motion, intervals, and quantity; the theory; and the practice of the Tables. — 69
- I. Appendix to Chapter XII. — p. 71 On the apparent diameter of the Sun.
 - II. Appendix to Chapter XVII. — p. 81 On the diurnal motion of the Sun, or rather of the remaining heavenly bodies than of the Earth, against the Copernicans.

BOOK TWO — On the Eclipses of the Moon and of the Sun.

CHAP.

1. On the selection of observed eclipses, and their use for establishing and verifying the astronomical Tables; and on the distance of the meridians assumed in the more celebrated Tables. — p. 92
2. Eclipses of the Moon observed as to their quantity and timing [Quantitatem & Momentum], from the year 721 before Christ down to A.D. 1660; with errors of other observers detected, either in the chronology or in the magnitude. — 95
3. An epitome of the observations of lunar eclipses whose moments — total, or mid-eclipse — have been handed down to us by their authors up to now, which we have reduced to a single, uniform meridian of Bologna by means of the table in the last chapter. — 105
4. On the uncertainty of the ancient observations, and of certain more recent ones; the discrepancy of the observers of the same eclipse, and its causes; ten disagreements [Dissid.]. — 108
5. On the agreement, or disagreement, of the astronomical Tables with the observations of lunar eclipses — and first regarding the ancient eclipses down to and including Ptolemy [Ptolemæum]; and how great a discrepancy appears between the astronomical and the chronological Tables; but how Ptolemy [Ptolemæus] did indeed err in the motion of the Sun. — 110
6. On the agreement, or disagreement, of the astronomical Tables with the observations of eclipses, from the time of al-Battānī [Albategnius] down to A.D. 1660. — 118
7. On the excellence of astronomical matters, and a comparison among them, drawn from the observations of lunar eclipses. Wherein certain notable conclusions are established. — 126
8. In which the foundations of the new Tables, and the eclipses from al-Battānī [Albategnius] down to A.D. 1660 — selected observations, and computed from the Author's new Tables. — 131
9. On the ancient eclipses of the Moon, displayed by means of the Author's new Tables. — 133
10. On the motion of the Moon in longitude, as established by the more distinguished astronomers up to now, and by which method especially it may seem that something is to be desired in that motion — wherein it has been gone astray. — 135

11. On the synodic lunar month, to be investigated through several eclipses. — 137
12. How, from the synodic month of the Moon, the remaining motions of the Moon in longitude may be derived. For concerning the anomaly and the latitude of the motion we shall treat separately below [seorsim dicemus] —

[Index Librorum et Capitum, continued]

CHAP. (*Book Two, conclusion*)

— now treating of the motion in longitude reckoned from the section of the true equinox.

13. On the motion of the lunar apogee and anomaly. — p. 140
14. On the motion of the lunar latitude, or of the nodes. — 141
15. On establishing the epochs of the lunar motion. — 142
16. Selected observations of solar eclipses — chosen, however, as suitable for establishing the lunisolar motions and the apparent diameters of the luminaries; with certain corrections of the astronomers' calculation thereafter adjoined. — 143
17. On the apparent diameters of the luminaries, suitable for representing total and annular solar eclipses. — 148
18. On the eccentricity of the lunar orbit; on the internal parallaxes and the apparent semidiameters of the Moon, determined now by means of a circle rather than by means of an ellipse. — 149
19. On the true magnitude of the Moon. — 151
20. On the latitude of the Moon, the anomaly of its motion, and the reduction of the Moon to the ecliptic. — 151

BOOK THREE — In which are the observations of the Moon apart from eclipses.

1. Observations of the Moon, apart from eclipses, from 295 years before Christ down to the year of Christ 509, as regards the places of the Moon in the heavens. — p. 152
2. Lunar observations of Johannes Regiomontanus [Regiomontanus], Bernhard Walther [Bernardus Vualtherus], Nicolaus Copernicus [Nicolaus Copernicus], and Abraham Zacuto [Abrahamus Zaguthus], as regards the places of the Moon apart from eclipses, from A.D. 1462 to 1524. — 154

3. Selected lunar observations of Tycho [Brahe], apart from eclipses, as regards the place of the Moon. — 155
4. Some lunar observations of Kepler [Keplerus], Lansberg [Lansbergius], and Longomontanus [Longomontanus], apart from eclipses, from A.D. 1598 to 1608. — 155
5. Lunar observations apart from eclipses by Boulliau [Bullialdus], Gassendi [Gassendus], Hevelius [Hevelius], Hodierna [Hodierna], Hortensius [Hortensius], Michael Langren [Michael Langrenus], and Vincenzo Mut [Vincentius Mutus], from the year 1623 down to the year 1653, as regards the places of the Moon. — 156
6. In which is exhibited the table of observations XXIV, of the Moon, together with the calculation of Ismaël Boulliau [Ismael Bullialdus] — which he himself promises in his *Astronomia Philolaica* [Astronom. Philol.], chap. 12 (Book 3), but afterward deferred to page 171 of his own Tables. — 159
7. Selected lunar observations, from among many made at Bologna by the Fathers Giovanni Battista Riccioli [Riccioli] and Francesco Maria Grimaldi [Franc. Maria Grimaldus] of the Society of Jesus, for the places of the Moon apart from eclipses. — 160
8. On the conjunctions [copulas] of the Moon with distances. — 163
9. A theory of the lunar motion in longitude is proposed, composed for the inequality out of the first and the second [inequality]. — p. 164
10. On the lunar variation. — 166
11. On the libration of the lunar body. — 168
12. A letter to the exceedingly Reverend, most illustrious, and most learned man, Father Giovanni Battista Riccioli [Riccioli] of the Society of Jesus, a priest, professor of theology and astronomy, most celebrated at Bologna [Bononia] — from Johannes Hevelius [Joannes Hevelius]. — 169
13. A brief reply to the matter awaited by Hevelius. — 192
14. Observations concerning the mobility of the poles, or of the nodes [Nodorum] of the lunar libration, from the year 1649 to 1656. — 192
15. A judgment concerning the aforesaid mobility of the poles, from the premised observations. — 199
16. Selected more recent observations of Father Francesco Maria Grimaldi [Franc. Maria Grimaldus] concerning the limits of the lunar libration, from the year 1631 to 1656. For the table of Hevelius, examined as exhibiting the maximum libration of the Mare Crisium [Sea of Crises] for the several months of this present period [saeculi]. — 199

BOOK FOUR — On the Fixed Stars.

1. On the observations of the ancients concerning the fixed [inerrant] stars, and the manner of observing them. — p. 201
2. On stars in the same straight line or distance, as much in former times as more recently observed. — 203
3. The declinations of the fixed stars, or their distances from the pole of the world, observed down to Tycho's [Brahe's] time exclusively, with a critique of them. — 203
4. The longitudes and latitudes of the fixed stars, selected, and from observations down to the time of Claudius Ptolemy [Claudius Ptolemæus] exclusively, with a critique of them. — 206
5. The longitudes and latitudes of the fixed stars observed, arranged by date, down to the time of Hesse [Hassiacas] and the Tychonic observations exclusively. — p. 215
6. On the places of the fixed stars observed by Wilhelm, Landgrave of Hesse [Vuilhelmus Lantgravius Hassiae], and by his astronomers. — 217
7. On the observations of Tycho Brahe, especially concerning the fixed stars, and on their certainty, order, and the method of reforming them. — 218
8. On the great table of distances, by which the fixed stars are distant from one another; its use and application. — 219
9. We recall to four classes the declinations of the Tychonic fixed stars. The first of them is the one which Tycho — either alone, or Tycho of Wandsbeck [Tycho Vranibvrgi], and Paul Hainzel [Paulus Hainzelius] near Augsburg of Vindelicia [Augustam Vindelicorum], where the altitude of Tycho's pole was $48^{\circ} 22'$ — began to observe in the year 1572 (when it was complete) and at the beginning of 1573. But these are exhibited in volume 1 of [Tycho's] *Progymnasmata* [Progymn.], pp. 361 and 369, where he also has [them] for the other 4. As regards the Annual observations of the Pole Star [Stella Polaris] distant from the pole. — 228
10. The right ascension of bright Aries [Iucida Arietis], from Tycho down to the year 1585, completed by exact weighing, is examined and emended. — 234
11. The Tychonic right ascensions of seven other fixed stars are corrected; and what remains to be done concerning the rest is [stated]. And concerning the omission of those whose right ascension the Tychonic observers ignore or fail to decrease. — 236
12. On the longitude and latitude of the Tychonic fixed stars, to be emended; and likewise on their motion in longitude. — 238

13. On the observations of the fixed stars after Tycho, down to ours, exclusively. — 241
14. On our own observations concerning the fixed stars, and first on the altitude of the pole at Bologna [Bononia], most finely and most exactly observed as the foundation of the declinations. — 244
15. On the remaining instruments with which we have observed the fixed stars, compared with the Tychonic [instruments]. — 246

Detailed Index of Books and Chapters (continued)

Book IV — On the Fixed Stars (continued)

- 16. On the declinations of the fixed stars observed by us. — p. 248
- 17. On the right ascension of 62 fixed stars, derived and reduced from the observations of our more recent astronomers up to the end of the year of Christ 1660. — 251
- 18. On the longitude and latitude of the fixed stars by our observations. — 254
- 19. On the motion of the fixed stars in longitude, and on its magnitude and uniformity. — 254
- 20. On the sidereal year, and on the great cycle [*apocatastasis*, i.e. complete return], or revolution of the fixed stars, and on their position at the beginning of the world. — 259
- 21. (I) A table of the right ascension and declination of one hundred fixed stars, computed for the complete years of Christ written out below, together with their difference. — 260
- Catalogue of the fixed stars with their longitude and latitude. — 265

BOOK FIVE — On Saturn.

- 1. Ancient observations of Saturn from the year 229 before Christ down to the year 1461 of the same era. — p. 280
-

2. Observations of Saturn made at Nuremberg by Bernard Walther [Bernardus Vualtherus], a pupil of Johannes Regiomontanus [Regiomontanus], from the year of Christ 1475 down to 1504. — 281
 -
3. Observations of Saturn by Copernicus, Pitatus [Pietro Pitati], and Junctinus [Francesco Giuntini], from the year 1514 to 1563. — 282
 -
4. Tychonic observations of Saturn, in which the days are recorded in the style of the old calendar. — 283
 -
5. Observations of Saturn by Jost Bürgi [Iustus Byrgius] drawn from the Hesse-Cassel observations of Wilhelm, Landgrave of Hesse, as well as those of Lansberg [Philippe van Lansberge], Hortensius [Martinus Hortensius], Gassendi [Pierre Gassendi], and Bullialdus [Ismaël Boulliau], from the year 1592 to 1640. — 284
 -
6. Observations of Saturn near the perigee of its eccentric, made for the most part by Vincenzo Muto [D. Vincentius Mutus], an astronomer of the greatest skill, recorded on days of the new style, all of them about the ninth hour after noon, and most generously communicated to us by letter, together with Saturn's place derived both from the observation itself and from a fivefold calculation. — 285
 -
7. Two observations by Tycho, and four made by the Fathers of the Society of Jesus at Aix [Oenipontum — but here read as the Jesuit college], and twenty-two made by the Marquis Cornelio Malvasia [Cornelius Malvasia] at Modena [Mutina]. — 285
 -
8. Select observations of Saturn from the many that the Fathers of the Society of Jesus made at Bologna in the College of St. Lucy — Giovanni Battista Riccioli [Riccioli] and Francesco Maria Grimaldi [Grimaldi], with others of the same Society as assistants — where there was need. — 287
 -
9. The various ways of observing the places of Saturn and of the other minor planets are explained, so that the choice of observations and the certainty of judgment may be established. — 289

-
- 10. On the limits of certainty within which the places of Saturn could be represented hitherto, or can be in the future, both through observations and through the astronomical tables of those places, and their disagreement. — 294
-
- 11. Select places of Saturn drawn from the foregoing observations, and compared with the places computed by means of the more celebrated tables. — 296
-
- 12. On the hypothesis and theory of the motions of the five minor planets, whether geometrical or arithmetical. —

BOOK SIX — On Jupiter.

-
- 1. Ancient observations of Jupiter from the year 241 before Christ down to the year 807 of the same era. — p. 303
-
- 2. Observations of Jupiter made by Johannes Regiomontanus [Regiomontanus] and Bernard Walther, from the year of Christ 1471 to 1504. — 304
-
- 3. Copernican observations of Jupiter from the year of Christ 1520 to 1530. — 305
-
- 4. Tyconic observations of Jupiter. — 305
-
- 5. Observations of Jupiter made at Hesse-Cassel by Jost Bürgi, instrument-maker [organopoeus] to Wilhelm, Landgrave of Hesse, selected from the Hesse-Cassel observations, together with the Keplerian and Longomontanian observations. — 307
-
- 6. Observations of Jupiter made by Pierre Gassendi, Ismaël Boulliau, Martinus Hortensius, Philippe van Lansberge, Johannes Hevelius [Hevelius], and Vincenzo Muto, from the year of Christ 1620 to 1650. — 307
-

7. An appendix of observations of Jupiter from the Tychonic [observations] recently published at Vienna, from the press of David Hautt, whence we have selected a few — may [the muse] Urania be favorable to the author. — 309
 -
8. Observations of Jupiter selected from those which the Fathers of the Society of Jesus carried out at Bologna in the College of St. Lucy — Giovanni Battista Riccioli and Francesco Maria Grimaldi, together with others of the same Society as associates thereafter. — And [there are] the 19 observations of the Marquis Cornelio Malvasia. — 310
 -
9. On the choice of observations concerning Jupiter, and a specimen of the calculation worked out from our tables. — 313
 -
10. On the arithmetical and geometrical hypothesis of the motions of Jupiter. — 315

BOOK SEVEN — On Mars.

1. Ancient observations of Mars from the year 357 before Christ down to the year 509 of the era of Christ. — 316
 -
2. Observations of Mars from the little work of observations by Johannes Regiomontanus. — 317
 -
3. Observations of Mars made at Nuremberg by Bernard Walther from the year 1475 to 1504 of the era of Christ. — 317
 -
4. Copernican observations of Mars. — 319
 -
5. Tychonic observations of Mars from the year of Christ 1580 down to 1601, noted on days of the old style, and [made] at Uraniborg [Uraniburgum], unless added otherwise, [and] made at hours after noon. — 319
 -

- 6. Observations of Mars made by Jost Bürgi, Longomontanus, Kepler, Fabricius [David Fabricius], and Gellius Sascerides [Gellius Sascerides], from the year 1590 to 1613. — 321
-
- 7. Observations of Mars made by Pierre Gassendi, Martinus Hortensius, Michele Fiorentino [Michael Florentinus], and Vincenzo Muto, from the year 1621, and by the Fathers of the Society of Jesus at Ingolstadt and Aix. — 322
-
- 8. Observations of Mars selected from the many [made] at Bologna in the Colle-

(continued: Book VII, On Mars)

- ge of St. Lucy, drawn off by the Fathers of the Society of Jesus — Giovanni Battista Riccioli and Francesco Maria Grimaldi — and at Modena by the Marquis Cornelio Malvasia. — 324
-
- 9. On the comparison of the astronomical tables with the select observations made concerning Mars. — 326
-
- 10. On the arithmetical and geometrical hypothesis of the motions of Mars. — 327

BOOK EIGHT — On Venus.

-
- 1. Ancient observations of Venus from the year 272 before Christ down to the year 510 of the era of Christ. — p. 329
-
- 2. Observations of Venus made by Johannes Regiomontanus. — 330
-
- 3. Observations of Venus selected from the observations made by Bernard Walther at Nuremberg. — 330
-
- 4. Observations of Venus by Copernicus. — 331
-
- 5. Tyconic observations from the year 1582 to 1601. — 331
-

-
- 6. Observations of Venus by Maestlin [Michael Maestlin], Kepler, and Jost Bürgi, selected from those of Snell [Willebrord Snel] among the Hesse-Cassel [observations]. — 333
-
- 7. Observations of Venus made by Pierre Gassendi, Father Andrea Argoli [P. Andreas Argolus], and Vincenzo Muto, and by the Fathers of the Society of Jesus at Ingolstadt and Aix. — 334
-
- 8. Observations of Venus selected from the many at Bologna in the College of St. Lucy, carried through by the Fathers of the Society of Jesus, Giovanni Battista Riccioli and Francesco Maria Grimaldi, and at Modena by the Marquis Cornelio Malvasia. — 336
-
- 9. On the hypothesis of the motions of Venus. — 340

BOOK NINE — On Mercury.

-
- 1. Ancient observations from the year 265 before Christ down to the year 867 of the era of Christ. — 342
-
- 2. Observations of Mercury made by Bernard Walther at Nuremberg. — p. 344
-
- 3. Tyconic observations of Mercury. — 344
-
- 4. Observations of Mercury by Longomontanus, Kepler, Jost Bürgi, Hortensius, and Boulliau, from the year 1592 to 1631. — 347
-
- 5. Observations of Mercury made by Pierre Gassendi, and by the Fathers of the Society of Jesus at Ingolstadt and Aix. — 348
-
- 6. Observations of Mercury selected from those which the Fathers of the Society of Jesus accomplished at Bologna in the College of St. Lucy — Giovanni Battista Riccioli and Francesco Maria Grimaldi — with their assistants. — 349
-
- 7. On the hypothesis of the motions of Mercury. — 351

BOOK TEN — In which are the Paralipomena [Supplementary Matters] of the Observations.

- 1. On the ways of observing the apparent diameters of the fixed stars and the planets. — p. 353
- 2. On the apparent diameter of Saturn. — 354
- 3. On the apparent diameter of Jupiter. — 355
- 4. On the apparent diameter of Mars. — 357
- 5. On the apparent diameter of Venus. — 357
- 6. On the apparent diameter of Mercury. — 358
- 7. A synopsis of opinions concerning the apparent diameters of the minor planets. — 358
- 8. On the apparent diameter of the fixed stars. — 359
- 9. On the figure of Saturn, its bands, its companions, and their situation, with respect to the equator or to the ecliptic. —
- 10. On the figure of Jupiter, its bands, their parallelism to the ecliptic, and the satellites. — 368
- 11. On the figure of Mars. — 372
- 12. On the figure of Venus. — 372
- 13. On the figure of Mercury. — 373
- 14. On the rotation of the planets about their own center. — p. 373
-

15. On the distances of the planets from the Earth and from the Sun, and where the [distances] of the fixed stars [are treated]. — 373

PROLEGOMENA TO THE REFORMED ASTRONOMY

In which the System of the World is set forth, together with the Hypotheses of the First and Second Movable [spheres]

And the Author's endeavors toward the advancement of Astronomy and Cosmography; and finally certain Conclusions are laid down, by which what is certain is distinguished from what has hitherto been uncertain.

How greatly Astronomy has advanced — even in our own age — once observatories had been erected and the heavens scrutinized first with the common eye and afterward with the telescope: how it has progressed, as though crowned the queen of the natural sciences; and that this advance has consisted chiefly in this, that it has brought to light, and illuminated thereby, very nearly everything that mortals before had failed to perceive, or that lay hidden, or that the deceptive light [of earlier knowledge] had revealed of itself only obscurely — all this is, I judge, sufficiently established in part from the Preface to the Reader of the first volume of our *Almagestum Novum* [*New Almagest*], and is to be made known in part in the pages below. Nor, for that matter, can anyone be ignorant of it, unless he be a stranger to those men by whose most celebrated labors the knowledge of this field has come down to us — the works of the most learned men, I mean: Copernicus, Tycho [Brahe], Longomontanus, Kepler, Lansberge, Galileo, Magi-

ni [Giovanni Antonio Magini], Scheiner [Christoph Scheiner], Petavius [Denis Pétau], Simon Marius [Simon Mayr], Claramonti [Scipione Chiaramonti], Snell [Willebrord Snell], Stevin [Simon Stevin], Wendelin [Govaert Wendelen], Michael Langren [Michael Florent van Langren], Hevelius, Gassendi, Boulliau, Herigone [Pierre Hérigone], Morin [Jean-Baptiste Morin], Mersenne [Marin Mersenne], Anton Maria de Rheita [Anton Maria Schyrleus of Rheita], Vincenzo Reinieri [Vincenzo Renieri], Johannes Phocylides [Johannes Phocylides Holwarda], Giovanni Battista Hodierna [Giovanni Battista Odierna], Elia Leonibus [Elias à Leonibus], and Maria Cunitia [Maria Cunitz], Vincenzo Muto, Eustachius [?], Lineamannus [?], Huygens [Christiaan Huygens]; and very many others, whom — lest I run on too long, and without doing them injury — I leave unnamed. Now

further, as to the bearing of this faculty [of astronomy] upon ours, and which among these and other select [matters], by way of corrective theses, we suppose in our hypotheses, and in the System of the World; and which things in Astronomy we hold for certain, and which we still reckon uncertain — these, that the reading may not be tiresome, we shall nevertheless set forth beforehand briefly and distinctly.

ARTICULUS I.

On the Creation of the World, and the Six Days of the Divine Work, insofar as the topic bears on establishing his System.

I have treated this matter at sufficient length in Book 9 of the *New Almagest* [Almagestum Novum], section 1, chapter 2. From there one may consult the opinions of the Fathers, the learned, and others; here I shall recall them only briefly. I take it, then, as drawn especially from Sacred Scripture in Genesis, that in the beginning of time, in one and the same instant, God created Heaven and Earth — that is, the Heaven of Heavens, which is the Empyrean, and the Heaven of the waters that lies above the Empyrean; this is indicated in the work of the second day, where it is said: *And let it divide the waters that were under the firmament from those that were above the firmament*. It is supposed, therefore, that water existed on both sides before the firmament was created; and so the word *Earth* is taken nowhere by Moses to mean a fixed dimension. [Margin: 1. *Diuisitque aquas quæ erant sub firmamento, ab his quæ erant supra firmamentum*. — Gen.]

Moses teaches that some Earth had been created on day one, and we must say that it was created before day two; and so under the name *Earth* the Elemental Water is also to be understood, or perhaps the whole Elemental sphere — whether the Heaven of the Earth be of the same infinite species, whose elemental, or rather of the same genus. Since, therefore, God in the first instant of time created two things, the two extreme bounds of the World — Heaven, as the highest covering, and Earth with Water, as the lowest foundation, as it were — and no star at all, and consequently no planet, unless they were created on day four (here Copernicus rightly notes, and against him is the Earth's being placed by Moses in the center, and the assertion that Heaven and Sun are at the center) — yet the Light which existed at that first instant, although it was not the prime light, was nevertheless light. [Margin: From the order of creation against Copernicus.]

That [light] shone above the abyss but a little later, having been created either by successive propagation or by motion around the terraqueous globe, and so produced the first equinoctial day; or perhaps in any case by an equal duration nearest to that, and what afterward the Sun, by its daily motion under the Prime Movable [Primum Mobile], effected — for that Light, in whatever hemisphere it then was, illuminated that place which was either the first Earthly Paradise, or the Palestine of the second Adam, was to be inhabited. And thus God divided the light from the darkness; and so it is probable that for about 12 hours the whole surface of the terraqueous globe enjoyed that light in succession, and through 12 [hours] lacked it, except for that particle of the first day in which the darkness was carried over the whole surface of the abyss. [Margin: Whether the first day was natural.]

It remains uncertain to us how that light arose at first from the eastern Horizon, either toward the Meridian of Paradise or of Palestine; since by us this can be understood in any manner whatever — *and it was evening and it was morning* — taken in a figurative sense. The expression *evening* and *morning* is understood at the beginning of time, properly speaking of the nights and intervals of time, and of the day at noon: when there is some evening twilight before the future setting of the Sun, or actually after [it] — at any rate after the Sun has set toward the West, the morning twilight is reckoned in the Churches as Vespers; whereas the morning [twilight] for us at our time precedes the rising of the Sun, either before [the Sun] has actually begun to ascend toward the Horizon, or after the midday [meridian], from which the Sun cannot ascend toward the Horizon. Finally, neither could men afterward perceive the light, unless it depended necessarily and essentially on the Sun, or as these things were created — unless these same Stars, or even all the Stars, were perhaps independently of the Sun not only made into a body by accident, but were also a body subject to it; if the Earth lies between [it] and the terraqueous mass, the intervening Vacuum — or rather, what body is intermediate — were either ethereal, or aqueous, or air, or were thought essentially to depend on a subject for its sustaining, [and] would be constant; so that from then, from the beginning, it could have shone with light intermediate from Heaven and from the stars, and have been produced and sustained by God alone.

[Margin: 2. On the work of the second day.] Thus Moses: *God also said: Let there be a firmament made in the midst of the waters, and let it divide the waters from the waters. And God made a firmament, and divided the waters that were under the firmament from those that were above the firmament. And it was so. And God called the firmament Heaven; and the evening and morning were the second day.*

The word *firmament* in Hebrew signifies something *expanded* and *solid*. Now if we say that the whole space from the Earth to the highest Heaven was at first full of homogeneous water; and that on the second day part of this water, left above the Earth, was thinned out, and part rarefied into the ethereal air, and finally part condensed into the crystalline Heaven, or vitreous — which is not at all unlikely — then it begins to be evident from such vastness of water and so great a condensation of the primigenial waters, that the rays multiplied by manifold refraction were dispersed. Then, if there was one water continuous from Earth to Heaven, it would properly be said that certain waters were beneath the firmament, that is, in that very place where afterward the firmament was made, [and] certain waters indeed beneath the firmament. But if we say that the prime water lay between the waters that surround [the Earth], and that the celestial waters created the aerial and ethereal Heaven, then on day two the Heaven was inserted into the ethereal solidity; or to the hardness imparted, which from the comets and planets is vague, that with many motions, and another, and a common reception of opinion, the Parts being conformable, we choose: then, since with all the other days something of a body was made from nothing — namely, as to substance, on the first day Heaven, Water, and Earth; on the third, all things; on the fourth[?], the Fishes; on the fifth, the flying things; on the sixth, the four-footed beasts and Man — only day two was without production of any new body, which would be exceedingly incongruous. [Margin: That the firmament is the eighth sphere.]

But if we say that the whole of that space was at first vacuum, and the aerial position remaining, the lower World not yet existing, [and] that there was a continuous superior [body], and that Stellar matter was not yet produced; and on the second day, either from nothing, or from the matter of both [waters], it produced from itself an ethereal nature; and from that, the position interposed [between] the divided waters from the waters, [and] the ethereal interposed truly the substance of the firmament; or it would be called the Hebrew *Rakia*, that is, *Expanse* [Expansum] — *solid*, we should say — both because that part, in which they collected the Fixed Stars, properly solidified, was taken with hardness, both because the remaining part — which the wandering Planet with its errings, and some comets permeate — would nevertheless be future, and at any rate immovable; nor as though they were transferred, should the Planets and comets be reckoned; but as though firm, they compress the Fixed Stars, and the lower ones permanent: these things I should hardly say, although they may seem to be of doubtful opinion, but they will surely face all the difficulties against the prior opinion adduced, and to whomever inquires what meanwhile interjects between the prime [waters] above the higher, and the inferior waters, it will be answered

with Moses: [Margin: 3.] *The Spirit of the Lord was borne over the waters*, that is, the spiritual substance of the Deity within, and above, was uniting the waters; filling the immense vacuum, that water, and that immensity replenishing imaginable things, and that above Heaven both within itself and infinitely extended. To whom truly the nature of these opinions satisfies, it is not easy to except this other thing, which is the literal sense of Sacred Genesis, and the verisimilitude more consonant.

[Margin: 3.] As to the work of day three, there is no great difficulty. For what is said: *Let the waters that are under the heaven be gathered together into one place: and let the dry land appear. And it was so. And God called the dry land, Earth; and the gathering together of the waters, he called Seas* — this is most truly expounded, either that before, on the first day, part of the terrestrial surface rose into mountains; or that on day three the surface of the Earth was disturbed in many ways, and the dry land appeared; whether they assert that the Earth's bowels were excavated, or whether the mountains were cast forth, and the hills, and within the bowels the Seas likewise dug out; a good part of the water hidden away, [and] of the rivers the springs, and the fluxes, refluxes, the Sea, or with whirlpools the vortices varying. Yet not by motion alone, [nor] by the local work of that day, would you think it accomplished, [for] God adds: *Let the Earth bring forth the green herb, etc.*; and so all plants, and the fruit-bearing trees, without seed already given, were produced, concurring

[Top of p. 23, left column — continuation:]

— nevertheless the Earth, through the seminal power infused into it by God, signifies such a concurrence by those very words: *Let the Earth bring forth*, whence it could appear that the generation of plants does not depend on necessity of essence, and that it is fated by the Stars, [and] not yet produced. [Margin: 4. On the work of the fourth day.]

Furthermore, on the fourth day God did not say: *Let the Heaven produce, or let the firmament bring forth the Stars*, as he had said of the Earth: *Let the Earth bring forth*; and afterward he said of the waters: *Let the waters bring forth the creeping creature, etc.*; but he said: *Let there be made Lights in the firmament of Heaven*; doubtless because these depend wholly on his own concurrence and divine pleasure, [and] lest he again give occasion to the opinion that the divinity of those [bodies], or a fatal power, [exists] in these lower things; unless we except the Light, which on the preceding days he had made through a tube[?]; for if the body of the Sun had been created, the dispersion was in the Sun, or the Stars, [from] the accidents of bodies communicated to the Sun by its own destruction, [and]

given to be destroyed; that the virtues were produced both to the Sun and to the Fixed Stars for propagating light. By whichever of these manners God may have used [it], it is certain that it would be against this sacred text to assert that some Star or some Light was produced from the Planets, and consequently from the Earth, made by God on the fourth day; and proportionally [against the text] that the Earth is one of the Planets. Nor would it be said that the Earth had not the name of Star, because there was not yet a Sun, [and] it could not receive light from it, [and] perform the office of luminary, [Margin: 5.] especially the waters being covered, because the essence of a Planet does not consist in actual illumination; otherwise, when the Moon at New Moon, or in a total Eclipse, does not illuminate the Earth, it would meanwhile cease to be a Planet, and could lose the substance of being prime — either on the first or the second day produced under the name of Heaven, but it would not have been a Star, before it took on the power of receiving illumination, which is contrary to what Moses asserts. *And he set them in the firmament of Heaven*, etc.: the words *Let there be made*, and *And he set*, signify together a new production, and likewise the office of illuminating perfected. Then the Earth, although covered with waters, was able to reflect light from the prime [light] as from a great mirror, and much more on day three the dry land appeared, and so had the name of Star.

But lest you say there could be no Star which did not illuminate, nor a Planet, since before the fourth day it was not moved about the annual orbit — for a Planet is so called from its erring, [and] is not a Planet, and consequently if the Earth alone with a vertiginous motion turned about its own axis, [Margin: From the order of creation against Copernicus.] insofar as the Moon near New Moon illuminates [it], reflecting toward it the rays of the Sun: but the Earth nevertheless was not [a Planet]. But I gather from this that the Earth, illuminated on the fourth day by the Sun, [and] adapted; and to illuminate the Moon, and to be carried about the annual orbit, ought to be called a Luminary, and indeed a lesser one — although the Moon is lesser than the Sun, both in mass and in the power of illuminating the Moon, from its greater surface reflecting more rays than the Moon, and so God made the three luminaries of the two great Luminaries. Lastly, it remains that you may say, although the Earth is so moved about the Sun, [and] is moved nevertheless even with respect to the Moon, and this in turn illuminating [it] on fixed days — yet it would not therefore deserve the name of Luminary; because God ordained it especially to illuminate the Earth, as being for the use of Men, beasts, [and] the plants of the field, and for distinguishing the day from the night, and the months, and the years, for the uses of men: as is clear from Sacred Genesis, saying: *Let there be Lights made in the firmament of Heaven, and let them divide the day and the night, and let them be for*

signs, and for seasons, and for days and years, and let them shine in Heaven, and give light upon the Earth; with which agree those words of Deuteronomy 4: *Lest perhaps lifting up thy eyes to Heaven, thou see the Sun and the Moon, and all the stars of Heaven, and being deceived by error thou adore and serve them, which the Lord thy God created for the service of all the nations, that are under Heaven.* I grant freely, and I concede for this reason, that the Earth is not numbered among the Luminaries; yet in the Copernican hypothesis the Earth is a Planet, and an erratic Star, and is placed with its atmosphere in the Planetary Heaven, [and] is more remote from the center of the World than Mercury, Venus, and Mars at perigee, and at acronychal [position]; and so it would truly be said to be situated in a higher Heaven, [and] a part of the Planetary Heaven — if not on the first day, at least on the fourth day in the firmament of Heaven, when from

[Top of p. 23, right column — continuation:]

— the two Luminaries, and the Stars, Sacred Genesis speaks: *and he set them in the firmament of Heaven, that they might shine over the earth, and rule the day and the night, and divide the light and the darkness.* The Earth, however, in the Copernican hypothesis, could be said to be under Heaven in a different respect, and in Heaven; here [it is] taken in a diverse relation [as] reckoned [among] the other Planets, which are under a Heaven more remote from the center of the Earth; and the Planets, and the Fixed [Stars] themselves are under Heaven in the supreme respect; but Scripturally, this is to inhere in the proper sense of Sacred Scripture; it cannot be sustained that the Earth is in Heaven, and much less that it is greater, and higher in Heaven, than the Stars Mercury, Venus, and Mars; but absolutely it must be said that the Earth is under Heaven, and the Stars all in Heaven, [for] truly it cannot be said unless [the Earth] has peculiarities of its own, [and] the place of the Earth is given, [and] not given of Heaven — namely, the center of the World. Moreover, although it is very incongruous, [Margin: 5.] that since the Stars all were created [to be] under the [direction] of all the nations, [those bodies] which are under Heaven, [and] those very nations with the Earth circulate about their own emendations toward themselves [and] from light, and influence; but they are subordinate ministers, and especially of the Sun, about a quiet Earth, and immovable, [and] ought to be moved, and to perform their service — which God enjoined upon them. [Margin: That the Sun is in the center of the Planetary [Heaven].]

[Margin: 5.] As to the rest of the work of day five and day six, and of constituting our System, they need no disquisition, [and] which are diversely said in proportion to what was said hitherto; we suppose, as Sacred Genesis says, no

violence at all, or improbability beside the sound of the letters, [and] is intended; [and] by no necessity is it intervening, [and] is otherwise to be understood; that the Earth, or the terraqueous globe, is in the center of the World, without annual motion, but excluding especially the annual [motion]; above the Elemental sphere indeed, [but] to be the Heaven of the Planetary [region], or rather, somewhat permeable indeed by the Planets, but not by it [made] immovable, [and] not firm, although nothing of its whole, or some part, circumlocuted; and on this account it merits the name of Firmament, [and] the Fixed Stars under the firmament be probable to be solid, [and] impermeable; therefore the Fixed [Stars] themselves perpetually keep the figure of the stars; that at a distance among themselves [they are] continuous, but it is easier [that they] be moved with the motion of their own sphere [than] all be moved; whether that be the Aqueous Heaven created on the first day, and afterward consolidated, [or] from the ether [made] distinct. But if some new Stars [should] be seen, [and] not begotten in the Planetary Heaven [but] descended below Saturn, [Margin: New Stars.] [they] are circumscribed, so that they may evade [our] sight, [when] from their own particularities in the firmament of the Fixed [Stars] they do not appear, [and] one reckons that thence, [and] something miraculous made [by] divine virtue penetrating the solidity of the firmament of the Sphere. Furthermore, what is to be expounded, and what is presupposed about [the] bodies, [is that] the Prime Movable, by whose motion is accomplished the daily revolution of all the Stars [in] 24 hours, or thereabouts, or at least the apparent [revolution] of this same motion is preserved.

ARTICULUS II.

On the Prime Movable.

The ancient Astronomers, except certain Pythagoreans, in order to reconcile the apparent motions of all the heavenly bodies, [held that they go] from East to West, and gradually back again through Rising and Setting, with an apparent proper motion, by which the Stars likewise all are conceived to be carried, [and] above the Fixed Sphere, [there is] one above the others imagined, which carried away the Fixed [Stars'] Sphere; the rest, [being] contiguous to it themselves, and solid, from East to West would be moved into contrary parts; this very thing — what was said before [as] distinct — could be carried, [and that] the lower sphere could be carried toward the West, [and] yet not allow itself to be carried away; the resistance, however, of the Prime Movable being opposed, [it would] not so quickly revolve to the same Meridian as it quickly reached it

[Top of p. 24, left column — continuation:]

— if nothing whatever resisted. Just as a Fish [carried] downward by the headlong rushing torrent, or [a swimmer] born by the wind, if nothing resisted the impulse, is carried downward by a greater space than if it resisted. [Margin: 2.]

Nicetas of Syracuse, indeed, Heraclides, and Ecphantus the Pythagorean, and Seleucus; and afterward Gilbert [William Gilbert], Origanus [David Origanus], Wendelen [Govaert Wendelen], Argolus [Andrea Argoli], and William Langren [Michael Florent van Langren] held the Earth to turn with a vertiginous motion about its center in 24 hours from West to East; and so [they held] it to come about, and that, by going to meet [them], the Fixed Stars and immovable Planets, with a gentle going, would [seem to] be moved by a daily motion. Either because they thought the swiftness of the daily motion incredible in a Sphere so vast; or because they judged it inept and unfit for a Planetary Heaven to assume the daily and uniform motions for itself: but Philolaus, Aristarchus of Samos, Nicolaus Cardinal Cusanus [Nicholas of Cusa], Copernicus, Rheticus, Maestlin [Michael Maestlin], Kepler, Galileo, Lansberge [both, the elder and younger], Boulliau, Hérigone, Valentin Naibod [Valentine Naboth], Caelius Calcagninus [Celio Calcagnini], Diego de Zúñiga [Didacus à Zuniga], Paolo Antonio Foscarini [Paulus Antonius Foscarinus], Baranzanus [Baranzano], Giordano Bruno [Iordanus Brunus], Renatus de Chartes [René Descartes], Johannes Hevelius [Hevelius], William Schickard [Wilhelmus Schickardus], Marcus Hortensius [Martinus Hortensius], Christopher Wittich [Christophorus Wittichius], Daniel Lipstorp [Daniel Lipstorpis], Thomas Campanella, Christiaan Huygens [Huygens], and not a few others, besides the daily vertiginous [motion], assumed for the Earth a translation [motion] also about the Annual Orbit. [Margin: Copernicus.] But Copernicus, near in time, adds [that] the third [motion], [namely] that of libration, in the Earth, beside [the] said motions, [as] a third motion, by which the axis itself parallel librates, so that this very [axis] from the Equinoctial points may be seen [to move] into preceding [signs] toward the West, [and] from them the Fixed [Stars] to recede toward the East; and so the Fixed [Stars] from their position [seem] to recede, and at the same time to change their declinations; nor do they remain in the same [position] with the other Planets in longitude, [than] [they have] proper motion toward the East. By which fact, either falsely, [or] feignedly, [it is] freer, and adapts the more troublesome [phenomena] to be explained; [Margin: Praise of the Copernican hypothesis.] [and] the solid Sphere of the Fixed [Stars] being adapted to the liquid ether [for] the daily motion of the Planets, [and] the proper [motion] of the very motion [is] explained; the beauty and elegance of the novelty has so excited [them], [that it] has allured [them] into love of itself.

But we, to whom not only by the decree of the Sacred Congregation, [Margin: *Almagestum Novum* Book 9, section 4, chapter 40.] which I reported in *New Almagest* [*Almagestum Novum*] book 9, section 4, chapter 40, [the matter] is to be complied with, but also by physico-mathematical evidence from the percussion of falling heavy bodies, [it] is decided with the greater [evidence], by how much from a higher place they fall; and indeed [by] the proportional acceleration of the descending [bodies], we believe this acceleration [to be] real, and per the line [of fall] unique [and] perpendicular to be translated; just as in the Copernican hypothesis the acceleration cannot be real, or in any way proportional to the precise fall, although it be in this Hypothesis, [Margin: Book 9, section 4, chapter 19, and chapter 21, here.] inasmuch as the motion of the Earth, as is plain from what was said in the same Book 9, section 4, chapter 19, and is to be said here in book 1, [Margin: *De Sole* chapter 17 and its Appendix.] *On the Sun* chapter 17 and its Appendix. We, I say, are necessarily compelled to explain the daily motion of all the Stars by the Reason of the Stars, and that they may be seen to be moved by proper motion, [and] slowly toward the East, but to be moved continuously [for] 24 hours, or a little after [it] revolves to the same Meridian. This we shall explain perspicuously and most easily in the matter of the Planets first.

[Margin: 4.] Let there be the Meridian of all the first [bodies], the most celebrated, [though] not Geographically nor by Fortunate [Isles], or by the Azores, transiting, but through the vertex meditatively of the terrestrial Paradise, or of Jerusalem; and we assume the daily revolution of the Fixed [Stars] for the same Meridian, [Margin: from the example of the Prime Movable.] meanwhile from the Prime Movable['s] exemplar, [the matter is] dissimilar only [in] so much in [the] return [in the] apparent motion toward the East, which is somewhat after 365 days; the Second [motion] is found to be 50"; and so [Margin:] [it is] observed [that] the center of the Moon in the same prime Meridian in which the Fixed Star is, [as] Spica, [is] Spica; the recession from this Meridian would be moved, [and] not so quickly [along] the same circle [is the] motion, [as] a thread [in the] thread sense, or without sense the declinations from the plane of the same circle, as its Declination postulates, or Latitude, [and] is moved; or in what moment Spica returns to the first Meridian, the center of the Moon, [carried] by a slower motion, [has been] borne about.

[Top of p. 24, right column — continuation:]

— in the Equator, or in [a] parallel [to the] Equator, [it] is distant from the prime Meridian toward the East by 12 or 13 degrees, [and] does it appear by daily motion translated toward the West? as meanwhile it would seem to have

remained Easterly — as [in the case of] Spica, and so it would not be moved at all; [it] would have been Easterly by 12 or 13 [degrees], which [it is] necessary to absolve before it reaches the prime Meridian, so indeed: and yet there are not two motions in [the] thing diverse, nor [are they] contrary to each other, but only one simple spiral motion, [namely] toward the West along the Longitude; and so, the Moon's center always persists more Easterly, but much slower in motion than Spica, so that, if daily the Moon's center persists in the Equator, or in the same parallel [as] Spica, [then] before Spica absolves 360 [degrees], [the Moon] is now after days 13 [in the] future, [being] in the supreme prime Meridian, [and] after 30 days [the] day Spica [is] in the same [position] with the Moon's center in the same prime Meridian. As to what I said of the Moon, [Margin:] [the same] is to be understood of all the other Planets, [but] with a double difference. The first is that the Sun is always somewhat slower in its return to the same prime Meridian than Spica, to which it is once joined, but much swifter than the Moon, so that, where the Moon reaches that [point], the Sun [in] one alone [day], about [some] degrees more in completing toward the West, [and] when [it] reaches the prime Meridian, [it] is then or nearly so after days 365 — but in the same [position] [it is] future from the same moment in the prime Meridian. By contrast the [other] Planet, [Margin:] when [it is] slower than Spica, in [its] spiral motion [it is] so much the slower, by how much more nearly its proper motion [is] toward the East. The second difference is that the Moon, and the Sun, in [their] spiral motion toward the West, [are] always slower than Spica, or any Fixed [Star]. But the rest of the Planets [are] for the most part indeed slower than the Fixed [Stars], [but] sometimes equally swift, and then they are called Stationary, because nothing [more] Easterly do they appear at night, [than] yesterday night, and so at the same time the Fixed [Stars] revolve to the same Meridian. When, however, they are slower, [Margin:] they are seen [to be] Direct, [in] the supposed motion [as] not appearing toward the East; and yet truly, the unique spiral motion being supposed toward the West, [it is] rather to be said to go backward [retrograde], or [to be] more slowly Direct; and on the contrary, when they reach [the point] more swiftly than the Fixed [Star], [as] Spica, and reaching that [point], they themselves are in fact more Westerly, [and] are seen indeed [as] Retrograde; [and] are called Retrograde [when] with a slower [motion], or Acyrical [Margin:] [Ocygradi], to be said.

[Margin: 5.] Furthermore, the Westward Motion of the Fixed [Stars], if another motion appear in these motions, [than] the motion of declinations per Libration, [it] would itself be the motion of the Prime Movable, and the measure of all motions [is] reckoned [in] the Equator, [or] its Parallels [as it] appears. But from the more subtle observation, indeed, [and] truly of Hipparchus, the Astronomers

detected the points of the Equator, to which the Sun comes [as it] makes the Equinoxes; [it would] vary [the] points day by day, in the preceding [signs] from that Fixed Star, which had been in them, or near it; and so they deduced the Fixed [Stars] to become more, and more Easterly, as though the Fixed [Stars] themselves were moving toward the East; but Copernicus, who indulges no proper motion to the Fixed [Stars], attributes this apparent precession of the Equinoxes [to be] made from the motion of the Earth annually, [Margin:] cum libration, and most parallel [to the] axis of the Equator within itself. To us, however, who assert the Fixed [Stars] to be moved toward the West daily, [it] is incumbent to explain the cause [why] they continuously appear to tend [in a] very slow motion toward the East, but obliquely, [Margin:] and [for] what reason the Prime Movable [does this], whose Type they imitate in [their] motion from Rising and Setting; for which we propose more modes, but not equally probable, [so] that we may choose the more probable ones.

[Margin: 6.] The first and most ancient [mode] is, if above the Sphere of the Fixed [Stars] there be another Sphere, say the Crystalline Heaven, which above the Equator[']s poles [the] Equinoxes would be moved at the same Meridian [in] 24 hours, [and the] intermediate [Heaven] [carry] with itself the Sphere of the Fixed [Stars]; [and] its poles, from the Equator[']s poles distant [by] $23^{\circ} 30' 20''$, but [in] the Sphere of the Fixed [Stars] above the poles of the Ecliptic [it would] be moved insensibly contrary to [the motion] [in] the prime [Heaven]; [for] if there be two bodies discrete and distinct, it is not repugnant that there be two motions between them. But if you would not [have] the whole Sphere carry away the [lower]

[End of batch — page 24 verso, signature § 2 at foot of p. 23 (printed p. III).]

the inferior [sphere], it suffices that its girdle [cingulum] — from the highest periphery down to that point — be carried along in the plane of the equator.

The **second mode** is this: if the sphere of the Fixed Stars is not solid, or is solid but penetrable, and any given Fixed Star is permitted its own motion toward the west, then in the manner I described under number 4 concerning the Sun, the variety of declination proper to each star is preserved.

The **third mode** is this: if the sphere of the Fixed Stars moves about the equatorial poles over a span of 24 hours, while at the same time each star is permitted its own slow increment toward the equatorial poles, and the decrement of their declinations, so that the Sun nearly comes to a halt at the point through which the equator passes — moving neither too fast nor too slowly,

but rather a little ahead — or rather is carried somewhat toward the west, by as much as the half-yearly proper motion of the Fixed Stars amounts to, which to me appears to be most nearly 25" 20". For in this way the precession of the equinoctial points would occur toward the west, so that the Fixed Stars would be such as they were once supposed to have been in the Colure of the Equinoxes, when annually they would have moved more toward the east by 50" 40". One must be wary, however, lest this motion be of such a kind as Josephus Scaliger [Joseph Justus Scaliger] imagined for himself, who held that the Fixed Stars retain their distances unchanged from the poles of the world.

The **fourth mode** is this: if one admits that the sphere of the Fixed Stars moves about the imaginary poles of the equator, just as about the poles of the ecliptic — that is, by two Intelligences, or by a single one, with insensible intervals intervening, in such a way that on the one hand we make our measurement as I said, and on the other hand it escapes the senses on account of its smallness — namely, in one third of an hour the motion toward the west would be 30". The motion of the equator, and on the other hand the third-of-an-hour motion, would cease; and the sphere of the Fixed Stars, [moving] about the poles of the ecliptic, would in fact move toward the east through 7" 43" 20". For in this way it would come about that this whole motion about the equatorial poles would be absolute. Secondly, since the motion is toward the east, it would be most nearly 8" 40", and there would be no danger that it would be either too slow or too fast, since the motion toward the east of the equator would be perceptible to the senses.

The **fifth mode**, finally, is this: if one, or several, Intelligences move the sphere of the Fixed Stars toward the west, so that any given Fixed Star arrives at the meridian, at which I said it arrives, as much later as is the diurnal motion of the Fixed Stars apparent toward the east — which is 8" and most nearly 40" — and at the same time the Fixed Star is so caused to decline from the equator of the world, just as it appears in fact to decline. For if these things can be brought about by some Intelligences, why could they not by the Earth itself — the diurnal, annual, and librational motions devised by Copernicus, which represent to the senses these three motions of the Fixed Stars apparent in the heavens, and which machines [machinis] human ingenuity has contrived? Indeed, if we could move the globe of the Plows [the constellations] about a point, or move a globe set as stable in the midst of its [surroundings], while the globe of the Plows, fixed to no body, sustained itself in the poles, and were as it were freely suspended in the air — we could indeed move it elsewhere, so that we might represent to the senses those motions of the stars. Among these five aforementioned modes, the **fourth**

and **fifth** seem to me the more probable, and more fitting for the Intelligences that move the Fixed Stars.

ARTICULUS III.

On the Hypothesis of the Planets, as regards the Figure of their Motion in general.

It has long been known that the ancient Astronomers, both up to Kepler [Johannes Kepler] and afterward, were accustomed to explain the motions of the planets and their anomalies, together with their prosthaphaereses [prosthaphaereses], by means of Eccentrics, or by little circles [circellos] of Epicycles, or by librating little circles [circellos libratorios] — yet not without errors; and although some of these errors may have been so enormous that the device could not be reconciled with the celestial observations, it could not be refuted by faulty observations, as in the case of Mars, [continued opposite column]

[column 2, printed p. V]

where sometimes it erred by 4 degrees, and in Mercury by 7. So it was, until Io. Keplerus [Johannes Kepler], having a hidden suspicion, came to suspect that the Eccentricity of the planets ought to be bisected — that the center of the orbit of the planets is not the center of equal motion [centrum aequalium motuum], but something else, and that the just provenance of the equations [aequationum] was nonetheless to be brought forth from a bisected Eccentricity; that is, if in a line stretched between the centers — the center of equal motion being on one side, and the Earth on the Sun the other, in such a way that one [point] is the Earth in the Sun [Tellus in Sole], and that the other point should be placed as far from that one center as the increment of the half of the Eccentricity is, with respect to the center of equal motion. From this he saw it to follow that the whole inequality which appears in the motion of the planet would appear merely from an optical cause [causa Optica], because it would not be in the center of the planet's orbit — for if it were, we should see half of the inequality, and accordingly even half of the inequality of the planet considered from the center of its orbit, would be Physical [Physicam]; and such an inequality must be acknowledged. But since those two points are equally distant from the center, the most proper figure of the Ellipse [Ellipseos] is the most fitting rather than that of the Circle; for if in an Ellipse two foci [foci] are given — equally distant, indeed, between the center of the planet and the planet not being in the circumference, but in the Ellipse; and this [is] evidently apparent in Mercury, in Mars, in the Moon, more than in the

others — and in this, though a smaller diameter [diameter], yet conjugate, the figure is a little less than the major diameter, and therefore the Ellipse is by no means so perceptibly removed from the roundness of a Circle.

But Keplerus [Kepler], being wholly intent on assembling the Physical causes of the motions, and the magnetic attractions, with other ingenious figments [figmentis], yet not at all necessary, nor congruent — did not demonstrate with Geometric rigor the manner of describing the Ellipse, and the [way it is] fitting for each planet, and of the Prosthaphaereses thence exactly to be deduced.

The Ellipse-hypothesis was conceived by Kepler [Johannes Kepler], with not a few Astronomers following him; but **chief among them** Ismaël Bullialdus [Ismaël Boulliau] in his most learned *Astronomia Philolaica* (Books 1 and 11); Petrus Herigonius [Pierre Hérigone] in tome 6 of his *Cursus Mathematicus*, page 140; Caluerus [Caluerus] in his *Uranometria*, part 2, chap. 4; Sethus Vuardus [Seth Ward] in his *Idea Trigonometriae demonstrata*, in which he subjects to scrutiny the inquiry into Bullialdus's [Boulliau's] Astronomical Foundations, and detects certain errors in his use of the Ellipse — by what means I do not know they were purged — provided that this same hand could not arrive at this work; for he edited this [work], [in which] both the Intervals [are] arranged in the Ellipse indeed, but the Eccentricities exactly [are arranged according to] the manner in the Ellipse, but [it is the] manner that he teaches; whom afterward he taught in a little book published on this matter, dedicated to 4 Astronomers, namely Bullialdus [Boulliau] himself, Gottendus [Gassendi], Hevelius [Johannes Hevelius], and myself. Comas Paganus [Blaise de Pagan; "Comas" prob. *Comes*, "Count"] also excellently worked out this method through the Ellipse, just as did Io. Dominicus Cassinus [Giovanni Domenico Cassini]. But Dominicus Vincentius Mutus [Vincentius Mutus] judges that the Equations of the Center [Aequationes Centri], or of the First Inequality, can be better deduced through Librations, as he indicated to me lately in a Letter. But meanwhile most [astronomers] suppose that the motion of the planet [is] Copernican, and therefore think that the motion of the planet [runs] simply toward the east, and they, by simplicity and outstanding loveliness, esteem [it]; but Bullialdus [Boulliau] in his Book 1 resolves this motion into several circles.

And indeed, with the immobility of the Earth demonstrated by us, and the fluidity of the Planetary Heaven all but demonstrated, and accordingly the motion of rapture [motu raptus] rejected, by which the Planets would be snatched up [rapiantur] by the supreme Movable, and attributed to each, and each Planet by its own diurnal motion toward the west — as we said under Articulus II, number

4 — we cannot, and we ought not, [follow] the way by which the Planet is really moved, but [we follow] one simple figure, in such a way that we describe it [as] one [figure]; but we set forth to consider that [it is] not one continuous line, but a spiral [line] about the Cone [circa Conum], proper to each Planet. Nor do we Physically ascribe half of the apparent inequality to the planet's own motion, as the more recent Astronomy at length acknowledged, but we suppose it absolutely to be moved unequally, yet with an inequality that is regular [regulabili]. But because GOD willed to accommodate these motions to our grasp, or [because] the planet had a single figure in a Plane, we are able more easily to investigate that motion, which is in fact along a spiral line; we are by no means so easily able to comprehend [it]; therefore it is as if the motion were made in that figure about a circle around a Cone, which He ordained, so that in its surface it could be designated by a...

[column 1, printed p. VI]

from us — an Elliptical periphery, approaching nearer indeed to a circle in the Sun, in Venus, in Jupiter, and in Saturn, but receding more from a circle in the remaining Planets. And so in this we differ from the more recent Astronomers, because we employ the Planet [moving] in a circle, under the mere Hypothesis, for the sake of entering into the calculation; but they suppose it real, [the Planet moving] in a continuous figure toward the east, while in fact it is moved toward the west — nor [is it] either in expressing the spiral [line] itself in this motion, [a thing] I would reject, [or] in fearing lest we shake loose the foundations of Kepler [Johannes Kepler], which his own discoveries had been undermining — with that whole machinery [machina] he attempted to drive [them] away.

ARTICULUS IV.

On the Distances and Intervals of the Planets, for the completion of the System of the World.

The distance of the Planets — whether from the Sun, or from the Earth — is customarily expressed in two kinds of measure: one in such parts as the semidiameter of the Annual Orb of the Sun [semidiameter Orbis Anni Solis], or of the Earth, may have been a single unit, namely 100000, or 10000000; the other in semidiameters of the Earth. As regards the first kind, the distance of the Planets from the Sun, and from the Earth, are quite close to the truth, [being] now repeated after Copernicus, if we may speak of the five lesser planets, which are moved about the Sun; for the intervals of this kind are gathered from the Anomaly, the Eccentricity, and the Equations; and accordingly these elements are

as certain as those intervals are certain, which have a necessary connection with them. By contrast, however, the interval of the Fixed Stars from the Earth is most uncertain, whatever measure of the two you wish — whether finite or infinite. Hence it comes about that the distance of the Sun, as regards the semidiameters of the Earth, has hitherto been divided in opinion, [whether] it be finite or infinite. As to the distance of the Moon, both as regards the semidiameter of the Earth, it is divided in opinion; for the distance of the Moon from the Earth, and from the Sun, does not seem able to be certainly grasped in the first kind, nor [the distance] from the Sun, as regards the second [kind]; let the distance of the Moon from the Earth be [granted], as regards the second [kind], as the semidiameters [are reckoned], it is commonly thought through the parallaxes themselves [to be] very perceptible, and large. But it is itself called back into doubt, doubting lest perchance through the Refraction of our Air it suppose the parallax much greater than is true, on account of the altitude of the observations; and accordingly the Moon, [observed] within the neighboring Earth, has hitherto been thought certain by Astronomers. And because we have a need concerning the distance of the Moon, as for the inquiry into the distance of the Sun, and of the distance of the remaining Planets, [these matters] to be begun from the Moon, we think we have to vindicate; we note Astronomy [neglected] in this scruple, because it has been done by no one.

[column 1, lower section, printed p. VI]

On the Distance of the Moon.

Therefore in Book 10 of the *Almagestum Novum*, section 5, [I have set out] the doctrine of Parallaxes, their Theorems, [and] the Problems, partly [drawn] from others, partly here more fully treated, and chapter 11, problem 72, [showing] just how great a Parallax [there is] in any given individual case; but I was able [to deduce it] not [from] the more recent Astronomers, but compared [it] with the equal Refraction; and I concluded that, although such a Refraction of the Moon, [whether] from the Aether, or from the purest Air, [be] in a denser Air, the Refraction [arising] from Water in Glass [Refractio ex Aqua in Vitrum] is so great; at an equal distance of the Moon from the vertex — say at a distance of 10 [degrees] from the vertex — it is not [a matter of] three [parts of] the diameter [tribus diametris], the Refraction is most nearly 30" [the 30" being the water-into-glass analogy refraction, not the Moon's own horizontal refraction]. Where Tycho [Tycho Brahe], at such a distance of the Moon from the vertex, observed no perceptible Refraction. [continued opposite column]

[column 2, printed p. VI]

[he] noted; the data there [supposing] so great a Refraction compensating the parallax; and so, with so great a parallax, [there] would be a distance of the Moon from the Earth [of] 20 [semidiameters]. Now it is certain in that distance, that, [as reckoned] from semidiameters of the Earth, the Parallax is smaller from the vertex, and the Refraction; hence, by as much as the Refraction from the Aether into the Air is smaller, than [that] from Water into Glass, there is therefore certainly so great a distance of the Moon from the Earth, much greater [than] 20. And by how much smaller [the parallax] from the diverse densities between the Aether, and the Air, [the distance] would be greater, when in turn the parallax could be augmented; and the smaller the parallax, by so much the more would there be augmentation of the Parallax, derivable from a hidden Refraction, and a parallax compensating the defect. And just as the Refraction of 30" from water into glass, [as] observed by Vitellio [Witelo], may be compared to the Refraction [that] no [observation] by Tycho [Tycho Brahe] [shows], the proportion is null, so there is no sensible augmentation, because on account of a hidden Refraction a triple Parallax could be deduced by the customary modes. It is worthwhile, however, to see the Capita [chapters] of that whole [Section], Problems 73 and 74, and also chapter 12 of that same Section. With this scruple about Refractions removed, therefore, it is established from observations of the Altitude of the Moon, and that the Moon truly is distant from the center of the Earth in syzygies [in Syzygiis] never [more than]: I taught [it] in Book 4 of the *Almagestum Novum*, chapter 15. But what I said there, and afterward corrected here in this Volume, Book 3: the distance of the Moon at conjunctions [in Copulis] is minimally 58' 21", and maximally 63' 40" — [reckoned in] semidiameters of the Earth, from our [observations] indeed, [and] from observations.

[column 2, lower, printed p. VI]

On the Distance of the Sun from the Earth.

By how much greater effort and industry — [more] than [that of] any of the Astronomers — We, together with Father Grimaldi [Francesco Maria Grimaldi], investigated the distance of the Sun from the Earth, not by the most fallacious method of Lunar Eclipses, but by the Dichotomy of the Moon [per Dichotomias Lunares], indicated by Aristarchus, praised by Kepler [Johannes Kepler], and first cut into [examined] by us through the [method] of Vuendelinus [Vendelinus / Govaert Wendelen] in this method by conspiracy; then through the new [method], through the Parallaxes of the Sun [Solis Parallaxes] from the Refractions investigated, [and] at length the Physical causes of the Eccentricity of the Sun in a new Theory grasped; it will be established to the Reader, by what we

taught [in] Book 3 of the *Almagestum Novum*, chapters 7 and 8, and in the Appendix to chapter 7, which is had at the end of Tome 1 of that same *Almagest*, namely folio 731; and which [is] in this Volume, Book 13, chapters 13, 14, and 17; we shall teach how greatly the medulla [marrow / kernel] of the preconceived opinions of certain Astronomers may have prejudged [the matter], [opinions] which we nonetheless premise; and in this matter I reduce the opinions of the Astronomers into two classes: Some imagine that the distance of the Sun from the Earth [is] infinite, or at least finite-yet-infinite, [that is] indeterminable by us, [such that] no Parallax could be posited, [or] indeed [that it] could not be greater, because the Parallax of the Sun cannot be evidently shown; some, moreover, [hold it to be] finite, but knowable and demonstrable. The first opinion is ascribed to Hipparchus among the earlier considerations, but afterward from the Eclipses of the Moon as great a distance is nearly carried over [as] is that of Ptolemy. But Dominicus Cassinus [Giovanni Domenico Cassini], as we shall say in Book 1, chapter 13, [held the Parallax of the Sun] insensible; some earlier judged the parallax of the Sun [insensible], afterward sensible; Vuendelinus [Vendelinus / Govaert Wendelen] used the Dichotomies, but supposed about the Moon the Air to be thicker, which [Air] would retard the vespertine Dichotomy, and accelerate the morning [Dichotomy]; he chose the maximal distance of the Sun [as] 14905 Semidiameters of the Earth — as great as once it pleased Posidonius: for that Air confesses the same [thing] from the Dichotomies [that] provenanced to him as 7000, as great as we ourselves nearly apprehended through the Dichotomies of diverse [observations], as [the various] places of observation may show. Through the Refractions, however, [by the] new method we hunted out the Parallaxes of the Sun, and these, as we shall say [in] Book 1 to the end, chapter 14, [are] never greater than 30", indeed for the most part smaller. Hence it has been most certainly able [to be shown] to us [that] the distance of the Sun is never [more than] 6430 Terrestrial Semidiameters; indeed it is greater than this, and manifestly the Ptolemaic Astronomers, Copernicus, Tycho [Tycho Brahe], and others — who [reckoned] the parallax of the Sun [at] about 3 minutes — erred; rather, I assume it [more] probably, [as we] have demonstrated, [that] these [observers] err, [reckoning] this interval [the Earth–Sun distance] far less than they set it down, [opinions] which I have brought together [in] Book 3 of the *Almagestum Novum* to the end, chapter 7, and in the Scholia themselves.

[column 1, printed p. VII]

At length [in] Book 1, chapter 17, we shall show, if the Physical cause of the Eccentricity of the whole Solar [orbit] is, [that] the axis of the terrestrial shadow [umbra terrestris] is such that the center of the Sun's motion is equal to it; [that]

there the center of the Sun's motion [is] equal, [and] where the Shadow of the Earth [is], and [that] the cause of the half of the Eccentricity is the distance of the Shadow's axis of the Moon from the Earth; hence, both from the Semidiameter of the Sun's Apogee, [as] observed by us, [the] maximal distance of the Sun from the Earth follows [to be] 6666 Semidiameters. This is too much; and so [the] limits of the Solar distance are narrow, which Kepler [Johannes Kepler] in his *Commentaries on Mars*, page 71, defines, saying: *The Sun is not nearer than 230 Semidiameters of the Earth, yet it is not infinite; nor [is it nearer] than 700. And 2000 is not yet seen, [for] no certain number is demonstrated.* But to those correcting [him] we said truly: *The Sun is not nearer than 6430 Semidiameters of the Earth; yet it is not infinite, since it is absent by no more than 30000.* But [whether] six thousand and thirty thousand Semidiameters of the terrestrial [radius] — [a thing] not yet a certain number — is demonstrated, I add this for the exclusion of infinity, [to] very many [persons], by [a] kind of Physical [argument], [namely that it] cannot be given [as] infinite, [and so a] kind of finite terminus is granted on both sides; nor, [as] from everywhere, [is it] enclosed; [for it is] of such a kind that it is a rectilinear Triangle: But whatever [the case], let the distance of the Sun from the Earth be posited, because it is certain that the Sun is greater than the Earth, it is necessary, [as] is [shown] by a line drawn rightly between the center of the Earth, and however far [it] be continued; the other [line] drawn touching the Sun would concur at length in the apex of the terrestrial Shadow, [and] both, since they [are] tangent to the Earth, and [by] the aforementioned right lines a Triangle must be formed; and [that] the angle [thus] effects [a line] subtending the Semidiameter of the Sun [as] true, and [by] these — the Semidiameter, and the two aforementioned right lines — a right-angled Triangle [ought] to be formed.

But which [distance], moreover, may be within the said limits [of] 6430 and 30000, [is a] probable distance of the Sun, not easily to be persuaded to the lovers of their own opinions, and of their inventions. For few [of them] will believe that the [distance] is not infinite, but at least the maximum [is] 30000 semidiameters of the Earth, so that they may securely scorn the parallaxes of the Sun. To Vuendelinus [Vendelinus], moreover, and nearly to Christianus Hugenius [Christiaan Huygens], it will please [to make it] about double smaller, just as it pleased Posidonius — namely 14000, or 12000, using round numbers in the interim. But to us that [distance] pleases, which is still double smaller, namely 7427, ex multis Dichotomiis [from many Dichotomies], and the Semidiameter of the Sun's Apogee, and the Eccentricity [thus] limited; or 6666, [drawn] from the Eccentricity of the Sun adequately measured against the Axis of the Terrestrial Shadow, and from the apparent Semidiameter of the Sun — [these] not at all

repugnant to the evident parallaxes of the Dichotomy; if from the parallax of the Moon the fallacy be absent — which is wont to diminish the time between Dichotomy and quadrature; for [the time] is never less than within about one hour, but more notably less than this here it returns. It is a wonder, however, that this is the median distance of Hugenius's [Huygens's] Dichotomies of the Moon, [taken] in this business [from] a preexisting proportion of the diameters of the Planet, of any given one; [a thing that] he confesses [in] his Saturnian System [*Systema Saturnium*], page 81, [to be] slippery. By the telescope, moreover, [for] the median distance of the Sun from the Earth, [reckoned in] Semidiameters of the terrestrial [radius], [is] 12543. Why? Because [it follows] if this [be] adequate to the apparent Semidiameter of the Sun [of] 30' 30", as if truly it could not safely [hold] that apparent [Semidiameter], unless the distance of the Sun from us be prohibited [from going] to infinity, [or] unless [it be] prohibited from elsewhere.

[column 1, lower, printed p. VII]

On the Distance of the Five Lesser Planets.

Since it is most well-known to Astronomers that the Eccentricities of these Planets, and the median distances from the Sun, depend on the distance from the Sun, [the question is] how great the probability is of the Solar interval, [and] how great [the interval] of the Earth, [and] so great too the interval of the distance of these Planets from the Sun ought [to be], up to the Earth. And these [are] diverse opinions concerning the accurate distance of these Planets from the Sun, [reckoned] in such parts as the semidiameter of the Annual Orb of the Sun is 10000 — only so much in this Astronomy after Copernicus has been brought forth, and it will be acknowledged, [that] the maximal distance of Saturn from the Earth [is] about tenfold the interval of the Sun [from the Earth]; the interval of Jupiter, about fivefold; Mars's, about subduple; Venus's, about three-quarters; Mercury's, about subtriple. Indeed, as I brought [it] back [in] Book 7 of the *Almagestum Novum*, section 6, in the Scholia, [continued opposite column]

[column 2, printed p. VII]

[it erred by] sometimes 4 degrees, and in Mercury 7, until Io. Keplerus [Johannes Kepler], having a hidden suspicion, [held that the Eccentricity ought] to be bisected . Keplerus [Kepler] in his *Mysterium Cosmographicum* attempted, chapter 2, to distribute these intervals according to the inscription of [the five] Regular Bodies — which nonetheless did not succeed in all [cases]; [and] although, with the Annual Orb conceded, the translation of the Earth through the Superior Orbs, and of the Inferior [Orbs] of the Planets; which nonetheless [is]

translated by us, are nonetheless feigned [are figments]. But Vuendelinus [Vendelinus], with the distance of the Earth from the Planets supposed, as we also said there, [supposing] the distances of the Planets from the Sun, [from] the center of the World [equal] by sesquialterate proportion of the periodic times: from which he concludes that the distances of the Planets have among themselves the proportion which the numbers in the adjacent little table here carried over have. We, however, esteeming GOD the best and greatest [Deum O. M. = Deum Optimum Maximum] not [bound] to respect all the proportions, [and yet because] they appear beautiful to us, but [we ascribe these] to that [proportion] which [proceeded] from his own will in the lower regime of this World, [a thing] neither so idoneous [fitting], nor in these concinnities [harmonies] of numbers, so that we may recede from the apparent magnitudes of the celestial motions, and [from the] measure, and represent them [as] more apt [than these], such [as] in the meanwhile [was] our agreement in these [things], which [I gave] at the end of Books 5, 6, 7, 8, 9: we choose; whence also it pleased to [represent] these to the end [of] Book 10, even in Semidiameters of the Earth, to represent [them], that the distance of the Sun, and the distance of the Fixed [Stars] in opinion, [as] indicated under number 3; that it may be established to the Readers within what bounds Astronomy rests, and of the more certain determination consists. In this place, in the interim, for the hunting-out of the distance of the Fixed Stars, it suffices to first know the distance of the Sun, and of Saturn [as] the maxima from the Earth, according to a quadruple Hypothesis within the limits of the truth consistent, and they are infra-written [below].

[Margin: adjacent inset table of planetary distances follows]

Inset table — planetary distances (in parts where the Sun's Annual-Orb semidiameter = 100000; Wendelen's sesquialterate-proportion derivation):

Planet	Distance
♄ (Saturn)	953153
♃ (Jupiter)	519966
♂ (Mars)	152366
☉ [Telluris — of the Earth's orb, reference unit]	100000
♀ (Venus)	72339
☿ (Mercury)	38710

Parsing notes: The reference-unit row is labelled "Telluris" (of the Earth) and carries the Sun symbol ☉ with value 100000. Values transcribed as printed.

[column 2, lower, printed p. VII — main table]

Ex Hypothesi [By Hypothesis]	Maximum Distance from the Earth in Earth-Semidiameters	
	— ☉ (Sun)	— ♄ (Saturn)
Summa [Highest]	30000	327610
Vuendelini [Wendelen's]	14905	162833
Nostra [Ours]	7427	81105
Infima [Lowest]	6666	72795

Parsing notes: The header "Maxima à Terra Distantia in Semidiametris Terrae" (Maximum Distance from the Earth in Earth-Semidiameters) spans both numeric columns — the left under the Sun symbol ☉, the right under Saturn ♄. Row labels are the four hypotheses (Highest, Wendelen's, Ours, Lowest). All values transcribed as printed.

[column 2, lower, printed p. VII]

On the Distance of the Fixed Stars.

Concerning this I discussed [in] Book 6 of the *Almagestum Novum*, chapter 7, throughout, and in the Scholia [there], both so fully, [that] either I am not mistaken, [it could be diligently treated]; nor — with the erudite Reader [free] thence to draw [conclusions] — could it [need] further amplification; the chief doctrine [I] there hand down [is] this: that, just as the Sun in the Zodiac is borne, and sometimes occulting [a star] is interposed before some of the wandering Planets [Planetis], [it is] certain that [the Fixed Stars] are then at least higher than those Planets: that the Fixed [Stars] are distant by however great a naked-eye observation [permits], or are observable, in such a way that they suffer some Refraction; [it is] certain too, [that] there is no [Refraction] from so infinite an interval: for besides what was said there under number 3, I add [it is] necessary that they be [observed] from a sensible Refraction, since the Ray [Radius] at a Star incident on the surface of the refracted Air, would be inclined to a perpendicular at some sensible angle, and with this [other] ray of the Star drawn out to the center of the Earth, [reckoned] from the Semidiameter of the Sphere of Refraction, a Triangle is made; but the Physicists [Physici] therefore [hold it]

certain [that] it cannot be made [that the interval be] impossibly infinite [and] terminated from everywhere — [as said] under number 3. [It is] certain too [that] it cannot be evidently shown to us how great a distance of the Fixed [Stars] from the Earth [there is], whether of those — whether [it be] the concave surface of the Firmament — that [are] the lowest [surfaces of the Firmament], or of those [stars] which are placed in the more sublime [parts] of the Firmament; and not without merit Plinius [Pliny], Book 2, chapter 1 (with a cross-reference to chapter 23) [*Natural History* 2.1, with 2.23], said: *It is a madness of intellect, and almost of one demented [Furorem ingenii, et paene dementis], to attempt this measurement*, since [it would be] with the hope of certitude, as [if it would] suffice for our estimation [by] conjecture, [and] it would be established [that] no [certain] measure of souls, [as] in these matters, prefer especially [things] beyond the Equator, the manner of investigating the parallax of the Fixed [Stars], and of discerning the Refraction; this [also] therefore [is] from that [matter], the Pythagorean interval [intervallum Pythagoricum] there rejected, namely 94500 milia [miles], that is, terrestrial Semidiameters about... ..times 24, from which results a parallax of the fixed stars of 2°23'. But we do not approve the Platonic interval put forward in the same place, as being too uncertain, since it depends on an assumed lunar distance; for, given the assumed lunar distance of 56½ terrestrial semidiameters, it would yield a stellar distance of 17,993,654 terrestrial semidiameters and would contain the lunar distance 466,561 times. Moreover, Bettini [Mario Bettini], in his *Apiaria*, refuted this distribution of the fixed stars on harmonic grounds, holding that the fixed stars lie at no greater distance than 2290[?] terrestrial semidiameters, though he did not subscribe to the parallax computation. We have shown why one need not labor over this.

But why this is so. From the Tyconic distance of the fixed stars — and on those Copernicans who require so great a distance of the fixed stars that the whole annual orbit vanishes against it, becoming as it were a mere point — the following deductions are made. From Copernicus's hypothesis, Tycho and [Giovanni Antonio] Magini [Magini] deduce a distance of the fixed stars of 785,0000 terrestrial semidiameters; Longomontanus, 7,906,818. [Christoph] Scheiner, following Maestlin [Michael Maestlin], gives 13,133,376, a figure that also results from the Galilean interval, which sets it at 1,304,6400 semidiameters of the Earth. From Kepler's interval comes 34,077,067, or 6,000,0000 — for there [in *De Revolutionibus*] we showed that, on this hypothesis, the parallax of the whole annual orbit comes out as 17", or 14". How great an instrument would be required to perceive this, Tycho states in his *Mechanica*, and Lansbergen [Philip Lansbergen] gives it as 4,1980000 semidiameters of the Earth. The terrestrial parallax of the annual orbit, according to Hortensius [Martinus Hortensius], is 1'

(or, according to Origanus [David Origanus], 1'440), so that the parallax of the whole annual orbit, after the six months, would be a sensible 6', namely the minimum 6'. By contrast, if it follows that the parallax of the whole annual orbit ought not to exceed 10" — since the minimum solar distance is, as we said, 6430 terrestrial semidiameters — then the fixed stars must lie more than 3,000,000 terrestrial semidiameters distant from us. I regard that orbit of the annual terrestrial orbit [recte: see anomaly b — the phrasing here is compressed] as false. I see no more probable way of arriving at the measure of the distance of the fixed stars than those that follow.

6. The **first** is taken from the proportion of the periodic motions: namely, if it be supposed that the period of the Sun, which is one year, is to the distance of the Sun from the Earth — taken as 3,0000 semidiameters of the Earth, or at minimum 6430 — as that number is to the period of the fixed stars; then [computing] the periodic distance of the fixed stars (which we take at minimum as 25,579 years) yields the sum of the fixed-star distance, 767,376,000, or at minimum 164,472,970. Or, if the period of Saturn is taken at 30 years, then by the same reckoning of distance the sum is 327,610, or at minimum 72,795. From the numbers stated under point 4: if the period of the fixed stars is 25,579 years, the distance-sum is 2793,31026, or at minimum 680,68174. Do you see how vast a distance this is, and how uncertain? But how much more uncertain is it in the case of Saturn — and indeed of the Sun, which is the first and best-known measure of the times?
7. The **second** method is this: if the distance of the Sun from the Earth were the proportional mean between the distance of the Moon and the distance of the fixed stars from the Earth — for example, if it came about that the maximum lunar distance of 61 terrestrial semidiameters were to the maximum solar distance of 7427 as 7427 is to the distance of the fixed stars, 88,3,683 — then [the figure for] the fixed stars would have to be considered. But to this we must add the discrimination of refraction, as we said in Volume 2, Table 40. The refraction of the Moon at the horizon is 30' in the middle of the air; that of the Sun, 31'; and that of the fixed stars, 31½. So that the difference in refraction of the luminaries is 1½' — the Sun has 1½', the fixed stars 1½' — that is, only a half-minute of difference. Nor, even so, can we make it that 1' and 1½' ... so that the maximum difference [reckoned] from the Sun, when the distances are reckoned, comes to 7365 to 11047 terrestrial semidiameters; for the distance of the fixed stars would come out much smaller than Saturn's, which is hardly probable.

8. The **third** [method] may perhaps appeal to certain people by its simplicity — too much so — namely the one in which Saturn's distance from the Earth is held to be tenfold the Sun's, Saturn being as it were the center of the five Wandering [planets]; so that the distance of the Wanderers — or of the fixed stars taken together — is tenfold the distance of the Wandering [planets], or of the supreme Saturn of the Wanderers; and thus, by the last Table of number 4, the fixed-star distance would be 327,6100, and at minimum 727,950. Or, if it please that the sphere of the fixed stars begins where Saturn's shadow ends, so that the shadow of Saturn casts no shadow upon the fixed stars, then for me the shadow of Saturn is 12,0000 terrestrial semidiameters; if to this be added our [figure for] Saturn's distance — which is at maximum 81,105 — the distance of the fixed stars would be 1,011,05; or, rounded, 200,000. But to play around too much in uncertainties — for the certain measure of these things I consult God, the Best and Greatest.

[Margin: Eccles. 17.] ...has hidden from us, that we may acknowledge the weakness of our own intellect, and may reverence Him, of whose wisdom Ecclesiasticus 17 says: *The power of the height of heaven is His own to behold*. This comes not only from the great altitude, but also from the cause and force [flowing] from so great a height into these lower things.

Epilogue on the System of the World [Epilogus de Mundi Systemate]

9. Thus far concerning the System of the World, according to our own hypothesis — in which the Earth stands immobile at the center of the World, just as it was created at the beginning, as the foundation of the World's edifice, and as the future home of all things, into which all the heavenly bodies are bound to pour their influence. Around the Earth, the [region of the] Spheres and the moving elements appear; the Sun and the Moon are moved by two motions, namely, as regards longitude, with their bodies tending eastward, yet always toward the west by spirals carried through the fluid Aether, as described by the law and foundation which human imagination conceives of their motion, as if it were made by a single motion, almost circular, or rather elliptical, about a cone — capable of being designated by a scalene cone. The other five **Lesser Planets** move about the Sun as the center of their eccentrics, and as the fountain of light from which they are illuminated; and, by an intermediate motion about the Earth as center, with the light reflected, they are moved through the Aether always westward by spirals, as described. Nor are they ever truly retrograde, nor stationary; rather, they appear to stand still because at the

same moment they revolve, together with the same fixed star, about the same Meridian, and recede again more swiftly, and toward the rising — when they slowly revolve to the same point. Finally, the fixed stars, set in a solid heaven, move daily, or by two motions imperceptible to us: in proportion to their distance, and by an alternating repetition, with greater or lesser velocity, now westward, now eastward, [the motion] perceived as oblique, owing to the latitude retained with respect to the Ecliptic and reckoned by us. Or, by a single real spiral motion, they are moved by Intelligences always westward, of their own accord, so as to represent to us an apparent oblique motion eastward. Moreover, the distance of the fixed stars from the Earth, though it appear to us to be finite, nonetheless differs, in that the lunar distance is certainly within the nearest limits to the Earth, so that observations, when carefully carried out, evidently exclude the error that would otherwise creep into the terrestrial semidiameters. The solar distance is nearly certain to within fewer terrestrial semidiameters — never indeed fewer than 6430, nor more than 30,000 — so far as it can be assumed. The intervals of the other planets, indeed, with respect to the Sun, are very nearly certain from their apparent motions about the Sun itself, and from the aphelia [needed] for representing them; but with respect to the Earth they have a latitude such that they depend upon the certainties of the solar and terrestrial distances and intervals. The distance of the fixed stars, finally, rests only on conjecture, probable in part, in part more than probable; from this [arise] probabilities to be measured, though not certain, nor demonstrable. It remains, then, that in treating of the fixed stars, the planets, and the Earth, we should indicate how far Astronomy and Cosmography have been advanced in each.

ARTICULUS V. [ARTICULUS V.]

On the Fixed Stars [De Stellis Fixis.]

1. As the sight of new stars [novae] was for Hipparchus the occasion for numbering them for posterity, and for resolving once and for all the [number of the] stars and of the heavens — and as Pliny relates (Bk. 2, ch. 26), so the new star of the year 1572 stirred...

stirred [Tycho] to rectify the fixed stars by the thousand, and to restore them to one place [in the catalogue] as nearly as possible — by the new method of the observation of Venus together with the fixed stars, so that Hipparchus ought to be no less indebted to posterity than [Tycho was]. We must indeed correct these by a not inconsiderable amount, not only because of the excessive parallax of the Sun and of Venus employed by Tycho. Kepler too confesses that he founded his

Ephemerides upon this; but [he holds] that the evening observations of Venus are to be compensated by the morning ones, and by our own observations, with a larger instrument; and the Right Ascensions and Declinations of very many of the fixed stars are corrected — as will be shown in our Book 4 in their proper places.

2. And since, in the Tychonic Catalog of Right Ascensions, the star in the shoulder of the Lesser Bear was lacking — that star of the second magnitude which shines in the second [magnitude] of honor [recte: i.e. is reckoned among the second-magnitude stars], once called the Pole Star [Stella Polaris] and the Cynosure — we ourselves, by the latitude of that star and by its Right Ascension for the years 1600 and 1700, by a trigonometric calculation, found its longitude to be decreasing, which is new and unheard-of, and which we have set out as the cause for astronomers. We perceived this not only in that star but in all the others whose latitude is greater than the radius of the polar [circle of] circular motion: namely, that the Right Ascension decreases as the longitude increases, according to the theorem set forth in *Almagestum Novum* Bk. 6, ch. 19, Problem 11 — to which we refer the reader [*Almagestum Novum* Bk. 4, ch. 1].
3. Furthermore, the latitude of the fixed stars — not only their Right Ascension and Declination — we corrected and emended; yet we also taught, in *Almagestum Novum* Bk. 6, ch. 15, that the latitude is immutable, especially as regards the obliquity of the Ecliptic, as we say below. As for the motion of longitude, their apocatastasis [ἀποκατάστασις, apokatastasis, "restoration" — the return to the starting point], and the Sidereal Year, [these are] not from one comparison or another, as Tycho did, but from 72 collations, [whence] we shall more certainly determine [*Almagestum Novum* Bk. 4, ch. 19]; and meanwhile [we judge] the Year to be neither greater than 49' nor less than 49" — within which limits the more probable [value] lies, as we teach in Bk. 4, ch. 19.
4. Finally, as to the number and apparent magnitude of the fixed stars, we know what and how much the telescope has revealed to astronomers. For by it we learned that the Milky Way is, as it were, a dense aggregation of innumerable little stars heaped together; and thus the nebulous [stars] coalesce out of several obscure little stars, dim in their light — for in the nebula of Praesepe there are 36, and in the nebula of Orion 21; and within two degrees Galileo detected more than 500 stars in Orion, 80 in the Pleiades; Antonius Maria de Rheita [Anton Maria Schyrleus de Rheita] first

counted 1000, then 2500 new stars in the single [region of] Orion; and our own Father Giovanni Battista Zupi [Giovanni Battista Zupi] noted them in the Pleiades, the Hyades, and the sword of Orion. Recently too the Christian Christiaan Huygens [Christiaan Huygens] saw the middle one in the sword of Orion divided into 12 stars, by a large and powerful telescope. Hence the number of the wandering [stars] is not infinite — as Giordano Bruno [Giordano Bruno] contended in his book *De Infinito*, and the innumerable [stars], saying there are as many worlds as stars, and these infinite — and Kepler in his book *De Stella Nova*, ch. 21, refutes [this], wonderingly: that there be innumerable men to us, by the powers of Divine Counsel and wisdom — that they should congregate and number them, [though] David, who is present, *numbers the multitude of the stars, and calls them all by their names*. For Astronomy has gained, at every price, that by its aid the eclipses, or the proximity of the fixed stars to the planets, can be known, [and] the places of the planets in the heavens far more evidently noted than by any other instrument.

ARTICULUS VI. [ARTICULUS VI.]

On the Lesser Planets, in General and in Particular [De Planetis Minoribus in communi, & in particulari.]

1. **Once upon a time the Egyptians, and with them [Martianus] Capella [Martianus Capella], Macrobius, and Bede [Bede], observed that Mercury and Venus always revolve about the Sun; that the [orbital] periphery of Venus [Aptragina[?]] — suspected source corruption] always [lies] above Mercury; that Mercury always runs its course below Venus, against the Pythagoreans and Ptolemaics, who placed Venus below the Sun, and below Mercury; against Plato and Porphyry, who [placed] Mercury above the Sun; against those who placed Venus above. Copernicus first placed all five lesser planets about the Sun, so that they sometimes pass above, sometimes below the Sun — Mercury sometimes above, sometimes below the Sun; the rest go about the Sun, so that Venus, within these very orbits of the World, is moved; Tycho, with the Earth retained [as center], the rest of the planets about the Sun, asserts that they too are moved by their own motion from the mean motion of the Sun, as Ptolemy, Copernicus, and Alphonsus [held], but truly moved [recte: see anomaly c — compressed]; for the line of apsides passes through the center of the Sun. Moreover, from the System of both Copernicus and Tycho, it follows — if the planets receive their light from the Sun — that Venus and Mercury, as if at the apogee of the Sun's conjunction, appear full of light in respect of our eye, but in perigee indeed**

cast off all light, unless a little [latitude] permitted them [to be seen]; in other aspects, with respect to the Sun, they [appear] in proportion. So that the Moon, the Sun, by these little globes of light [recte: see anomaly d], when naked, appears nearly round [in] their aspect, [their] disks always seen as round. But what the naked eye [judges], the sharp [eyes], aided by the telescope confirmed, judged to be true through the long-glass [longobcope] — as we shall soon say of these matters in their place.

2. There was then removed, by Copernicus and Tycho, that old farrago of solid orbs and Epicycles, Eccentrics, [and the rest]; likewise the Eccentrics, retained, [were dropped] in the liquid Aether, where the peripheries of the planets designate the eccentric [paths], free of epicycles. Kepler simplified the elliptical peripheries [and] eccentric circles, which most of the more apt teachers of astronomy acknowledge against [epicyclic] motions; and so Kepler left it imperfect; Bullialdus [Ismaël Bullialdus], Seth Ward [Seth Ward], and Comes Pagani [the Comte de Pagan] attempted to reduce it to the exact demonstration assumed from the nature of the Ellipse — though they did not succeed. Moreover, the inequality which is discerned in the motion of these [planets], the real [inequality] — and its proper cause, that the orbit be moved truly but unequally — Kepler and the rest of his followers refused to elucidate; Longomontanus [denied] it, refusing to admit it into Astronomy as an axiom, since it follows from the ancient principles of Copernicus and Tycho. Both these and Longomontanus took for an axiom that the heavenly bodies are moved equally by themselves, in respect of the [point] about which they are seen to be moved unequally, [a point] which lies outside the center of their own orbit. But meanwhile Kepler and his followers, moving the Earth about its own center, were not solicitous about the motion of the Prime Movable, and turned the motion of the planets eastward.
3. We, having demonstrated the immobility of the Earth, [hold] that the motion of the planets is really unequal, though it appears to us so unequally — that, though unequal, however great it appears to us, [it is] always westward, by spirals so carried out [recte: see anomaly e], that yet it pleases God, in [view of] our weakness, to commend it; and they seem to describe an elliptical periphery about a cone, as I have already insinuated above, and that, free of librations, which Kepler too upheld by a greater or lesser breadth of the spiral, we do not doubt that all that variety...

variety comes about [in the motion], which appears in Declination and in Latitude. Now we shall set forth in particular what our age's Astronomy has, by the benefit of the Telescope, detected in these planets, [and] we shall run through them.

SATURN is sometimes solitary and round, sometimes three-bodied [tricorporeus] — when seen with imperfect telescopes — and sometimes seen variously oval-shaped [ellipticatus]: by Galileo, Scheiner, Blancanus [Giuseppe Biancani], Gassendi, Hevelius [Johannes Hevelius], Rheita, Schiraleus [recte: Schyrleus, i.e. de Rheita], Fontana [Francesco Fontana], the Fathers of the Society [Jesuits] Zupi, Zucchi [Niccolò Zucchi], and Bartoli, Eustachio de Divinis [Eustachio Divini], and others of the present day. We too, and many others, have shown these figures in [the schema] subjoined — as also Christiaan Huygens [showed them] by a larger Telescope. He asserts that he observed in this Saturnian system a certain little planet of about 16 days, [moving] about Saturn near the days [of its] circuit, which he calls accordingly the Moon of Saturn [i.e. the satellite Titan]. He judges, moreover, the phenomena of Saturn as regards the handles [ansae] to be safe — that is, that they tarry within the bright ring, which always accompanies Saturn, and [that they are] otherwise [than what] others have tried to explain. We, however, show all things more clearly than they, if Saturn be placed near the elliptical [figure] continued to itself, by that alternation of libration which they expound likewise. The line indeed through the handles, or the little ring, [we hold] always to preserve a perpetual parallelism with the plane of the Equator — as we confirmed by evident observations, with Father Grimaldi [Francesco Maria Grimaldi], in the *Almagestum Novum*; which Galileo suspected, Gassendi and Bullialdus asserted, Hevelius denied, [and] Huygens [held] to be by no means exact about the solstitial points — a thing which we, and afterwards Huygens, thought [to lie] in the very body of Saturn near the handles, not improbable in respect of the aforesaid little ring.

5. **JUPITER**, by [the testimony of] the most penetrating Italo-Belgian [observers], from Galileo in Italy, at the same time [that] Simon Marius [Simon Marius] in Franconia observed [it], [is found to have] four little planets revolving about Jupiter within a few days; which afterwards Scheiner, Blancanus, Hevelius, [and] Rheita very often saw, but especially Father D. Vincentio Reinerio [Vincenzo Renieri], a disciple of Galileo, who edited his *Ephemerides* of their [motions]; we, too, hope [for the like]; and the absolute [reckoning] of Father Giovanni Battista Zupi [touches on] the celestial secret. The careful observer in these noble matters [proceeds]: but from the frequent eclipses of the little planets [satellites] falling into the

shadow of the Jovian body, we have inferred two things, namely, that we should know that Jupiter, and that the satellites about it receive their light from the Sun — whence the same of Saturn, as is conjectured of Mars, the other [satellites], if [they are seen] at least in Mars, [and] that the agitations of Jupiter could be observed in diverse places on the Earth, [and from these] the distance of Meridians could be gathered. But whether two, or perhaps four, Satellites are to be had — or others, five, [is debated]; as Rheita contends, who is refuted in the *Almagestum Novum* Bk. 5, ch. 3.

The bands [fasciae] on the disk of Jupiter — now one, now two, now three, of diverse situation, yet [of] fixed [place] — were seen not once by the Fathers of the Society, our own Giovanni Battista Zupi, Niccolò Zucchi, and Daniel Bartoli, [and by] Francesco Fontana [and] Huygens — and by us, with Father Grimaldi — so evidently that they cannot be denied with serene brow. Whether they arise from a diverse situation, or from a libration about its own center, is believed [to be debated]. The most illustrious Marchese Cornelio Malvasia [Cornelio Malvasia] saw [them], and that not once.

6. **MARS**, by the gibbous figure seen between the quadratures, [as observed] by Francesco Fontana [and] Huygens, [is found] to receive the indications of its light from the Sun. A spot [macula], indeed, sometimes single, [seen] now broader, now narrower, [is found], though there is none the same in [the observations] — sometimes by Father Niccolò Zucchi; sometimes [the] double [spot] seen at Naples by the Fathers Sirsalus [Daniello Sersale] and Daniel Bartoli, [providing] indications of the rotation about its own center, or [of] the vertiginous [spin] of its body, not slight. But especially that new [discovery], worthy of the knowledge of Kepler, who showed it: namely, having attained [the truth] that Mars in perigee becomes far nearer to the Earth than the Sun.
7. **VENUS**, [as observed] by Galileo, Scheiner, Gassendi, Hevelius, Fontana, [and] Huygens, [and by] Father Grimaldi [and] us, is most often seen by the optical Tube now gibbous, now dichotomous, sometimes cornicular [horned] or sickle-shaped — as we show most fully in [the] schemata in Bk. 7 of the *Almagestum Novum*, Sect. 1, ch. 2. By an evident argument, [it is shown to behave] not otherwise than the Moon illuminated by the Sun, and so [it appears] in those circumlustrations [phases]; whence it is more evidently established that, near the perigee, in conjunction with the Sun, by reason of [its] great latitude...

it was seen by Tycho and by us with horns turned downward, and illuminated by the convexity upward toward the Sun — as is to be seen in the schema of the same chapter, p. 485.

8. **MERCURY** also, [seen] not rarely by [the] Rheinisch [observer], Father Grimaldi, and ourselves, [is found] deficient, and appeared corniculate [horned], as we predicted [in] *Almagestum Novum* Bk. 7, Sect. 1, ch. 2; and Gassendi [observed] Mercury [passing] beneath the Sun, [which] you will be persuaded of [recte: i.e. Gassendi's 1631 transit of Mercury]; and the astronomers, by this very Heliocyclic [observation], and about the Sun, [hold] that they circumvolve [revolve], [and] change nothing in the [order]. [recte: see anomaly f — compressed.]
9. The whirling [vertigo] of the planets — of which the indications [are seen] in Saturn, Jupiter [Joue], and Mars, as we touched on above — is from the Rheinisch [observer], [defined] by certain conjectures and by certain analogies, [within a span] of days, hours. About which matter, when I was discussing it face to face — when I was at Bologna — I heard from the very learned [observers], that by the binocular Telescope such periods had been observed, though as yet imperfectly. Let the faith of [the matter rest] with its Authors.

ARTICULUS VII. [ARTICULUS VII.]

On the Sun [De Sole.]

1. The elliptical figure of the rising and setting Sun could not have been seen but once by antiquity [recte: i.e. was unknown to antiquity]; nor [did anyone] before Scheiner study to investigate the cause — [the] same [Scheiner who] first [observed] the spots [maculae] on the Sun, as Galileo [did]; he convinces [us] in his *Rosa Ursina* that he not only noted the spots with the long-glass [telescope], but afterward, by so many accurate observations, prosecuted [the inquiry] — as René Descartes [René Descartes] testifies, who, regarding the remaining hope, predicted that something better would be furnished in this part: namely, whether [the spots] are moved by the motion of the solar whirling [vertigo], whether by a single motion within about 28 days, as he [Scheiner thought] (Bk. 3 of the *Almagestum Novum*, ch. 4); but certainly the 24-hour rotation of the Sun introduced by Kepler is gratuitous [gratis], as we introduced [in Bk.] 24.
2. We, [holding] the aforementioned motion to be uncertain in its disputation, having dismissed [it], with all our forces, together with Father Grimaldi,

applied ourselves [to determine] its motion in longitude, and in latitude as regards the declination, and the apparent Diameter, and finally the distance, and the parallax — a thing more certain, [and] more accurately, than was done before — that we might attain the inquiry. And we determined the motion in longitude indeed not from observations of two pairs of years, as Tycho [did], but from the interval of 1812 years, [from] selected Hipparchan [observations], and the other [observations] of our equinox, by the ingenuity of S. Petronij [the Gnomon of San Petronio], the Gnomon of Bologna being made — [we determined] the Eccentricity, the equation [aequatio] necessary [for] the Sun, and its Diameter — most subtly [and] most accurately — confuting those who, by a much larger diameter [drawn] from the Cysat [Johann Baptist Cysat] and Scheiner observations asserted [it], detected [the error], and [the] cause of the error [committed] by them, through their ignorance, [or] from a certain mode of propagation of the light of the Sun, as we shall teach below in its proper place. But we also confuted those who, against Kepler, denied [recte: this passage is compressed] in this matter the diameter of the apertures [of the foramen], [and] inferred the diameter of the species [image] of the Sun [to be other than] what it truly is — as I shall expound more fully in the Appendix to Bk. 1.

3. The maximum Declination of the Sun [we determine] to be $23^{\circ}30'20''$ [printed *gr. 23. 30'. 20'*. — second prime where a seconds mark is intended], [to have been] perpetual, and not changed within memory, as the observations of the ancients teach us — so that the place left for doubt seems [to be] inconsiderable. We finally [determine] the distance, and the parallax of the Sun, [to be] not only far smaller than the Tychonic [value], as we show, but [to lie] within limits not to be despised for certainty, by [the methods of] the Lunar Dichotomies, and by a new method [drawn] from the Refractions, [as] we conclude.

Prolegomena — Articuli VIII–XII; Liber Primus, Caput I

ARTICULUS VIII. — On the Moon and Eclipses

1. We owe a real debt of gratitude to [Tycho Brahe], for it is from him that we learned that the Moon's maximum latitude at the quadratures is about a third of a degree greater than at the syzygies; that the motion of the nodes

themselves is not uniform; and that the Moon undergoes — besides the two inequalities — a certain third variation around the octants. We have nonetheless determined the Moon's motion in longitude more certainly in several respects: not, indeed, by deriving it from a greater number of lunar eclipses, but by taking great pains over the disagreement among the Tables in their comparison with observations, and over the lapses into which other otherwise distinguished men have fallen — as will be evident in Book I.

As for solar eclipses, we have measured the Sun's diameter against the Moon's diameter, already known from another source — not only in the total solar eclipses that [Tycho Brahe] had denied, but also in annular ones, and that without any violence to the data, such as those eclipses demand.

2. Furthermore, the lunar spots — which some call *Selenographia* — were studied with great zeal and assiduity by [Langren], Sirsalis [Giovanni Battista Zupi / Sirsalis?][?], [Hevelius], [Eustachio Divini?][?], and Rheita [Anton Maria Schyrleus de Rheita]. Father Francesco Maria [Grimaldi], an emulator of these men, equipped with a telescope, depicted them on the largest scale — or at least on no smaller scale than the one in which we have set them out in Volume 9 [*Almagestum Novum*], chapter 7, with a small figure. He had, however, often examined them with his own instruments and in their proper places, and committed them most excellently to a figure; and Marchese Cornelio Malvasia did the same. But as for the causes of this phenomenon, we have investigated them rather more diligently in chapter 7. And as for the matter of the Moon's libration — first noticed by [Galileo], and afterwards confirmed by the kind offices of our friends [Michele Langren] and [Hevelius] — we too have contemplated it many times together with Father [Grimaldi], insofar as it was necessary for us to know the limits and nodes of that libration. Some of these, though, differ from [Hevelius]; this will become clear, as it must be stated, in Book III, chapter 3.
3. It is remarkable what subtlety and industry more recent astronomers have already brought, after [Kepler]'s admonitions, to the observing of eclipses, surpassing all their predecessors by a long interval — chiefly with the help of the telescope, as may be seen in the observations of [Gassendi], [Hevelius], Lansberg [Philip van Lansberge], Eichstad [Lorenz Eichstadt], Bullialdus [Ismaël Boulliau], and many others. Indeed, with sharper insight than they did, we have detected the difference between the terrestrial

penumbra and the spurious beginning, middle, and end of an eclipse; and we have shown the legitimate beginning and end; and I have set out the cause — most shrewdly discovered by [Kepler] — why the Moon, though sometimes, but rarely, completely extinguished in the middle of a total eclipse, in other cases and rather more often does not wholly fail in the middle but appears reddish, or coppery, or sometimes of a leaden hue. This is because she is then illuminated by the Sun's rays refracted toward her, since she does not fall within the true shadow-cone of the Earth — a doctrine we have here recalled and asserted, against the contrary sophisms. We likewise made an accurate observation, on the admonition of our most dear friend [Vendelinus, i.e. Godefroy Wendelin], of those things that are of prime importance concerning eclipses, and added others in their proper place. And we have laid out most fully the causes of the discrepancy among observers of the same eclipse. Finally, we have enriched astronomy itself — and chronology along with it, more than anyone else — with our knowledge of eclipses, since we have helped our many friends in foreign parts who afterward shared with us no few useful observations. And throughout Book V of the *Almagestum Novum* we have untangled new questions, and several problems bearing on eclipses, hitherto open to dispute.

ARTICULUS IX. — On Comets and New Stars

1. There was a great controversy between the Tychonics on the one hand and the Claramontians [followers of Scipione Chiaramonti] on the other, as to whether comets and new stars were observed by [Tycho Brahe] in his day above the Moon — as Tycho and his school maintained — or whether, as the Claramontians, biting like Peripatetics, contended, they were below the Moon, and as Chiaramonti held, even retained below the Earth. We, for the sake not only of astronomers but also of natural philosophers, have here undertaken this labor too — though not without great toil — in Book VIII of the *Almagestum Novum*, perhaps at excessive length. We have examined the observations, and (with incredible labor in the reckoning) carried them through; and on this occasion we have thought out new theorems and problems, and settled the controversies by literal conclusions — though we do not yet repent of the labor. But as for the new star that guided the Magi, the cradle-companion of the infant Christ, we have added a little something against certain men's somewhat rash assertions, for the sake of those who delight in sacred letters; this may be read at the end of the said Book VIII.

ARTICULUS X. — On Refractions, the Height of the Refractive Air, and the Twilights

1. Since [Tycho Brahe] was the first to consider refractions — which had been pointed out and measured by some of his predecessors — and to publish them by number, all later astronomers acquiesced in the Refraction Tables issued by him; and [Kepler] himself, notwithstanding that correction of his which he had set in motion in the *Optics* and *Dioptrics* by an increment of secants, brought this subject to its perfection in *Almagestum Novum* Book X, throughout section 6, in Problem 57. And the refractions assumed by [Tycho Brahe] we have corrected three times over, in the Table of the same section, after first treating them at Problem 27, and have accommodated them to a triple refraction of the year. Afterwards, examining the matter again more deeply in [Tycho Brahe]'s own observations made on the day of the solstice, and along with me Father [Alberto Albertini?][?] — by Currus, transmitted from Tycho's own autograph — we detected that both Tycho himself and [Kepler] had erred in then confounding the optical refraction with the astronomical; for we shall show, in Book I chapter 14, and in many other places, and most worthily of being known concerning refractions, by what causes the astronomical refractions of a star nearer the horizon prove to be smaller when they ought to be larger.

But as to the height of the refractive air, the reader will learn with how much labor we have investigated it, in *Almagestum Novum* Book X, section 6, at Problem 43, and from 43 to 57; where, disproving even [Kepler], we have constrained that height to within two Italian miles. And from this, moreover, the natural philosopher too will be able to draw no small lessons for his own doctrine concerning the height of the air, if he combines what is handed down by us in Book I, *Almagestum Novum* chapters 30 and 31, and Book II chapters 1 and 19, with the most exquisite matter in Book VIII, section 1, chapter 14, on the twilights. From the haze of the twilights both the sublimity and the gleaming and clouds may be gathered — that is to say, from the threefold use of refraction in determining height — and from the differing depth of the Sun below the horizon when it is at one distance from it in the evening, and at another in the morning twilight; both in winter, when it is in the vernal[?] sign, and in summer, as well from the observations of others as from our own.

ARTICULUS XI. — On the Height of Mountains, the Levels of Rivers, the Distance of Vision, and the Tide and Depth of the Sea

1. You will ask, you say, what these matters have to do with the astronomer. The answer is that through them certain astronomical questions are better resolved — both those bearing on parallaxes and those on refraction, and those bearing on the exclusion of any motion of the Earth. To detect these things, then, many errors had to be measured out in the height of mountains — which we did in *Almagestum Novum* Book I, chapters 11 and 10, section 3, at Problem 31, and section 4 at Problem 50, and more fully in *Geographia Reformata* Book VI. Errors likewise had to be eliminated in the breadth of the physical horizon, that is, the distance up to which our vision extends above the Earth or the Sea; this we did in *Almagestum Novum* chapter 10, Book 10, section 4, at Problem 39, and these matters have since been more fully explained in *Geographia Reformata* Book VI. The places had partly to be examined as to the levelling of rivers, which we touched on in *Almagestum Novum* Book II, chapter 15. And concerning the Tide of the Sea, things are explained as found in Book IX, chapter 14, where, lest we should rake over again the conjectures of Galenists[?][likely "Galilæorum" — the Galileans], who derive the true cause of the marine tide from the motion of the Earth, whether diurnal or annual; on which occasion, when we have collected from every quarter the histories of the tide of the Sea, and the things to be known about its hourly flux and reflux, we have laid down rules, and against the Galileans we have brought forward our own opinion, having enumerated the causes of these motions — apart from the opinion of Reita[?]/Rheita, whose book was then lacking to us, which we afterward examined in *Geographia Reformata* Book X.

ARTICULUS XII. — On the Magnitude and Immobility of the Terraqueous Globe; on Heavy and Light Bodies; on the Acceleration in their Descent and Ascent; and finally on the Vibrations of the Pendulum and its Use in the Measure of Time

We have first set out the magnitude of the terraqueous globe, and treated it in *Almagestum Novum* Book VII, chapter 8, section 4, at Problem 2; then, renewing the observation, expounded it publicly in the Theses, and at length, with other

observations, attained it (by incredible labor and industry, with God's most evident help) together with Father Francesco Maria [Grimaldi], and demonstrated it in *Geographia Reformata* Book V — and that not by a forced reckoning but, as is necessary, by a measuring-out of the intervals, and by the method of others' correction, reconciling with some of the most celebrated opinions on this magnitude. As for its immobility, as we indicated above, we have asserted it both from the real acceleration of heavy bodies as they naturally descend, and from the proportion of the velocity, evidently deduced; and we shall say more in an Appendix to Book I. Concerning that acceleration, and other matters with it, the natural philosopher must read — many things by experiment not to be neglected — which we handed down in *Almagestum Novum* Book II, chapters 21 and following, and Book IX, section 4, chapter 16. Finally, the remarkable properties of the vibration of the pendulum, and its use first applied by us, and reduced to a certain measure of the motion of the primum mobile, see in *Almagestum Novum* Book II, chapter 20.

Thus far, perhaps not without some little offense to the reader, we have dwelt upon a matter often impressed — namely, what we have done to advance astronomy and geography. But be it far from us to boast: whatever good we have attained in this kind, we acknowledge that we received it, of God's bounty, from God the Best and Greatest, and we refer it to His Glory; for it was at the express command of our superiors that we first, at the prompting of Heaven, set ourselves to these studies. Nor indeed do I much linger over the man who said that the two earlier Tomes of the *Almagestum Novum* contain, indeed, an Astronomical Library and a collection of no common erudition, but nonetheless almost nothing newly contributed by us — when we reckon up in those same books nearly 95 new questions with their solutions, 88 theorems, the correction of errors admitted by others, and on top of that more than 320 refutations of the fallacies of arguments; besides many new Tables, or little tables newly constructed for the erudition of astronomy and geography. May GOD bless our labors — to whom be Honor and Glory forever.

BOOK ONE — IN WHICH ARE THE OBSERVATIONS OF THE SUN, AND THE FOUNDATIONS OF THE SOLAR HYPOTHESES

[Display title block] **LIBER PRIMUS, IN QUO SUNT SOLIS OBSERVATIONES, AC
Fundamenta Hypotheseon Solarium.**

CAPUT I. — On the Methods of Observing the Equinoxes, Solstices, and the Maximum Declination of the Sun, with the Least Possible Fallacy

This is not the place to treat these matters at length, since they belong to the part of astronomy concerned with instruments [Organicam Astronomiae partem], for which we have furnished an entire Volume. But in order that the observations of the Sun, which must be adduced, may be the better understood, and distinguished from the cruder ones — it must be recounted by what methods more refined observations have been made, by which the equinoxes, the solstices, and the remaining moments of the Sun's entry into the signs of the Zodiac are observed or observable; and the fallacies that lurk in them must be pointed out. We shall begin with the equinoxes, as being the most celebrated cardinal points of the whole year.

On the Equinoxes

1. [Margin: First method. Shadow of the gnomon.] First, the day of the equinox can be explored by observations of the line which the apex of the gnomon's shadow describes in the horizontal plane, from the rising of the Sun all the way to its setting. For if that line is straight, it will be an indication that the equinox has occurred on that day. But the hour at which the Sun reaches the equator cannot be discerned by this means.
2. [Margin: Reckoning of the half-day's time.] Second, if the time is reckoned from the rising of the Sun up to the Meridian, or rather, from the Meridian, it will be the sixth equatorial hour, or hour 6 with some minutes; the indication will be that the day is equinoctial; or, from the moment of the Meridian, up to the setting of the Sun, the physical reckoning will tell off the time of the Sun's setting at hour 6 with 4 minutes. This is because the horizontal refraction makes the Sun, optically, appear about 4 minutes more quickly in the horizon than it really is in the morning; so that it is seen later, in the evening, to set — at least in the Torrid and Temperate zones. But lest even this should give the hour of the Sun's entry into the equator — and much less, if it is not corrected by perpendicular oscillations [pendulum swings], of which I spoke in *Almagestum Novum* Book I, chapter 13. There is also the mercurial clepsydra [water-clock], of which [Tycho Brahe] writes in Tome 1 of his *Progymnasmata*, chapter 2, and Dudley [Robert Dudley] in *Arcani del Mare* [*De Arcanis Maris*] Book I,

chapter 4. But these are more fallacious; whoever uses such horologes, whether of water, or of sand, or of the sundial [horizon], beware.

3. [Margin: Eastern point of the true rising is observed.] Third, if the Meridian line is first exactly marked out in the physical horizontal plane, and one cuts it at right angles by another straight line, and on this line erects two very fine needles upright between the distant points — or something else that may designate a vertical plane, namely our Filar Triangle [Triangulum Filare], of which in *Almagestum Novum* Book V, chapter 15: for if the center of the eastern–western rising falls in the said line, drawn out by the imagination, or in the said plane produced, it will be an indication of the equinoctial day, and of the true rising or setting. But here too lurks a fallacy of horizontal refractions, which, both because of the horizontal refractions and because the figure of the Sun is so widened into an ellipse [Ellipticè], that whether you collimate to the center of the very rising, or whether the Sun set in the equator, they nonetheless represent it short of the true place, or beyond it; both from the horizontal parallax, and because the physical plane of the horizon differs from the true.
4. [Margin: Equinoctial shadow of the gnomon.] Fourth, the ancients observed the equinoctial by the equinoctial shadow of the gnomon — that is, if the gnomon, or stylus in the *scaphion* [hemispherical concave sundial], were perpendicularly erected, the meridian shadow projected the same; the height of the equator was demanded as foreknown. But because in *scaphia* the stylus was rather short, and hence the boundary of the shadow was liable to a notable error in arguing the Sun's altitude — and likewise the altitudes were inconspicuous, since they were measured by the shadow — therefore they were accustomed to erect obelisks, and gnomons many feet long, in measuring the conspicuous altitudes. Such was the obelisk of $116\frac{3}{4}$ feet in the Campus Martius, of which Pliny writes Book 36, chapter 10[recte: Pliny *Natural History* 36.15]; and a Byzantine gnomon, whose meridian shadow, observed on the equinoctial days, was found to bear the same ratio to the gnomon, as 111 to 120; as is evident from Strabo Book 2, chapter 5. And about other gnomons of this kind, from Pliny Book 2, chapter 72, and Vitruvius Book 9, chapter 8.

as Cleomedes does in his first book, and Ptolemy [Ptolemy] in his second (*Almagest* II), from chapter 2 to chapter 6, where he admits that this method is not very accurate. Moreover, once the altitude of the gnomon and the perpendicular line in the plane of the horizon have been given, two right

triangles arise in the same plane of the equinoctial, similar in species: in these the gnomon stands as the radius of the angle, or as the whole sine, and the shadow as the tangent of the said angle; and from the shadow subtending the gnomon, the distance of the Sun's uppermost limb from the zenith in the heavens is determined. Suppose, then, the gnomon and its shadow given: the whole sine will be to the shadow as one quantity to another, and the tangent of the said angle will result. If to this you add the apparent semidiameter of the Sun, and then subtract the corresponding parallax, you will have the true distance of the Sun's center from the zenith in the meridian. This, when subtracted from the true altitude of the pole, reveals the Sun to be on the meridian and at the equator. But if the result departs from this by some amount, then by however many hours the equinox falls short of, or after, the moment of noon — by just so many hours is the equinox distant from the moment of noon. Accordingly, in this business one must take care how far the error may run, whether in the altitude of the pole, or in the semidiameter of the Sun, or in refraction, or in parallax, or in the observation itself, or in the measurement of the shadow, or in all of these, or in several of these elements.

Concerning the use of gnomons by which the Sun's uppermost limb is observed together with the shadow of the solar limb, we shall say more at number 8, chapter 2 [chapter II].

§5. **A fifth solemn method** used by astronomers, especially the Alexandrians, was to observe the equinoxes by means of equatorial armillary rings, such as we described in *Almagestum Novum* III, new chapter 14, number 7. The equatorial armilla consists of two rings, or large quadrilateral-surfaced annuli, which intersect each other at right angles, dividing one another in two, of which one is set in the plane of the meridian circle, and the other precisely at right angles to the first, at as great a distance of the equator from the zenith and from the pole of the place as the equator is distant from the zenith, so that the Sun on the meridian falls upon it. When the Sun has reached the equator, the meridian armilla shows the Sun to be on the meridian and at the equator. But by however many minutes it should exceed this, or fall short, by just so many hours is the equinox distant from the moment of noon. Hence, by however many minutes the error has been committed in this business — whether in the altitude of the pole, or in the semidiameter of the Sun, or in refraction, or in parallax, or in the observation itself — the equatorial armilla represents the equinox. If, however, the armilla illuminates either cavity equally on both sides, the equinox is occurring at that very moment on the meridian; but if not, refraction stands in the way of this precise observation. If the lower cavity is illuminated more from

the northern part than from the southern, it is a sign that the vernal equinox has occurred, and the pole's path is for the northern observers: for to the southern observers all things happen in the opposite way, in alternation, as we shall presently say. Furthermore, when sometimes the cavity of the equatorial armilla appears illuminated in some way on the western part, the equinox will then occur after noon (if indeed on a clear day, since the said cavity is never wholly illuminated on both sides); but if the eastern part, it will occur after noon. Since on that serene day the equinox falls within the day, not by night — provided only that the region of illuminations be changed: for if the Sun illuminated the northern part of the cavity yesterday and illuminates the southern today, know that the autumnal equinox has occurred; by night, that the intervening northern equinox has occurred. On the contrary, if it illuminated the southern cavity yesterday and the northern today, in the morning, know that the northern equinox has occurred. Against this, if the Sun illuminated the southern cavity yesterday and illuminates the northern today in the morning, recognize that the northern equinox has occurred — at least insofar as physical appearances are concerned, even if it does not always answer to astronomical truth: for refraction, raising the image of the Sun above the horizon, can make the equinox to be perceived, although it lies in the very equator, before or after the equator, and on the contrary, in the southern signs, or, beyond, in the southern signs, it may appear to be in the equator. And this is indeed the cause why, in the same way that the cavity is equally illuminated on both sides once near sunrise, or once near sunset, by refraction, refraction makes the autumnal equinox earlier, and delays the vernal equinox, since refraction delays the autumnal and hastens the vernal: by which reasoning these fallacies correct themselves, and the equinox, when refraction ceases, departs by an equal amount toward the true [equator], as Bullialdus [Ismaël Boulliau] taught in his *Astronomia Philolaica* II, chapter 2, and as **we ourselves** noted in *Almagestum Novum* III, new chapter 14, number 9; but to no avail.

[Margin: Hipparchus, Ptolemy, and their fallacy in observation.]

But it is astonishing both that Hipparchus [Hipparchus], and Ptolemy after him, who attest in their own behalf (*Almagest* III), should ascribe a defect to the equatorial armilla, which Ptolemy thought (or believed) had collapsed from its original setting, the legitimate position having been changed: a contrary effect produced the parallax-fallacy, namely the optically autumnal one, and delayed the vernal equinox, since refraction delays the autumnal and hastens the vernal — because by this reasoning these fallacies correct themselves; and the equinox

departs by an equal amount toward the true [position], as we taught more fully in *Almagestum Novum* III, new chapter 14, number 9.

But we do not need this much: since we are able to make use of observations, by other methods in which the fallacy of refractions is not implicated, not only the more recent ones, but also the ancient ones. When we must use the observations of Hipparchus or of Ptolemy, by which the armilla in the meridian, or as nearly as it appeared on both sides, was illuminated equally — then at Alexandria the Sun was high, almost 60° [degrees], and yet beyond all sensible peril of refraction; indeed, by our reckoning the parallaxes, which do not exceed the second scruple [arcsecond], are 6. The remaining equinox, of which Hipparchus attests according to Ptolemy, was not safe from an error of nearly 6 hours: nor are they suitable for that subtlety which the more recent age demands; especially since here an error of nearly 12 hours could be committed, as Longomontanus [Longomontanus] contends in *Astronomia Danica* I, *Theoricarum* chapter 1. Kepler [Kepler] adds in *Astronomia [Nova] optica*, page 146, that the equinox observed by Tycho [Tycho Brahe] by means of the armillas, in which the same day might seem to be an equinox, was made false by the force of refraction; and therefore the equinox is to be sought by a more certain method.

§6. **Sixthly**, therefore, with very large instruments rightly divided, set up, and adjusted — namely, as you will best prepare now according to the Gregorian Calendar, from March 19 to March 24, and from September 19 to September 24 — observe the meridian altitude of the Sun's center, and reduce it, when it is apparent, to the true value, by the corresponding adjustment of parallax and subtraction of refraction. For if the altitudes of the equator are made equal, the equinox is made known. But by however many minutes, or scruples [arcseconds], the first altitudes of the equator differ — by just so many hours, before or after noon, has the equinox occurred. And indeed the vernal equinox precedes the meridian among the northern observers, if the following [meridian] altitude of the Sun should exceed the meridian altitude of the equator; but if indeed this should exceed that, the equinox will occur after noon. Conversely, the autumnal equinox precedes the meridian, if the meridian altitude of the Sun should exceed the meridian altitude of the equator; but if this should exceed that, the equinox will occur after noon. But by however many minutes the matter is uncertain in practice, you will go astray either in the altitude of the pole, or in the observation, or in refraction, or in parallax; by just so many hours you will wander from the true moment of the equinox. Therefore the equinox of not only the ancients, but also of Tycho himself, by parallax is off by two things, and indeed by a greater

minute than it ought, which Copernicus [Copernicus] also, and his predecessors, got wrong, as we shall say afterward, [and which] need correction.

Concerning the Solstices.

§7. **First**, the winter solstice [solstitium brumale], on account of refractions and parallaxes greater than those of summer, is liable to more fallacies than the summer one — whether it be observed by the minimum altitude, or by the foreknown numeration of the pole, or by the cessation of the increment of the meridian shadow, or by gnomons; and the shadow of the gnomon is reckoned otherwise than if the fallacies could be avoided. The true meridian altitude of the Sun, of all in the whole year, or the nearest to the solstice — that is, the altitudes observed near the solstice — the minimum would be the sign of the solstice having occurred. The solstice too, the summer one, is observed with difficulty, in which it is scarcely possible to agree to within hours of the day, by which the moment of the solstice is determined. Whence Ptolemy (*Almagest* II, chapter 2) says: *In the solstices indeed, neither we, nor Archimedes, in observation and calculation, have erred up to a fourth part of a day.* Yet Willebrord Snellius [Willebrord Snell] in his notes on the Hessian observations declares that the error of a quadrant of a day, or of 6 hours, is to be avoided in the solstices. The reason is that on the day next preceding, and on the next following the solstice, the declination of the Sun does not exceed by 14" a second in the whole year, nor by a third 56" [unless varies by 56"]: wherefore one must beware of an error of 6 hours in observations, unless the observations are made immune from error by 3 seconds, or a third 56". How great a subtlety scarcely could be furnished by observations of the meridian altitudes of the Sun on the days of the solstices, unless they are carried through with very large instruments very exactly.

[Margin: The fallacy of observation in the solstices.]

§8. But if anyone is content with the notation of the day of the solstice, the observation of the decrement of the meridian shadow having been omitted, and the numeration of the time being agreeable as to the half-day...

to it, because the altitude of the pole demands, by the greatest distance, that the points of rising in the west and rising in the east be observed in the horizon (for these are the modes of this kind whose error in the integration of the day exposes more than these neglected ones), the observer must take heed of the proportion of the meridian shadow to the gnomon. He gathers, as we said above, the distance of the Sun's limb from the zenith, on the one and the other day before, then after that day, on which the solstice is hoped for from the ephemeris. For when the

least of all distances from the zenith has been found, that least may be had: that day will be able to stand for the summer solstice; but if the greatest is found near midwinter, that day will be for the winter solstice. And let the same judgment be made concerning the meridian altitudes near either solstice, taken otherwise than by the shadow of the gnomon.

§9. But also for the hour of the summer solstice, as nearly as may be panted after, the continuous meridian altitudes of the Sun before and after that day must be captured. Convert the meridian altitude into the altitude of the equator, by the adjustment of parallax, and by the subtraction of refraction.

[Margin: For the summer solstice. 1st case.]

If it should happen that of two intermediate altitudes the remaining ones exceed, so that they themselves are equal between themselves: the solstice will have occurred in the middle of the intervening night, and then add to each the second scruple 7"; and to the aggregate take away the altitude of the equator, formerly more exactly foreknown, and so you will gain the maximum altitude of the Sun's declination by the same operation, if the obliquity of the ecliptic should be equal; but if it should depart from the foreknown altitude of the equator, refer the aforesaid aggregate — for it will be useful, as will appear below.

[Margin: 2nd case.]

The second case will be: if it should happen that of three meridian altitudes, the truest, the remaining ones being exceeded, the intermediate of the day should be greater than the two nearest days, and these two should be precisely equal between themselves; know that the solstice has occurred on that very meridian of the day, and subtract the altitude of the equator from the altitude of the Sun, and the maximum declination of the Sun will be left. Yet this case is rarer than either.

[Margin: 3rd case.]

With these two cases lacking, choose more meridian altitudes of a continuous series of days, two of all the others greater, and differing from them, which (if the operation is exactly done, and subtle) ought not to exceed 14"; lead through 24 hours, and divide the product by 14". For the quotient will give the hours by which the moment of the solstice succeeded the meridian of the lesser altitude of the preceding day, or preceded the meridian of the lesser altitude of the following day. The moment of the summer solstice having been acquired, subtract 14" from the greater altitudes, and subtract the altitude of the equator from the residue, and you will have the maximum altitude of the Sun on that meridian, on which

meridian the solstice was made, to whose altitude the altitude of the equator being subtracted, the maximum declination of the Sun is left.

[Margin: For midwinter.]

§10. For the winter equinox [recte: solstice], certain similar things must be dispatched in the opposite manner, because then in the winter solstice, when the Sun obtains the minimum altitude of all the others on the meridian, the minimum altitudes are to be observed under other meridians. The first case, then, be this: if it should happen that, among more of a continuous series of days designated by the ephemeris as antecedent and subsequent, two intermediate altitudes are exceeded by the rest, and the remaining two are equal between themselves; then know that the winter solstice has been made at the middle of the intervening night. Then again subtract 7" from each of the equal altitudes, and from the residue again subtract the altitude of the equator, and you will obtain the maximum declination of the Sun in that meridian.

[Margin: 2nd case.]

The second case will be: if of three true meridian altitudes captured near midwinter, the smaller intermediate of all the others, that is, the altitudes being lesser on two days, and the remaining two should be equal between themselves; then know that the winter solstice has been made on the meridian of the intermediate one, and the altitude of the equator being subtracted from the altitude of that day, the maximum declination of the Sun is left. But this case is rarer.

[Margin: 3rd case.]

The third case, therefore, be this: if of three meridian altitudes of the Sun captured near midwinter, the rest being smaller, but unequal between themselves: choose, then, two of these smaller, and lead their difference through 24, and divide the product by 14. The quotient will give the hours by which the moment of the solstice succeeded the meridian of the greater altitude of the preceding day, or preceded the meridian of the greater altitude of the following day. Once the moment of the winter solstice has been acquired, subtract the minimum altitude from the residue, and you will have, in addition, the residue: subtract the altitude of the equator, and you will have, as still absolutely the minimum, the minimum meridian altitude of the Sun on that meridian, on which the solstice has been made. Therefore subtract that altitude of the equator, to obtain the maximum declination of the Sun in that year.

Concerning the maximum declination of the Sun, and the distance of the Tropics to be observed, and at the same time the altitude of the pole, if it is not foreknown.

§11. Above, at numbers 9, and 10, I taught how to observe the maximum declination of the Sun by the foreknown altitude of the pole, or its complement at degrees 90, that is, the altitude of the equator, foreknown by some other most exact means through the circumpolar stars. But if the moment of either solstice is unknown, or is to be ascertained by some other means: nevertheless, when the meridian altitude of the Sun is at its maximum in summer, and at its minimum in winter, as above I taught is to be observed. The difference, then, between the maximum altitude and the minimum altitude is the distance of the Tropics between themselves; of which the half will be the maximum declination of the Sun: and this subtracted from the maximum altitude of the summer solstice leaves the altitude of the equator; but this subtracted from degrees 90 leaves the altitude of the pole. Moreover, the obliquity of the ecliptic, and the distance of the poles of the equator and ecliptic, are always equal to the maximum declination of the Sun.

Concerning the solstices to be observed, when both the altitude of the equator and the maximum declination of the Sun have been foreknown.

§12. If from the ephemeris deputed to the solstice itself, or to the nearest preceding, or to the following, the meridian altitude has been found, and corrected — if in summer the Tropic, exacted by the aggregate made from the altitude of the equator and the maximum declination of the Sun, or in midwinter, exacts the residue left from the subtraction of the maximum altitude of the Sun's declination from the altitude of the equator — then know that the solstice has been made on the meridian of that day. On the contrary, if the meridian altitude of the Sun should differ from the aggregate required for summer, or from the residue required for the winter solstice, by more than 14", the solstice is distant from the meridian by more than 14" on either day; and if it is less than 14", observe the difference, and the required difference, by 14, and divide the product by 14. The quotient will give the hours by which the solstice is distant from the meridian of the observation, before or after, as the increments of altitude in summer, or the decrements in winter, will easily teach.

CHAPTER II.

Concerning the Instruments Most Suitable for Observing Subtly the Meridian Altitudes of the Sun and of any star whatever, and especially concerning the great San Petronio Gnomon at Bologna.

§1. It has been clearly shown by us, that in the preceding chapter we learned that in the equinoxes the error of one hour is to be avoided, that one minute of the first error is to be avoided, and so for excluding the error of an entire [day] in the solstices, excluding...

that one ought to be from the observation of a quadrant of one minute, or of the second 14"; whence consequently the error of one hour in the solstices, unless an error of thirds 16" be employed, and unless an error of thirds 54" be avoided, or at least an error of the second scruple — to this end, therefore, one must strive after subtlety, that one may attain the matter of times, as the minimum may be excluded, so far as the more certain it be: but if such a minute be admitted without error in the matter of times. In the first place, then, one must reflect upon the magnitude of the instruments, but a manageable one. Far hence, therefore, let there be absent the *Baculus Jacobi* [Jacob's Staff], the *Radius Astronomicus* [astronomical radius — the cross-staff], whether Greek or Latin, the *Astrolabium*, the armilla, the *Annuli* [rings], the *Torquetum*, and other organa of this kind; and the pendulum quadrant, which are to be moved and handled at a nod, and for that reason cannot be of such mass that single seconds may be exhibited by a scruple. But those organa truly succeed for this purpose, which are the *Quadrans*, the *Quadrant*, and the *Sextant*, fixed in a wall —

[Margin: The magnitude of instruments required.]

§2....the Geometric, or Astronomical *Sextant*, or the parallactic *Regula* [Ruler], and especially many *Gnomones* many feet [long], the *Forma*, the division, and the use of some *Quadrants*, of *Quadrants*, of *Sextants*, and of *Parallactic* [rulers], Tycho sufficiently taught in his *Astronomiae Instauratae Mechanica*, to which I refer the Reader; but besides, not a few things worthy of consideration for us in meditating upon this business.

[Margin: The minimum visible.]

For the first thing to be established is, how great is the minimum visible point, or a discrete point, to be designated by a pointed pin, or by acute styli to be pricked, or by a color to be painted, or by the keenness of the sight's edge, or by an abraded section [is indicated]. But here I name no one of sound and most acute sight among men, who can discern a point between point and point, or a point between a little line and a little line, if they occupy the smallest space, such as the

simplest silk thread from a silkworm's cocoon could uncoil; of this thread, however, three hundred filaments, and sixty are contained, [or] the most subtle one chooses three hundred, of a foot of the ancient Roman [foot], or by a movable dioptra, displayed in the work of Ezekiel at Villalpando [Villalpandus]. Therefore in the periphery of a quadrant, or sextant, of astronomical instruments observed, so a sight is transferred from one point to another, so that one second of arc of one degree may be evidently discerned, the chord of this whole sight ought to contain ten inches of the Roman foot, that it may take the said minimum evidently visible 360, ten times, this is 3600. By however many seconds the second scruple contains, of one degree. Nor should you say, that lines can be obtained by transversal lines, even more subtle thirds, indeed by a quarter or by a subdivision. For although interludes of greater length can be put in transversal lines in the Tyconic manner, than in the peripheries of the limbs, at least so that the interlude of those be made by a thread, or by a movable dioptra, but without an intermediate physically sensible, if in the limb itself the spaces of the threads do not stand farther apart than the indicated little spaces, we shall say.

[Margin: The minimum visible.]

§3. You will now ask how great the semidiameter of the instrument ought to be, of which one degree captures the inches of the Roman foot, from center A, nearly 573. Therefore it must be of such inches nearly 573. This being so in the schematism here adjoined, from center A, the portion BKC is described, the portion of one degree, of which there are 360 [degrees] in the whole periphery of the entire circle, of which the extremes B and C are connected then with the center by straight radii, or by the straight lines AB, and AC, then between themselves by the chord BC, the perpendiculars AK then being bisected, and orthogonally at D, will be in BD. The sine of the angle BAD, subtending the smallest degree, or the minute 30', and AB will be the radius, or the whole sine. Since, therefore, BC is given as 10 inches...

[Margin: The magnitude of the instruments.]

Diagram. An isosceles triangle illustrating the geometry of an instrument's degree-arc. The apex A is at the top (the instrument's center). Two long sides descend to a short base. The base vertices are labeled B (left) and C (right), with the chord BC connecting them. A vertical line drops from apex A through the midpoint of the base, labeled D where it meets the base, and continuing to K just below the base. The figure represents the chord BC subtending an arc of one degree (here treated as the angle BAD subtending a half-degree, 30'), with AB and AC as the radii and AK the bisecting perpendicular.

- A (apex, top): the center of the instrument
- B (lower left vertex): one extreme of the one-degree arc
- C (lower right vertex): the other extreme of the arc
- D (midpoint of base BC): foot of the perpendicular from A
- K (below D): terminus of the bisecting line AK

§4....and BD is 5 inches, let it be made that as 30' of minutes, the sine BD, 87265, to the radius AK, of 10000.000 parts; so the same BD, of 5 inches, to another, will give the semidiameter AK, of inches, as we shall say, nearly 573 [inches]. This being so at *Pedi* 47 $\frac{2}{3}$. By this method the Table here adjoined has been constructed, for the semidiameter of an instrument suitable for one, or two, or more seconds, as far as concerns the magnitude of the organ itself; but besides this, the figure soon to be considered.

[Margin: The magnitude of the instruments.]

For [seconds]	Feet	Inch
1	47 &	9
2	23	10 $\frac{1}{2}$ [?]
3	15	10 $\frac{2}{5}$ [?]
4	11	11
5	9	6 $\frac{2}{5}$ [?]
10	4	9 $\frac{1}{4}$ [?]

[Margin: Radius in Roman feet & inches.]

Parsing notes: The header reads "Radius Pedum Rom. & Unc. Pro" over columns "[Pro]", "Pedes", "Uncia". The leftmost column gives the number of seconds (1–10) the instrument resolves; the second gives whole Roman feet; the third gives inches with fractional parts that are partly difficult to read at the right margin — the fractions on rows 2, 3, 5, and 10 are flagged [?].

§4 (cont.). With the Instrument constructed, whose radius would be of so many feet and inches as the optimal precision of seconds requires, and from center A, with the described arc of a quadrant, this same arc is divided into degrees 90, or into a sextant of 60, with such equality of intervals, and subtlety, that no sensible interval of error be admitted; which, although it may seem easily done, demands at least dexterity, with circumspection, such as you would scarcely find in any Mechanic-craftsman, who at the same time has been initiated in the elements of Geometry and Astronomy. Therefore we ourselves are not accustomed to trust

the Instrument, which either I myself, or Father Francesco Maria Grimaldi [Francesco Maria Grimaldi] of Angeli (if it is permitted to say so, in this subtlety a rival, indeed a divider), have divided. For the division furthermore of degrees into the first scruple of sixty, and of minutes into the second, whether single, or ternary, or senary, or denary; and that the intervals of these can be discerned by the smallest unit — Tycho devised transversal lines, of which he treats in *Astronomiae [Instauratae] Mechanica*, folio B 2 of the penultimate folio, because for so long now this use has been with us; in our *Sextants*, or *Quadrants*, which Tycho doubly named because of the division, that is, of the kind of division — second, because it is of equal magnitude, both in radius, and in the band of the limb, of that, which Tycho himself described at folio B 2; and he named the *Tychonic*, as the maximum of his *Quadrants*. But afterward by the very use he advised, not only is it too troublesome that this subdivision uses transversal lines 540, and points 9540; and so the operations are 7000, as we shall say at chapter II, number 4, & 5; but also from so great a multiplicity the peril of error is exposed. Therefore I chose another simpler one, of which I shall speak below, on the occasion of the *Quadrans Grimaldicus* named from the Author and executor of the division, which we devised; the Illustrious Count Carlo Manzini [Carlo Manzini], and the most Excellent Doctor Giovanni Domenico Cassini [Giovanni Domenico Cassini], each most outstanding not only in the Theory of Astronomy and Geometry, but also in the practice and Mechanics of organa of this kind. Yet I add that we are not antecedent in subdividing transversal lines, nor are the intervals equal, as Tycho made; but the Geometric ratio requires it, unequal. For Tycho confesses at the end of the said *Mechanica*, that he was able on account of that inequality of the instrument to err by threes, and more by seconds. *How great a subtlety, that there the keenness of sight may discern in any whatsoever; at length the instrument in no way sustains.* By how much the more, therefore, did Tycho despair of being able to attain single scruples?

[Margin: Division of degrees into scruples.]

§5. Concerning the *Dioptrae* [Dioptras] and *Pinnacidia* [Pinnules], by which the stars are observed at night, we shall say at chapter 4 [Book IV?], chapter 5. But the luminous body, chiefly the Sun, must be observed by a direct beam falling collinearly into the center of the instrument, or alternately, by a thread stretched in some way, or by two pinnules perpendicularly erected on the instrument, or by a section of two perpendicular orthogonal threads intersecting each other in the same plane, of which one is extended perpendicularly at the center of the instrument, the other represents the vertical plane, or by a Cylinder, whose axis

is fixed perpendicularly at the center of the Instrument, and which is of such thickness, that to the eye placed at the center of the Instrument the whole...

[Margin: Solar dioptras.]

the whole disk of the Sun, so that it does not obstruct it, but lets the parts be clearly discerned as equal — the part above, say, and likewise the part below — and does not deceive. Most often, however, the Sun is observed either by a beam reflected from the Sun itself onto the instrument [aversô à Sole intuitu], or through a perpendicular cylinder set at the center of the erect instrument in a small board, marking the middle of the shadow; or else by admitting the bright image of the Sun through a small aperture and setting it likewise on a board fixed there. By marking that middle, or by capturing the bright image of the Sun in a proper arrangement of board, cylinder, plumb-line, needle, and so forth — and provided that the silken threads be subtle enough — one can make out as many seconds as there are threads on an instrument of 48 feet. And the finer the threads, the more accurately one is brought to the very point at the center; or by a line at whose extremity stands the other pinnule [pinnacidium].

[Margin: Examination of the Tyconic Quadrant]

But on an instrument whose radius is only 24 feet, this would require either pairs of seconds, or a board of 9 feet to locate them upon. For if one were to lay down so many seconds on a board, the multiplication of the error of the seconds in proportion to the smallness of the instrument would be very great. And it is of great necessity to us that a small shadow be cast on instruments with small shadow; for the bright image, by reason of the diverse disposition of the boards, deceives — to the extent that on great instruments the error introduced into the very measurement of a foramen [aperture], or of the shadow, is so great that the boundary of the bright image, or of the shadow, can scarcely be discerned uniformly. The first danger of error lies in the use of it: that the measurement comes out either too great by the middle of the bright image, or too small by its margin, by so great a space as the silken thread [filum sericum]; or that error is incurred in the seconds, to within a few minutes, or that error arises in proportion as above indicated.

[The text is dense and the column-edges are tight at the gutter; the foregoing renders the substance of §5's continuation: comparison of thread-, cylinder-, and aperture-dioptras and the magnification of subdivision error on a small instrument versus a large one.]

Further, on a quadrant a plumb-line, or a movable perpendicular, indicates a single point; and a movable sight [dioptra mobilis] indicates the degrees and minutes; and its place is fixed by the mobile dioptra. But since this very motion of itself, on a vertical plane, requires firmness of the thread — and so a rather thick thread, of a coarser sort than the simple silken thread — therefore some fallacy of a few seconds is introduced into the reckoning.

Finally, I warn that it is not enough to have set up the Quadrant or Sextant stable in its own situation, unless you are certain of the level of the pavement [pavimentum]; otherwise, even an instrument set up at rest will, when moved from its former situation, become a matter for investigation. Concerning the Rule [Regula], moreover, if the instrument's other extremity has been rightly placed, so that it stands at right angles both to the horizon and to the same vertical — this Tycho [Tycho Brahe] proved in his *Mechanica*. And we ourselves likewise, however great our industry, would frequently fall into errors of two, and even more, minutes.

—even if we should grant a parallax of 8 minutes.

[7]

Up to this point, the things we have said tend toward this: that we first recognize how probable is the fear of an error of one minute in Tychonic observations, as we shall confirm both by examples and by authorities in Book 4, chapter 4. From this I infer that astronomers who study with too little diligence are prone to incur a second error — beyond the first — when they neglect some second error, namely, the imperfection of our nature; and so, generally, into the scope, or the proposed quantity, they let a declination slip. Certainly in the Altitude of the Pole, and in observing the Equinoxes, and the Solstices, and the obliquity of the Ecliptic — which are the primary elements and, as it were, the foundations of Astronomy — no diligence ought to seem superfluous. Hence, all things considered, in the perfecting of the customary instruments we run no small risk regarding the **Gnomons** [Gnomones]: which some even of the ancients are known to have employed — not only in obelisks, but also elsewhere.

[Margin: The great Altitude of Gnomons]

For although the Gnomon is nothing other than a kind of style, of which Strabo speaks (Book 2). At Byzantium, indeed, the longest day is of fifteen equinoctial hours, with the Quadrant. But the Aestival [summer] Solstice — the Gnomon, by the shadow which it has at the ratio that nine has to forty-two — even though twenty-five was assigned to it; yet to a sufficiently great extent it is gathered, from

the parts which the more discerning, and commonly the more learned, used to require, by the division [diuisio]. Greater still was that one which Gassendi [Pierre Gassendi] attests (in his *Life of Tycho Brahe* [*Vita Claudii Fabricii Peireskii*]), and in the little work *On the proportion of the Gnomon to the Solstitial Shadow* employed: that of Pytheas of Marseilles [Pytheas Massiliensis], which obtained the Solstitial shadow there as 213. And likewise Gassendi, in the year 1636, made use, in the two said little works, for the Gnomon of the College of the Fathers of the Congregation of the Oratory at Marseilles — whose roof was higher than that of the Orgyia, about 9 feet, or 52 Parisian feet; albeit in altitude it was reduced to another shadow-reckoning, and at the same time was divided into parts about 90000, that is, exactly into the parts 89328. And of such a Solstitial shadow he found it there to be 21743.

[Margin: The Gnomon of Pytheas, and of Gassendi]

Before this, at Gratianopolis [Grenoble] he employed the *sphaeristerium* [vault] of the Comestabulis, whose roof for the Gnomon by his own style — at the circle of the Orgyia, or of the said parts — exactly indeed for the particular part 64690; but the summer shadow as 5410. By far the greatest was that Gnomon-Quadrant which Ulugh Beg [Ulug Beigh], grandson of the great Tamerlane [Timurlanus], employed about the year of the Lord 1437. For, as Johannes Gravius [John Greaves] asserts in his *Epistle on the Persian Tables of the Ulughbeigian* (set forth above) — to which is added that altitude of the summit of the vault of the Temple of Sancta Sophia [Hagia Sophia], whose hemisphere at Constantinople surpasses one hundred and eighty Roman feet. From these examples too I gathered, by the most subtle reckoning, the Altitude of the Pole of Bologna [Altitudo Poli Bononiensis], having weighed two Gnomons of the Temporals in this Bolognese Gymnasium [the University of Bologna]. Of these, Giovanni Domenico Cassini [Giovanni Domenico Cassini], at the Palace of Malatesta, set forth with me, in our College, in the new Temple of St. Lucia, the Gnomon not under the vault, but brought out under the open sky — those Gnomons which, with their observations, I set forth in Book 4 (which is *On the Fixed Stars*, chapter 4), with that observation made per a fixed star [per stellam] from the circumpolar absolute, with respect to its place. But by the Equinoxes, the Solstices, the Diameter of the Sun, and the maximum declination, we choose, from those stable Gnomons in the Temple of San Petronio in Italy — I will not say, of all Europe, the most outstanding — concerning which a separate discourse must be given.

[Margin: The Gnomons of Cassini, and the Authorities]

On the Gnomon in the Temple of San Petronio formerly raised by Egnazio Danti

[De Gnomone in Sancti Petronij Templo ab Egnatio Dante olim excitato]

As the controversy was growing concerning the Precession of the Equinoxes — which already for nearly ten whole days had been displacing the days that ought to precede, as established in the old Calendar — and as Gregory XIII, Supreme Pontiff, was earnestly soliciting the foremost astronomers to undertake the reform of the form of the Calendar: the Reverend Father Master Egnazio Danti [Egnazio Danti] of Perugia, of the Order of the Friars Preachers [Dominicans], in the renowned Bolognese Gymnasium [University of Bologna] Professor of Mathematics, and afterward Bishop — by the Authority of the most illustrious Senators, namely Count Giovanni Pepoli, perpetual Prefect of the Fabric of the Temple of San Petronio, and of his Colleagues — in the same Temple in the Year of Christ 1576, in the Month of April, erected a vast Gnomon, to demonstrate clearly, to those moderately learned, the anticipation of the Equinoxes and Solstices, and other matters; observations notable in Astronomy. And this Gnomon lasted right up to the Year 1656 — that is, for 80 years — of which arrangement, of whatever sort, we here append the following.

[6]

Diagram. A geometric figure illustrating the San Petronio gnomon as a vertical aperture-gnomon casting the Sun's image onto the pavement. At the upper left, a tall shaded vertical bar (the wall/column of the temple's south side) is marked **A** at its top. From **A** a sheaf of straight lines (the solar rays through the aperture) descends rightward to a long horizontal base line running from **B** (lower left) to **D** (lower right) — the meridian line laid in the pavement. Along the base, between the foot of the vertical bar and **D**, are marked the points **G, H, E, F** (clustered near the foot), then **I, M, C** toward the right end near **D**. Small ellipses are drawn on the base near **F, I/M**, and **C**, representing the elliptical solar images at different seasons. The vertical edge of the bar is **AB**; the meridian base is **BD**.

- **A** (top of vertical bar): top of the wall, where the aperture is
- **B** (foot of vertical bar): base of the wall on the meridian line
- **D** (far right end of base line): southern end of the meridian line
- **G, H, E, F** (clustered near foot of wall): points marking the summer-solstice solar image positions
- **I, M, C** (toward right of base): points marking equinoctial / winter-solstice solar image positions

AB, on the wall of the Southern side of the Temple, and on the left, was the chosen Altitude from the pavement to the vault, namely all the way to **BC**. A marble band [zona marmorea] was laid in the pavement of the Temple, whose straightness from the Meridian line **BD** declined westward toward the degrees, about 9; for if it had been constructed on the Meridian itself, Egnazio would not have fallen into an error in the pillars, or columns sustaining the vault, or would have come out somewhat shorter than the length of the Winter shadow, and yet he reckoned it could be on **BC** itself — judging from the hour of the Equinox. The reason, moreover, why the diameter of the aperture of Bologna is 5: in a metal plate of a thickness of half a digit, enclosed in the wall, and to the vault of the Temple itself. **IC** was the diameter of the elliptical Solar image, and as it were Elliptical, transmitted through the said aperture on the day of the Winter Solstice; and then **AC**, the radius of the lowest limb of the Sun; and **AI**, the radius of the highest limb. But there are also, by another disposition of the marble boards, four little marble tablets, noted with the marks of the remaining eight Signs of the Zodiac, one for each, so that one might know on what day the Sun would enter them. Suppose, therefore, the marble line **BC** to be parallel to the Horizon, and **AB** straight to the Horizon, and the quantity of each to be known: Egnazio believed, by the quantity, that in the triangle **BAC**, at right angles to **B**, he could know the angle **BAC**; by measuring the distance of the lowest limb of the Sun from the vertex of the triangle, and likewise **BI**, the distance of the highest limb; and so the Solar distance at the center, in the very Solstices of the Sun in the winter Solstices — not otherwise in the Equinoxes, and in the semidiameters of the Solar Solstice — observed by the quantities **BG**, **BH**, and in the Equinoxes, observed by **BE** and **BF**. And being known, the distance of the Equator from the vertex of Bologna, namely the Altitude of the Pole, one can know the hour of the Equinox, and of the Solstice, and the middle of the day.

[Margin: 6 LIBER I.]

But because the masons, not once in repairing the plate of the aperture **A**, removed it from its former place, or inclined it, and because the pavement frequently subsided near the side door **B**, and removed our measurement from the Horizontal plane — for that reason the measure of the altitude **AB**, and the length **BC**, and the rest, as Egnazio once handed down, or as others have handed down, do not exactly agree with our own, except that they differ by diverse diligence; nevertheless I am pleased to refer the Equinoctials from the point **B** to the center **Q** of the Ellipse, and to the center **V** of the Solstices, and the Winter ones from the point **B**, and the extreme **C**: the intervals of the remaining Signs are treated by the Appendix to Tome I of our *Almagestum Novum*, page 736. For three

sufficient observations, afterwards recounted, of the Elliptical Diameters we add — when we made the observation of the Sun's diameter in this Temple.

[Margin: Measurement of the Bolognese Gnomon of Egnazio]

[Table — dimensions of the San Petronio gnomon as measured by successive surveyors. Columns: the measurers (Dimensores); Bolognese feet (Pedes Bonon.); inches (Uncia). The first column also carries the segment label (AB, BV, BQ, BM, BC) at the left.]

Segment	Dimensores [Measurers]	Pedes Bonon. [Bolognese feet]	Uncia [inches]
AB	Egnazio Danti	67 (circiter [about])	—
AB	Nobis [By us]	65	9 $\frac{3}{4}$
BV	Co.[unt] Carlo Ant.[onio] Manzini	26	0
BV	Bartholomaeo Pronalio [Bartolomeo Pronalio]	25	6
BV	Nobis [By us]	25	6 [?][?]
BQ	Com.[es / Count] Manzino [Manzini]	65	1
BQ	Barthol. [omaeo] Pronalio	64	7
BQ	Nobis [By us]	64	7 $\frac{22}{?}$ [?]
BM	Com.[es] Manzino [Manzini]	167	7
BM	Nobis [By us]	166	8 $\frac{7}{?}$ [?]
BC	Egnazio Danti	170	—
BC	Nobis [By us]	169	2 $\frac{7}{?}$ [?]

Parsing notes: The fractional inch-denominators in the right column are partly obscured at the printed fraction-bar (small superscript/subscript type in the gutter-side column); flagged [?] where the denominator could not be resolved. The "Dimensores" column groups, per segment, the figures of Egnazio Danti, Count Carlo Antonio Manzini, Bartolomeo Pronalio, and Riccioli himself ("Nobis").

The whole **IC** was once for us 4 inches and 11 $\frac{1}{2}$; the aperture **A**, as I said, partly 3 [parts], partly 4 inches of a Bolognese foot, that is, 5: therefore, of whatever sort **AB** may be, of parts it would be 101. Of 100000 such parts the diameter of the aperture **A** was of parts 101, or roundly 100. And its finest part is always to be added: the length from the highest limb, and the date from the radius of the lowest limb, that it might have a length — which agrees with the radius per the center of the aperture **A**; and as we pass through, the imagination of the aperture meets there in indivisibles, and there they cut one another.

On the Gnomon in the Temple of San Petronio lately raised by Giovanni Domenico Cassini

[De Gnomone in S. Petronij Templo nuper à D. Io. Dominico Cassino excitato]

The Egnazian Gnomon, besides an intrinsic defect — in that it exceeded the Meridian by some degrees [from the true meridian] — wandered by two other defects of the times, having contracted them: namely, a disturbance of the plate of the aperture admitting the Sun, brought about by the masons' workmanship, and the wearing-down of the pavement by the trampling of feet, on account of which the angle **ABC**, otherwise right, had become acute. And although, in our time, it still supplied some notable uses, yet I often thought of having it restored, and of correcting it; and about this, with certain persons to whom the fabric of this Temple had not yet fully pertained, we sometimes consulted — among them, the most excellent Doctor Giovanni Domenico Cassini, a Genoese, for whom the Chair of Mathematics, and especially of Astronomy, in this Bolognese Gymnasium [University of Bologna] had been destined. Therefore, occasion being given that the aperture in the southern wall had to be removed, and the fabric of the rest restored — the work having been begun, and obtained from the most illustrious Marchese Facchinetti, Prefect of this fabric, and his Colleagues, or, by the assumptions [made], it being at the expense of the fabric itself — it was permitted to him to erect a new Gnomon on the very Meridian line, and at more exact ratios, which was sought after. But that the foundation of all great things might be a novelty, [and] solicitude for the success was a matter of consultation: D. Cassini, doubtful regarding the ratio of some things, with that subtle ratio undertaken in Astronomy with Geometrical certitude, which he promised he

could exhibit — I, among all the consulted and eyewitnesses, having been a witness before, and an observer betrothed to him as initiated, and, as regards the most subtle designation of the Meridian line, an assistant, and corroborator — being more certain of the man's outstanding talent, and of his prudent skill, I pronounced the business would proceed most excellently, and with outstanding success.

[Margin: 9 — and at the column: see the following figures]

Therefore that most ingenious man saw that the Meridian could be led well lengthwise, in such a manner that, by alternation, the columns might lie open all the way to the wall **AB**, [the columns] being Boreal [northern], and the aperture **AB**, in the very thickness of the Temple, parallel to the Horizon, having been arranged so that it could be located, from a certain center of the apparatus at the pavement — by a plumb-line, at length by titubation [wobbling], and at rest in the spinning — he noted, on the plane of the horizontal marble of the stone, the point **D**, over which perpendicularly hangs the center **C** of the aperture; and the Altitude **CD** by wooden brackets fitted together, and likewise let down from **C**, in **D**, and afterward...

[Margin: See the following figures]

[7]

Diagram. A geometric figure for the Cassinian San Petronio gnomon. At the upper left a small circle marked **S** (the Sun) with a point **P** beside/within it (the aperture-image point), from which dashed and solid rays descend rightward and downward. Below, a short horizontal segment carries the points **A**, **C**, **B** (the aperture region, with **C** the aperture center). The rays converge on a long horizontal base line at lower portion of the figure, marked with the points **D**, **M**, **H**, **O**, **K** and ending at **L**, **N**, **E** toward the right. The base line is the meridian line on the pavement; **DE** is the swept length, and the rays from **S/P** through the aperture strike the pavement at the seasonal image-points.

- **S** (small circle, upper left): the Sun
- **P** (point at upper left near **S**): the aperture/image point through which the ray passes
- **A**, **C**, **B** (short upper segment): the aperture, with **C** its center
- **D**, **M**, **H**, **O**, **K** (along base line): pavement points along the meridian (seasonal solar-image positions)

- L, N, E (right end of base): the far (winter) end of the meridian line / extreme image positions

afterward stretched out over the horizontal plane, [the altitude **CD**] was measured, and the ancient Roman feet were found again (such as Villalpando exhibits in Ezekiel) to be $95 \frac{3}{4}$; but the line **DE** [was] of 238 [parts] [?/?]: yet, the more expediently to serve the finding of angles, since the Radius **CD** is 100000, of such [parts] it makes the Tangent **DE** of parts 251100; and of the aperture the Diameter **AB** of parts 100. The angle **CDE**, moreover, is right, since the channel of the water-level lies along the line **DE**, by the level [ad libellam]; and so, the experiment having been more often repeated, by equidistances on both sides, the marble [edges] being bound fast, provided that the line **DE**, at the said equidistance, can endure for very many years. Furthermore, the elliptical Solar image, on the Equinoctial days, occupies a longitude in three Roman feet — the greater [feet] subtending — and in the Sky about 32 minutes; and so, degree 1 occupies feet 6 very nearly: at such a time, therefore, if in the determination of the boundaries of the Ellipse the keenness of the knife should hit upon any errors, it would surely come out imperceptible, and far smaller than in the maximum Tyconic Quadrant, whose degree 1 occupied about 1 inch of a Roman foot.

[Margin: 12]

The use of the Gnomon will become clearer by example, supposing it demonstrated (Book 1 of the *Almagestum Novum*, chapter 5) with Nonius [Pedro Nunes] and Snellius [Willebrord Snellius], that the Sun's Rays, propagated to the earth from that very point of his, [namely] **SH** and **SO**, are sensibly parallel; and (from the things to be demonstrated in Book 4, chapter 4) the Altitude of the Pole of Bologna in the Temple of San Petronio to be degrees 44, 30 minutes, 20 seconds; and [the Altitude] of the Equator [to be] degrees 45, 29 minutes, 40 seconds.

[Margin: On the discrepancy of the Solar Diameters; and of the Declinations; and of the Equinoxes]

SO LET THIS BE AN EXAMPLE

[SIT ERGO EXEMPLVM]

In the year 1656, on the 21st day of March, at midday, in the presence of expert witnesses, the distance was observed from the point **D** of the plumb-line to the boundary **H** of the Sun's Ellipse — that is, the Tangent **DH** — of parts 95225; and

to the other extreme **L**, the Tangent **DL**, 97098. But the semi-aperture **AC** [was] of parts 50, and likewise **CB**; therefore, by the parallelism of the Rays **SH** and **SO**, **HO** was as parallel as **KL**, namely parallel to **ACB** itself, of parts 50. Add, therefore, **HO** — that is, parts 50 — to the Tangent **DH**; it was **DO** 95275. The Tangent of the Angle **DCO**, [is] degrees 43, 36 minutes, 50 seconds [gr. 43. 36'. 50"], which **S** of the higher limb of the Sun is the distance from the vertex. Contrariwise, [take] the Tangent **DL**, deduct **KL**, of parts 50; there remains **DK** 97048. The Tangent of the Angle **DCK** [is] degrees 44, 30 minutes [gr. 44. 30'.], measuring the distance of the lower limb [of the Sun] from the vertex. The difference [is] in fact 53 minutes 40 seconds [53'. 40"], which gives the apparent Solar diameter **IS**, of which the half [is] 15 minutes 50 seconds [15'. 50"]; the added degrees 43, 30 minutes 50 seconds [43. 30'. 50"], give the distance of the center **P** of the Sun from the vertex degrees 43, 52 minutes 40 seconds [43. 52'. 40"]; to which, if you add a refraction of seconds per our theses, [namely] 5 seconds [5"], and at last subtract the parallax [parallaxis] 1 minute, there remains the corrected distance of the center of the Sun from the vertex degrees 43, 52 minutes 34 seconds [43. 52'. 34"]. And this distance subtracted from the vertex, [there is] left the Solar Declination [Declinatio Solis] toward the North, degrees 37, 46 minutes [37. 46'.]; to which, in the Table of Declinations, according to our obliquity of degrees 23, 30 minutes 20 seconds [23. 30'. 20"], there correspond degrees 23, 14 minutes 43 seconds of Aries [Arietis gr. 23. 14'. 43"]. But the Sun (as it was in the Equinox) [was reckoned] by collecting the Declinations of the single minutes, the single hours of the false Equinox [aequinocetium falsum] [at] hours 17 minutes 46 [horis 17'. m. 46.] before the midday of the 21st Day of March. Likewise one must proceed in the other observations of the Equinoxes, which we press upon in the more recent chapter following.

[Margin: Observation of the Solar Diameters; and of the Declinations; and of the Equinoxes]

CHAPTER III

[CAPVT III]

Observations of the Equinoxes, or near the Equinoxes, from the Year 162 before Christ, up to the Year of Christ 1656

[Aequinoctiorum Obseruationes, vel prope Aequinoctia ab Anno 162. ante Christum, vsqz ad Annum Christi 1656]

1. Ptolemy [Ptolemy] (*Almagest* I.3, chapter 3) reports 9 Equinoxes, related to Hipparchus [Hipparchus] (in the Book *On the magnitude of the Year*), and

observed by himself at Alexandria from the Armillae Aequinoctiales [equinoctial armillary rings], and likewise (chapters 6 and 8) he adds 3 Equinoxes observed by himself. But Hipparchus...

assigns these to the Years of the Third Period of Callippus [Periodus Callippi]. Ptolemy, moreover, indicates the years of Alexander for Hipparchus, and the years respectively for these, and likewise for Nabonassar [Nabonassar], for Adrian [Hadrian], and for Antoninus. We, from the Reformed Chronology, add in the subjoined Table all these years, with one cumulative sum before [each], or after; the Epoch of Christ being employed, and the days of the Julian Months responding to the Egyptian, or to their Intercalary [days].

[Table — Equinox observations with their dates reckoned in several era-systems. Spanning the page; the table continues below. Columns: Aequinoctia (equinox type / observer group); years of the III Period of Callippus; years of Nabonassar; year of Christ; Months & Days, Egyptian & Roman; parts of the Day at Alexandria. The left margin groups the rows under the observer headings "Autumn. Hipparchi" (Autumnal, of Hipparchus), "Verna" (Vernal), and "Ptolemaei" (of Ptolemy).]

Aequinoctia	ANNI	ANNI	Anno Christi [Year of Christ]	Menses & Dies Aegyptij & Romani [Months & Days, Egyptian & Roman]	
	LABENTES — III Per[iodi] Callip[pi]	LABENTE S — Nabonasari		Aegyptij & Roman]	Diei partes Alexandriae [Parts of the day at Alexandria]

Ptolema ei [of Ptolemy]	1 — 17 (Antonini [of Antoninu s])	456	880	132	Athyr 7. Sept. 25
	2 — 3	463	887	139	Athyr 9. Sept. 26
	3 — 3	463	887	140	Pachon 7. Mart. 22

Parsing notes: This table is laid out in narrow vertical rules and packs two parallel era-systems (Callippus-Period years and Nabonassar years) plus the Year-of-Christ column. For the "Autumn. Hipparchi" and "Verna" blocks the leftmost numeral pair is the observation index (1–9) followed by the year in the Third Period of Callippus; the "Anno Christi" column gives years *before* Christ (the chronology runs backward from 162 BC). For the "Ptolemaei" block the era-heading switches to Adriani/Alexandri/Nabonassar; the row "1 — 17 / Antonini" links Antoninus's reign. Several values verified against Ptolemy's *Almagest* equinox list. The day-parts column gives the time of day (Evening/Morning/Midday/Midnight) at Alexandria. Table continues into the following text/page.

2. Furthermore Hipparchus — a lover of truth above all [φιλαλήθης [Greek: philalēthēs, "truth-loving"]], faithfully relating to Ptolemy — confessed that the Autumnal [equinoxes] of [observations] 2, 4, and 6 appeared by a quarter of a day [quadrante diei] sooner than they ought; and that he had observed, by the magnitude of the year, an error of $365 \frac{1}{4}$ and $\frac{1}{6}$ — which was for the Vernal: the

Armillæ appeared twice, equally illuminated on both sides, namely in the morning, and again at the 5th hour of the day, near midday. Which defect was attributed to the Armilla, since the rising of the Sun could be represented higher than it really is, that is, [the Sun] ought to be said to rise. These Equinoxes — all of them, and some others — Christmannus [Christmann] expends in Alfraganus [al-Farghānī] (page 328); Mulerius [Muller / Nicolaus Mulerius] in the Frisian tables (figure 86); Longomontanus [Longomontanus] (*Astronomia Danica* I.1, Theoretical chapter 1); Petavius [Denis Pétau] (Book 4, *On the doctrine of times*, chapter 19, and chapter 2); Lansbergius [Philip Lansberge] (in the *Thesaurus*, observed, class 2); Bullialdus [Ismaël Boulliau] (*Astronomia Philolaica*, chapter 2); and Franciscus Levera [Francesco Levera] (*Astronomy*, chapter 5). To me, now, the Chronological errors of certain men around the said Equinoxes are evident: the Fourth, indeed, [the] Autumnal — they note [it at] the Year of Alexander 178. Albategnius [al-Battānī] (chapter 27); Regiomontanus [Regiomontanus] (in the *Epitome* of the *Almagest* I.2); and Longomontanus, above, on account of the version of [the era of] Trapezus[?]....

[Margin: Chronological errors of some men]

the [era of] Trapezus[?] must be read; that is, for 178, [the] year 177. Christmann, above, p. 341, and Boulliau, above, in his account of the Autumnal Equinoxes, place it likewise as 177; and so does Lansberge, above, Book 3, ch. 13. As for me, in Book 3, ch. 14, I too maintain it should be year 177, and indeed I have demonstrated this. By contrast, the *Alphonsine Tables* place it in Year of Christ 147, where Pétau too errs in saying it had thus far been the third year of the [Callippic] Period — that is, year 1 — whereas it was in fact year 31. Pétau likewise, Book 4, ch. 26, assigns this same equinox to [Year of] Christ 147. He notes correctly that it began in [Julian] Period 4567, namely Year of Christ 147, on September 27, at the start of Feria 1 [Sunday]. Then he immediately adds: "*In this year, Thoth 1 of [the era of] Nabonassar 602 begins September 29. Therefore Day 31 of September; not yet had it entered Nabonassar 602. The slip of the pen is to be excused, or the failure of memory.*" But page 27 of Pétau is faulty: "*This equinox observed by Hipparchus is designated in the Year from the death of Alexander 178, [Year of] Nabonassar 602, [Julian] Period 4567.*" This Year from [the death of] Christ 147 — that is, the Day of the Equinox, September 27 — Nabonassar 178 had not yet begun, nor Alexander 178; and besides, [Year of] Christ 147 began only two days after [the equinox]. But it is certain that Ptolemy, in Book 3, ch. 8, and Censorinus, ch. 8, reckon from the first day of Thoth the years both of Alexander the Great and of Nabonassar.

[Margin: Errors of certain men: Longomontanus, p. 4; Levera, p. 4.]

Moreover, Longomontanus errs, as also does Levera, in assigning all the Autumnal Equinoxes of Hipparchus to the year following the one to which they truly belong, and likewise [a year off] in [the era of] Nabonassar. Levera, furthermore, has no scruple in calling them by their relation to Ptolemy, which Hipparchus had been [using], and erroneously names them; for in the three last Autumnal [equinoxes] of Hipparchus he substitutes 31 for [the year] of the Callippic Period; and for 31, he substitutes 32; and for year 31 — what is most absurd — he gives 36; and year 33, while pursuing his own commentaries of years, [he follows] the epilogisms. The cause or occasion of the error was the nearness of the year of the death of Alexander — or rather it was Ptolemy's subjection, when he followed Ptolemy and Hipparchus, because they use the first day of Thoth, the Egyptian month, the year of the first day of Thoth of [the era of] Nabonassar, and the beginning of [the era of] Alexander, which Christmann had supposed in al-Farghānī, p. 305, but afterward retracted, pp. 329 and 338. He retracts this falsely: false [too] that Hipparchus took the beginning of the Callippic years from a preceding Summer Solstice, when they were beginning the year of the Olympiad; and likewise Ptolemy — let alone that Hipparchus should reckon the beginning of the Callippic exordium from the [Year of] the Prutenic [Tables], as Reinhold wishes, before [chapter] 4; Boulliau and Pétau, above, and these clearly contradict Ptolemy, Book 3, ch. 1.

[Margin: Year 1 of the Callippic Period, that is, its terminus; for thus it would be held in Greek; therefore around the Summer Solstice of the Callippic year 51, when Alexander died.]

There is another cause of error in marking the Equinoxes a day too early, which was the false supposition presupposed by Levera, p. 4. He brings out, p. 10, the page 228 of the year 1, the first year from the death of Alexander, both Lucidus and Saliano assign as before [Year of] Christ 321. He adduces, for Reinhold, who nevertheless, before [chapter] 6, expressly says: "*If the first day of Thoth, the year 314 before Christ, that is, the first year from the death of Alexander:*" The same Levera, p. 227, makes the first year of the Olympiad agree with Saliano's 775 before Christ, but on p. 228 he makes the first [year] of Nabonassar 747; whereas in order that they cohere with Saliano (yet erring), he would have to make it 746; and on pp. 214 and 235, the year conceived and the [year of the] Nativity of Christ — in which he ought to make Christ consequently agree with Saliano — he places as 44. He misreckons with Saliano, both, p. 20, 102, and 117, [perpetrating] false Chronology; he draws it from himself and incurs imprudently into another false

[chronology]. For he supposes the opinion of Saliano and of those who assign the beginning of the years of the Olympiad, Nabonassar, and Alexander to one and the same year to be false — which in our *Chronologia Reformata* we have demonstrated from the Eclipses noted among the Historians, together with a series of Consuls and of Censorinus (whom the Chronologists acknowledge as their master) [as] authority. For...

[Margin: Saliano's faulty Chronology.]

for example, [the testimony] of the Consular *Fasti*, which are corrupt in the first Julian year and right up to Trajan, and certainly with the consensus of all, it is agreed that they begin from Julian year 90. He maintains the Consuls were M. Vinicius and Statilius Corvinus; but in these same Consuls there happened, on the day of the birth of Claudius the Emperor — that is, on the Kalends of August — an Eclipse of the Sun, as Suetonius and Dio relate. But that Eclipse [fell] on the Kalends of August: in no other year of the Era of Christ does any Astronomical Table show it, except by 45 [years] subtracted; for from the Kalends of January in the Julian year 45 — complete — and from the 90th [year] there follows the beginning of the Era of Christ, which I maintain to be in the Julian year 45, as Censorinus too, ch. 8, asserts was written by him in the Book *On the Day of Birth* [*De Die Natali*], to have been [Year of] Christ 238.

[Margin: Nabonassar and Alexander, the true Eras.]

This same author, in that very year, says the year of Nabonassar 986 there began, and Alexander 562, so that each at noon, by exactly counting backward through the individual years in our canon — for the years are expanded — the first year of Nabonassar began February 26, year 747 before the Epoch of Christ, and the first [year] of Alexander on November 12, in the year before Christ 324, together with [year of] Nabonassar 425, since the very same kind of years runs; and by counting backward in the same way Ptolemy [in] Book 3, ch. 8, computes — what he says of Nabonassar — at the beginning of Alexander, that from the death of Alexander he reckons completed years 424. Therefore the first year from the death of Alexander began with [year of] Nabonassar 425. At last, from Censorinus above it is established, [in] the Julian year 283 — this [year], and that we show from the Eclipses, [Year of] Christ 238 — around the Summer Solstice the year of the Olympiad 776 began. The first Olympiad therefore [began] around the Summer Solstice [of the] Olympiad 776, and the year 777 [began]; and the first [day] of the Olympiad before Christ 776, around the Summer Solstice [at] the New Moon, current and before Christ 776. The first Olympiad began around the Summer Solstice, year before Christ 224. Since Alexander died, the [first] year

before [Year of] Christ 324 was the Olympiad 114. Arrianus, Book 7, and Diodorus, Book 17, indeed profess this, as Josephus too [does in] Book 1, *Against Apion*; Eusebius, however, [in] Book 8 *On the Preparation of the Gospel*, ch. 2, asserts that Alexander died ἐν ἀρχῇ τῆς ἑκατοστῆς καὶ τεσσαρεσκαίδεκάτης Ὀλυμπιάδος [Greek: "in the beginning of the hundred-and-fourteenth Olympiad"]; that is, in the beginning of the first year of the hundred-and-fourteenth Olympiad. Hence it is confirmed that [Alexander] died in the year before Christ 324; and Levera reckoned this badly, not 323; nor did Lucidus and Saliano feel correctly.

[Margin: Olympiads, the true Era.]

[Section] 5. Now from Ptolemy, Book 3, ch. 1, and Aristarchus, defining the beginning of [year] 10 of the first Callippic Period; Aristarchus [places] the Summer Solstice in [year] 44 [before] Alexander; therefore the Callippic Period 50, before [year] 44, is absolute; and the [year] before Alexander 44 began at the Summer Solstice [of] the Callippic [Period] 51, since [year] before Alexander 45 [began] with [year of] Nabonassar 469; nor did it begin except on the Kalends following [in] November, in the year before Christ 280: the period of the Callippic years was 76; by the witnesses Geminus, Ptolemy, and Censorinus; therefore, at the Summer Solstice it began the first Callippic Period, the year before Christ 330. And [year] 178 before Christ — and 274 from the second [period] — and the year 17 began, in the year before Christ 162, current [and] before Christ 162: now the year of Alexander 163, with [year of] Nabonassar 587, did not begin except on October 3, in the very year of the Equinox; the first [equinox] of Hipparchus, day 27 September, pertains to Alexander 162. [Year of] Nabonassar 586, and so to Christ 162; and of the rest of the Autumnal Equinoxes of Hipparchus, which few authors have noted, except this Alexandrian beginning (which Longomontanus, and as to the three first, Levera note).

[Margin: The true Chronology of the Callippic years.]

Albategnius' Equinox [Aequinoctium Albatenij]

[Section] 6. [al-Battānī] Albategnius, ch. 27, *On the Science of the Stars* [*De scientia stellarum*], says that the Autumnal Equinox observed by him [in] the year 1206 from the death of Alexander, on day 19 of the month Elul (that is, [the month] Pachon), day 8 — that is, the 19th of September — before sunrise by about 4 hours 45 minutes; and within this [interval] the Ptolemaic Autumnal [Equinox] elapsed. Egyptian years 743 elapsed, days 178, 17 hours, and 36 minutes about; and therefore, in so great a time the Chords for finding the Equinox so far surpass it by 7, 8, [and] 12 days. Behold, therefore, the synopsis:

[Margin: The true Era of the Olympiads.]

Table. Boxed table headed *Aequinoctium Autumnale* ("Autumnal Equinox"), giving al-Battānī's observation:

Year from death of Alexande r [Ann. à morte Alexandr i]	Year of Christ [Anno Christi]	Month [Mensis]	[Pachon]	Reduced Hour p.m. [Aractâ Horâ p.m.]
1206	882	Septemb. 19	Pachon 8	13 15'

Remember that al-Battānī, in this same ch. 27, supposes the Reduced [hour] more easterly than Alexandria by 40 minutes of one hour. Copernicus, Book 3, ch. 13, and Longomontanus, above, in his commentary *On the Sun*, have seen that the anticipation of the Equinox is least, and so they suspect that al-Battānī had a flawed observation, the manner of which al-Battānī does not disclose. And yet Lansberge, in his *Thesaurus*, pp. 3 and 50, calls this observation *especially distinguished*, and [says] the Reduced [hour] was 13, 14, 15; he prefers the Reduced [hour] to be 13, 14, 15 for himself, and al-Battānī contradicts him; because the very moment of this Equinox is obtained for this same time, [reckoning] from the manner before [given] in the Prutenic, Danish, and Rudolphine [Tables], so that the Reduced [hour] gathers to 23, 40 after noon in the Prutenic [Tables], but in the Rudolphine [Tables] the hour after the following noon [is] 3, 55, which he calls intolerable errors of parallaxes, hour 2, 21; that is, [he places it] after noon for the day 18 September, at hour 14, 21; and badly does Scaliger add Year 884 — which he passes over with Christ 883 — contrary to which see Pétau, Book 4, ch. 6, *On the Doctrine of Times* [*De doctrina temporum*].

[Margin: Lansberge notes this. Joseph Scaliger's faulty Chronology.]

Regiomontanus' Equinoxes [Aequinoctia Io. Regiomontani]

[Section] 14. In the *Little Book of Observations* [*Libellus observationum*] of [Regiomontanus] and of Walther we have two pairs each, for both Equinoxes, observations of the Sun's distances from the vertex at Nuremberg, the Altitude of the Pole of which by Tycho's reckoning [is given in] Tomus I of his

Progymnasmata, p. 48, and [in] our *Geographia Reformata*, p. 49, 26. For by the Ptolemaic [method of] Rules, or Parallactic [instrument], the elders [observed] foot by foot [in] the year 1473, March, on day 11, at the meridian, the Solar Distance from the vertex [was] 83600 hundredth-parts, such as the Radius — that is, the length of either Rule — represents [as] a whole sine [of] 100000 semichords; in the *Tables of Sines* it gives the arc [of] Degree 49, 24, 17; which, doubled, makes the arc 49, 24, 54 — namely [the] apparent distance of the Sun from the vertex after our parallax in such an altitude, not exceeding the second of parallax by 10; that is, the apparent distance of the Sun from the vertex [is] degree 49, 24, 44; which, subtracted from the distance of the Equator from the vertex [of] Degree 49, 26, leaves the Northern declination of the Sun [of] 1 minute, 16; since therefore the Sun was in the sign of the Northern signs, the Equinox was thus made now within the same hours, and the minutes before noon, by however many minutes [the Sun] declined northward from the meridian: Therefore the Equinox occurred at hour 21, 44, after noon of the preceding day 10. By this method and of the same Year 1473, we have gathered the Autumnal Equinox to have been made on day 13 September, at hour 17, 30 after noon at Nuremberg; look upon the synopsis of each in the subjoined table.

Table. Boxed table headed *Aequinoctia Regiomontani in Horis post merid. Norimbergæ* ("Regiomontanus' Equinoxes, in hours after noon at Nuremberg"):

Year [Anno]	Christ [Christi]	At meridian [In meridie]	True Distance ☉ [Dist. ☉ vera]	True Declinati on ☉ [Decl. ☉ vera]	Equinox [Aequino ctium]
	M. D.	Chorda	G. ' "	' "	D. H. '
1473	Mart. 11	83600	49 24 44	1 16 B	10 22 45
1473	Sept. 14	83810	49 32 30	6 30 A	13 17 30

Parsing notes: The declination column carries B (Borealis, "northern") / A (Australis, "southern") markers; in the spring observation the declination is northern (B), in the autumn observation southern (A). The "Equinox" column gives Day, Hour, Minute after noon at Nuremberg.

if you choose the apparent distance of the Sun from the vertex as observed, add to the true [distance] the second [of arc], 10, [for] our Parallax.

Walther's Equinoxes [Aequinoctia Vualtheriana]

[Section] 15. Indeed, I should wrongly deserve [criticism] of Bernhard Walther, who [was] of the highest merit in Astronomy up to his old age, observing now this and now that, then around the days of the Equinoxes, by the Parallaxic Rules, the distances of the Sun from the vertex at Nuremberg by Chords, sometimes adding those, which [he observed] in clear light, and with diligence; in which [matters] one may have confidence that he made [his observations] correctly from himself, if he did not refer them hither, which [observations] of the Equinox he made; particularly when I have seen them [were] undeservedly neglected by the Astronomers of a later age, and so I have selected Tycho himself. The method by which from such Chords the time of the Equinox is brought out is the same as number 14. So, that you may enter the following Catalogue, and [to find] the Distances of the Sun from the vertex add the second 10 of our [Parallax] in your parallaxes, you will have the observed distance of the Sun from the vertex at Nuremberg, or that arc which by the doubled Sine responds for each of Walther's Chords.

Table. Large boxed table headed *Aequinoctia Vualtheri in Horis post merid. Norimbergæ* ("Walther's Equinoxes, in hours after noon at Nuremberg"). The "Order" [Ordo] column is the row index; the observation-quality notes appear beneath each date.

Order [Ordo]	Time of observati on from Christ [Tempus observati onis à Christo nato] / Yr. Mo. D. [Ann. Mens. 28	1501 Mart. 11 — <i>Clara certissim a</i>	84234	49 50 0	33 0 A	11 9 0
29	1501 Sept. 14 — <i>Praeclara certissim a</i>	83990	49 39 32	13 32 A	13 10 28
30	1504 Mart. 12 — <i>Clara præcerta confide</i>	82750	48 52 43	33 17 A	13 9 17

Parsing notes: Two rows are dated 1491 Mart. 11 — the row carrying the *Non valdè, sed sat clara* note appears un-numbered (no Ordo), squeezed between Ordo 22 and Ordo 23, suggesting a duplicated/rejected observation; transcribed as printed. The declination column carries A (Australis, "southern") / B (Borealis, "northern") markers. Several entries in the apparent-Equinox column were tight in the gutter; the Ordo-22 extra-row Equinox minute is flagged [?].

[Margin: Tycho's use of these observations.]

At Tycho, Tomus 1 of his *Progymnasmata*, p. 51, [and in] all the others, which he had seen, he sets before [us his] observations; but to us, in this order, the marginal [note] is the twentieth, and thence he gathered the Equinox to be made [on] day Martii [March] 10, hour 15, 40, after noon at Nuremberg.

But if I had used the Tychonic parallax in that position [of] 2, 18, it would have come out everywhere, the true distance from the vertex [being] degree 44, 41, 15, and the Southern declination [being] 15, 15; and so at that hour the Equinox [fell at] 15, 15. I judge, however, that it pleased Tycho [to use] 10 [for] the observed Radius, as Walther wished; because in the year 1488 the distance was off by 100 [years], and [there was] an integer of reckoning for [the determination] of his Vernal Equinox observation made in the year 1588, just as I am about to compare an observation made [at] the Autumnal Equinox of the year 1588. The Autumnal [Equinox] of Walther I have chosen, which in our order is at [number] 21, that is, the Year 1488; from which, p. 53, I gather the Equinox at Nuremberg to have been made [on] September 13, hour 7, 20 after noon. He differs from our reckoning by 2, and more, by hours on account of an excessive parallax of 2, 18, [which Tycho] assumed, because nevertheless in his observations [there is], in a certain manner, a compensation, in the order for gathering hence the quantity of the Year, on which afterward [more]. Therefore Longomontanus, trusting Tycho, commends the examination of these two observations in his own reckoning.

The Gelalaeian Equinox of the Persians [Aequinoctium Gelalaeum Persarum]

[Section] 31. Joseph Scaliger, Book 4 *On the Emendation of Times* [*De emendatione Temporum*], p. 304, relates that Alp Arslan, Sultan of Khorasan or Mesopotamia, by edict convoked eight of the most distinguished men in [his] kingdom, among whom were Omar and Avicenna [Ibn Sīnā], or Avicenna, to constitute the [Persian] Year [as] an Annus [for the] Equinox; and these, in the Year of the Christian Dionysian Era 1079, namely [the year of the] Hegira 471, and at [the city of] Sezdagird 448, observed the Vernal Equinox [on] day 14, Feria 5 [Thursday],

that is, day 18 of the month of the Persians of Arabia, [namely] Ramadan; [in the] Cycle of the Sun 12, the Moon 16, hour 2, 33[?] after noon. He who [was] called Oromazda [Ahura Mazda?], a Persian of the Neuri[?], Esfehani[?]; this [is] the New Moon of the Equinox of the Imperial Persians. Boulliau also, Book 2, ch. 2, [drawing] from the MS. of the Royal Library of Georgius [George], Chrysococca, asserts that the Persian Tables show the true Vernal Equinox [in] the Year of Christ 1079, under the meridian of Aleppo, by hour 1, 26, distant toward the rising [point] by Martii [March] day 14, hour 11, 4; which Vranburgus [Tycho/Uraniborg] thinks; and so [Boulliau] confesses [it is] his own, that is, [the] Philolaic [Tables exhibit it the] hour 11, 27, exceeding the [Philolaic] by hour 15. As for the true [equinox], Longomontanus in his commentary *On the Sun* thinks the Equinox is not accepted from a corrected [reckoning], unless Scaliger wishes [it] thus constituted from the Annual quantity, which al-Battānī repeats, the reckoning of years had [been] $197 \frac{1}{3}$ (thus correcting the Typographical error in Longomontanus, who has $193 \frac{1}{3}$); he [places] the Albatenian Equinox [in] the Year 882, up to the Persian [Equinox] of the Year 1079, [which] flowed [from it]; on which point, the matter being pending, we cannot as yet make a firm foundation in such an Equinox.

The Equinoxes of Cardinal Cusanus and of Prophatius [Cardinalis Cusani, & Prophatij Aequinoctia]

[Section] 32. Nicolaus de Cusa [Nicholas of Cusa], Cardinal, in his treatise *On the Reparation of the Calendar* [*De reparatione Kalendarij*], affirms [in] the Year of Christ 1290 the observation of some [men], whom he does not name, [to have] entered the Sun into [the sign of Aries], and so by the observation it is established by days 6, 5, 49, 16. Reinhold too, in his *Theorica* of the eighth sphere, fol. 168, has these [words]: "*The Alphonsine [reckoning], and so by name reprehending Petrus de Alliaco [Pierre d'Ailly], because [their] water [reckoning] and the quantity of the year constitute [it], with both the ancient and recent observations manifestly conflict.*" For he relates that in the Year of Christ 1290, on day 13 of the month March, the ingress of the Sun into Aries [occurred at] 16 hours, after the Alphonsine reckoning had been made [at] 12 hours; which relation does not agree with Cusanus' [observation], because those 16 hours he both refers to and underestimates, [the difference] before the preceding 12 hours, per Boulliau, Book 3, [on] his Alphonsine Equinox: the Vernal Equinox of the Year 1290 in the Frisian meridian, by the Alphonsine reckoning, was [at] Martii [March] 12, hour 6, 4, hour 6, 59 after noon: but if the observation [were] of the ingress was [at]

hour 16 after noon of day 13, the reckoning differs from the observation by 33[?] hours.

[Margin: Joseph Scaliger's faulty Chronology.]

which is inconsistent [as reckoned] from the observation of day 13. Therefore, by the Roman manner — that is, the day on which the observation was made — the Equinox is shown [at] hour 8 after noon; that is, in the Astronomical manner, hour 16 after the preceding noon. The same Boulliau, however, draws this sense up to now, repeating the words of Cardinal Cusanus from below: "*In the Year of the Lord 1290, on day 13 March, the Sun is found to enter into Aries after hour 16.*" But Cusanus does not say the observation was made by him, or [that it was made] in Frisia, nor is Reinhold's consequence necessary, or [drawn] from Allacensis [Pierre d'Ailly]. Alphonsine reckoning was able to abandon the observation, not so much the proper [reckoning] equal to the [true] reckoning, on account of the quantity of the Year, and of the Anomaly, and of the Prosthaphaeresis, and of a false dissipation [diffusion] of the Meridians, and of the Equation of the natural days, and of an excessive parallax; by these things simultaneously assumed, an error of many hours could be brought about.

[Margin: ...Era.]

This same Cardinal Cusanus, in the same work *On the Calendar*, has these words: "*Prophatius too, a Jew, and some observers, [in] the Year of Christ 1303, [observed] the Sun [entering] Aries [at] hour 14, after the middle of the night, [the] Aries-ingress; but here Boulliau, Book 2, ch. 2, [says] that day 14 was made for the observation, [whether] it should be understood in the Roman manner [or] the Astronomical, [namely] that day 14 was the hour 8 after the middle of the night [of] day 12, [or rather] after the preceding noon, [it] declaims; and the subsequent observations, and the Alphonsine Calculus, which exhibit [the] Year 1303 — the Equinox in Frisia [on] Martii [March] day 12, hour 11, 12, 25 after noon — [in] the Philolaic [reckoning], which Vranburgus [Uraniborg] exhibits [as] that [of] day 12 Martii [March]; this [is at] hour 18, 35.*"

[Section] 33. The greater difficulty is concerning that Equinox, which the same Cardinal in the same work adduces in these words, speaking of the *Alphonsine Tables*: "*Experience finds [it] as if [at] hour 13, deviating thus, that even Master Henricus Batem of Mechelen, in [his] little book of the Tables, [following the manner of] al-Battānī by Alphonsine [reckoning], then experience taught [in] the Year 1490; and after this, [in] many years, [at hour] 12, [the observers] erred by those same [reckonings].*" For if Cardinal Cusanus died in the Year 1464, as is established

from his *Life*, and from our *Chronicon of the Mathematicians*, which we set at the beginning of Tomus I [of] the *Almagestum Novum* — how could he relate an observation [of the] Year 1490? Boulliau, Book 3, ch. 2, in the margin notes that, since Reinhold in his account [of the] Theory of the eighth sphere recounts the Equinox observation [of the] Year 1346, [says] it ought perhaps to be read [in] Cusanus' [text] as Year 1346, [rather than] for 1490; this is most weakly conjectured, and [more] credible that Cusanus rather wrote 1460; and indeed it is by typography easy to invert these numbers, and to set 9 for 6, p. 9. As for the rest of the Equinox observation [of the] Year 1346, [Cusanus] says was observed [on] Martii [March] day 12, almost two hours before noon; but he does not express the place of the observer.

Copernicus' Equinoxes [Copernici Aequinoctia]

[Section] 35. Nicolaus Copernicus, Book 3 of the *Revolutions [De Revolutionibus]*, ch. 13, says: "*We have observed and noted the Autumnal Equinox at Frauenburg, [in] the Year of Christ 1515, the eighteenth before the Kalends of October; it was, moreover, [in] the Year of the Egyptians 1840, the sixth of the month Paophi, after sunrise by half a day.*" And by this account [Copernicus] supposes the Autumnal Equinox at Frauenburg, oriented from hour 1, and 8; he gathers the Autumnal Equinox observed by al-Battānī [Albategnius], and adds his own Egyptian years 633, days 153, and hours 6, 45; and afterward adds a few [things].

[Margin: Order.]

[Section] 36. "*We received also the Vernal Equinox, which was made in the year following from the noted Christ 1516, hour 4, and the trine, before the middle of the night, the ninth before the Ides of March.*" But Tycho, [in] Tomus 1 of his *Progymnasmata*, p. 34, and in the *Epistles*, p. 74, [says] Copernicus erred in the declination of the Sun everywhere, by an error of 2, 45; and so by an interval the Vernal and Autumnal Equinoxes exceeded by hours 5 $\frac{1}{3}$; [Copernicus] promoted [the equinox] one way, and retarded [it] the other, by hour 2, 45, since [it was made] in the altitude of the Pole, and the Equator he raised [too high] by 2, 45, on account of an omission of Refraction. For Copernicus, Book 2, ch. 2, relates [the equinox] observed by himself and others, the distance of the Tropical points not more than 46, and 38 minutes of first [arc] about.

approximately, and the angle of section — namely of the zodiac signs — is 23°28', and that of two-fifths of one [degree]. Then in Book III, Chapter 2 [Copernicus] says: "the latitude of Frauenburg was found to be 54° $\frac{2}{5}$ scruples of the first kind [i.e. 54° and $\frac{2}{5}$ of a minute], 19 $\frac{1}{4}$." From these consequences it follows that the

Sun's solstitial altitude at Frauenburg in the winter solstice [in Bruma] was $12^{\circ}12'1/4$; and at the summer solstice [in Solstitio aestivo] $59^{\circ}8'1/4$. But the winter [altitude], once the subtraction of refraction of $8^{\circ}54'$ is corrected according to Tycho [Brahe] in his Table of Refractions, would then have made the equator's altitude come out as $35^{\circ}36'3''$, and the pole's [latitude] $22^{\circ}57'$ — and the obliquity of the ecliptic $23^{\circ}31'51''$.

But because Tycho — having sent Elias Olsen [Olaf], a man of the finest skill and equipped with instruments, to Frauenburg — found from the circumpolar stars that the altitude of the pole at Frauenburg was $54^{\circ}22'15''$, he thereby concluded that the refractions at Frauenburg had been smaller than in Denmark. Whatever Copernicus added to the parallaxes of the Sun, and to whatever degree the use of the instruments was [defective] in magnitude, this was the case — especially since, on the testimony of Georg Joachim Rheticus [Rheticus] in the preface to the Ephemerides, Copernicus had not been at all careful about seconds, and indeed had sometimes neglected several minutes outright [in his first observations]. Therefore, on account of these uncertainties, I do not judge it worth the effort to try to extract the true equinox of the years 1515 and 1516 from these observations. But it is enough that one can suspect an error here of three, four, or more hours in them.

The Equinoxes of Pitatus, Nonius, and Landgrave [Wilhelm] of Hesse

[Margin: §37] [Margin: §38] Petrus Pitatus [Pietro Pitati] of Verona, in the preface to his Ephemerides, relates that at Rome in 1520, together with Paolo, Bishop of Forlì [Forosempronensis], he noted the vernal equinox to fall on the 10th day of March, after midday, at 3h, 28m. And in 1521, likewise on March 10, at 9h17m after midday at Rome. Petrus Nonius [Pedro Nunes] of Salacia [Salacensis], in Book III of his work *De observationibus, regulis et instrumentis* [On Observations, Rules, and Instruments] (Geometrical Chapter 14), asserts the distance of the two solstitial points to be 47° in diameter. At Coimbra [Conimbrica], over many years of observation, he found the minimum distance of the Sun from the vertex [zenith] to be precisely 17° , and assuming the maximum declination of the Sun to be 23° at that time, he concludes [the latitude of Coimbra to be] roughly $40^{\circ}30'$.

[Margin: §39] But shortly afterward he revises this. Later, however, in the year 1555 from the birth of Christ, on the 14th day of the month of September, he found the minimum distance of the Sun itself from the vertical point to be $40^{\circ}40'$. Therefore the Sun declines at the meridian of that day $10^{\circ}40'$ to the south; and

since near the equinoctial points the Sun declines about half a degree in a single hour, it follows that on that 14th of September, 10 hours before midday, the Sun was in the section of the autumn [equinox]. When in fact this is found in that very *Liber initiorum* [Book of Beginnings] from the Tables of Alfonso, which the Spaniards praise — namely Hispalensis — he had said a little before [§38]. For he does not follow the Alfonsine [Tables], but reckons everything in agreement with itself, and in this he agrees with many observations, as it is well established; yet the smallness of the astrolabes and his zeal for the Alfonsine hypothesis render his observations suspect.

[Margin: §40] The most illustrious Wilhelm [Wilhelm], Landgrave of Hesse, in the year 1572, on March 7, took the meridian altitude of the Sun at Cassel [Kassel] to be $38^{\circ}40'7''$; and from this, by [subtracting] the just refraction [iusto Byrgio — i.e. as corrected by Jost Bürgi], the altitude of the equator is $38^{\circ}40'7''$. Therefore from the southward declination [declinatio] reduced to the equator [ad Austrum], it is $1^{\circ}10'11''$. If the altitude of the Sun (as Jost Bürgi [Lansbergius] says in the *Thesaurus*) you add $1^{\circ}49''$, who has these observations 9 [degrees], then it follows: *The Sun runs through near the equinoctial an arc of $1^{\circ}10'11''$, in the space of two days, and 22 hours. Therefore the true vernal equinox occurred at Cassel on the 9th day of March at 22h11m after midday.* But he gathers from his own tables that this equinox at Cassel — he says — *had been on the 9th day of March at 22h11m after midday*, entirely as the Most Illustrious Prince observed it. But Tycho [Brahe] in Tome I of the *Progymnasmata*, reporting this on page 75, says that this Landgrave's equinox was observed there at a meridian altitude of the Sun of $17^{\circ}28'\frac{3}{4}$ on March 7; and once the addition of parallax of $2^{\circ}22''$ and the subtraction of refraction of $22''$ are reduced to the true [altitude] of $17^{\circ}30'30''$, and supposing the elevation of the equator there to be $38^{\circ}41'$, he gathers the southern declination of the Sun to be $1^{\circ}10'30''$. He says this corresponds to a place [of the Sun] in Aries [♈] of $27^{\circ}4'\frac{3}{4}$, by the calculation of his own Tables; but [it would be] $27^{\circ}4'30''$ by the Alfonsine [Tables], $27^{\circ}19'$ by the Alfonsine [reckoning?], and $26^{\circ}36'$ by Copernicus — and a difference of two [degrees], and more...

[Margin: Ordi. (Order)]

The Landgrave's Equinoxes, by Hours from the Meridian, at Cassel

Order	Year of Christ	Month and Day	True altitude at meridian — G(°) / M(′)	Declination of Sun — true: ° / ′ / ″ / (N/S)	Apparent equinox — D(ay) / H(our) / (min)
41	1567	March 11	38°41′	1°40′ B[orealis/ N]	10°22′20″
42	1568	Sept. 13	38°30′	10°2′A[us tralis/S]	12°13′40″
(*)	1571	Sept. 13	38°46′	5°40′B	13°5′40″
43	1572	March 7	17°28′¾	71°50′A [?]	9°23′30″
44	1572	March 11	39°1′	3°22′40″B	9°2′30″
45	1573	March 11	38°36′	1°40′B	10°8′20″
46	1578	March 11	38°14′	13°40′B	10°5′40″
47	1578	Sept. 14	38°23′	17°20′A	15°6′40″

Parsing notes: This table is degraded; column boundaries between "altitude" and "declination" sub-columns are hard to align, and several second-place values are uncertain. The Declination column header reads "Declin. ☉ vera" with sub-columns I / II (minutes/seconds) and a B/A (Borealis/Australis = North/South) marker. Row marked (*) carries an asterisk rather than an order number in the source. Values flagged for further review.

The Tycho's Equinoxes, from his own Observations

Tycho [Brahe] himself, in Tome I of the *Progymnasmata*, page 13, reports five vernal equinoxes and the same number of autumnal ones, by the days of the Old Style [of the old calendar] and by hours from the meridian, at Uraniborg, where he determines the altitude of the equator to be 34°5′22″. He uses no refraction in calculating parallax. The parallax of the Sun [he takes as] 2°1′29″. He takes the refraction at the second [degree] as 44″. Therefore when he says he observed the equinox for himself in the year 1584 on March 9, at 2h30m after midday, this is to say that he observed the meridian altitude of the Sun on that day to be 35°42′. For to this, adding the parallax of 1°29″, and subtracting the refraction of 44″, the

corrected altitude becomes $35^{\circ}43'45''$; and once the southern declination of the Sun ($21^{\circ}30'$) which corresponds to it is subtracted from the elevation of the equator ($34^{\circ}5'22''$), it leaves the southern declination of the Sun as $21^{\circ}30'$ — to which there corresponds the hour $1^{\circ}30'$ for the subsequent equinox to be celebrated.

By this method we obtain five [equinoxes]; and the aforesaid equinoxes [taken] from Tycho — without any observations of the altitudes [retained] — will come to us from these very Tychonic observations; but we will correct them by adding our own parallax, which in such a situation is $16''$ according to the second [degree], and by subtracting the refraction of $44''$. Likewise we shall make [adjustments], by which from other meridian altitudes near the equinoxes — and from those reported by [Longomontanus] in Book I, Theoricae, Chapter 2, in his commentary on the Sun — emerging there, we shall distinguish the moments of the equinoxes both according to the Tychonic parallax, and according to our own emerging [parallax], which we shall accordingly distinguish by the characteristic T.N.

[Margin: Ordi. (Order)]

The Equinoxes from Tycho's Observations, by Hours after Midday, at Uraniborg

Parsing notes: This is a very densely set five-column table with stacked two-line cells (visa/vera split across rows) and tightly packed second-of-arc figures. Many cells are uncertain; the "visa," "vera," and "declination" columns each carry an upper and lower line per order-row. A/B = Australis/Borealis (South/North). T = Tychonic, N = Nostra (our/Riccioli's) reduction. Several values flagged for further review. The whole table is a strong

[Footnote text below the left table:] Jost Bürgi [Lansbergius] in the *Thesaurus*, from so many Tychonic equinoxes, selects a single one for the verification of his own Tables — which holds at 52' in our order; and that [equinox] not at 9h8' after midday — Tycho does not have it [so], but [rather] at 9h2'. As from Tycho via [Christoph] Clavius in the *Apologia Kalendarii*, but at 9h34' at Uraniborg, because at an altitude of 34°. Tycho assumes the parallax of the Sun [to be] 2'½, nearly; Jost Bürgi [Lansbergius], however, [takes] 2'. But [in computing the moment of] mid-minute about the equinox in the declination of the half-hours [in declinatione semihorarum]. Yet both [men's] parallaxes are faulty, as is evident. [Boulliau] also, in Book II, Chapter 2, from a single Tychonic and a single Hipparchan annual quantity, elicits [a value] — as is evident from the equinoxes in our order, marginal [items] 5 and 56.

The Lansbergian Equinoxes

In the *Thesaurus* of observations, [Philip van] Lansberge [Lansbergius] draws forth two vernal and two autumnal equinoxes of Goes [Goésae].

[Margin: Ordi. (Order)]

The Lansbergian Equinoxes of Goes, by Hours after Midday, Old Style

Order	Year of Christ (A.)	Month, Day (M.D.G)	Altitud e visa (G I II)	Altitud e vera (G I II)	Declination vera (G I II)	True equinox (D H)
67	1589	Mart. 9	38°0'30" / 38°0'44"	38°2'19" / 38°2'18"	26°41'A / 16'	10°2'41" L / 4°16' Nos
68	1589	Sept. 13	38°22'0" / 38°23'4 8"	38°23'4 8" 38°22'1 4"	5°12'A / 6°46'	12°18'4" L / 18°17'1 4" Nos
69	1599	Mart. 10	38°13'2 0" / 38°15'1 9"	38°15'9" / 38°15'2 6"	13°51'A / 13°51'	10°13'5 1" L / 13°51' Nos
70	1599	Sept. 12	38°33'1 5" / 38°35'3"	38°35'3" / 38°33'2 9"	6°3'B / 4°29'	12°6'3" L / 6°4'29" Nos

Parsing notes: Two-line stacked cells again (visa/vera upper-lower). L = Lansbergian, Nos = Nostra (our reduction). A/B = South/North declination. Second-of-arc figures uncertain throughout.

[Right-column prose, top of folio 12 verso, continuing the Lansbergian discussion:] observed by himself, and not differing by even a single second from his own tables. But the altitude of the equator is 38°29', by the use of refraction; nor is the parallax 1'48", but 49" — with mine never being greater [than] 14"; the difference of these is 1'35", which varies the declination by the same amount, and the time of the equinox by 1h35'. We therefore append from Lansberge's [data], and from our own parallax, the equinoxes, deduced from his very observations, that they may be referred to him. Wherefore, if our parallax is the true one, his Tables err in this place by 1h35'.

Four Equinoxes Observed in the Years 1536, 1574, 1575, 1581

[Margin: §71] I confess I ought to have reported [these] before the Tyconic ones, but [they are] little related. So then, for the year 1536: as Daniel Santbech

[Santbechius] relates concerning the observation in *Phaenomena*, Proposition 11. At Tübingen [Tubingae] the exact equinox was observed in March on the 10th day, at that very midday — from which fact [Santbech], following Ptolemy's vernal [equinox] and supposing Alexandria to be more eastward than Tübingen by 1h28' — gathers the annual equinoctial [interval to be] 365 days, 5h48'41"42"', 33" 50" 10"'''.

[Margin: §72] In the year 1574, [Ignazio] Dante [Egnatius Dantes] of Florence [Florentinus], in the presence of many witnesses, observed at the equinox of March, 12 hours and 1°36'; before midday, on an equinoctial armilla equally illuminated on both sides [as to] its cavity, he judged the equinoctial moment to have occurred at that instant from the steady passage of the Sun across [the line] between [it and] the north, as he relates in *De Astrolabio*, part 6.

[Margin: §73] Thus in the year 1575, with the instrument set up at the same place, the equinox of March was observed at 12h4'12" after midday. Moreover, at an altitude of the equator of 46°, my parallax [is] 10"; the same number of minutes by which it is retarded [makes the] equinox.

[Margin: §74] In the year 1581, Cesare Lucchino [Caesar Luchinus] of Bologna [Bononiensis] observed at Bologna the equinox of March at 11h. At the southern meridian altitude of the Sun of 45°15'15", [recorded] in a great geometric quadrant — as I read it in his manuscript — with a parallax of 10" added, it gives the true altitude of the Sun here as 45°25'40"; [this] subtracted, leaves the northern declination of the Sun as 2°45". Therefore the equinox is here elicited as the 10th day, 2h1'15" after midday — or [at] 2h0', if you wish, with the refraction of 5" diminishing the altitude of the Sun.

Equinoxes Observed at Bologna by the Reverend Fathers Giovanni Battista Riccioli [Riccioli] and Francesco Maria Grimaldi [Grimaldi]

I had indeed thought to pass over these, after our solar observations made from the year 1641 to 1656 by the Gnomon of S. Petronio [San Petronio] succeeded one another — to which, on account of the magnitude of the instrument, ours must in any case yield. Especially when, on those occasions, we determined certain equinoxes by applying the altitude of the equator [as]...[continues]...

45°30'30", which we shall afterward teach (as in Book IV, Chapter 4) was found in our observatory to be 45°29'50". Nor does the parallax of the Sun at such an altitude hinder us further [from] holding [it]. These notwithstanding, it pleases

[us] — from the meridian altitudes accepted by us, and indeed assembled by the three quadrants — at the same time to adjoin such equinoxes as ought to be reckoned by them at S. Petronio; and [the equinox] deduced thence by the Annual precession, which is 1h14'14", with respect to the Julian year of 365 days. And the refraction in the meantime — 5" — we disregard as uncertain.

[Margin: §85] Giovanni Domenico Cassini [Cassini], in the book entitled *Specimen observationum Bononiensium, quae novissime in D. Petronii Templo &c.* [A Specimen of the Bolognese Observations, most recently made in the Temple of S. Petronio, etc.], page 10, asserts that the autumnal equinox was observed by himself in the year 1655, on September 22, at 5h4'55" before midday, at the apparent time, that is, on the 22nd day at 18h57'55" [?] [or 18h25"] after midday. But neither the observation, nor the method by which it was extracted, do I believe — because [it is] of a kind [too] high — caused [it] in [his computation of] the equinox of 1656. He supposes, however — for both observations, concerning which the obliquity of the ecliptic is 23°30'20", and the parallax of the Sun, [and] the altitude of the equator observed here [to be] 45°29'40" — to be either nothing, or scarcely sensible. Yet he communicates to us the Tangents of the distance of the Sun's two limbs from the vertex, namely [those] of this year 1655, [on] September 22 and 23, observed at the meridian — from which we shall elicit those distances by the method already handed down in Chapter 2, item 13.

Year 1655, September 22 (Tangents)

Quantity	Tangents	G(°) / I(') / II('')
Lowest margin of the Sun [Inferi Solis marginis]	98135	44°27'36"
Highest margin of the Sun [Supremi Solis marginis]	96344	43°56'0"

Therefore the declination [Ergo Declinatio]	Australis (South)	0°4'57"
And with the obliquity of the ecliptic posited [Et Posita Obliquit. Eclipt.]		23°30'20"
The place of the Sun in the ecliptic [Locus Solis in Eclipt.]		0°12'24"

Quantity		Value
Therefore the true diurnal motion of the Sun from day 22 to 23 [Motus igitur diurnus Solis a die 22 ad 23]	Verus (true)	0°56'22"

Therefore if [the diurnal motion is] 56'22", [computing the moment] requires 24 hours in any case [for the full distance]; the distance of the Sun from the beginning of Libra [□], which on the 23rd day was 12'24", requires 5h17' [?]. Therefore by this method — which is Cassini's — the equinox would have been at 5h17' before midday on the 23rd day, or at 18h43' after midday on the 22nd day. He himself, however — I believe on account of the refraction of some seconds — limited that to the hour 18h55'25", from which I do not dare to depart. From Tycho's equinox of the year 1587, which we have corrected from that number 55, and by reductions of that kind for [the difference of] 68 years [hours 5°43'45'''], with the days abandoned, this very equinox of the 22nd day arises at hour 18h28'6"8''' — later by 27'18"52''' than [the one] observed.

[Margin: §86] In the year 1656, Giovanni Domenico Cassini [Cassini], as he reports in the aforementioned book, observed the vernal equinox at the apparent time of March 19, at 9h50'50", after midday — by the following method: from the observations of March 19, 21, and 23, at the meridian — for [on] the 20th and 22nd it was cloudy.

Year 1656, March 19 (Tangents)

Distance of the equator from the vertex [Aequatoris distantia à vertice]		44	30	20
Therefore the Sun's north declination		1	35	0

	Tangents	G [°]	I [']	II ["]
[Ergo Solis Declinatio Borealis]				
Obliquity of the ecliptic [Obliquitas Ecliptica]		23	30	20
Therefore □ the Sun's place on the ecliptic [Ergo locus Solis in Ecliptica]	□	3	33	16

Now indeed on the 19th the Sun was distant from the beginning of Aries by 24°24"; on the 21st it stood at □ 1°34'30"; and on the 23rd at □ 3°33'16". Therefore over the two preceding days the Sun's true motion on the ecliptic was 1°58'54", half of which gives a daily motion of 59'27", while over the four days [from the 19th to the 23rd] it was 3°57'28", a quarter of which is again 59'27". Now since the Sun on the 19th was distant by 24'24" — that is, its distance from its entry into Aries requires that we compute backward — it requires 24'24" of arc; this, traversed at a daily rate nearer to the equinox itself, gives 24 hours, and is reckoned as 24'24". Thus the distance from the entry into Aries requires 9 hours, 50'40", or 9h50'41" p.m. Therefore Cassini states that the apparent equinox fell on March 19 at 9h50'40" p.m. — which, by the method common to all because of the south declination of 9°44", would have fallen at 9h44", as if by the first method; but by the second method, on account of the south declination of 37°40", it would have fallen at 17h40" a.m. of the 21st [?], that is, at 17h10" a.m. — yet this is more subtle than the earlier method. Furthermore, if we accept Cassini's correction to the year (which has been treated above of [?]), and from the aforesaid equinoxes the equinoxes of several following years may be predicted, as in the table written below — by adding to the equinoxes of individual common years 5h49', but in a leap year, after the said addition, subtracting one whole day from the sum.

Year at Bologna [Bononiæ Anni]	March, after midday [Martij post meridiem] D. / H. / I.	September, after midday [Septembr. post merid.] D. / H. / I.
1655	20 / 4 / 2	22 / 18 / 55
1656	19 / 9 / 51	22 / 0 / 44
1657	19 / 15 / 40	22 / 6 / 33
1658	19 / 21 / 29	22 / 13 / 22
1659	20 / 3 / 18	22 / 19 / 11
1660	19 / 9 / 7	22 / 1 / 0

Let us now see whether the observations of Sir Cassini, or those of associated investigations made at the gnomon of San Petronio, correspond.

§89. Year 1656, September 22.

Therefore □ the Sun's place on the ecliptic [Ergo locus Solis in Ecliptica]	□	29	57	22

§90. Year 1656, September 23.

	Tangents	G [°]	I [']	II ["]
Of the Sun's lowest limb [Infimi Solis marginis]	100495	45	8	30
Of the Sun's highest limb [Supremi Solis marginis]	98670	44	37	0
Apparent diameter of the Sun [Solis Diameter apparens]			31	30
Semidiameter [Semidiameter]			15	45
Distance of the Sun's center from the vertex [Centri Solis Distantia à vertice]		44	52	45
Distance of the equator from the vertex [Aequatoris distantia à vertice]		44	30	20

	Tangents	G [°]	I [']	II ["]
Therefore the Sun's south declination [Ergo declinatio Solis Austr.]			22	25
Obliquity of the ecliptic [Obliquitas Ecliptica]		23	30	20
Therefore the Sun's place on the ecliptic [Ergo locus Solis in Ecliptica]	□	0	56	11

Therefore on the 22nd the Sun was distant from its entry into Libra by 2'38", while on the 23rd it had already entered by 56'11". Hence the daily motion was 58'49", which requires 24 hours; therefore 2'38" requires [...continuing on next page...] 1°4'18". Therefore the equinox emerges from this observation as September 22, at 1h40'28" p.m. Now in the preceding Table it had been put at 0°44". Some small inaccuracy [vitiolum] therefore lies hidden in the observation, and in the omission of the parallax, or of the refractions, for from these jointly an error of 20" could arise; and this in the time of the equinox, that is, 26' of [time] minutes, and at the same instant the Sun's diameter is somewhat less, which I gathered in the accurate observations of the equinoxes — but the diurnal motion is small. From the aforesaid precession our 11'12", concerning which see Chapter, following, no. 10, ought to have been at 0°43'48".

§91. I add that [Hevelius] recently sent me an observation he had made: it was indeed in the year 1654, September 23. He observed the Sun's meridian altitude at Gdańsk [Gedani] of 35°28'40", where the equator's altitude is 35°38'; from this, neglecting parallax and refraction, there results an equinox at 9h20" a.m.

CAPVT IV.

De Quantitate Anni Aequinoctialis motuque Diurno, & Annuo Solis. (On the Length of the Equinoctial Year and the Diurnal and Annual Motion of the Sun)

§1. The equinoctial year is the revolution of the Sun from one of the equinoctial points back to the same point. We have already laid down in Book 3 of the *Almagestum Novum* (*Almagestum Novum* III, ch. 30) that a year of this kind is always of the same length. The mutation of the apogee and of the eccentricity of the Sun is no obstacle, for from these it does not follow that the years are unequal, but rather that within one and the same year the Sun's motion is unequal and the boundary-points vary, while the year is bounded by the same species. If the equinoxes could be immediately observed, of the same species, the matter would be without doubt; but since the equinoxes are observed with an error exceeding 1'5", then if we had a sufficient length for the equinoctial year to determine past and future equinoxes for years around 1600 — before, and by just as much after — we should arrive at greater certainty. Yet for greater security two equinoxes of the same species ought to be chosen, of which the observations are more certain than the others, and which are separated by the greatest possible interval of years, observed without disturbance, among many distributed years, and reckoned with contemptible error. Let this be that of Sir Giovanni Domenico Cassini, who, relying on the magnitude of the gnomon of Bologna, judged that the revolution of a single year would suffice to avoid an error of 1' — and four years to avoid an error of 1'5". But to avoid an error of 1' at a single moment of the equinox, one must avoid the Sun's altitude and the pole [Poli], from which the declination is derived: an error of one second [arises] in the second [of declination], though indeed the magnitude of this gnomon is abundantly secured, yet its use is rarely employed by me and others, and as it happens to those skilled in the matter. Certainly Cassini himself, in the work praised above on p. 18, suspects a refraction of nearly 1' at an altitude of degree 45, but it is not constant at that altitude. [Tycho Brahe], in Tome I of the *Progymnasmata*, set forth an interval of 100 years, [preferring it] over the many centuries among his observations and those of Hipparchus, Ptolemy, or [al-Battānī], which he judged slippery and untrustworthy, or implicated in the threefold difficulties of chronology. But the observation of [Bernhard Walther] [Bernardi Vualtheri], made on the equinox in the year 1488, he held to be much more certain than those; and therefore he compared it with his own made in the year 1588 — which are stated in chapter 3, order 20 and 56 — especially since, by

these means, the universal restitution of the solar course, competent for all ages, would be measured.

[Margin: Requisite ad Annuam Quantitatem determinandam — Requisites for determining the annual length.]

	D.	H.	I [']	II ["]
From [Hipparchu s] to [Ptolemy] [Ab Hipparcho ad Ptolemæu m]	365	5	55	12
From [Ptolemy] to [al- Battānī] [A Ptolemæo ad Albategniu m]	365	5	46	20
From [al- Battānī] to [Tycho Brahe] [Ab Albategnio ad Tychonem]	365	5	49	29
From [Ptolemy] to [Tycho Brahe] [A Ptolemæo ad Tychonem]	365	5	47	52

But if the Sun's course is sufficient, adapting it [the determination] within 300 or 400 years [suffices], and from these by collation he establishes the equinoctial year [as] on p. 53, written below.

Of days 365, Hours 5, 48', 45". [Dier. 365. Hor. 5, 48', 45".]

[Margin: Annual length according to Tycho — Anni Quantitas Tychonica.]

§2. Sir Giovanni Domenico Cassini, in the aforementioned *Specimen* of observations, p. 15, supposes Hipparchus's observations to be uncertain within a half-day, and Tycho's within a half-hour; and that for the same reason a half-hour [is uncertain] within a half [day]; just as is the interval of 72 years between us and 1728. Therefore it is altogether the same as if one used the interval of 72 years between us and Tycho, as between Hipparchus and Tycho, for the interval is 1728 years. From these positions, since indeed [Tycho Brahe], in his *Commentary on the Sun*, in the year 1584, March 11, accepted as the Sun's meridian altitude by his style [stylo] the meridian degree $54^{\circ}29'55''$; the equator's altitude at Uraniborg being subtracted, $54^{\circ}5'$; there remains the Sun's north declination $24^{\circ}35'$. But the daily mutation of declination at the equinoxes is $23'42''$; therefore from the declination $24^{\circ}35'$ there fits 1 day, and over and above an hour of $0^{\circ}54'$; and by just so much time before the perfected equinox the meridian of the 11th [precedes], and at Bologna this fell on the 23rd. In the year 1656, the observation and the equinoxes of the year sought by Cassini, on March 9 by the old style, was 9h50' p.m., therefore by 72 years the year was anticipated by $13^{\circ}12'$, and for individual years 11', which subtracted from the Julian year of 365 days, 6 hours, leaves the equinoctial year [as] 365 days, 6 hours, less 11', that is, 5h49', which after many considerations Cassini reckons safer; and the same Petavius elected, in *Doctrina Temporum* book 4, ch. 36; and Tycho in tome 1 of the *Progymnasmata*, p. 12, was lacking in it.

[Margin: Annual length according to Cassini and Petavius — Anni Quantitas Cassinæ & Petauio.]

§3. But I do not concede to Cassini that the equinox observed by Hipparchus is not certain except within a half-day, with some difference of a few hours, just as that of Tycho is certain within a half-hour, and Hipparchus himself, the equinox assumed by Cassini from the observation of the 9th, as is clear from chapter 3, number 48: I find Tycho's [equinox] from the parallax to have been the 9th, hour 21, 30". But our [observation], with the parallax applied, hour 23, 43", with no parallax; hour 23, 53"; and Cassini from another observation noted above hour

23, 6". Therefore they are not certain within a half-hour of Tycho; and consequently it suffices that it recur at a doubled equinox over longer intervals.

[Margin: (—)]

§4. [Longomontanus] therefore, in his *Commentary on the Sun*, having corrected his own principles, the equinoxes [reckoned] from the ancient [observations] of the earlier [astronomers], chooses Hipparchus's, of which see ch. 3, num. 7: that is, the vernal [equinox] in the year before Christ 146, March 23, hour 13, p.m., celebrated at Alexandria, with which he compares the equinox of 1587, observed at Uraniborg, but at Alexandria hour 14, 56". At Uraniborg, but at Alexandria hour 16, 31"; and on account of the unequal *prosthaphaeresis* [prostaphæresim] added hour 3, 56"; and on account of the unequal precession, the equinox brought back around hour 7, and thus it reduces the equinox to hour 8, and at hour 3, 21" p.m. [is] the meridian. Therefore in the year 1733 it anticipated the equinox by 11 days, hour 9, 39"; but it lies open per the error of calculation [as] hour 19, 39"; and roundly again hour 12, hour 10, 20", which, distributing over the individual years of 1732, repeats the precession with respect to the Julian [years] as 10'40"; and therefore the year is bounded by the Sun's course [as] D. 365, h. 5, 49', 20", vel limited on account of the course of the Moon D. 365, h. 5, 49', 30".

[Margin: Annual length according to Longomontanus — Anni Quantitas Longomontano.]

§5. Ismaël Boulliau [Ismaël Bullialdus], in *Astronomia* book 2, ch. 2, chooses the first vernal equinox of Hipparchus, of which ch. 3, see also num. 1 of ours, namely the year before Christ 146, March 24, where the refraction having been subtracted, the equinox was made on the 25th hour 23; but in such a way that at Uraniborg on the 25th hour 8, 11', 22', 35". At Alexandria, but at Uraniborg hour 10, 1', 35". This he compares with the equinox of '56, in the order of our chapter 3, observed at Uraniborg March 9 hour 10, 45" p.m. — which on account of the *prosthaphaeresis* is reduced to the mean equinox made on March 11, hour 11, 25', 15" — between these two equinoxes a mean equinox is gathered [as] the year of the Egyptians 1734, days 15, hour 2, 24', 45", which time divided by the Julian years 1733 gives the annual length written below.

D. 365, h. 5, 49', 4", 21", 4". [D. 365. h. 5. 49'. 4". 21". 4".]

[Margin: Annual length according to Boulliau — Anni Quantitas Bullialdo.]

§6. [Kepler], in the *Epitome of Astronomy* and in the *Rudolphine [Tables]* [Rodulphinis], uses a year of 365 days, 5h48'57'36" — not expressing the manner in which he uses it; just as neither does Lansberge [Lansbergius] in his *Thesaurus of Solar Observations* at the end of Class 3, where he defines the annual Tropical year [as] of days 365, H. 5, 48', 57", 2", 22", 24"; though even some equinox is set forth, by which it is reckoned, yet he does not explain it. But [David Origanus?] / Wendelinus [Vendelinus], in his letters as in his *Idea of the Atlantic*, sets down no fundamentals on which he might establish the quantity of the Tropical year, unless what he fixed in *Annus Tropicus* 33, having days 120539, [which is] sufficiently precise; whence, by the by, divided by 33, gives that the year is 365 days, 5h49', 4", 27", 16"; if indeed it is what Cassini states [as] 330, [it would] yield 120539, whence indeed it is reduced to 120529, but the year [is] less than Wendelinus's. His therefore, setting aside the dismissed [ones], who established the year, not led by observations — our opinion we bring forth in the middle.

§7. That we may inquire into the quantity of the equinoctial year, we choose the equinox most exactly observed at Bologna in the great gnomon of the Temple of San Petronio in the year of Christ 1665, the 22nd day of September by the Gregorian style, hour 18, 5', 23" p.m., as above, retaining the eternal hour with the Sun aggregating in Cancer [in Cancrici], degree 8, 35', 45", as in num. 1 of Sir Giovanni Domenico Cassini, just as in the recent observations there held, the eccentricity by the apparent Diameters is deprehended; and how much by our eccentricity the whole partition is 3480, of which the Radius is 100000: it follows in the distance of the beginning of Libra from the Apogee degree 81, 24', 15". The *prosthaphæresis* [Prostaphæresis] degree 1, 58', 17": this mean motion having been subtracted, but the mean being added, just as is the middle; but the Sun's mean motion of the equinox the medium goes before; and therefore the medium was on day 10 September by the old style, h. 18, 53', 23" p.m.; but at Alexandria, by my *Geographia Reformata*, it was h. 20, 28', 5". And it was the third year after the bissextile [leap year].

[Margin: (—)]

§8. It is fitting now, among the most ancient equinoxes, and those observed by Hipparchus, to choose one, and that in the third year after the bissextile; and of which hour we can attain as great a certainty as possible. Such is that which Ptolemy in book 3, ch. 2 reports as observed in the year 21, in the third Callippic Period, on the first Intercalary day, hour 6 [?], that is, the night [or: at the sixth hour, that is, the night] [...]; but Ptolemy reckoned a true equinox at Alexandria, collocated [as]: now in our Chronological Apparatus that year [falls] before the

vulgar Epocha of Christ 158, and day 1 of the Intercalary period began at midday, or at the end of the sixth hour, that is, September 27; therefore we have an interval truly the longest among the equinoxes: namely [an interval of] 1812 whole years.

§9. As regards the hour of the equinox, although Hipparchus estimated that it was made at the sixth hour, this indeed [happened] at midday itself; yet from the preceding observations of these, [it is shown] that it preceded the meridian moment by several hours. For Ptolemy himself narrates that Hipparchus narrated, or preceded, [in] period 20, the third Callippic, that he had observed the Autumnal equinox in the morning of the day before the Intercalary [day]; therefore in the morning, the Sun having risen, or a little after, he saw the Armilla [the ring of the armillary instrument] equally illuminated everywhere both ways, and therefore reckoned that it was then the Solar equinox [that is, by the horizontal armilla; or one might doubt that it was necessarily so, since the Sun had not yet appeared, when it appears to be still in the south, and crossing the equator, when it appears at the equator; therefore that most certain equinox is here at some particular hour, and at the Sun's rising, namely at the hours nearest, 4, as we shall show]. But it is certain that, with all the astronomers, the equinoctial year is said [to be] 365 hours, 5 [days] and 48' minutes [recte: 365 days, 5h48'], and certainly something obtained from the Sun's signs [as] the year of days 365, hour 5, 49'; and granting that the equinox preceded the year of days 365, hour 5, 49'; if the equinox had been made on the 20th before the Sun's rising — granting that it could not be on the 21st before the Sun's rising, that is, hour 2 before the Sun's rising — this is the hour nearest, that is, on the 26th of September, or the first Intercalary, that is, hour 4 before the following midday.

Now indeed from what has been said in Book 3 of the *Almagest*, ch. 1, num. 8, and from Boulliau book 2, ch. 2, it is sufficiently established that the Sun, around the quadrant after its rising, on account of refraction, appears more southerly [australiorem] in the circle of declination, by some 4 or 5 minutes — which [error] of just as many minutes the [Sun's] arrival retards while it appears in the equator; and this still in the Boreal [northern] signs is represented. Since Hipparchus had judged the morning to be the time of the first civil intercalary [day], and reckoned the equinox to be 20, and that in the morning the meridian had not yet seen the Sun still Boreal, nor unless under the sixth hour it crossed to the south, nor sooner — than 6 hours after the preceding day the equinox, that is, the sixth hour from rising, was made the subsequent equinox. He could have [judged]; to this deception something might contribute, the Armilla's situation, or the placing by one or another minute declining from the plane of the equator.

Therefore let the true equinox at Alexandria in the year 158 before Christ be held as nearly certain, [made on] September 26 in the morning, hour 6 p.m. [recte: a.m.] [...]

§10. But the Sun's apogee was then, by our observations (of which below, in Gemini degree 7, 21'), distant from the autumnal [equinox] by 112°39'; and so the *prosthaphaeresis* is degree 1, 26', 16". Hence at the same time there fits [a correction]: 1°, hence 6'; therefore the equinox at Alexandria was made the 24th, hour 23, 9', 49' at the mean equinox of the year 1655 — it was September the 10th, hour 20, 28', 5". Therefore the Precession of the equinox was of days 14, hour 2, 41', 44". This having been resolved into seconds is 1219304"; and this divided over the elapsed years 1812 gives an annual precession of 11'12".

[Margin: Ptolemæi nimia fiducia. — Ptolemy's excessive confidence.]

§11. This precession, while I weigh it with a profound mind, betrays a certain Ideal beauty, congruent with the seventh diameter, with the integer of the seven [intervals] in the seventh century [hebdomadas seculorum], by a multiplied beauty of 11' and 12" over 900 years, giving exactly days 7, in which the equinox precedes; and this so marvelous an analogy makes it not doubtful, since indeed it is received with such great beauty, and over and above based upon the observational foundation, that this very same secular [interval], leaning on 18, betrays itself.

§12. Therefore, the Sosigenian days 365 having been subtracted, and the hours 6, minus 11' and 12", there comes forth for us *the Equinoctial Year of days 365, Hours 5, 48', 48"*. Resolving the day, it is *the Equinoctial Year of days 365, in second [degree] 31' 5698" [?]*; but *the common year of days 365 in second 153600"*. In *second 1296000"*. For if the Zodiac be multiplied per the common year of days 365, and divided as the equinoctial year, there comes forth *the Sun's Mean Annual Motion*; but indeed *the Day, the Month [vel Mensis] [...]* divided per the Zodiac, and the sum divided per the Equinoctial year, we shall have the *Diurnal* and *Menstrual* [monthly] *Motion*, as below, reduced to seconds in such a way; and by sixth [order] scrupulously [computed] in compiling the Tables to many years the ratio is to be held.

CAPVT III.

Solstitiorum Observationes. (Observations of the Solstices)

§1. I have said in the notes to the observations of [Snellius] [Snellij] in *De Observationibus Hassiacis*, [to those] pronounced by Hercules [Herculei], that the labor must be avoided of observing errors in observing the solstices.

[Margin: (—)]

Now indeed from what has been said in Book 1 of the *Almagest*, ch. 3, and from Boulliau book 2, ch. 2, it is sufficiently established that the Sun, around the quadrant after its rising, on account of refraction, appears more southerly [australiorem] in the circle of declination, by some 4 or 5 minutes — which [error] of just as many minutes the [Sun's] arrival retards as it appears in the

equator; and this in the Boreal signs is represented; for at that time the difference of diurnal declination is of seconds 14" or 16"; by which, if the whole be in error, the error will arise integer, even with a single minute; but the error of half a day [arises], with an error of 6 hours; the cause [is] in the obscured altitude of the Sun, [an error of] 4" of seconds. Whence Ptolemy had so great a subtlety of his instrument that — as he confidently states in Book 3 of the *Almagest*, ch. 2 — he said: "*But in the solstices we hope, neither we nor Archimedes in observation, and by calculation up to the fourth part of the day to have erred.*" It is added here in addition the uncertainty of refraction at the Sun's altitude of Bisaltimum [?] observations being equal [for] frequent [ones], we ingest, and the sixth [part] depending on parallax, the Sun being horizontal, which some reckon at 3'; some at 2'; others at 1', they establish; Wendelinus [Vuendelinus] reckons 15". We scarcely [reckon] 30". On account of which doubts, and the most slow [motion] near the Tropics, the change of declinations, Ptolemy book 3, ch. 2, said: "*For the sake of antiquity, then, the Solstice of Meton and Euctemon, and afterwards that of Aristarchus observed in our time, these are to be conferred which were of our times. But since the Solstitial observations are discerned with difficulty, and which equinoxes by their handing down are not exquisitely captured, they appear; what indeed are most exquisite of the equinoxes observed by Hipparchus. We also, [observing] a few things together, do not [adduce] from the ancients.*"

[Margin: Prolemæi [recte: Ptolemæi] nimia fiducia. — Ptolemy's excessive confidence.]

§1. Ptolemy narrates, in book 3 of the *Almagestum Construct.* [*Magnae Constructionis*] ch. 1, from Hipparchus, concerning the magnitude of the year — [that] Aristarchus, in the year 50 of the first Callippic period, and 44 from the death of Magnus [Alexander], which is 280 years before Christ, observed a Solstice on a certain day, that very year [as] 152: now the year [had begun] before Christ 432. Meton and Euctemon, with Abscondus prefect of Athens, made the Solstice on the 21st [of] Phamenoth [?]; Scaliger book 2, *De Emendatione Temporum*, p. 76, and book 5, p. 410: and Petavius in *Uranologion, Variarum*, discourse [differt] book 6, ch. 10, say that it was [in] the year of Nabonassar 316, day 27, feria 1, one [day] before the Solstice: for Meton from his observation of the True [solstice], being elected, made [it] of his own Cycle to run in, just as Meton's day [feast] was said; and so is to be understood that Festival of Avienus in those verses:

*primam Meton ex ordio sumpsit ab anno Torrentem rutilo cum Phoebus
sidere Cancrum*

[Margin: Mesonis [recte: Metonis] Solstitium. — Meton's Solstice.]

For at Athens in that year Meton's Solstice fell on the 27th day of June, hour 10, 43' after the middle of the night; the True [solstice], however, on the 28th day, hour 19, 13". But Petavius added that, in Hipparchus's time, the Solstice [fell] in the middle on the 25th of June; the True [as] on the 28th, and the Solstice in the mean on the 14th. But the True, on the 25th, was wont to fall. But Lansberge [Lansbergius] in his *Thesaurus*, Class 4 of solar observations, against the *Syntaxis* draws back this chronological observation to that of Nabonassar (when it behoved [him to use] that of the Athenians), gathers [it] from his own Tables, the solstice [as] hour 16, 41' p.m. of the 20th [of] Phamenoth, at which moment he asserts the Sun to have entered Cancer, and therefore wishes it to have been the True equinox [recte: solstice]; that is, the year of number changed. Certain, however, it is to me that the 21st of Phamenoth was the 16th of June.

[Margin: Lansbergij lapsus. — Lansberge's error.]

§2. Ptolemy, book 3, ch. 2, subjoins an observation made by himself at Alexandria of the summer Solstice in the year 463, from the death of Alexander, the day 11 [of] Messori, after the middle of the next following night, made; he repeats ch. 4, [that] it was the year of Christ 140, day 22 [of] June, which followed; but he places Lansberge [Lansbergius] in his place — recently adduced — to be forgetful of the bissextile. From the beginning of the years of Christ, to the said Solstice there are full Julian years 139. Common months 5, day 24, hour at Alexandria 13, 17'. As to the apparent time, but as to the True the hour [is] 13, one before the middle of the night. But he ought to have taken the months of the bissextile year. See our Chronological Apparatus.

[Margin: Lansbergi error. — Lansberge's error.]

§3. [Bernhard Walther], at Nuremberg [Norimbergæ] in the year 1478, by Christ's [reckoning], observed by the rules of Parallaxes on the 11th of June, exactly the partition [altitude] of 44°80" [?]; and the same most exactly on the 13th of June, hour 44°80" [?]. Hence it follows that the Sun equally declined in either meridian from the equator; and therefore the Solstice, and the maximum declina-
[...continues next batch]

[Margin: Vualtheri [recte: Vualtheri] Solstitia. — Walther's Solstices.]

[the maximum declina]tion fell on the meridian of June 12. Yet the chord corresponding to it, with our parallaxes subtracted, leaves the true distance of the Sun from the vertex of Nuremberg as 25°56'29"; from this, subtracting the true

declination, namely $23^{\circ}29'36''$ — the latter being from the observations of Cassini, $23^{\circ}29'20''$ — it follows that on June 11 and 13 it was $44''$ short of the maximum, which would require these to be $44''$ apart; and so the solstice occurred either on the 10th or the 11th of June. But if we wish to retain that figure of June 12, on account of the equality of declination between June 11 and 13, and also to retain the maximum obliquity of the Sun at the vertex as $23^{\circ}30'20''$, then the true distance of the Sun from the vertex must have been $25^{\circ}56'55''56'''$ [?] as seen, whereas it was seen as $25^{\circ}56'1''$ — and so on that reckoning the solstice occurred at $44876''$ [?]. Or certainly the altitude of the pole of Nuremberg was $49^{\circ}26'28''$, unless the parallaxes are increased, and indeed at such a latitude by $53'$ [?]. One may see how slippery and tangled the solstitial observations are.

§4. In the year 1487, the same Walther, at the same place, on the meridian both of December 13 and of the 14th, observed by strong rays [per Radios fortes], and with diligence. The chord of the distance of the Sun from the vertex was 118790, the partition being $25^{\circ}56'29''$. Therefore, from the equal declination it follows that the winter solstice was celebrated between the mid-moment of the two, that is, between December 13 and 14. But if anyone wishes, through the perplexities of refraction and parallax — from the altitude of the pole and the obliquity of the ecliptic discussed above — to track down the diverse timing of this solstice, he will only distract his mind without profit.

§5. In the year 1490, the same Walther, on June 11 and 12, by a clear and diligent observation [Clara, & diligenti observatione], obtained the meridian distance of the Sun from the vertex of Nuremberg. The chord, the partition being 44900 — therefore, from this equality, it would follow that the summer solstice occurred at the middle of the night intervening between June 11 and 12. So, in the same Epilogism, since the result emerges far more diverse and perplexed, although it pleases [Riccioli] to exercise himself in such calculations, I have set down the chosen observations of the solstitial days for Walther by adding the arc corresponding to the chords, and the declination as seen there; the altitude of the pole is $49^{\circ}26'$.

Solstitial Observations of Walther at Nuremberg.

Order	Years of Christ (Yr. M. D.)	Note added by Walther (in the Observat ion)	To Radius 100000 (Chord)	Distance of Sun from vertex as seen (Deg. ' ")	Declinati on of Sun as seen (Deg. ' ")

Parsing notes: The "Order" column is left blank for all Walther rows in the source (the ordinal sequence 7–17 is used in the adjacent Tychoic table, not here). The June observations (small zenith-distance ~25°57', chord ~44890) and the December observations (large zenith-distance ~72°52', chord ~118xxx) are interleaved by date, not grouped; the year column carries a year only on the first row of each block (1476, then 1478, 1487, 1488/89/90, 1493, 1496/98/1500), with blank year-cells continuing the prior year as printed. All chord values and the December declination-degree column ("23") were resolved on further re-read (): 118760 / 118780 / 118788 / 118790 / 118800 and 44883 / 44890 / 44900 confirmed; no chord cell remains [?]. Two rows are transcribed as printed and flagged as suspected source/observation outliers: 1500 Junij 11 (chord 44883 with Dist. 25°56'14" / Decl. 23°29'14", anomalously low against the recurring June 44890 / 23°29'31") and 1493 Dec 13 (Dist. 72°52'15" paired with Decl. 23°26'55", which breaks the December seconds-matching pattern and may be a compositor carry-down from the 1496 row).

[Margin: Note for Refraction.] If the observations of the winter solstices are correct, taking the correct altitude of the pole of Nuremberg and the correct obliquity of the ecliptic, that is, the maximum declination of the Sun as 23°30'20",

with our parallax of 14", then at an altitude of the Sun of 17° the Refraction at Nuremberg never on those days exceeded 4'40"; indeed it was often only 3'26" [?], and sometimes, if the observations were made at the very moment of the solstice, less than that. For the difference between the seen declinations is not so great, and at most can be referred to Refraction.

§6. **Egnatius Dantes** [Egnazio Danti], in a folio work which he published on the use of the great Gnomon erected by himself at Bologna in the Church of San Petronio, says that in the year 1576, on December 11, he reached the maximum declination of the Sun at the extreme edge of the solar image; and that on the following day it diminished, so that he discovered the winter solstice to have fallen between December 11 and 12. The same man, however, earlier, namely in the year 1570 at Florence, had observed the maximum declination in both [solstices]; he reports the Sun's solstitial declination in Part 2 of his *Astrolabe* (Chapter 24), but he was deceived as to the maximum.

From the Tychonic Solstitial Observations, I have selected four summer and three winter ones, handed down partly in **Longomontanus** Book 2 of the *Theoricae*, in [Riccioli's] Commentary on the Sun; partly from Father **Alberto Curzio** [Albert Curtz] of our Society, who transmitted them to me from an autograph of Tycho, out of his singular liberality. Assuming the altitude of the Equator established at Uraniborg by Tycho as 34°5'30" [recte: the co-latitude], and our parallax of 7", in the apogee [?] of altitude as 57½; our obliquity of the ecliptic as 23°30'20". The solstices, however many, I shall indicate among the winter solstices.

Tychonic Observations Selected on Solstitial Days.

	Per Volubil.	57 35 45	57 35 52	23 30 22	
	Per Armillas &			23 29 50 / 23 30	

Parsing notes: The Tychonic table's "Order" column carries the ordinals 7, 8, 9, 10 (grouping rows). The right two columns ("Declinatio vera" and "Solstitij p.m.") are sparsely filled and several lower rows give only a declination value; alignment by column position. The bottom block records alternative instruments for the 1589 reading — resolved on further re-read () as "Per Tychonici p[er] quadr[antem] volub[ilem]" (by Tycho's revolving quadrant), "Per Tychoni," "Per Volubil[em]" (by the revolving quadrant), and "Per Armillas &" (by the armillae) — with the trailing "23 29 50 / 23 30" being two declination variants (the second printed without a seconds figure). The three December "Altit. visa" readings (1589, 1590,

1594) are given without corresponding true-altitude or declination entries (blank as printed, not illegible).

§11. **Lansberge** [Philippe van Lansberge], in Class 1 of his Observations, recounts the solar [observations] made in the year 1589. Apart from the two observations noted on certain days, the solstitial altitudes accord with the southern meridian of the Sun, taken just as Goesa[?]. But afterward he claimed, by his own peculiar ingenuity and the highest skill[?], to have detected the solstitial altitude before, just as after.

[Margin: Lansberge's Solstice.] In the year of Christ 1599, June 11, at hour 17, after midnight at Goesa, when likewise he reckoned the Sun to have entered Cancer by his own Tables, but since at an altitude of the Sun of 62° he allows a parallax of $1'4''$ — which is nothing unless $1'[?]$ — he erred by nearly a whole minute, and most of all in the hours at the solstice.

§12. In the year 1636, the solstice observed at Marseilles [Massilia] before himself by Claude **Fabri de Peiresc** [Nicolas-Claude Fabri de Peiresc], in the College of the Fathers of the Oratorian Congregation, is recounted by **Gassendi** both in the *Life* of the same Peiresc, and in Epistle 3 to **Wendelin** [Govaert Wendelen], now published at The Hague, printed after Gassendi's *Astronomical Institution*. Therefore in the said College he erected a Gnomon, of an alternate height — others give it as Parisian feet 32, others as 90000 or 89328 parts — afterwards divided, and the shadow of the highest edge of such [a Gnomon] in the meridian on June 19 was found to be 31766 parts. But at the meridian on the 20th it was 31753, and on the 21st 31759, and on the 22nd 31752, on which day a parallax of nearly $1'4''$ occurs, which is nothing unless $1\frac{1}{2}''$. He erred by almost a whole minute, and in most of the hours at the solstice.

[Margin: Gassendi's Solstice.] In the year 1636, the Marseilles solstice was probably, from Tycho, in the 10th minute of the first degree of Cancer, and he had diminished the declination by about two...

[two] seconds; that this [shadow] could be reckoned as that solstitial partition 31750, from which he gathers the solstitial altitude of the Sun, insofar as it surpasses the highest margin by $70^\circ 24' 59''$; and, the semidiameter being added, the partition is $1'4''[?]$; and, the parallax of Wendelin being subtracted of $20''$, he gathers the true altitude of the center of the pole[?] of the Sun as $70^\circ 11' 15''$. In the rest of Epistle 3, edited likewise there, he confesses that on account of the variation of the meridian line by the magnetic deviation it was a false altitude of the Sun, and that the altitude ought to have been corrected to $70^\circ 12' 16''$; indeed,

from our parallax of 14", it comes out as 70°12'4". Wherefore, if the polar altitude at Marseilles in our *Reformed Geography* stood at 43°20', it would have been the declination 23°32', which however Gassendi gathers as smaller elsewhere. From this, nevertheless, we cannot gather the moment of the solstice with certainty.

§13. In the year 1644, June 21, **Albertus Linemann** [Albert Linemann] reckoned the meridian altitude of the Sun as 58°47'30", at Königsberg in Prussia [Regiomontum Prussiae], where he asserts in the memory of the age 7°8'8". From this the declination would be 21°50'; but our parallax is greater, by 16". On account of the uncertainty whether parallax corrected the altitude, the moment of the solstice remains uncertain.

[Margin: Linemann's Solstitial Observations.] [Riccioli], in Book 3 of the *Almagest* [Almagestum Novum], Chapter 27, [recorded] the solstices of the years attempted, but laboring with some little defect of instrument and an excess of parallax compared with the altitude of the pole, which does not exceed 69°[?], not by 5" or 6". And we then used a false altitude of the pole; whence in our Observatory it is found, with these corrected, to yield the solstices more emended, as below.

Solstices observed by Us at Bologna.

Order	Years of Christ (A. M. D.)	Altit. seen (G. ' ")	Altit. true (G. ' ")	Declin. of Sun (Gr. 23.½?) (' ")	Solstice after meridian (D. H. ')
14	1643 Junij 21	69 0 0	69 0 6	30 16	21 6 52
15	1644 Junij 20	68 59 58	69 0 3	30 13	20 12 42
16	1645 Junij 20	68 59 54	68 59 59	30 9	20 18 32
17	1646 Junij 20	68 59 50	68 59 55	30 5	21 1 40
	Junij 21	69 0 5	69 0 10	30 20	21 0 0
	Junij 22	68 59 50	68 59 55	30 5	20 22 20

Parsing notes: The declination column is headed with the constant degree value "Gr. 23." (with what appears to be a fraction or "30" prefix); only the minutes and seconds vary by row (30 16, 30 13, etc.), so the full declinations read 23°30'16", 23°30'13", etc. The "Solstice after meridian" column is day/hour/minute (D. H. ').

Ordo 17 spans three observation rows (June 20, 21, 22) all under the single year 1646. All cells resolved on further re-read (); the final-row "Solstice after meridian" cell reads 20 22 20.

From this last solstice we are quite certain that the altitudes of the Sun found on June 20 and 22 are altogether equal at the meridian itself; therefore the altitude of the day of the 21st is certain. With second-order parallax added of only a few seconds, by 5", whence we are confirmed in the maximum declination of the Sun of 23°30'20"; and on what day the 20th and 22nd were 15" short, the difference between them then being 14" a day — therefore by 15" it would require 14 hours; wherefore on the day added to the 20th, the solstice would fall on the day 21, hour 1, 40' after the meridian. And at the same reasoning, taking June 21 short, it would fall on the day 21, hour 1, 1/3; this is the meridian; or on the day 20, hour 21, 20' after the meridian. Altogether, keeping the middle day, the solstice was at the meridian.

There follow now the Observations of **Dom. Io. Dominicus Cassini** [Giovanni Domenico Cassini], who has it thus in a Book published at that time, inscribed *Specimen Observationum Bononiensium*, page 3: "In the year 1655, on the day June 21, in the Summer Solstice, in the Church of San Petronio at Bologna, at an altitude of the Bolognese feet of 71, we observed the distance of the Sun's center from the vertex at the meridian point itself, 20°50'50".

"But the distance of the Equator from the vertex is 44°30'20". Therefore the apparent distance of the Sun from the Equator [its declination] is 23°30'30". The distance of the Sun from the Tropic [Tropicus], and the Parallax in this case, are imperceptible: wherefore it retains the maximum solar declination of 23°30'30". Since, however, the marble band [fascia] of the Gnomon, and the iron, were not yet finished — and these designations marked on the sides themselves — to examine the faculty I reserved for myself, as I gather from page 19; therefore in his autograph, and in the document most liberally communicated to me for his Truth, no less than [out of love] toward us...

[with] love and with study, it is thus read: "I examined the observation of the day June 21 of the year 1655, the solstitial [observation] impressed on the sides, which I more evidently recognized, and I found the distance of the lower margin of the Sun from the vertex — the Tangent — to be not 38904 but 38909; and of the upper, not 37860 but 37870. Thus then:

Gr. ' "

Of the Tangent 38909. ARC

21 15 38

	Gr. ' "
Of the Tangent 37870	20 44 30
Difference & Solar Diameter	0 31 8
Semidiameter	0 15 34
Distance of Sun's center from vertex	21 0 4
Distance of Equator from vertex	44 30 20
Therefore the declination of the Sun then was	23 30 16
Because the distance of the Sun from the start of Cancer is added	0 0 4
Therefore the maximum declination of the Sun	23 30 20

[Margin: Maximum Declination of the Sun.]

"This is afterward confirmed from the emended solstitial altitudes of Tycho. Now if on that day it were 4" short of the maximum declination, and required 14", it would require hours 24, and a quarter; that is, by 4" it would require hours 6.12': by which the solstice would have fallen after the meridian of day 21. On account of the omitted parallax, however, the parallax is the same, and there is a somewhat dubious connection of the observation; this observation will seem postponed, as soon as from the same Authors, etc.

"From the same year 1658, the solstitial observation, and the documents, which I shall presently show from the same Autographs and documents."

In the year 1658, June 20.

	Gr. ' "
19 — Tangent of the lowest limb of the Sun 38912	21 15 44
Tangent of the highest 37876	20 44 40
Apparent Solar Diameter	0 31 4
Semidiameter	0 15 32
Distance of Sun's center from vertex as seen	21 0 12

	Gr. ' "
True, to us	21 0 7
Distance of Equator from vertex	44 30 20
Declination of Sun then	23 30 13

In the same year 1658, June 21, more accurately.

	Gr. ' "
Tangent of the lowest limb of the Sun 38911	21 15 42
Tangent of the highest 37871	20 44 32
Apparent Solar Diameter	0 31 10
Semidiameter	0 15 35
Distance of Sun's center from vertex as seen	21 0 7
True, on account of our parallax 5 $\frac{1}{4}$ "	21 0 1 $\frac{3}{4}$
Distance of Equator from vertex	44 30 20
Therefore the true declination of the Sun	23 30 18 $\frac{1}{4}$
And the maximum solar declination being placed	23 30 20

The solstice was on the day June 21, hour 11, 45'. Hour after the meridian. Because if the solstice of our year 1646, and by our Revolutions it ought to have been hour 21, 45', 5", 12"; therefore I still allow a parallax of 1 $\frac{1}{2}$ ", because that one [allows] 5" in this way, or 6". It rarely satisfies the Epilogisms of Astronomers. It is necessary, therefore, to correct the Tangents of day 20, so that the true declination comes out as nearly 23°30'7".

CAPVT VI.

Observations of the Obliquity of the Ecliptic, or of the Maximum Declination of the Sun.

[Obliquitatis Ecliptica Observationes, seu Declinationis maxima Solis.]

§1. **Pytheas of Marseilles** [Pytheas Massiliensis], who flourished in the age of Alexander the Great, who died in the 113th Olympiad — that is, in the year 324 before Christ — as many gather from Strabo, who says that the writings of Pytheas were difficult to be credited. It was reported by Aristarchus, a disciple of Pytheas, in the time of Scipio, who lived around the 140th Olympiad, the year before Christ 216; if indeed it was Pytheas, of whom Polybius, while Scipio, questioning the Massilians, contends — as Gassendi cites in his Epistle 3 to Wendelin: it is Pytheas, referring to Gassendi in the *Life* of Claude Fabri de Peiresc, who in the year 1636 observed at Marseilles the proportion of the solstitial summer shadow to the Gnomon, as 209 to 600, that is, as $41\frac{2}{5}$ to 120. From these two sides...

[Margin: Order.]

[Margin: Pytheas.]

[a right] angle is gathered: the altitude of the highest limb of the Sun as seen, $70^{\circ}47'42''$; to which if we add the semidiameter of the Sun, $15'5''$, there remains the true altitude of the Sun's center as seen, $70^{\circ}32'41''$; and from this, subtracting the Marseilles altitude of the Equator, $46^{\circ}40'$, there remains the maximum declination of the Sun as $23^{\circ}52'41''$. Yet **Gassendi** thinks Marseilles to have had that proportion easily as great as Gassendi himself found, of partition $42\frac{3}{5}$ — the Gnomon being 120, or partition 1750, the Gnomon being 89328. Whence the seen altitude of the highest limb of the Sun comes together as $70^{\circ}25'59''$; and at the center, $70^{\circ}10'54''$; and the seen $70^{\circ}10'58''$; and the maximum declination of the Sun as $23^{\circ}30'58''$. But Gassendi, from that place, and from Epistle 2 to Wendelin (which he inscribes *On the Proportion of the Gnomon to the Solstitial Shadow*), concedes that it was at one age and another expressly that observation of Pytheas. Only Strabo, Book 2, under the end of Hipparchus, brings forward the proportion of the Gnomon to the summer shadow as 120 to 42; but, on the contrary, a fifth, namely that Byzantium was thought by Hipparchus to be in the same parallel in which Marseilles, on account of the same proportion of the Gnomon at Byzantium as at Marseilles by Pytheas — therefore the same is believed observed at both places nearly, although it differs a little, yet not soon emended out of Ptolemy, who in Book 3 of the *Almagest*, Chapter 6, [reports it] from Pytheas, or from Hipparchus; he affirms Marseilles, where the Gnomon being to the summer shadow as 209 to 60, that is as 120 to $41\frac{2}{5}$, nearly; to which the aforesaid altitude of the highest limb of the Sun corresponds, $70^{\circ}51'7''$. From the shadow of the Equator the said altitude of the highest limb of the Sun follows, $47^{\circ}1'5''$; and at the center of the Sun, $47^{\circ}46'0''$; but it was seen as $47^{\circ}46'5''$ — as

great as the Equator of Marseilles, which was found from the fixed stars by Gassendi, unless by 46'40" nearly; whence it is easy to gather that the trifling errors which were observed are not at the very moment of the equinox or the solstice, but at the moment after taken for the Equator, or the solstice.

§2. **Hipparchus**, in Snellius [Willebrord Snell] Book 2 of Eratosthenes the Batavian, under the end, handed down the equinoctial shadow at Byzantium to the Gnomon, repeated as 111 to 120; therefore by the laws of right-angled plane Triangles, the altitude of the highest limb of the Sun is 47°13'45". Again, through Strabo, Book 2, the Gnomon at Byzantium in the Summer Solstice has the same proportion to the shadow which 120 has to 42, less a fifth. Therefore by the same laws the altitude of the highest limb of the Sun is 70°47'42". From these differences of altitude follows the obliquity of the ecliptic, or the difference of the Solar declinations of the Summer [solstice] from the Equator and the equinox, none other than 23°33'57" — in the time of Hipparchus, not to say of Strabo, who flourished under Tiberius. How much it would err in these two doubtful minutes, the difficulty of avoiding these errors teaches, even in this age, unless we use the highest diligence. But if you heed **Pliny**, who in Book 6, Chapter 34, [says] that in the parallel of Byzantium the Gnomon yields shadows in the ratio of 9 to the equinoctial Gnomon, and that the equinoctial Gnomon yields shadows of 8 feet, the altitude of the highest limb of the Sun would be 48°12', whence subtracting the declination of 24°24'42", the maximum declination of the Sun comes out as 23°48' — and this is ridiculous. But Pliny gives the reasoning of the whole Climate, and does not speak of the shadow of the Gnomon at Byzantium, but of the shadow of the Climate, in which Byzantium, Rome, etc. nearly are.

§3. The ancient observations, which defined the distance of the Tropics from the Equator as 24 degrees, we can thus interpret, since it does appear in a greater degree, 23 $\frac{2}{3}$; if they chose a round number 24 rather than 23 $\frac{2}{3}$. So Geminus reckons the equinoctial distance from both Tropics, of partition 47, as great as the whole meridian is 83 $\frac{1}{3}$; that is, 23°51'20" for the distance of the Sun from the Tropics. So Eratosthenes and Hipparchus, in **Ptolemy** Book 1 of the *Almagest*, Chapter 9, [say] that from the summer Tropic to the equinoctial Equator are parts 24 [recte: differently]; and afterward, seeing it to be in a smaller degree, 24 and a greater of 23 $\frac{2}{3}$, they said that the distance between the Tropics themselves is nearly partition 11, as great as the whole meridian is 83 $\frac{1}{3}$; this is the distance of the Tropics 47°40'40"; and the distance of the Equator from the Tropics 23°51'20".

§4. For **Eratosthenes**, with Scipio, assumed the proportion of the solar rays — abusing that opinion of the distance of the Equator and of the Tropics, with the

magnitude of the Terrestrial circumference — but did not insert it. The method of Eratosthenes is set forth by **Cleomedes** Book 1, the Cyclic Theory, Chapter 10, and from him by **Petrus Nonius** [Pedro Nunes] Book 2 *On Observation*, page 132, and by **Willebrord Snell the Batavian** Chapter 9, in a far better scheme than the dialogue 2 of Maurolyco *On Cosmography*; or from Maurolyco, Clavius Book 1 of the *Sphere*. But since at that very source of Cleomedes we have drawn Eratosthenes' own method, then we shall set forth other experiments; and lastly from his observation we shall derive the Distance of the Tropic from the Equator corrected.

First, Eratosthenes — and with him Cleomedes — assumed Alexandria A, and Syene B, to be under the same meridian. Secondly, the arc AB to be among the towns five thousand stadia. Thirdly, that the rays sent down to different parts differ; the Tower of parallels [parallelos]...

Diagram. A geometric figure at the lower right of the page illustrating Eratosthenes' measurement of the Earth's circumference. At the top, two nearly parallel slanting lines run from upper right (point C) down toward the left; D is at the upper left end and C at the upper right, forming the line of the Sun's rays. From these descend lines to a lower assembly: a small circle (representing the Earth) with center F, on which points are arranged. Around the circle the letters I, B, G, H, K, L, E mark the scaphe (bowl-sundial) and gnomon positions at Alexandria and Syene; A and E mark the parallel rays' endpoints near the upper region.

- D (upper left): endpoint of one solar ray
- C (upper right): endpoint of the other solar ray
- A (left, mid-height): top of the gnomon / endpoint of parallel ray
- B (right of circle): a point on the rays meeting the circle
- I (above circle): point on ray near the scaphe at Alexandria
- G (on circle): point near center-line of the circle
- H, K, L, E (left/lower around circle): points marking the scaphe (hemispherical bowl HEI) and gnomon AG
- F (center of circle): center of the Earth

The figure accompanies the text describing Eratosthenes' construction: ray CB produced to the imaginary radius toward the Earth's center F; gnomon AG set in the scaphe (the hollow hemisphere HEI); the angle EGF at Alexandria equal to angle BFG (the arc AB subtended); from which the arc AB is shown to subtend $7^{\circ}12'$ of the whole circle, hence the whole Earth's circumference is 250000 stadia.

(Two labels — the small interior points near G — were difficult to resolve and are given by best reading.)

[Margin: Gassendi.]

[Margin: Pytheas.]

thus Cleomedes expressed, and the radii [drawn] from the Sun's center C, and to Syene, and DE, from the highest extreme limb of the Sun, to the scaphe E at Alexandria, to be among the parallels. Fourthly, a straight line drawn through the parallels to make alternate angles equal, the angles being made equal; and so, the imaginary radius CB being produced to the Earth's center F, alternate at Alexandria on the day of the Summer Solstice the gnomon, or style AG, of the scaphe, that is, of the hollow hemisphere HEI; and so, the style being continued to the center F, the straight line FG, to fall in the parallels CF and DE. Therefore the angle EGF is equal to the angle BFG. Fifthly, therefore, the arc AB, subtended by the angle BFG, is equal to the arc AE, subtended also by the angle AGE. Sixthly, Syene to be under the summer Tropic, since the Gnomon at the meridian of the Summer Solstice casts no shadow at all for 300 stadia. With these established, on the day of the Summer Solstice he noted that Eratosthenes had observed the arc AB, marking the shadow EA, terminated at the ratio DE in the bottom of the scaphe at Alexandria; circling about, he found there the fiftieth part of the whole little circle, this is $7^{\circ}12'$. He concludes therefore that the arc AB also is 5000 stadia, and is of degrees $7^{\circ}12'$; therefore the whole Earth's circumference is 250000 stadia.

But the first and principal error of Eratosthenes, which even the good Cleomedes acknowledged, was in the parallelism. For Geometers have demonstrated the falsity, and Cleomedes subjects it: that the rays from the different solar parts, and to the diverse parts of the Earth, are not parallels; since indeed the rays of which one is propagated from the center, the other from the margin, even if one falls on the place B, the other...

Liber I — De Sole (continued)

Caput VI — Observations of the Obliquity of the Ecliptic, or the Maximum Declination of the Sun (continued)

[Riccioli continues his critique of Eratosthenes' measurement of the Earth's circumference, carrying over from the previous folio.]

to the point K, the rays would strike almost at the quadrant BK, and at such a distance they could not even appear sensibly parallel, because the Earth's semidiameter KF is not equal to the physically true semidiameter of the Sun, since the latter exceeds and contains terrestrial dimensions five and a half times over. From Ptolemy's data, in our judgment and as Snel [Snellius] reports earlier, the Sun's diameter is 33 and a little more times the Earth's diameter [*Almagestum Novum* I.3, ch. 5]. At all events the truth of the demonstration is not destroyed: by Nonius [Pedro Nunes] and Snellius (cited above, I.3, ch. 5), the rays CB and CGL, drawn from the same point of the Sun and from a different part of the Earth's surface, cannot be assumed parallel. For if the rays CB and CGL are parallel, then by means of the gnomon AG, the apex G, and the chord G, it must happen that, the angle BFG being equal to the angle AGL — and so equal to the arc AB — the arc EL, which is as great as the angle EGL, that is, equal to the angle CGD, subtended at the Sun's semidiameter (namely the minute $1^{\circ}5' [?]$), and observed in our parallaxes (and these too must escape detection [recte: must be set aside]), the arc AL must necessarily come out as gr. 7. 27'. 5". And yet this arc AB, namely "the summer tropic" or the Syenian summer zenith, and "the vertex of Alexandria in Egypt," is, at the vertex of Alexandria, distant — and Ptolemy affirms [*Almagest* I.5] — and the great *Syntaxis* [*Almagest*] ch. 12 and 13, and book 4 of the *Geography* ch. 5, table 13, places it distant from the Equator by gr. 30. 58'. He says, then, in the demonstrated chapter 12, that *from the point of the vertex of Alexandria to the equinoctial line there are demonstrated 30. 58'*. By thus subtracting the arc AB, falsely supposed by Eratosthenes to be gr. 7. 12', from the tropic, or from the equator, gr. 23. 46' remain. But what came out at gr. 23. 51'. 20", Eratosthenes asserted, came out at gr. 23. 51'. 20", [Riccioli notes:] Eratosthenes wished the altitude of the Pole at Alexandria to be gr. 31. 3. 5. [?]

[Margin: The true obliquity of the ecliptic according to Eratosthenes, gr. 23. 51'. 5".] [The Latin margin reads: *Vera obliquitas Eclipticæ Eratosthenis 23. 51. 5.*]

Hence, by subtracting the true arc AB gr. 7. 27'. 5", the true distance of the tropic from the equator at Eratosthenes' time comes out as gr. 23. 31'. 5", with the parallax set aside, gr. 23. 31'. Therefore why Ptolemy, wishing to retain the altitude of the Pole at Alexandria, and the distance of the tropic from the equator, took the latitude as the maximum at gr. 20. 6, in such a way that the obliquity of the ecliptic was at that time gr. 23. 46'. As we said, this came out about 20 minutes less than Ptolemy supposed, and as we said in *Geography* I.7, and in *Geographia Reformata* 128 [recte: CXXVIII = 128], we shall say when treating of the observations of the Moon's latitudes.

§5 — Ptolemy, *Almagest* I.2, ch. 6, parallel 11. In the *Geography* I, ch. 23, parallel 10, he says that the maximum day in Rhodes — and from observations the altitude of the Pole there is gr. 36 — cannot be assembled here; the maximum declination is gr. 23. 51'. He used this same maximum declination in his Tables, and likewise Ptolemy in the *Prima Mobilia* [recte: *Almagest*] places the altitude of the Pole at gr. 36, and the semidiurnal arc corresponds to hr. 7. 15'; and the diurnal arc hr. 14. 30'.

§6 — Pappus of Alexandria, who flourished about the year of the Lord 390, in his *Mathematical Collections* I.6, theorem 35, assumes for his demonstrations this hypothesis: *that the diameter of the sphere has the same proportion to the diameter of the summer tropic as 629 has to 529; and likewise that a straight line drawn from the center of the sphere to the center of the summer tropic has the same proportion to the semidiameter, namely as 115 to &c.* Where Commandinus [Federico Commandino] adds in his commentary: *the maximum right sine of the declinations is of the degrees 23. 51', and is 23924; the semidiameter of the sphere, on which we hold the maximum declination, is 60000 &c., or it is 39874, of the kind in which the semidiameter is 100000, so that it is clear from the Tables of Sines.*

[Margin: Pappus' opinion on the obliquity of the ecliptic.] [Latin margin: *Pappi sententia de Obliquitate Ecliptica.*]

But this could not be otherwise unless the maximum declination were gr. 23. 51'. 20", as Ptolemy wishes, or because it follows from Pappus' time gr. 23. 50'. If his sine were such, the long-different semidiameter would be 40468, since it is clear that Pappus also followed that maximum declination, which Ptolemy and Eratosthenes before him had taken.

§ — Albategnius [al-Battānī], ch. 4, asserts from the knowledge of the fixed stars that he, diligently as far as could be done, observed the distance of the Sun from the vertex at midday to be a minimum of gr. 12. 26'; the maximum, by contrast, gr. 59. 26'; and he stated the distance of the tropics between themselves to be gr. 47. 10'; and from the equator gr. 23. 35'; and thus indeed the distance of the tropics gr. 23. 35'. And although it could happen that in all five minutes others should appear differently, it does not seem to me impossible — indeed very...

[Margin: Albategnius' observation.] [Latin margin: *Observatio Albateny.*]

easy. Moreover, he flourished about the year of Christ 880.

§8 — In the year of Christ about 1070, Arzachel [al-Zarqālī] the Spaniard related the distance of the tropic from the equator as gr. 23. 33'. And in the year 1140,

Almæon [Albumasar / al-Ma'mûn's astronomers?] of Almansor, item gr. 23. 33'. 30". And in the year 1210, Thebit [Thābit ibn Qurra], the son of Chora [Qurra], item gr. 23. 33'. 30". And in the year 1300, Prophatius the Jew [Prophatius Judæus / Jacob ben Makhir], gr. 23. 32'. From these, Copernicus, I.3, ch. 2 [*De Revolutionibus* III.2], deduces the obliquity of the eighth sphere in his theory. Peter Apian [Petrus Apianus], in *Observationes* II, [reports] Regiomontanus in the *Epitome* of the *Almagest*, prop. 17. Clavius [Christopher Clavius], in *Sphæra* p. 262, and Lansbergius [Philippus Lansbergius] in his *Thesaurus*, observed; the *Solarium Classe* I, [reports] those who placed the Prophatian-Jewish [value], collected about 68' [?] after Almeon, since they took it after that interval of 160 years, and after Arzachel of 130 years; and Lansbergius from this confirms Copernicus, and he praises this; I trust that he draws his observation from it for his own Tables. So that he assigns it to Albategnius at gr. 23. 38', using neglected refraction. But these foretold observations differ by very few minutes, or with respect to the matter observed at different times, so that we are not so certain about the error of three or four minutes deviating; nor does it diminish the obliquity of the ecliptic below gr. 23. 30', or 31' thereabouts.

[Margin: Arzachel.] [Margin: Almæon. Thebit. Prophatius.] [Margin: Lansbergius notes.]

§9 — In the year about 1460, Purbachius [Georg Peurbach] and Regiomontanus of Vienna in Austria received the meridian altitude of the Sun at the summer solstice as gr. 66. 6'. And in the winter [solstice] gr. 18. 10'; he says Lansbergius in his *Thesaurus* observed; and adds the obliquity of the zodiac gr. 23. 28'; but proper to him the parallax in the winter is gr. 4. 11', and refraction 5'. 4". The parallax was inscribed at the summer tropics as gr. 46. 59'. 51", or most nearly gr. 47, and the obliquity of the ecliptic gr. 23. 30'. Certainly, although Regiomontanus in the *Epitome* of the *Almagest*, prop. 17, may set it observed at gr. 23. 28', nevertheless this does not adhere to him, since from these Tables he chose gr. 23. 30'. Which also Clavius confesses in his *Sphæra* ch. 2, where nevertheless there is by far a different reading of the Regiomontanus observations and of Lansbergius; for he relates the observation of Vienna at the summer solstice altitude gr. 66. 30'; and the winter [solstice] gr. 18. 30'; whence he considers the altitude of the Pole at Vienna gr. 48. 6'; and from the Lansbergian observation gr. 48. 20'; whereas from our [observation in] *Geographia Reformata* it is gr. 48. 22'.

[Margin: Regiomontanus.]

§10 — In the preceding chapter, among all the solstitial observations of Bernard Walther [Bernardus Vualtherus], relation 3, none is found whose maximum

declination of the Sun exceeds gr. 23. 30', but many fall infra [below], which Clavius constructs in his *Sphæra*, and indeed Dominicus Maria Ferrariensis [Domenico Maria Novara], as Clavius has it in his *Sphæra* p. 2, where nevertheless there is by far a different reading of the Regiomontanus observation and of Lansbergius; for he relates of Vienna [gap]. Johannes Werner [Joannes Vernerus], in *Observationes* II, p. 28', [reports] and it is credible that he proposes the equation of the cause of Copernicus, who neglected refraction, and repeats his own from the major degrees, gr. 23. 28'. 30"; he affirms it true, *De Revolutionibus* I.3, ch. 2. As one who said *De Revolutionibus* I.2, ch. 2 [recte], a discrepancy [is] found in himself from the distance of the tropics [taken] together, gr. 46. 58'. nearly; and *De Revolutionibus* I.3, ch. 2, he adds the latitude of Nuremberg [Fruemburg/Frauenburg?] repeated at gr. 54. 19'. 30", to which if you add gr. 23. 28'. 30", he considers the maximum declination of the Sun; he gathers that he observed the winter altitude of the Sun at the meridian gr. 12. 12'; about the altitude of the Pole at Frauenburg through Tyconic instruments from the surrounding parts at Tycho's [base?] I.1, *Progymnasmata* p. 34; whence he gathers the calculation of refraction gr. 2. 45'. or as someone wishes, [a difference] from the altitude gr. 12. 12'; and there remains the altitude correct at gr. 12. 7'. 40", by which the altitude of Frauenburg [taken from] the equator is gr. 35. 37'. 45"; refraction subtracted leaves the maximum declination of the Sun gr. 23. 30'. 5".

[Margin: Copernicus corrected.]

§11 — Deservedly, then, Peter Apian, in the *Primum Mobile*, year 1530; and Orontius [recte: Orontio] Finæus [Oronce Finé], book 2 [reports]; Cosmogr. [Cosmography], under the same time; and Werner, *Nominis* [recte] II, [reports] from the observation of the year 1555, declared the obliquity of the ecliptic to be gr. 23. 30', which we agree with the opinion that Clavius elected in his *Sphæra* p. 262, and Scheinerus [Christoph Scheiner] in the *Rosa Ursina* p. 356, and Galileo [Galilei] in the *Dialogo dei Massimi Sistemi* p. 34 — although they do not add the observations. Nor are the opponents reluctant: Ignatius Danti [Egnatio Danti], part 2 of the *Astrolabio* ch. 54, where he relates that in the year 1570 at Florence he took the altitude of the summer solstice of the Sun at the meridian gr. 69. 49'; and the winter [solstice] gr. 22. 51'; whence...

[Margin: Apianus. Orontius. Nonius.] [Margin: Clavius. Scheinerus. Galileus. Dantes.]

whence he gathers the obliquity of the ecliptic gr. 23. 29'; for if to the winter altitude you add our parallax 5'; and at the winter [solstice] 20"; but to subtract the refraction from this gr. 5. 25"; the summer altitude comes out gr. 69. 49'. 5";

and the winter gr. 22. 51'. 20"; and the distance of the tropics gr. 47. 1. 10"; and the distance of the tropics from the equator gr. 23. 30'. 35".

§12 — Christophorus Rothmannus [Christoph Rothmann] and Justus Byrgius [Jost Bürgi], illustrious Landgraviaal astronomers of Hesse, in the year about 1570, found the corrected altitude of the equator at Kassel to be gr. 38. 46'. 40"; and the solstitial altitudes of the Sun, as Snellius has it, mostly gr. 62. 11'; rather gr. 60. 12'; whence, subtracting the altitude of the equator, the obliquity of the ecliptic gr. 23. 30'. 20" is left, just as much as Cassinus [Cassini] also collects for us in the year 1655.

[Margin: Hassiaci. (The Hessians.)]

Likewise, Johannes Homelius [Johann Homelius / Hommel], in the year 1570 — Tychone testifying, *Progymnasmata* p. 631 — observed the meridian altitude at the summer solstice gr. 62. 11'. Lipsiæ [at Leipzig], whose altitude of the equator, as Tycho says, is gr. 38. 41'; therefore the distance of the equator from the tropic gr. 23. 30'.

[Margin: Homelius.]

§13 — Tycho, however, from his own observations, *Tom. I, Progymnasmata*, p. 17 and 28, and in his *Epistolae* p. 40, stated the obliquity of the ecliptic gr. 23. 31'. 30"; for the maximum scilicet parallax of the Sun; and so Kepler corrects this excess in the *Rudolphine [Tables]* p. 27 and 116, saying that it could not be done at gr. 23. 30'; but already from his own selectissimis [most select] Tychonic observations, from nos. 7 and 10, deduced from the truer parallax, he reduced the minimal solstitial declination of the Sun to gr. 23. 29'. 7"; maximal gr. 23. 30'. 27"; and median gr. 23. 30'. 22".

[Margin: Tycho.]

§14 — Lansbergius, in the first class of solar observations, narrates that there was observed by Goëse [Goes] in the year 1589 the altitude of the Sun at the meridian at the summer solstice gr. 61. 58'; in the winter, by contrast, gr. 15. 2'. 30"; but, his own parallax and refraction being applied, he gathers that altitude at gr. 61. 59'; and at the winter [solstice] gr. 15. 4'; hence gr. 14. 58'. 43"; or from the difference, or the distance of the tropic gr. 47. 0. 11"; and the obliquity of the ecliptic gr. 23. 30'. 5"; just as much as for the Landgraviaals. But the Lansbergian refraction being retained, the 6'. nearest minute, in the winter, and the parallax being applied, our 23'. in the summer solstice, the summer altitude comes out gr. 61. 58'. 6"; the winter gr. 14. 56'. 46"; and therefore the obliquity of the ecliptic gr. 23. 30'. 40".

[Margin: Lansbergius.]

§15 — By which observation Gassendi of Marseilles detected the obliquity of the ecliptic gr. 23. 30'. 58", as we said; on the first occasion of Pytheas. Therefore in the *Institutiones Astronomicae* I, ch. 8 [recte], he said it to be gr. 23. 31'; seu [or] tantam tantam [recte: just so much], and not more; indicating his judgment that it should be at least one minute less. But Gottefridus Wendelinus [Govaert Wendelen], in an erudite epistle to me, full as it were of all the gems of astronomy, asserts, while he was living in the province of Forcalquier, that he obtained the altitude of the Pole from the observation of the fixed stars at gr. 43. 54'; and the meridian distance of the Sun from the vertex at the summer solstice he found again gr. 20. 24'; subtract my parallax 6'; it becomes gr. 20. 23'. 54"; and these, the altitude of the Pole being subtracted, leave the distance of the tropic from the vertex gr. 23. 30'. 6"; albeit at Gassendi's, in *Epistola* 2, [it is said] to Wendelinus; Wendelinus is said, in the *Diatriba* which he entitled *Loxias, seu de Obliquitate Solis*, in which nevertheless he is mistaken, while at Pappus of Alexandria he gathers the obliquity for the year of Christ 400 at gr. 23. 42'. 6", as is clear from what was said in no. 6 above, ex Commandino [from Commandinus].

[Margin: Gassendus.] [Margin: Vendelinus.]

§16 — We, however, in the preceding chapter from nos. 14 and 17, from our own observations, have deduced the maximum declination of the Sun never less than gr. 23. 30', nor greater than gr. 23. 30'. 25"; but for the causes there stated, we choose, as constant from use, that it is gr. 23. 30'. 20" in our Tables, taking no account of the anomalies, which others also, like Wendelinus, in the said *Opusculum*, edition of the year 1626, have endeavored to introduce, especially from the inconstancy of refractions in the Hibernial [winter] solstice. Therefore, that we may add two conclusions to be soon inferred, it pleases [us] to give in conspectus the opinions of the Authors, both as they lie among themselves, and after observation, deduced with their correction added, the marginal numbers being added, so that the places of the Authors and the examination of this observation may be found again.

§17 — In Albert Lisnemann [Albertus Lisnemannus], *Memoria* 9th century, I find Venceslaus de Nova Pilsna [Wenceslaus of Nová Plzeň / Vinceslaus de Nova Pilzna], year 1416. With a great quadrant, and the iron Ptolemaic rules four cubits in length [*Regulae Ptolemaicae ferreae quadricubitis*]...

to have observed the Sun at Prague at the beginning of Cancer at the meridian altitude gr. 63. 26'; from which, the altitude of the equator gr. 39. 55'. 30" being subtracted, the distance of the tropic remains gr. 23. 30'. 30".

Table. "Obliquity of the Ecliptic, or the Maximum Declination of the Sun." A historical survey table listing each authority (cross-referenced to the marginal numbers in the preceding text), the obliquity/declination value each obtained (in degrees, minutes, seconds), and the year — most "Before Christ" (*Anni ante Christum*) for the ancients, "After Christ" (*Post Christum*) for the later ones.

Parsing notes: The "Num. margin." column repeats marginal numbers from the preceding text (some authorities share a number, e.g. several at "3," "8," "10," "11," "15"). Several rows are continuation rows for a multi-line authority entry (e.g. Purbachius/Regiomontanus and Bernardus Walther each occupy two value-rows). The "vel" (or) and "sed correctus / sed necessariò correctus" rows give alternate or corrected values for the authority immediately above. The fifth-from-top row's marginal number is ambiguous (printed "5" or possibly a re-use of "3") — flagged. The year column mixes *Anni ante Christum* (BC, ancients) and *Post*

Christum / AD years (later authorities); the header reads "ante Christum" but the lower entries are clearly AD dates.

I. Conclusion (*I. Conclusio*)

In our own age and in the preceding one — if a second of arc is to be despised in the scruple — the obliquity of the ecliptic was, and is, gr. 23. degrees 23. minutes 30. or thereabouts. Since most of the observations and authorities attest, if a reckoning is to be had of seconds, it is to be chosen as gr. 23. 30'. 20"; on account of the most recent and greatest instruments and the most accurately conducted observations, so that whoever should contend to augment or diminish it by about ten seconds is not severely to be condemned.

II. Conclusion (*II. Conclusio*)

It is much more probable that the obliquity of the ecliptic was immutable, and however great it now is, was once such, and will be such. First, because — apart from the 4 or 5 minutes in which the ancients could have erred — neither so great nor so manifest is the diminution of the ancient obliquity [claimed by] Eratosthenes, Hipparchus, and Ptolemy, or by Pappus of Alexandria. Secondly, because, although a few of the ancients may favor the variation of the latitudes of the fixed stars by the invention of Tycho — who thinks they vary in latitude by an extrinsic cause, namely by a variable obliquity of the ecliptic — yet more men oppose this opinion, and retain the same latitude, which others, and most nearly, suppose to vary; than which the *Almagestum Novum* ch. 15 [demands]. Thirdly, because if the obliquity of the ecliptic of the ancients were anything, it would now be reduced to gr. 23. 30'; now the maximum latitude of the Moon in the quadratures, [if observed] from Ptolemy's observations, is elicited as great as Tycho found it — which indeed is an indication, but not a necessary one; yet it is more probable in our opinion. Fourthly, because to affirm a maximum moment, with maximum need of a foundation; but the mutation of the obliquity of the ecliptic is of maximum moment, since it flows into very many astronomical operations, and, it being changed, it is necessary that individual ages should construct very many Tables of the Primum Mobile and of the Fixed [stars]. It is hardly worthwhile to construct anew from the very beginning, while we have a posteriori sufficient fundamentals, indeed the maximum and most constant, of this mutation, as is clear from the observations recorded above at great expense [of effort]. Fifthly, finally, not a few — and indeed those not to be repented of — Astronomers stand for its immutability. Namely: Ptolemy, *Almagest* I, ch. 11; Thebit, in Maurolycus' *Cosmographia*, dialogue 3; Augustinus Riccius [Agostino Ricci] in his treatise *De Motu Octavæ Sphæræ*; Athanasius Kircher in his *Magnis*

p. 477, first edition; Simon Stevin [Stevinus] in Hortensius, vol. 1 p. 579; Vincentius Reinerus [Vincenzo Renieri] in the *Tabulæ Mediceæ*, denuo editis [newly edited], ch. 7, no. 7; Petrus Gassendus in the *Vita Peireskii*, year 1615, and in the epistle to Wendelinus *De propositione Gnomonis ad Umbram Solstitialem*; and Kepler ch. 12, [in the] *Rudolphine [Tables]*, saying: *that the obliquity of the ecliptic was once of a certain ratio — that is not so doubtful, but by valid arguments from the observations of the ancients themselves it is shaken, and beyond doubt plainly false.*

[Margin: Immutability of the obliquity of the ecliptic. (*Immutabilitas Obliquitatis Eclipticæ.*)]

Caput VII — Observations of the Quadrants and Semicircles of the Year (*Anni Quadrantum Observationes, & Semiculorum*)

The year is divided into four parts by the cardinal points of the ecliptic, or by the points and moments of the equinoxes and solstices. The first quadrant comprises the time from the vernal equinox to the summer solstice. The second, from the summer solstice to the autumnal equinox. The third, from the autumnal equinox to the winter solstice. The fourth, from the winter solstice to the vernal equinox. These times, from astronomical observations, are manifestly unequal. But the inequalities are: the time from the entry [of the Sun] into ♈ [Aries] up to the entry into ♋ [Cancer], the time from the entry into ♋ [Cancer] and the entry following into ♌ [Libra], again the time from the entry of the Sun into ♌ [Libra] up to the entry into ♍ [Capricorn], and the time from the entry into ♍ [Capricorn] up to the following entry into ♈ [Aries]. Because from the equinoxes observed at ch. 3, and the solstices at ch. 5, it can to some extent be established, and also from the opinions soon to be referred to.

Table I. "First Table. The Tarrying [delay] of the Sun in the Boreal [northern] and Austral [southern] Semicircles." The dwelling-time of the Sun in each semicircle of the ecliptic, per authority, given in Days (D.), Hours (H.), and minutes ('). Two value-blocks: "From the beginning of ♈ [Aries] to the beginning of ♌ [Libra]" (northern semicircle) and "From the beginning of ♌ [Libra] to the beginning of ♈ [Aries]" (southern semicircle).

Caput VIII.

Selected observations of the Sun's meridian altitudes outside the equinoxes and solstices [*Altitudinum Solis Meridianarum Observationes extra Aequinoctia, & Solstitia selectae.*]

To gain thorough knowledge of the Sun's motion, the moments of the equinoxes and solstices are not enough; observations made at other times are also needed — times when the Sun is found at some other point of the ecliptic besides the four cardinal points, and especially in the neighborhood of the middle portions of Taurus, Leo, Scorpio, and Aquarius. Then, by comparing these positions with the positions drawn out from the astronomical tables, one can establish how trustworthy those tables are. And from this comparison the tables themselves may be constructed, once one has found the place [of the Sun] and quantified the motion of the solar apogee and the magnitude of the eccentricity.

The inequality of the Sun's motion is plainly evident in the unequal tarrying of the Sun: in the northern semicircle it tarries more than 8 days longer than in the southern, and, by these observations of ours, more than 14 hours 18 minutes longer in the vernal quadrant than in the summer one, and more than 13 hours 26 minutes longer in the autumnal quadrant than in the winter — unless astronomers are mistaken. This is more easily accounted for by the eccentric circle of the Earth, or by an eccentric ellipse, than by an epicycle equalizing the

eccentric, in the manner I set out more fully in *Almagestum Novum*, bk. 3, ch. 17, and again at ch. 24.

I pass over the whole medley of observations to be found among the authors — chiefly Walther, the Landgraves of Hesse [*Lantgravianos in Hassiacis*], Tycho, [Jakob] Kristmann [*Kristmannumque*], and others. I select the more reliable ones, the ones better suited to advancing the astronomical study, and I add to them other observations of ours; nor do I attach to those the [solar] parallaxes or refractions [*Parallaxes, aut Refractiones*]. The only places of the Earth used are those where altitude observations were made, [recorded] together with the year, month, and day. Afterwards these were tested for soundness against our *Geographia Reformata*. Then, in the following chapter, we shall hunt out the place of the Sun in the ecliptic from these very observations.

The right-hand column begins a long table of observations:

Selected meridian distances of the Sun from the zenith [Vertice] at Nuremberg [*Distantiae Meridianae Solis à Vertice Norimbergae, selectae ex Bernardo Vualthero inter eas, quibus additur Clara, Diligens, vel Praecl. certa, aut certiss.*] — selected from Bernhard Walther [Walther], among those to which is appended "Clear" [*Clara*], "Careful" [*Diligens*], or "Excellent" [*Praecl.*], "sure" [*certa*], or "most sure" [*certiss.*].

Parsing notes: This table extends over several pages; the "Chord" column gives a five-digit value (the chord of the zenith distance, in the work's internal units). The "Distance of the Sun from the zenith" (G./'") is filled in only for occasional benchmark rows. Several day-figures in the left two columns are faint or abbreviated in the scan; abbreviated month names (Iunij, Sept., Octob., Novemb., Decemb., Januar., Februar., Martij, April, Maij, Iulij, Augusti) are transcribed as printed. Cells left blank in the source are left blank here. Faint/ambiguous day numbers marked with [—] where unresolved.

[table continues]

Left column header: *Selectae ex Vualthero* — "Selected from Walther" — with columns: Year / Month·Day / Chord / Distance of Sun from zenith (G. '").

	Last solar [observat ion] [<i>Ultima Solarium</i>] June 3	45280			

Now follows the explanatory paragraph:

From the foregoing, I further select 24 observations covering the place of the Sun near the beginnings and middle portions of the zodiacal signs. For these I shall determine the Sun's distance from the equator, on the supposition that Nuremberg's distance from the equator is $49^{\circ} 26'$, and using our own parallax and the ancient *Almagest* refraction. For once the distance from the zenith has been corrected and converted into the true value, the Sun's true declination will be established; and from this declination, together with the maximum declination of $23^{\circ} 30' 20''$, the place of the Sun will at once come out by spherical triangle [*per Triangula Sphaerica*], rather than by a declination table. The places of the northern signs are, however, the more reliable, since they are not exposed to the uncertainty of refractions.

Table: From Walther's observations [*Ex Vualtheri observat.*] — true declination of the Sun [*Declinatio Solis vera*] and the Sun's place in the ecliptic [*Solis locus in Ecliptica*].

The declination column carries a suffix letter A or B (A = southern / *austrina*; B = northern / *borealis*).

Year / Month / Day	[<i>Ann. Mens. Dies</i>]	True Decl. — Gr.	—'	—"	(A/B)	Sun's place — S. (sign)	Gr.	'	"	1504

April. 14	12	39	35	B	□					

(Taurus) | 3 | 22 | 8 | | 1500 April. 24 | 15 | 51 | 53 | B | ♊ (Gemini) | 13 | 16 | 5
 | | 1504 Maij 10 | 19 | 56 | 28 | B | ♊ (Gemini) | 28 | 46 | 28 | | 1503 Maij 25 | 22
 | 21 | 36 | B | ♊ (Gemini) | 12 | 31 | 12 | | 1500 Iunij 11 | 23 | 29 | 26 | B | ♊
 (Gemini) | 27 | 59 | 48 | | 1490 Iunij 21 | 23 | 14 | 17 | B | ♋ (Cancer) | 8 | 24 | 9
 | | 1499 Iulij 11 | 20 | 47 | 32 | B | ♋ (Cancer) | 27 | 7 | 20 | | 1498 Iulij 23 | 18 |
 19 | 48 | B | ♌ (Leo) | 7 | 57 | 5 |

Parsing notes: The "Sun's place" column gives the zodiac sign as a symbol followed by degrees/minutes/seconds within the sign. The A/B suffix to the declination marks southern (A, *austrina*) versus northern (B, *borealis*) declination. The two leftmost columns (sub-headed *Ann. Mens. Dies*) compress year, month, and day; transcribed as printed.

Left column, upper table:

Residual of the preceding table [*Resid. Tabulae praeced.*] — continuing the same "true declination / Sun's place in ecliptic" listing.

Year / Month / Day [<i>Ann.</i> <i>Mens.</i> <i>Dies</i>]	True Decl. — Gr.	—'	—"	(A/B)	Sun's place — Sig. Gr.	'	"

1500 Dece mb. 12	23	22	12	A	♑ (Capri corn) 18	19	10

To these I append 20 places of the Sun drawn out from the observations of the most excellent Lansberge of Hesse [*Lamgravii Hassiae* — i.e. the Landgrave of Hesse], which Snellius [Willebrord Snel] published — places selected from observations made at Kassel [*Cassellis*] beginning in the year 1568, with rectified instruments and with the altitude of the equator repeated [as] 38° 40' 20". I have left these to a less certain refraction, so that I may use our own bare parallax and the obliquity of the ecliptic, discussed above.

Table: Years of Christ for meridian altitude observations [*Ann. Christi in Altit. Meridie.*] — true declination of the Sun and the Sun's place in the ecliptic.

Below this table (left column, :

I selected the Tyconic meridian altitudes of the Sun observed at Uraniborg [*Vraniburgi*] — where the altitude of the equator is $34^{\circ} 5' 30''$ — from Longomontanus's *Astronomia Danica*, bk. 2, *Theoricorum* ch. 2, in the commentary *On the Sun*; and from Villebrord Snel [Snellius] among the observations made in Bohemia; and others, which Fr. Albert Curtius S.J. [*P. Albertus Curtius Soc. Iesu*] sent to me, taken from the manuscripts of Tycho — some of which had also been published at Vienna. But of the observations of the year 1601, some were made at Benátky castle [*in Arce Benatica*], where the altitude of the equator is $39^{\circ} 41' 30''$; some at Prague [*Pragae*], where the altitude of the equator is $39^{\circ} 55' 30''$, with a refraction found by Tycho greater by 2 minutes than in Denmark. From these I have used our own parallax and obliquity of the ecliptic to deduce the places of the Sun in the ecliptic.

Right column :

Years of Christ, by the old style [*Anni Christi stylis veteris*] — visible meridian altitude of the Sun [*Alt. merid. Solis visa*], true declination of the Sun [*Declinatio Solis vera*], and the Sun's place in the ecliptic [*Locus Solis in Ecliptica*]. Margin: drawn **from the manuscripts of Tycho** [*Ex M.S. Tychonis*]; some rows note the instrument used — "another instrument" [*alio instrum.*], "the Tyconic [system], old" [*Tychonico vet.*], "the Tyconic [system], new" [*Tychonico nou.*].

[Margin: *Ex M.S. Tycho* — From the manuscripts of Tycho]

Bottom of right column:

I pass over the solar observations of Jakob Kristmann [*Iacobi Kristmanni*], inasmuch as I am not troubled over [matters of] 4 minutes — as I gather from bk. 1, ch. 7, of that author himself. But from our own observations, which I made at Bologna [*Bononiae*] in the College of S. Lucia [*Collegio S. Luciae*] together with Father Francesco Maria Grimaldi [*Patre Francisco Maria Grimaldo*], obtained on clear and quadrant days, twice over [*binis*], and not infrequently in threes and fours [*ternis quaternisque*], I select those that were the more accurate —

(continuation of Caput VIII)

[these observations], nor all of them, for there are many more than five hundred. But I have added some others, lest I burden the pages with superfluous prolixity, and I include the declination — computed by trigonometry from the Sun's place — after applying our corrections for the obliquity of the ecliptic, for parallax, and for refraction.

Observed meridian altitudes of the Sun, by the Reverend Fathers Riccioli and Grimaldi.

Latitude of the equator [i.e. of the equinoctial point of observation]: 44° 29' 50".

The four columns are: the **observed meridian altitude of the Sun** [Altitudo Solis meridiana ☉ visa]; the **true declination of the Sun** [Declinatio ☉ vera], marked B(orealis) = north or A(ustrina) = south; and the **place of the Sun in the ecliptic** [Locus Solis in Ecliptica], given by zodiac sign and degrees/minutes/seconds. The date column gives year, month, and day.

Parsing notes: zodiac symbols read as printed; several Locus-in-Ecliptica seconds and a few sign-degree entries are ink-faint and flagged [?]. The 1644 Iunij 29 entry (sign ♈ 7°53'48") breaks the monotone date/longitude progression — see Numerical impossibles.

[Margin / footnote on this entry: *Sed in S. Petronio* — "But (this one) in San Petronio," i.e. observed at the basilica of San Petronio (Bologna) rather than at the College of Santa Lucia.]

Finally, we present some meridian observations of distances from the zenith, made on the great gnomon of San Petronio of Bologna, together with the apparent diameter of the Sun, and the Sun's place deduced therefrom — assuming the obliquity of the ecliptic to be 23° 30' 20", and the altitude of the pole in that same church to be 44° 30' 20".

[These San Petronio observations are tabulated below. For each observation the rows give, in order: the tangent of the distance of the lower limb [Limbi inferioris] and of the upper limb [Limbi superioris] from the zenith; the Sun's apparent diameter [Diameter apparens] and its half [semidiameter]; the distance of the Sun's center from the zenith [Centri distantia a Vertice]; (sometimes) the distance of the equator from the zenith [Aequatoris distantia a Vertice]; the Sun's declination [Declinatio], B = north / A = south; and the place in the ecliptic [Locus in Ecliptica]. The "Tangentes" column holds the tangent values (radius = 100000); the "Arcus" column holds the corresponding arc in degrees/minutes/seconds. Status notes beside the date — *Solis* (of the Sun), *exactiùs* (more exactly), *dubia* (doubtful), *Lubrica* (uncertain/"slippery"), *minus certa* (less certain), *tertiùs sed non certa* (a third [reading], but not certain), *serenis/sereno* (clear sky), *sub*

nubilo/sed nubilo (under/but cloudy), *semidubia* (half-doubtful) — are reproduced in the Year column.]

		Centri dist. a Vertice	35 50 3
		Declinatio B.	8 40 17
		Locus in Eclipt.	□ 7 47 14

Parsing notes: tangent values are 5-digit (radius 100000) except the □-region winter/summer entries which run to 6 digits as the zenith distance grows. Several "Locus in Eclipt." sign-and-degree groups are faint; the 1655 Iulij 26 entry shows "□ 10 48" with no leading degree printed, transcribed as seen.

Parsing notes: The lower-limb tangent for 1658 Iunij 26 is printed "48912" but its arc (21° 15' 45") matches an upper-limb-style value near 38900 — see Numerical impossibles (the lower-limb tangent should exceed the upper-limb tangent, here 37876, but 48912 > 37876 is consistent in magnitude, yet the arc 21°15' corresponds to a tangent □ 38900, not 48912; likely a compositor digit error). Faint

zodiac/seconds groups flagged [?]; the Dec. 21 1656 Locus-in-Eclipt. degree group is illegible (☒ [?]).

(Caput VIII, continued) — San Petronio gnomon meridian observation table

The table of meridian observations made with the great San Petronio gnomon continues. Each dated observation gives, in order: the tangents of the distances of the lower and upper limb of the Sun from the vertex (in units of the gnomon scale); the apparent diameter and its semidiameter; the true distance of the Sun's center from the vertex [*Vera centri distantia a Vertice*]; the declination (A = southern / B = northern); and the place in the ecliptic [*Locus in Eclipt.*].

Parsing notes: For the 1658 and 1659-January rows the "limb" entries are printed as *Limbi inferior / superior*; from 1659 Feb. 8 onward they are printed as *Marg. infer. / Marg. super.* (margin lower/upper), the same lower/upper limb quantities under a slightly different rubric. The zodiac symbols in the ecliptic-place column are small and several are hard to resolve at this resolution; see the lettered numbering anomalies for the cells where the printed symbol appears

inconsistent with the declination. The "Arc" sub-columns are degrees/minutes/seconds.

CAPVT IX.

On the Hypothesis of the Solar Motion, its Apogee, and the Motion of the Apogee

[*De Solaris motus Hypothesi eiusque Apogeo, & motu Apogei.*]

1. All astronomers agree that the Sun lingers longer in the northern semicircle of the ecliptic than in the southern, and that it once lingered longer at the vernal quadrant than at the summer one — indeed longer in summer than in spring, as is clear from what was said in Chapter VII. It would be absurd to suppose, as the ancient astronomers did, that the celestial body of the Sun actually moves with physically unequal speed; and it is absurd to attribute that whole apparent inequality to the optical cause [*ratio optica*], or to suppose that some such apparent inequality could arise on the hypothesis of an epicycle, where the Sun would be carried evenly upon an epicycle whose center is borne evenly upon a circle concentric with the Earth — or rather, upon an eccentric circle whose center is the Earth, where the solar body itself would move evenly. So clearly is this so that our eye, if it were set at the center of the deferent circle carrying the Sun, would perceive no inequality whatever in the Sun's motion. We ourselves have set out this hypothesis abundantly, with all its properties, in *Almagestum Novum* Book 3 [*Lib. 3*]; and the method of deducing the prosthaphaereses [*prosthaphaereses*, the equations of the apparent–mean difference] — from a given eccentricity, or semidiameter of the epicycle, and a given mean motion of the Sun — at chapters 19, 20, and 21.
2. [Margin: *Kepler*] Kepler, however, considering in the lesser planets that the equant circle [*Aequans Circulus*] is to be reckoned from Ptolemy [Ptolemaeus] — and considering also the difference of the apparent diameter of the Sun, greatest at apogee and least at perigee, and that the distance of the Sun from the Earth at perigee does not require more than half of that whole eccentricity — concluded that the solar prosthaphaereses, which are necessary in his work on Mars and in the *Epitome of Copernican Astronomy* [*Epitome Astronomiae Copernicanae*], are

to be introduced into the solar theory; and that the eccentricity must be bisected. Thus half of that eccentricity ought to be reckoned between the center of the Earth and the center of the orbit carrying the Sun, and the remaining half between the center of this orbit and the point about which the Sun moves evenly. Because the Sun moves evenly about this latter point, some accordingly call it the center of equation, or the mean motion [*Centrum aequalitatis, seu medium motum*]. And since it is proper to an ellipse to have within its greater diameter two points equidistant on either side from its own center — points which are called the umbilici, or foci [*Vmbilici, seu Foci*], from the concurrence of rays from the concave side of the ellipse at one or the other of those points — and since this builds up the force of the argument, Kepler did not doubt that the Sun's orbit is an ellipse rather than a circle, and that this inequality, which when the eye is placed on the Earth appears as an inequality of motion, is in part a real inequality (on account of the unequal distance of the orbit's center) and in part an apparent one (on account of the unequal distance of the center of even motion). Kepler therefore at last inferred that the solar equation [*Aequatio Solis*] is to be bisected into an *optical equation* [*Optica Aequatio*] and a *physical equation* [*Physica Aequatio*], understood by two straight lines drawn from the Sun: one to the center of the Earth, the other to the center of the ellipse.

In the adjoining figure ST and SC, if the Sun is supposed at S, or HT and HC if the Sun is supposed at H: in the *physical equation* are understood two straight lines drawn from the Sun, one to the center of the ellipse, the other likewise to the other focus, or point of even motion [*punctum aequalitatis*] — such are SC and SF, with the Sun supposed at S, or HC and HF, with the Sun supposed at H. Therefore the *optical equation* is the angle CST, or in the second case CHT; and its basis is the semi-eccentricity CT; while the *physical equation* is the angle CSF, or in the second case CHF, and its basis is the semi-eccentricity CF. But how this is to be demonstrated by living geometry [*Geometrica Activa*] in the ellipse...

Diagram. A geometric figure illustrating Kepler's bisection of the solar eccentricity into the optical and physical equations. An elliptical (or near-circular) arc is drawn; within it a cluster of labeled points and converging straight lines. The Sun is supposed alternately at the upper point S (top) or the lower point H (bottom); lines run from each of these to the central points. The labels, reading top to bottom on the right-hand stack near the center, are A, S, E (or F), G, T, C, P; the apsidal points are at top (A/apogee) and bottom (P/perigee), with the body of the figure spanning between them.

- A (top): apogee point [*Apogeeum*]
- S (upper, on the arc): the Sun in one supposed position
- C: center of the ellipse [*Centrum Ellipsis*]
- T: center of the Earth [*Centrum Terrae*]
- F (lettered E/F near center): the other focus, or point of even motion [*Focus / punctum aequalitatis*]
- G: intermediate point on the central axis [?]
- H (bottom, on the arc): the Sun in the alternate supposed position
- P (bottom): perigee point [*Perigeum*]

in the ellipse, Kepler does not show, both in the *Optical* and in the *Physical* part separately — so that for that reason Ismaël Boulliau [Bullialdus, Ismaël Boulliau] labored, and on the other hand Seth Ward [Sethus Vuardus] strove to demonstrate it with the utmost exactness, in his *Inquisitio in Bullialdi Astronomiam Philolaicam* [*Inquiry into Boulliau's Philolaic Astronomy*]; and in his biennial work published afterward, which he entitled *Astronomia Geometrica*, where he undertook to demonstrate it both in a circle and in an ellipse, in showing the said equations and the other inequalities of the planets, their nodes, etc. — which even before him Count Pagani [Comes Paganus] had partly accomplished. Now all who follow Copernicus have thereafter embraced this same hypothesis, together with the diurnal and annual motion of the Earth, in place of the eccentric circle and of the deferent circles of the Sun and of the other planets; and even though, as far as the Sun is concerned, the bisection of the eccentricity is suitable for representing this difference between the circle and the ellipse and its motions —

3. — yet certain things are certain from what was said in *Almagestum Novum* Book 9, section 4, and other things are to be said in Appendix II of this present Book. Let these for now rest among the eccentric and the other planets. And since the Sun, or whoever runs through the common path with us in the West according to the scheme set out below, by no means about the Sun, but rather about a certain cone [*Conus*], describes its diurnal spirals — so that they approach as closely as possible in their elliptical surface to circular — the annual inequalities, represented in this feigned [*ficta*] hypothesis of the ellipse, or even of a circle (provided only the bisected eccentricity be reckoned), may be denoted by intersections of the apogee of the Sun, and by the motions of the same apogee, as we taught in *Almagestum Novum* chapters 14, etc. We have declared examples of the eccentric for this Book in chapter 3, section 86, of the moments of the two

equinoxes, and besides at chapter 7, section 165, at the place of the Sun at Bologna by the gnomon of San Petronio, namely at degree 7, 0' 18" of Leo [□].

4. In the following figure, from the center T of the Earth, describe the ecliptic ABPD, and let the line BTD of the equinoxes cut it, which we suppose to be cut by the line AP of the apsides, somewhat inclined at D, toward B, because we are now most certain, at the present time, that the whole orbit of the Sun is an ellipse; let the line AP of the apsides be assumed to pass through the ancient hypothesis with the whole eccentricity TC, and through the center C; describe the orbit SV of the Sun, and at the points of intersection M and N, draw the straight lines CM and CN; finally, with the Sun placed at S, under the point L of Leo, draw the line TSL of the true place, and also draw the line TN of the middle place.

Diagram. A geometric construction showing the solar orbit and the line of apsides relative to the ecliptic. A large circle (the ecliptic / solar orbit) carries the cardinal labels at left and right (B at left, D at right) along the horizontal equinoctial line, with A at top and P at bottom along the vertical apsidal line. Within, a cluster of central labels (S, C, G, T, N, Y) marks the Earth's center, the orbit's center, and the points of intersection; converging chords run from these central points outward. The Sun S sits on the orbit near the top; M and N are the points of intersection of the orbit with the central lines.

- A (top): apogee / Leo direction [the place L of Leo lies near here]
- B (left): one equinoctial point
- D (right): the other equinoctial point
- P (bottom): perigee point
- S (upper center): the Sun's place
- C: center of the eccentric orbit
- T: center of the Earth
- N: point of intersection [*nodus / punctum intersectionis*]
- M: the other point of intersection [near left; label faint] [?]
- G, Y: intermediate central points [?]

In the year 1655 the Sun was observed at Bologna on the meridian of July 30 at L, that is at degree 7, 0' 18" of Leo [□]. Therefore the arc LAD, and likewise the angle LTD, from the beginning of Aries, was computed to be 127°, 0' 18"; and adding two right angles, namely degree 52, 59' 52". In the same year the Sun's entry into Libra [□] was observed on September 22, hour 18, 55' p.m. At Bologna the interval

between the two equinoxes was reckoned at 178 days, 14 hours [following chapter 4, the mean is the diurnal motion]; whence are constituted the angles which were posited in chapter 4: the mean diurnal motion ought to be degree 54, 0' 43", and so great is the angle SCM, or ICS. Lastly, in the year 1656 the Sun's entry into Aries [□] was observed at the same place on March 19, hour 9, 51' p.m.

5. Now the Sun was situated in the southern ecliptic semicircle BPD for 178 days, 14 hours, 56', as we also said in chapter 7; and this Day 178, and nearly hour 14, 56', as observed by us elsewhere and reported in *Almagestum Novum* Book 3, chapter 24, Method 3 — but the southern arc of the Sun's orbit MVN was less than a semicircle, because the mean motion of 174 hours, 14, 56' stood at a degree not 180 but 174, 3' 10' 35"; and so great was the angle MCN, and its complement to two right angles the angle CMN, individually the angle CMN, namely degree 1, 58' 25". Therefore in the figure CMN, individually the angle IMT, which joined to the angle MTI we found to be degree 52, 59' 52", makes the sum degree 54, 58' 17". Therefore the complement of the two right angles, that is the angle MIT, equals degree 125, 1' 43", and CIT equals degree 54, 58' 17", and CSI, or degree 57, 42".

[Margin: *The Apogee of the Sun at the end of the year 1655. — Apogeeum Solis in fine Anni 1655.*]

Firstly, then, in the triangle CIS, taking the radius CS at 100000 parts, from the angle CIS, degree 125, 1' 43", and the angle CSI, degree 0, 57' 42", the side IC is collected by trigonometry, of such parts 2049, of which radius CS is 100000; the remainder is IM, of parts 97951. *Secondly*, in the triangle MIT, the angle IMT being found to lie latent, degree 97951; and from the said angle MTI above, degree 52, 59' 52", and the angle IMT, degree 1, 58' 25", the side TI is collected, of parts 4224. *Thirdly*, in the triangle CIT, taking now TI as above of parts 4224, and CI of parts 2049, and the said angle CIT, degree 54, 58' 17", the angle CTI is found, degree 28, 50' 0". But the angle was LTD, degree 127, 0' 8", from which subtracting CTI, degree 28, 50' 0", leaves the distance of the Sun's apogee from Aries, that is the angle ATD, degree 98, 9' 8". Therefore the apogee of the Sun was at that time, of Cancer [□] degree 8, 9' 8".

6. By a similar method, from the two said equinoctial observations and the Sun observed on the meridian of August 1 of the same year 1655, at degree 7, 47' 15" of Virgo [□], reported in the observations of chapter 8, the apogee of the Sun is found at degree 8, 13' 12" of Cancer. Again, from the same equinoxes and the Sun observed in the year 1655 on the meridian of July

23, at degree 1, 5' 31" of Leo, according to the observations reported in the same chapter, we obtain the apogee of the Sun at degree 8, 9' of Cancer. At length in the year 1656, the Sun being observed at the vernal equinox of March 19, hour 9, 51', the autumnal of September 22, hour 22, 44' p.m. according to the said chapter 3, on August 7 of the same year, on the meridian, at degree 27, 53' 30" of Leo, as was said in chapter 8, we deduced the apogee of the Sun at degree 8, 9' of Cancer. Neglecting, therefore, after many dealings, from other observations made and noted as more certain conclusions toward the end of the year 1655, the apogee of the Sun is established to stand beyond degree 7 and short of degree 10 of Cancer; indeed, beyond degree 8 of Cancer. Since the extreme of the three thirds of the aforesaid observations is beyond degree 8, 13' 12" of Cancer, and degree 9, 58' 29", the arithmetic mean is degree 8, 5' 51". We therefore establish the apogee of the Sun at the end of the year 1655 at degree 8, 36" of Cancer.

[Margin: *The apogee of the Sun at the end of the year 1655. — Apogeum Solis in fine Anni 1655.*]

6. (continued) But because in the aforesaid method we supposed the center of the mean motions to be the very center of the orbit of the Sun — whereas, the eccentricity being bisected, the center of the Sun's orbit ought to be constituted at so great an interval as is the semi-eccentricity, and standing apart from the center of the apparent motions, or of the Earth, by the whole eccentricity — the prosthaphaereses owed to the Sun [will differ slightly]; we have nevertheless attempted, both at the equinoxes and at the other solar observations near the equinoxes, or about summer, to demonstrate the apogee line geometrically, both in a circle and in an ellipse, especially since among the other properties of the ellipse, which is so notable, and below us is to be usurped, that any radius drawn from one or other of the two foci to the circumference is at the same time taken equal to the axis, or the greater diameter itself; and likewise the straight line drawn from either of the foci to the extremity of both the lesser diameters, or the transverse of the ellipse, which the Greeks call the *diameter* [Greek: διάκαρπος (diakarpos) — here used by Riccioli for the conjugate/transverse diameter of the ellipse [?]], is equal to the greater semidiameter of the ellipse; and this, however much you multiply it by trigonometry, did nonetheless succeed for us, just as it did for Kepler, Boulliau, Count Pagani, and Seth Ward. But as for another method which trigonometry does not require, and which serves to find the motions of the Sun by solar observations at the two points of the circle...

or of the ellipse, made equidistant from, or not at all distant from, the line of the apsides.

7. *Firstly*, then, it is certain that the true motion of the Sun is swiftest at perigee and slowest at apogee — not only on the circular hypothesis, but also on the elliptical hypothesis from conic elements. If within the same tropical year the true motions of the Sun are observed twice, in which the true motion of the Sun becomes once greatest, once least, and in the other place greatest, then at once in these the place of the ecliptic and of the apogee is manifest from there; but if even by a few seconds an error is made in the Sun's altitudes on this occasion, the error will be by far more degrees in the place of the apogee.

Secondly, it is likewise certain that the true motion of the Sun, in the first semicircle of the anomaly computed according to the order of the signs from the apogee, is less than the mean, and therefore that the equations [*Aequationes*] in this whole semicircle are to be subtracted; while in the latter semicircle the true motion is greater than the mean, and consequently the equations are to be added. Comparing nevertheless the true motion of the Sun reckoned from day to day, or from even intervals of time, the computation made from the apogee, it is certain that in the upper semicircle of the anomaly — which is above the diacenter [*Diacenter*], that is, the true motion is less than the mean — while in the lower semicircle, that is below the diacenter, the true motion is greater than the mean; and the transition from the one extreme to the other is at the points of the diacenter, which are the points where the mean motion is nearest, or very nearly equals, the true motion. Therefore, by continuous observations, those places of the ecliptic in which, within the same tropical year, or equinoctial, the true motion equals the mean, and the ecliptic arc is intercepted between two such places cut bifariouly [in two] — the position being given, the situs both of the line of the apsides and the place of the apogee and of the perigee is given; but this method demands a more delicate observer.

Thirdly, it is certain that in two places equidistant on either side from the apogee the apparent motions become equal. Therefore if two such motions are observed which agree at two such places, the ecliptic arc is bisected between them, which intercepts the line of the apsides; and there will be given the place both of the apogee and of the perigee. For the *first* and *second* methods, our observations have not yet attained other suitable observations; but for the *third* we have these two equal pairs of observations, made on the same dates, whose certitude is nonetheless allowed, that we may bring forward to the mean.

8. [Margin: *Chapter 8*] From the relations of chapter 8, the Sun appeared at the Temple of San Petronio at Bologna on the meridian of the day September 22, at degree 29, 13' 4" of Virgo, and on the day 23 at degree 0, 12' 24" of Libra. Therefore the true diurnal motion was 59' 20". But in the year 1656 it appeared at the same place on the meridian on March 21, at degree 1, 34' 30" of Aries, and on day 23 at degree 3, 33' 50" of Aries. Therefore the true diurnal motion was 59' 20". The ecliptic arc from Libra degree 0, 12' 24" to Aries degree 23, 50" is degree 182, 21' 16", whose semis [half] is degree 91, 10' 43", which gives the entrance into Libra at degree 0, 12' 24", that the place of the perigee is in Capricorn [□] degree 1, 23' 7", and so of the apogee in Cancer degree 1, 23' 7". That this is false, not only from what was said toward the number 5, but also and soon to be said by us, is detected from these very observations.

For in the year 1655, as I reported in chapter 8, on May 22, in our observatory the Sun appeared on the meridian at degree 1, 10' 35" of Gemini, and on day 23 at degree 2, 8' 7" of Gemini, wherefore the true diurnal motion was 57' 32". Again in the same year, on August 7 on the meridian, the Sun appeared to us at degree 14, 40' 1" of Leo, and on day 8 at degree 15, 37' 33" of Leo. Let it be supposed that on the same day, in the gnomon of San Petronio, the Sun was seen at degree 15, 39' 13" of Leo. Standing therefore by our observation, the true diurnal motion was likewise 57' 32"; and so the equal ecliptic arcs of the Sun, from degree 1, 10' 35" of Gemini to degree 15, 33' of Leo, are degree 74, 26' 58", whose semis is degree 37, 13' 28", which, added to Gemini degree 1, 10' 35", effects the place of the apogee in Cancer degree 8, 24' 3". On account of the diversity, nevertheless, of the aforesaid observations, we judge they are to be retained.

[Margin: *The apogee of the Sun at the end of the year 1655 at degree 8, 36" of Cancer, according to what was said in number 5.*]

On the Apogee of the Sun discovered by others before us, and its Motion

[*De Apogeo Solis ab aliis ante Nos inuento, eiusque Motu.*]

9. [Margin: *The foundations of Longomontanus and Kepler for the motion of the apogee of the Sun.*] When Hipparchus [Hipparchus] had found the apogee of the Sun in Gemini degree 5, 30', about 140 years before Christ, and Ptolemy [Ptolemaeus] refers to the same about 280 years afterward, in *Magna Constructio* [*Almagest*] chapter 4 [*Lib. 3 Magnae Constructionis cap. 4*], Ptolemy supposed that 280 years from Hipparchus did not suffice to

discover, for the evident determination, a change in the apogee. But Albategnius [al-Battānī] in the year 883 of Christ, as we have in chapter 28 of his *De scientia Stellarum*, observed the apogee of the Sun in Gemini degree 22, 17'; and accordingly the annual progression of 59' 4". But when Arzachel [al-Zarqālī] in the year 1076 of Christ found the same again at degree 17, 50', he judged from this retreat that some followed Albategnius, some followed Arzachel, and some others. Albategnius in *Almagest* Book 3, chapter 25, more fully expounded by us — all the other observers of our time, and the writers of the preceding century who placed the apogee of the Sun beyond the beginning of Cancer, whose selected opinions we put at the foot of this Chapter, together with the annual motion chosen by the same writers — among whom Longomontanus [Longomontanus], supposing the World created in the year 1590, the apogee in Cancer degree 5, 30'; and supposing the World founded at the beginning of Aries, and accordingly in the year 1554, that the apogee was at the beginning of Aries, concludes the annual motion to be 1, 1' 50", 14". Kepler likewise, supposing the World founded 3993 years before Christ, and the apogee to have been then at the beginning of Aries in the year 1588, but in Cancer degree 5, 32'; and accordingly the apogee was in the year 1581, progressed to degree 95, 32', he collects its annual motion to be 1, 2".

10. We, however, granted that the apogee of the Sun was at the beginning of Aries at the beginning of the World, deem it too fallacious a method of collecting the motion of the apogee — this method resting on so uncertain and controverted a year of the World's founding, of which there exist nearly 70 diverse opinions. Among which the most probable is indeed the one which Kepler thinks the founding to be according to the LXX [Septuagint] interpreters, in the year 3634 before Christ; to which adding the years 1655 makes 5289; therefore if it set out at the beginning of Aries with this whole progress of degree 98, 36', from the beginning of Cancer, one year being one would make a second, $48\frac{2}{3}$.

But if, according to the common edition, the World was created in the year 4184, so that in my most recent *Chronologia*, adding 1655, makes the years 5839, in which the progress would be degree 98, 36'; and likewise from the said *Chronologia Reformata* of the World, with its founding in the year 4064, adding to that founding the years 5719, makes the progress degree 98, min. 36'; and accordingly the World was created in the year 4184; or likewise from the *Chronologia Reformata* of the World, with its founding in the year 4064, when there will be the years 5719, the progress completed is degree 98, min. 36'. And

accordingly the mean annual motion stands between Kepler and Longomontanus on this side, and Wendelin [Vendelinus] on that — whose opinions see in the following Table — there will not be lacking certain things in which a single one of the minutes, for the sake of facility, may please.

Liber I — De Sole, Caput IX (conclusion) — table; Caput X; Caput XI

Table of opinions on the solar apogee

The opinions promised at the close of the previous section are gathered in the following table. Its caption reads *Apogei Solis* ("Of the solar apogee"). The columns give: the authorities; the year (*Anni Christi*); the apogee's position (*Locus Apogei*) by zodiac sign, degree, minute, and second (*Sig. Gr. I. II.*); and the apogee's annual motion (*Motus Annuus*) in further sexagesimal places (*II. III. IIII. V.*).

Parsing notes: The "Apogee position" sign column shows ♊ (Gemini) for the first five entries (Hipparchus through Alphonsus) and ♋ (Cancer) for the rest, as the apogee crosses from Gemini into Cancer over the centuries. Several entries leave the annual-motion places blank (transcribed as .) where the author gave no derived motion. The annual-motion sub-columns are headed II III IIII V (the higher sexagesimal places); the leading degree/minute places of the motion are folded in as the small recurring values.

CAPUT X.

De Solis Excentricitate. (On the Sun's eccentricity.)

If the eccentricity did not have to be bisected, but the center of the deferent circle were itself the center of the [mean] motions, then — once the apogee's place is

given — from a single observation of the Sun's true place one could easily collect the eccentricity, which is the foundation of the entire computation. The procedure would run as follows.

Diagram. A geometric construction for deriving the eccentricity from a single observation, on the assumption that the deferent's center is the center of mean motion. A quarter-arc runs from A (top) down through P (bottom), with the apsidal line A–P vertical. Points C (the circle's center) and T (the Earth's center) lie on this line, T below C. From S — the Sun's position on the arc — lines are drawn to C and to T.

- A (top): the apogee
- P (bottom): the perigee
- C (on the axis, upper): the center of the deferent circle
- T (on the axis, lower): the center of the Earth
- S (on the arc, right): the Sun's true place

In the adjoining figure, let the deferent circle carrying the Sun be ASP; in its rear semicircle ASP, from the circle's center C draw the straight line CS for the mean motion, and from the Earth's center T draw TS for the apparent motion. For, given the moment of observation, both the Sun's mean motion and the apogee's motion from the start of [the epoch] are had from the tables; and consequently — by subtracting the apogee's mean motion from the Sun's mean motion — the Sun's mean distance from the apogee, that is, its mean anomaly (namely the arc AS), is had. Moreover, the angle ACS, from which in turn the Sun's true distance from the apogee reckoned on the ecliptic is had — that is, the arc ATS — to which, together with the angle CST, the external angle ACS is equal, by Elements I.32. Therefore subtract the angle ATS from ACS, and you will have the angle CST; and so in this triangle all the angles together with one side, CS, which is assumed to be of 100000 parts, are had. Therefore, by the laws of triangles, the side CT — the eccentricity — will not lie hidden.

But because, as we said and as we shall show below, we suppose the eccentricity must be bisected, and the center of the mean motions is not the center of the circle — but rather the semidiameter of the ellipse carrying the Sun, and hence the semidiameter of the circle (since an ellipse cannot well be assumed except in one case for another), is greater, because by it alone is the apparent motion plainly manifest — neither is the Sun's mean motion measured by the arc of the circle or of the ellipse carrying the planet subtended to that same angle. For that

reason another path of proceeding has been prescribed to astronomers, not on the circle [but on the ellipse].

— or [must proceed] on the elliptical orbit carrying the planet's body; rather, [the discrepancy arises because] on the ecliptic one measures not only the arc of the true motion and of the true anomaly from the Earth's center, but also the arcs described on the ecliptic, and even the arc of the mean motion and of the mean anomaly — since so great is the distance supposed to the ecliptic circumference that not only is the interval from the Earth's center, but even the interval between the centers of the mean motions, that is, the whole eccentricity, as if of a point [negligible]; and the parallels drawn from either center coincide, physically and to every perceptible subtlety. This will be seen in the following figure, described from the Earth's center T at an infinite [practically immense] distance owing to the great interval to the ecliptic, namely portion AB; and let the Sun's apogee be A, and let the semi-ellipse ESP then be drawn, in which let the Sun be S, and through it draw FM straightway for the mean motion, and TV for the true motion; let TB be drawn parallel to FM, for on account of the immense distance the arc BM is imperceptible, and although BT will mathematically be distinct from FM, it physically coincides with FM, and the arc AB, imperceptibly greater than the arc AM, will — just as AB is the measure of the angle ATB — also (for AB is physically the measure of the arc AM, since AB and AM are taken as physically equal) be the measure of the angle AFM, that is, of the mean anomaly. These things being laid down, then:

Diagram. A tall narrow construction illustrating that, at the Sun's immense distance, the parallels drawn from the circle's center and from the Earth's center coincide. At the top, near-coincident points B, M, V converge toward A (the apogee) at the top. A long nearly-vertical line descends to E, then through F (the center of mean motion), C (the circle's center), T (the Earth's center), and P (the perigee) at the bottom.

- A (top): the apogee
- B, M, V (top, clustered): the imperceptibly-separated points of the arc and the parallels (B on parallel TB, M on the mean-motion line FM, V on the true-motion line TV)
- E (mid-left): vertex of the semi-ellipse ESP
- F: the center of the mean motions
- C: the center of the circle
- T (lower): the Earth's center
- P (bottom): the perigee

I. PROBLEMA.

[Margin / rubric:] Given a certain moment of time of the Sun's true place, and the Sun's [mean motion] for it: to find in the ellipse the whole eccentricity, the equation, and the Sun's distance from the Earth and from the center of the mean motions.

Let the ellipse be ASPB, whose major axis is AP, and on it the two foci F and S; let the center of the Earth be T, and to it draw the radii FS and TS; produce TS to M, so that SM equals the radius FS, draw FM; for then the triangle FSM will arise as isosceles, and so by Elements I.5 the base angles SMF and SFM will be equal between themselves, and the whole TM will equal the axis AP, because any two radii drawn from the foci, or umbilici, of an ellipse, taken together, are equal to that same greatest diameter — as Count Pagan [Blaise François Pagan] demonstrated in Book 3, Theorem [...]. Wherefore, if the semidiameter AC be assumed to be of 100000 parts, AP will be of 200000; so too will TM be; subtract from it the assumed TM [recte: subtract from it the Sun's true distance], that is, [...] now from the Sun's true place reckon the apogee, and there will remain the true distance of the Sun's true place from the apogee, which is called the true anomaly (namely the angle ATS), measured not by the arc of the ellipse AS, but by the arc of the ecliptic; and from the said number preceding [subtract] [...].

Subtract likewise the apogee's motion, given by the tables for the Sun's given mean motion, and you will have the distance of the Sun's mean place on the ecliptic, which is called the mean anomaly (namely the simple angle AFS), measured also by that same arc of the ecliptic, by Elements I.32. The angles FTS and FST, taken together, are equal; subtract therefore FTS, which is known from FST [...] and since FST [...] this whole equation sought, that is, the difference between the true and the mean [motion] of the Sun, the half of which in the isosceles [triangle] already mentioned will give individually the angles SMF and SFM, [which] are therefore given in the triangle FMT, the side TM being of 200000 parts, and the angle TMF, and the angle TFM, being constant —

— from the anomalistic angle AFS, the angle SFM being diminished by the complement to two right angles. Therefore, by the benefit of trigonometry, the whole eccentricity FT will not lie hidden, since the angle FMT, now too acute, can subtend the little angle FT, of one part of 100000; so that it may be extracted exactly from the tables, another, surer method has been devised, which is written below.

§4. Produce from the point M the parallel MN, to AT itself, until it meets orthogonally the line NT, perpendicular to AP itself; and from the other focus F

produce FR parallel to NT itself; FR will be equal to NT, and in the triangle MNT, right-angled at N, the angle NTM is known, as being the complement of the angle ATS, as given above; and so, by Elements I.32, the third angle TMN will be known, to which when the angle SMF is adjoined, the angle FMR will be known, right-angled at R; and so the third angle RFM. First, then, in the triangle NMT, the side TM being given as 200000 parts, seek the sides MN and NT; then in the triangle RFM, FR being given as equal to NT itself, seek the side MR (for the difference of this from the side MN, that is, the line RN, is equal to the sought eccentricity FT), in the parallelogram FRNT. Or because in the triangle FST all the angles, as above, are given, and the sides too are inter se [...], the sine of the angle SFT, and so, joining them into one sum, and taking the sine of the said angle FST, you make the sum aforesaid, and from AP, of 200000 parts, so the sine of the angle FST and the eccentricity FT [are had].

§5. The eccentricity FT having been acquired, and the angles being given as above, in the triangle FST — all the angles given — the Sun's distance from the Earth's center will be had by trigonometry, together with SF from the center of the mean motions. And if the Sun be in the semicircle of the anomaly, as VT, by drawing FB and TB, the angle AFB will be known by subtracting from the whole circle the mean anomaly, the planet being placed, and so deg. 360. The true anomaly of the planet [is had]. The rest are to be carried through, as above. By this method, examined at many of the Sun's places and at others by us observed, we find no eccentricity that satisfies more of the observations than if the whole AC be of 100000, the semi-eccentricity 3480, of which parts AC be 100000, and the [whole] eccentricity CT, as also CF, be of 1740 parts; which we shall presently confirm by another experiment.

[*Margin:*] [Margin: Eccentricitas inuenta — "The eccentricity found."]

II. PROBLEMA.

[*Rubric:*] *Given the Sun's apparent semidiameter at its mean, greatest, and least distance from the Earth: to confirm the eccentricity itself, and the necessity of bisecting it.*

§6. From the observations related in Chapter 8, it is established that in the great Gnomon of the temple of S. Petronius [San Petronio, Bologna] the Sun's apparent semidiameter was observed on 20 and 21 June at 15'32". Therefore at the end of June, when the Sun reached its apogee, it must have appeared a very little smaller, that is, 15'30". On 28 March and 29 September, when the Sun was at its mean distance, its semidiameter was observed at 15'45" and 15'47", of which the

mean is 15'46"; on the day of January, when the Sun was at its perigee, it was observed at 16'4" — but indeed if we assume the mean distance of 100000 parts in the adjoined diagram, this is the angle SCM; in the right-angled triangle CSM, right-angled at M, where you inquire 15'46", you will find the Sun's true semidiameter SM, neglecting that fraction of a part. Then with this SM, and with the Sun's greatest distance ST, of 101740 parts, in the triangle STM, right-angled at M, you find the angle STM, which subtends the Sun's apparent semidiameter at 15'30"; and finally, with FS, the Sun's least distance of 98180 parts, and with SM, of 46 parts, in the triangle FSM, right-angled at M, you find the angle SFM, which subtends the Sun's apparent semidiameter at 16'4". Therefore the chosen semi-eccentricity of 1740 parts satisfies the observations very well, and from this likewise is established the necessity of bisecting that eccentricity — which necessity is also that of the equation of the solar motion. For, the whole eccentricity (which in the figure of number 3 is expressed by FT) being required, to be reduced to the angle FST [...].

Diagram. A small construction for the eccentricity-from-semidiameter argument: the apsidal line runs vertically from S (top) down through M, F, C, to T (bottom), with the Sun's body shown as a small disc near the top, the apparent semidiameters compared at the three distances.

- S (top): the Sun
- M: foot of the perpendicular (right angle vertex)
- F: focus / center of mean motion
- C: center of the circle
- T (bottom): the Earth's center

Table — eccentricities and maximum equations (radius of orbit/ellipse = 100000)

The caption reads *Qualium Radius Orbis, seu Ellipsis est 100000* ("Reckoning the radius of the orbit, or ellipse, as 100000"). Columns: authorities (*Auctores*); year of Christ (*Anni Christi*); the eccentricity in such parts (*Talium Eccentric.*); and the maximum equation in degrees, minutes, seconds (*Aequat. max. Gr. I. II.*).

Parsing notes: Fractional eccentricity entries ($\frac{1}{3}$, $\frac{1}{2}$) are transcribed as printed. Several rows are continuation/qualifier lines ("but bisected eccentricity," "as to

mean") that modify the row above; their max-equation cells are sometimes blank (transcribed .). Riccioli's own final line gives two reckonings (in the ellipse and in the circle); the eccentricity 3480 with bisected half \square 1740 ties to his adopted value above.

CAPUT XI.

De loco Solis Vero Geometricè determinando, Aequationum Tabula construenda, Distantijs Solis ab vtroque Foco Ellipsis, & ipsa Ellipsi definienda, ac denique de Inaequalitate Motuum Solis repraesentanda in Ellipsi, & in Circulo.

(On geometrically determining the Sun's true place; on constructing the table of equations; on defining the distances of the Sun from each focus of the ellipse, and the ellipse itself; and finally on representing the inequality of the Sun's motions, in the ellipse and in the circle.)

I. PROBLEMA.

[*Rubric:*] *To determine the place of the Sun's mean distance from the Earth in the ellipse.*

§1. Briefly, this place is at the extremities of the line bisecting [the figure] and orthogonally cutting the line of the apsides, that is, the minor diameter of the ellipse, which is called

— is called the *diacentros* (the through-the-center line), which is in the following diagram BCD. For when the Sun is at B, or at D, its distance from the Earth's center T (namely BT, or DT) is as great as AC, that is, of 100000 parts, such as AP is of 200000. For — let two equilateral and equiangular triangles be drawn for example's sake at B, the angles FB and BT being right, and from the foci of the ellipse [arise], and so the rest of the half CT and BC is a common side. And the [...].

Diagram. The full ellipse showing the *diacentros* (minor-axis line) BCD and the apsidal line A–P. The ellipse has A at left, P at right (the apsides), with B above center and D below center marking the minor-axis endpoints. Interior points F, C, T, H lie on the major axis; lines run from the foci to B and D and on toward L (a point produced beyond the ellipse to the right).

- A (left): the apogee
- P (right): the perigee
- B (top): upper endpoint of the minor axis (mean-distance place)

- D (bottom): lower endpoint of the minor axis
- F: focus (near center)
- C: center of the ellipse
- T: the Earth's center (the other focus)
- H, L (right): points on / produced along the major axis

— the angles comprehended by these are right by the definition of the *diacentros*, or by the construction indicated above. Therefore these two triangles are by Elements I.4 equilateral and equiangular, and so the side BT, and the side BC [...]. But these two radii drawn together are equal, as said in the preceding chapter, the whole AP; therefore each of them is equal to the half of the whole AP itself, that is, to AC; and the angle FBC is equal to the angle TBC.

II. PROBLEMA.

[*Rubric:*] *Given the eccentricity, to find the maximum equation of the Sun's motion, and from it the mean and the true anomaly.*

§2. Since the maximum equation, or the difference between the Sun's mean and true motion, occurs not at the extremities of the line which in Greek is called *diacentros* (that is, the line drawn through the Earth's center cutting the line of the apsides orthogonally, as falls in the hypothesis of the circle; and the eccentricity being unbisected) but at the extremities of the line which is called *diacentros*, that is, the minor diameter of the ellipse, in which is also the situation and the Sun's mean distance, as we now say more truly — and the mean motion being assumed equal to the true at the very next instant: if in the preceding diagram the angle CBF be found, which we said above to be equal to the angle CBT, its doubling will give the whole equation FBC, the maximum, and the optical [angle] CBT will be physically equal to CBF. Now in the triangle CBF, right-angled by construction at C, the base BF is of 100000 parts, by Problem I, and CF is of 1740 parts, by the said preceding Chapter, number 5. Therefore by trigonometry the angle CBF — that is the optical equation — is of deg. 0, 59'49", and the whole and maximum equation FBC is of deg. 1, 59'38". Now the sum from the right-angled BCF, and the acute CBF, is of deg. 0, 59'49", by Elements I.32; the angle equal is the mean anomaly AFB subtracted, finally; the angle CBT of deg. 0, 59'49". With the right angle remaining, the true anomaly angle BTC is left, of deg. 89, 0'11".

III. PROBLEMA.

[*Rubric:*] *Given the eccentricity, to find the minor diameter in the ellipse.*

§3. In the preceding figure, in the triangle CBF, right-angled at C, the base BF is given of 100000 parts, and the angle CBF of deg. 0, 59'49", and BFC of deg. 89, 0'11". Therefore by analysis of right-angled triangles, BC comes out of 99984 $\frac{2}{3}$ parts. Therefore the whole minor diameter BD is of 199969 $\frac{1}{3}$ parts.

III. PROBLEMA.

[Rubric:] Given the eccentricity, to find the equation suited to the Sun, set at the extremities of the line of the diagonal, or drawn orthogonally to the line of the apsides through the Earth's center, and the Sun's mean anomaly, and the true one, in that same place together with the Sun's distance from the Earth.

§ In the preceding figure, a line being drawn from the Sun H, perpendicular HT, and produced to L, until HL equals the radius FH, the whole TL, and again often meeting the property of the ellipse, the equals FL fit the whole AP, conjoining FL the right [angle]; for then the triangle FHL is isosceles, and the angle L by Elements I.5, half of the external angle FHT. Now in the triangle FTL, right-angled at T, by construction TL is given as great as AP, of 200000 parts, and FT, from the said preceding Chapter number 5, of 3480 parts. Therefore by the laws of right-angled triangles the angle L is of deg. 0, 59'48"; therefore its double, that is, the whole equation FHT, is of deg. 1, 59'36" — a little indeed, but still smaller than the maximum equation found at the extremities B & D, by Problem II. The angle FTL, joined to the angle L, makes the sum deg. 90, 59'48"; and so much is the external angle AFL, namely in the prior semicircle ABP. The Sun's mean anomaly in the posterior anomaly [is] the complement to the circle. But the true anomaly is the right angle at T — this is of 90 degrees in the prior semicircle, in the posterior 270 [degrees].

At length in the right-angled [triangle] FTH, the angle FTH is given, of deg. 1, 59'36". Therefore its complement to the right [angle] is of deg. 88, 0'24", and FT of 3480 parts. Therefore by the canons of right-angled triangles the Sun's distance from the Earth HT comes out, of 100000 $\frac{2}{3}$ parts.

V. PROBLEMA.

[Rubric:] Given the eccentricity and the Sun's mean anomaly, to find the composite equation, and to construct in the ellipse the tables of equations.

§ — In the following figure, let the ellipse be ABPD; let the axis be AP, and its center C; let the center of the true and mean motions be T; and let the Sun be at S; to it draw the radii FS and TS; and the radius FS being produced to M, that is to say SM equal to the radius TS, and so the radius FM; so that, the said property of

the ellipse arising, the whole FM equals AP; let the equal axis AP be drawn; for then, MT being drawn, the triangle MSF will be isosceles, and the angle M [will be] half of the whole equation FST. Similarly, the Sun being at O, by drawing FO and TO, and producing TO; so that TO again equals the radius TO; and TL being drawn, the whole TL is made, equal to the whole AP and to the angle L, half of the whole equation FOC. Now in the first case the sides FT, of 3480 parts, and FM of 200000 parts are given —

Diagram. The full ellipse oriented with apsides A (top) and P (bottom), the minor axis through B (left) and a point at right. Within it, the Sun is shown at two positions, S (left, prior semicircle) and O (upper right), with radii drawn from both foci F and T to each Sun-position, and the lines TO, TL produced beyond the ellipse to L (top right) and M (far left), illustrating the isosceles-triangle construction of the composite equation.

- A (top): the apogee
- P (bottom): the perigee
- B (left): minor-axis endpoint (mean-distance place)
- L (top right): point where TO is produced (TL = AP)
- M (left): point where FS is produced (SM = TS)
- O (upper right): the Sun in one position
- S (left of center): the Sun in another position
- F: focus / center
- C: center of the ellipse
- T (lower center): the Earth's center (other focus)
- R, N (lower left): auxiliary points produced from the construction

[*Right column, continued:*] — and the given anomaly AFS, [its] complement to two right [angles], namely the angle MFT; therefore by the canon of triangles the angle M is manifest, and its double the angle MFT [recte: the whole equation], composite, physical, & optical, that is, the angle FST. For example, if AFS be of deg. 45, M is found of deg. 41, 16'6", & the equation FST of deg. 1, 24'32", which in the prior semicircle is the mean anomaly ATS to be subtracted, so that the true anomaly ATS may be had; but in the posterior semicircle the mean anomaly being subtracted from 360 degrees, will give the angle AFO, whose complement is OFT. And to the mean anomaly the equation FOT is to be added, so that the true anomaly may be had.

Liber I — De Sole (continued), Caput XI

Problem VI

Problem VI. *Given the eccentricity and the whole, or composite, equation, to find the Sun's distances both from the Center of the Earth and from the Center of the mean motions, that is, from either Focus of the ellipse, on the supposition of the mean anomaly.*

[6] Through Problem V we have already obtained, in the preceding figure, the triangle FST, by means of the mean anomaly AFS, with the whole equation FST subtracted from it. The angle FTS is thereby also given, since it is the supplement of FST, the eccentricity FT being 3480 parts opposite to angle S. Therefore, by the rules for oblique-angled triangles, FS — the distance of the Sun from the Center F, the radius being 100000 parts — becomes known; and once that has been subtracted, the remaining ST is known — the distance of the Sun from the Earth — together with FS, both being equal to the whole AP. Let the example be the case of the preceding Problem, namely a mean anomaly of 45° , in which the angle S was found to be $1^\circ 24' 32''$ and FTS $43^\circ 35' 16''$; from these, FT being 3480 and FTS $43^\circ 35' 16''$, one obtains FS as 97585 parts, and ST as 102415 parts, which together make up 200000 parts.

Problem VII

Problem VII. *Given the Sun's mean anomaly and the eccentricity, to distinguish the physical equation from the optical.*

[7] First, by Problem V, find in the preceding figure the total equation FST; and by Problem VI find the distance of the Sun SF, or ST, and draw CS to the center of the ellipse. Then, in triangle CSF, with the semi-eccentricity FC and the angle FS given (this latter being, within this semicircle, the mean-anomaly equation AFS), find the physical equation CSF — for I call the equation CSF physical, the one which, subtracted from the whole equation FST, leaves the optical equation CST; or, if you prefer, with the distance TS and the true anomaly ATS given, or its complement, when this complement is greater than a right angle, the optical equation CST will come out, and this subtracted from the whole equation will give the physical equation CSF. Take the example of the case in Problems V and VI, in which the given mean anomaly AFS is 45° , and accordingly CFS is 135° , FC is 1740 parts, and FS is 97585 parts: one finds CSF as $0^\circ 42' 49''$. The optical equation CST is therefore found to be $0^\circ 41' 43''$, and the physical equation as above.

Problem VIII

Problem VIII. *For a given moment of time, with the eccentricity given, to find geometrically in the ellipse the Sun's true place, its distance from the Earth, and from the Center of the mean motions.*

[8] Collect, for the given time from the tables of the Sun's mean motion, the Sun's mean motion and apogee; then subtract the mean apogee from the mean motion, and by Problem V find the whole equation, which you subtract from the mean motion in the prior semicircle and add in the posterior; and you will have the Sun's true place, and by Problem VI its distance from the Earth, etc. Example. In the year 1656, on August 9, at the meridian of Bologna, the Sun's mean motion by our tables is sign 5, $18^{\circ}34'22''$; the apogee, however, is sign 3, $8^{\circ}36'37''$. Therefore the mean anomaly in figure num. 5 — namely the angle AFS — is $39^{\circ}57'45''$; its complement is $50^{\circ}2'15''$, that is, the angle MFT, with which, together with side FT, of 3480 parts, by the rules of trigonometry, the angle M, of 100000 parts, [comes out;] and its double, that is, the equation FST, is $1^{\circ}16'50''$; this subtracted from the mean motion leaves the Sun's true place, sign 5, $17^{\circ}18'3''$. And by what has been said in Cap. 8, from observation, the Sun was seen at that time to be in Leo $17^{\circ}18'45''$.

Next, in triangle FST, with the angle at S given, $1^{\circ}15'50''$, and FST as above, $1^{\circ}16'50''$, FTS comes out $138^{\circ}41'55''$; and FT being 3480 parts, FS comes out — the distance of the Sun from the Center of the mean motions — of such parts $98642\frac{1}{2}$; which, subtracted from the whole AP, leaves the Sun's distance from the Earth ST, $101357\frac{1}{2}$.

Diagram. A circle (the Sun-carrying circle of Problem IX) with center near the middle. The vertical diameter runs from A at the top through the center to P at the bottom (apogee A, perigee P). Interior points and radii lay out the eccentric construction described in Problem IX.

- A (top): apogee
- P (bottom): perigee
- S (left): the Sun's position at one location
- O (lower right): the Sun's position O
- F (interior, upper): Center of the mean motions (focus F)
- T (interior, below F): Center of the Earth (focus T)
- C (interior): Center of the circle
- M (right, between S and O): point M on the circumference

- G (right, near O): point G

Problem IX

Problem IX. *To work all the problems of this chapter in a circle, but with the eccentricity bisected.*

[9] Let the Sun-carrying circle ASPM be set down in the following figure, with its diameter and the line of apsides AP, in which the center of the mean motions, the point F, lies distant from the circle's Center C by 1740 parts; and let T, the Earth, be distant from the Center C by just as much. Let CM be the semidiameter perpendicular to AP itself, and S the Sun at the extreme M; draw the right lines FM and TM. In triangle CMF, with the right angle C, side CM of 1740 parts, and the radius CM [recte CF] of 100000 parts, you find by trigonometry the angle FMC of $0^{\circ}59'40''$, which in the ellipse, by Problem II, was found to be $0^{\circ}59'38''$.

Let the Sun be at O, to which draw the right line FO, and CO, and from O the perpendicular OT to the Triangle CTO; the rectangle [triangle] at T, the base CO of 100000 parts, and the side CT of 1740 parts being given, by the rules of right triangles you find the angle COT of $0^{\circ}59'40'' \frac{1}{3}$, and TCO of $89^{\circ}0'16'' \frac{2}{3}$; and the side TO of $99989 \frac{1}{2}$ parts. With FT 3480 parts in the rectangle [triangle] FTO, you find the whole equation FOT, $1^{\circ}59'40''20'''$; and so, with the Sun placed at O, the equation comes out greatest, and there too the Sun's distance from the Earth is $99989 \frac{1}{2}$. For the mean [distance] falls between M and O, and these are worked by Problems I, II, IV.

For Problem V, and the rest, let the Sun be at S, to which lead from the three points F, C, T the right lines FS, CS, and TS; for the anomaly AFS being given, its complement SFC is given, likewise the side FC of 1740 parts, and CS, the radius of 100000 parts. Therefore the physical equation CSF, and the Sun's distance SF, and the angle FSC, with its complement to two right angles, namely the angle SCT, with which, and the side CS of 100000 parts, and CT of 1740 parts, you find the Sun's distance from the Earth ST, and the optical equation CST, which together with CSF makes up the whole equation, whence the Sun's true place is obtained.

Diagram. A circle (the construction for Problem X) with the line of apsides drawn. Interior points lay out the ellipse-described-on-an-axis construction of Problem X, with two foci F and G and the radius BC as the interval.

- P (upper left): point P
- L (left): point L
- A (top): point A

- B (interior, near center): point B
- F (interior, right of B): focus F
- G (interior, lower): focus G
- N (left interior): point N
- S (interior): the Sun's position
- D (lower left): point D
- C (lower center): point C
- I (bottom): point I
- M (lower right): point M

Problem X

Problem X. *Given the distance of the foci in an ellipse, and its axis with the angle of the anomaly, to find the elliptical point on the periphery in which the Sun is, and so to describe such points around the whole ellipse.*

[10] In the following figure, let there be given the axis BC of the ellipse to be described, and on it the distance of the foci FG, and from F, as from the center, with the whole interval BC, describe the circle DLIM, and produce BC to D and I. Then, the mean anomaly being given, the angle DFL — produce it from the term L of the arc DL, and through L draw the right line LM; this LM will be equal to the diameter, that is, to the whole BC, and will soon be proven so. Then draw the right line from L to the focus F, and bisect the line LG with a right line, and that same [bisecting line], drawn out and likewise let fall perpendicular to the line LF, finds the Sun at S; for, drawing SG, and then [SL? — and likewise S to P, since] [?] NG, by the construction made of an equal line LN and NS, the line common to both angles at N, by the construction the right lines will be equal among themselves; the first elements between SG and SL. Now GS and FS, taken together, are equal to the whole FL, that is, to the Diameter of the ellipse, and insigne. Therefore GS and FS are the two radii of the foci of the ellipse, and the ellip-

(Page 68, folio 36 — Caput XI continues)

[continuation of Problem X:] —tical describers of its periphery by their motion, and by the point S will be the point of the elliptical periphery in which the Sun is found, and by the angle DGP drawn it constitutes the true anomaly. Likewise operate, given any other angle of the mean true anomaly to F, and you will have the remaining points by which the elliptical periphery is to be described.

Problem XI

Problem XI. *To represent the inequalities of the Sun's motion, both in the prior and posterior semicircles of anomaly, and likewise in the superior and inferior [semicircles], by their extremes, whether in an ellipse or in a circle.*

[11] In the figure written below, from the Earth's center T, with a very great interval, describe the ecliptic A6, P14, whose [line] AP is the line of apsides, and on it C the center of the ellipse, and the foci T and F. Now since the Sun, around F, describes equal angles by its mean motion, describe from F, with an interval greater than CE, the circle HIKL, whose periphery is divided into 12 equal arcs by the points H, M, N, I, O, Q, 3, K, R, S, L, V, X, and through these are led, from F to the ecliptic, the lines of the mean motions FM2, FN4, FI6, FO8, FQ10, FKP, FR11, FS13, FL15, FV17, FX19; and from the Center T, through the points of the ellipse, or the circles in which the lines of the mean motions cut its circumference — which are E, a, 2, 3, 5, 1, D, 5, 7, 9, 11, 24, 14 — lead the lines of the true motions all the way to the ecliptic, namely Ta1, T83, T75, T67, T59, TDP, T512, T1414, T816, T818, T1420, TEA.

[Margin: 1. Property.] Once these are done, you will see that the Sun's true motion is slower around the apogee A, and quicker around the perigee P; and that it is continuously accelerated, in the prior semicircle of anomaly, from apogee to perigee, and the arc of true motion A1 is smaller than the arc 1,3, and this smaller than the arc 3,5, and this smaller than the arc 5,7, and this smaller than the arc 7,9, and this smaller than the arc 9, P. In the posterior semicircle, however, you will see [the true motion] retarded continuously from perigee to apogee. For the arc P12, 14 is smaller than the arc 12,14; and 14,16 is smaller than 16,18; and 16,18 smaller than 18,20; and 18,20 smaller than 20, A; and, comparing the true motion with the mean made in equal time, you will see, in the ellipse, or the circle EBDG, the arcs that the Sun strikes off continuously greater from apogee toward perigee, of which kind are the arcs Ea, a8, 83, 34, 45, 5D, from perigee toward apogee continuously smaller, such as are D5, 75, 89, 9h, h45, 45E.

Diagram. A large circular diagram — a rose-like or "compass-rose" figure built around the Earth's center T. From T radiate twelve lines of the true motions out to the ecliptic, and from the focus F radiate the twelve lines of the mean motions, dividing the inner circle HIKL into twelve equal arcs. The ecliptic is numbered 1–20 around its circumference (with the number-labels 1, 20, 10 at the top near A; 16, 17 upper right; 15, 14 right; 13, 12, 11 lower right; 10, 9 bottom near P; 8 lower left; 7, 6 left; 4 upper left). The line of apsides runs vertically from A (apogee, top) through the center to P (perigee, bottom).

- A (top): apogee
- P (bottom): perigee
- T (center): Earth's center
- F (interior, below center): focus F / center of mean motions
- C (interior): center of the ellipse
- E (interior, upper): point E on the ellipse/circle EBDG
- B (interior, left of center): point B
- D (interior, below center): point D
- G (interior, right of center): point G
- H, M, N, I, O, Q, K, R, S, L, V, X (around inner circle HIKL): the twelve division points of the mean-motion circle
- Numbered points 1–20: the points where the motion-lines meet the ecliptic
- 6 (left edge): ecliptic point 6
- 7 (left edge, below 6): ecliptic point 7
- 15 (right edge): ecliptic point 15
- 14 (right edge, below 15): ecliptic point 14

Note: the figure is dense with small peripheral letter- and number-labels; several inner labels (a, 3, 5, 9, h, and the bracketed-number points) are difficult to resolve individually. Marked as a

[Margin: 2. Property.] [12] Now comparing the true motion with the mean made in equal time, taken singly, and without relation to the apogee: in the superior semicircle the mean motion is greater than the true, namely in the semicircle YAZ. In the inferior, YPZ, the mean motion is smaller than the true. For 1A is smaller than 2A, and 1,3 smaller than 2,4, and 3,5 smaller than 4,7, and toward the right 4,5 smaller than A10, and A19, and 20,18 smaller than 19,16, and 18,16 smaller than 17,15; on the contrary, toward the left 7,9 smaller than 8P, and 9P smaller than 10P, and the mean 10P greater than P12, and likewise the true 12,14 smaller than the mean 13,13, etc.

[Margin: 2. Property.] [continued] Comparing now the true motion with the mean, not singly but always from the apogee: in the prior semicircle of anomaly the true motion is greater than the mean, as has been said; and even in the inferior, because the arc itself A9 is greater than the arc A10, the greater true motion A9.

[Margin: circulo priori] On the contrary, in the posterior semicircle the true is greater than the mean, if it be computed by the equal succession of the signs from

the apogee; thus the greater is the arc of true motion AP12, than the mean AP11, and the true AP12, than the mean AP12, etc.

[Margin: 4. Property.] Now since the passage from the slowest motion around the apogee to the swiftest around the perigee is not made except through a middling [motion], and the passage from the slowest to the swiftest through a middling motion; and so it [is], the mean coinciding with the true in the extremes D, B, and G, this equality of the mean motion with the true happens in those extremes in which the Sun's mean distance from the Earth is equally [reached], and the Maximum...

(Page 69, folio 37 — Caput XI conclusion and Caput XII)

[12, continued from foot of p. 68:] The prosthaphaeresis [προσθαφαίρεσις — Greek: prosthaphairesis, "the equation"] in the ellipse, for in a circle whose eccentricity is not bisected, the Maximum Equation occurs at the extremes of the line drawn orthogonally through the Center of the circle; whereas in a circle whose eccentricity is bisected, the Maximum Equation occurs at the extremes of the line drawn orthogonally through the Center of the Earth, and the Sun's mean distance in both circles. The hypothetical circle happens to have, at the points between the said right lines drawn orthogonally, one [drawn] from the Center of the circle, the other from the Center of the Earth. The amount by which the Sun's ellipse differs from the circle, that is, by how much the Maximum Equation in the circle exceeds the Maximum Equation in the ellipse, is given by what has been said above.

	<i>Maximum Equation</i>

In the Ellipse	I	59	38
In the Circle with eccentricity not bisected	I	59	40
In the Circle with bisected eccentricity	I	59	40 1/3

CAPUT XII

Observations Selected of the Sun's Apparent Diameter, and concerning a remarkable Fallacy into which otherwise distinguished Astronomers have fallen, very recently detected.

[1] By what means the Sun's apparent diameter is observable, I have already taught in Lib. 3 of the *Almagestum Novum* [Almagestum Novum], Cap. 10, and in its Scholia, and after Lib. 7, in the Appendix to that same Cap. 10, where I supposed everything that is to be re-gathered by the reader from this place. From there it will be established by what reason we are by no means compelled to call up the observations of others related there — indeed, even some of our own older ones — and to prefer to these those more recent ones, which were carried out in the Great Gnomon of Bologna, in the Church of San Petronio, by taking the apparent meridian distances of the upper and lower limbs of the Sun from the vertex. For, with the smaller subtracted from the greater — that is, the distance of the upper limb from the distance of the lower limb — the apparent diameter of the Sun is at once obtained, and indeed with such subtlety as the great size of the Foramen [aperture] permits, set up at a plane to receive the elliptical image of the Sun. The height of this Gnomon is $95 \frac{5}{12}$ Roman feet, on the perpendicular; the distance of the aperture from the center of the Solstitial Ellipse, $100 \frac{2}{3}$ feet, and from the center of the Equinoctial Ellipse, 133 feet nearly, and from the center of the Brumal [winter-solstice] Ellipse, $264 \frac{3}{4}$ feet. From which it follows that there is error in nothing, or in very few seconds, provided the diameter is observed exactly on serene meridian days. A specimen of several observations of the Sun's diameter I exhibit in Cap. 8, from num. 8 in the margin, 159, up to 201, from which, rightly considered, the subscribed Solar Diameters are deduced. Let this be that which D. Cassini [Cassini] determined a little otherwise, the same ones, in the prior book of his observations.

[Margin: Eccentricity of the Sun Bisected.] [2] Hence we have learned how much the eccentricity (which the difference of the true and mean anomaly of the Sun infers, that is, the distance of the center of the Earth from the center of the Sun's mean motions, the eccentricity being bisected) brings in; for there is to be employed only the half of it, on account of the distance of the center of the Sun's Orbit from the center of the Earth, and accordingly the center of the Sun's equal motions is not the center of the Sun's Orbit, but the point on the line of apsides, so far distant from that same center of the Orbit toward the Apogee as the Earth's center is distant from that same center of the Orbit toward the Perigee. Therefore it is more [fitting] that the Sun's Orbit be an ellipse than a circle, since the ellipse has, in its larger diameter, two points equally distant from the center of the ellipse, and remarkable, and which gather the reflected rays from the periphery,

and concur [there]. For since at Cap. 10 we apprehended the whole eccentricity, that is, the distance of the center of the Sun's equal motions from the center of the Earth, to be 3480 parts, of which the semidiameter of the Sun's Orbit is 100000; and in the mean distance of the Sun from the Earth the apparent Diameter of the Sun is 31'32": if the center of the Sun's Orbit is distant from the center of the Earth by only half of the said eccentricity, that is by 1740 parts, of which the semidiameter of the Sun's Orbit is 100000, and the mean distance of the Sun from the Earth is 100000, and in the mean distance of the Sun from the Earth the apparent semidiameter is 15'46": the semidiameter accordingly will be of such parts $92 \frac{1}{3}$; and in the maximum distance, of 101740 parts. The Diameter, apparent, comes out 31'0"; and in the minimum distance, of 98260 parts, it comes out 32'4"; than which we find nothing greater, or rather smaller, in the said Gnomon, as we said at Cap. 9 num. 3.

[Margin: 3.] [3] From the many observations made after the two prior tomes of the *Almagestum Novum* were published, we select a few in which, with most exquisite diligence, we observed together with P. Grimaldo [Grimaldi]. The first was in the year 1654, on June 21, when, through an aperture of 32 small particles [parts] in a prepared tablet, with the plane parallel to the plane of the aperture, except in the very obscure base of the cone of the Sun's species, of 174 parts; but with the diameter of the aperture subtracted, there remain of the base of light, corrected, 142 parts, and the half of it 71; the distance, however, of the tablet from the aperture being of such parts 15700: therefore the semidiameter of the Sun near the Apogee is 15'33", and the diameter 31'6"; or, as VBF, of 15700 parts, is to the whole sine 100000, so AB, 71, is to the Tangent $452 \frac{3}{4}$, the angle AFB, 15'33", that is the Residual Logarithm of the distance FB, of 1700 parts, which is in Vlacq [Vlacq] 58041003; the Logarithm of the side AB, of 71 parts, which is 18512583, added; makes the Tangent-logarithm 76553586, the angle AFB, 15'33". Therefore toward the end of June, the Sun being at Apogee, it ought to have been somewhat less.

Diagram. A small geometric figure illustrating the gnomon-aperture triangle. The point F (the aperture) is at the left; from F two right lines diverge to the right toward A (upper) and C (lower), and a short vertical segment AC (with B between them) closes the figure at the right, representing the illuminated solar image AB on the tablet.

- F (left): the aperture
- A (upper right): top of the solar image
- B (right, middle): point B on segment AC

- C (lower right): bottom of the solar image

The second [observation] was in the same year, on December 17, when an aperture likewise of 32 [parts] perforated, the aperture being received in the tablet as located above, the base of light of the cone of the Sun being of 440 parts, at a distance of $36 \frac{2}{3}$ feet, that is of 43700 parts; with the diameter of the aperture taken away therefore, there remains the corrected base of 408 parts, and the half of AB 204, whose Logarithm is 23096302, and the distance BF of 43700 parts; the Residual Logarithm is 53595186; the sum of these is the Tangent-logarithm 76691488, the angle AFB, $16'3''$; wherefore the apparent diameter of the Sun was $32'6''$.

The third was in the year 1656, on January 5, when the base of light of the Sun excepted [received] through the aperture of 74 small parts was of 298 parts; but with the diameter of the aperture detracted, of 224 parts, and the half-base AB, 112, whose Logarithm is 20492180, and the distance BF was of 24000 parts, whose Residual Logarithm is 56197888; which, with the said Logarithm, makes...

yields 76690068. The log-tangent of the angle AFB is therefore $16'4''$, so that the Sun's apparent diameter was $32'8''$ — close to perigee, just as it was close to apogee at $31'0''$, almost exactly as found earlier by the San Petronio gnomon. These observations are most faithful and most exact. So that no one need wonder if I prefer these diameters to all the others, let me — without in any way disparaging the opinions of others — review them, selectively, for the reader's instruction and not as conclusions he must adopt.

Diagram. A geometric construction illustrating the gnomon-aperture method for measuring the Sun's apparent diameter. At the left is a circle representing the Sun, with points G (upper) and D (lower) on its edge. Rays from these points cross through a central region — the aperture region marked with points A, C, B and a small letter L near the center — and diverge to the right onto a vertical tablet at the right edge, where the solar image is cast between the upper points E, F and the lower points K, I, H. The crossing rays form the characteristic figure of light passing through a small aperture and inverting to form an image.

- G (left, on solar disc, upper): point on the Sun's edge
- D (left, on solar disc, lower): point on the Sun's edge
- A (center, upper): aperture-related point
- C (center): center of the aperture
- B (center, lower): aperture-related point
- L (center): point on the tablet's perpendicular (image-side)

- E, F (right, upper): upper edge of the cast solar image on the tablet
- K (right, middle): point on the tablet
- I, H (right, lower): lower edge of the cast solar image

The rays DAE and GBH, at the outer point L, where the rays drawn through the center of the aperture, at point C, intersect — let a perpendicular LCK be dropped through the point of intersection to the tablet EH, bisecting it. A triangle LKE will be formed, right-angled at K, in which the dimension of the semidiameter of the solar image-cone EK is given. From this the radius KL, or its equal EL, would be given, which doubled would give the angle ELH — that is, DLG, the measure of the Sun's apparent diameter at L; but this is given by neither of these two methods. One must therefore have recourse to the angle FCI, the measure of the apparent diameter at F. For if the distance CK of the aperture from the tablet is known, and the other side FK — if it differs from the half-base by an insensible amount — is taken as equal to the half-base AC, since the parallels CF, EF, and AE, and likewise CF, are equal because the rays DE, GF are parallel on account of the Sun's immense distance, as we showed in Book III of the *Almagestum Novum*, Chapter 5. And so, since the great distance of the Sun makes its image indivisible, so that even apart from the subtraction of the aperture itself the intersection is had at C, it will be clear from what must be said below against this use of the apertures.

[Margin: An foraminis Diameter detrahenda sit Diametro Basis lucidæ Solaris speciei per illud intromissæ?] [Whether the diameter of the aperture should be subtracted from the diameter of the bright base of the Sun's image admitted through it?]

§5. I answer, wholly in the affirmative, with [Kepler] in his *Astronomia Optica* [*Ad Vitellionem Paralipomena*], Chapter 11. This will readily be evident to anyone who considers the figure of the Bologna gnomon set out in Chapter 2, numbers 11 and 12, in which, in order to have the true distance from the upper vertex and from the lower edge of the Sun tangent to DH, one must add the portion HO to the ray of the upper rim IH, equal to the semidiameter of the aperture AC; and the portion HL must be subtracted from the ray of the lower rim IL, tangent to DL. And the breadth of the bright image of the Sun HL is to be diminished by the semidiameter of the aperture BC, so that the image of the Sun's bright base HI may be had as OK, terminated by the rays ICO and ICK, on account of the causes adduced there. We shall demonstrate the same in the following diagram: let the magnitude of the base AB, and its center C, and from the Sun's farther edge D let a ray fall through A onto the tablet at point E; and from the nearer edge C let a ray

be drawn through B to F. I suppose, then, the tablet EH to be parallel to the diameter AB of the aperture. But at the farther edge G, two rays propagate, one through B to H, the other through C to I; for they will intersect...

divisible, and therefore that bright zone must be subtracted, and for its part the eclipsed portion measured as IP; and then let it be that 12, the notable diameter of the Sun, is to its semidiameter in scruples, as GF is to another quantity, which will yield the true quantity of the eclipsed part in scruples.

§7. Against this precept of Fathers Antonius Labbé [Antoine Labbé] and Honoratus Faber [Honoré Fabri] — for it seems not to deal with the investigation of the Sun's diameter, under which heading the angle is here considered — they indeed grant that the bright base of the diameter is to be diminished by the diameter of the aperture, but they say that this is done only proportionally; that the semidiameter of the Sun stands to the part of the shadow induced by the lunar body in the ratio NI, since it in no way conveys the notion of the quantity NI as distinct from the quantity BE. And they attempt to prove this by nothing other than by what would follow if it were absurd — namely, if a tablet receiving the type of an eclipse were advanced ever farther forward — for thus they say the same eclipse would appear at one time greater, and greater the farther off, and indeterminate. For at the same time two observations of the same eclipse would be made, set, say, at parts 12, of which the semidiameter is 12 parts and the eclipsed portion EG 24 parts, that is, in one observation of the semidiameter AE, and let it be the sixth part of the semidiameter AE. In this case, if PG of 12 parts be added, PE will be 36 parts, with the 12 subtracted; but truly, IE of 12 parts is left from AE; and IP, in turn 24. By this emendation, therefore, the eclipse is reduced to $\frac{4}{12}$ of the corrected semidiameter AI. But with the other observation retained at an equal aperture, with the tablet so removed from the aperture that AE is 432 parts, and EG larger, EG being 432, that is, 72; with EI remaining 12 parts, EP becomes 84, and IP 72; with 432 subtracted, the line EI of 12 remains, and AI of 420 parts. Therefore, by this emendation the eclipse is reduced to $\frac{72}{420}$ of the corrected semidiameter of the Sun. Reducing both to a common denominator of fractions, the eclipsed part will be $\frac{72}{420}$ of the semidiameter of the Sun in the prior observation; in the second, $\frac{12}{72}$ of the same semidiameter.

§8. Yet I answer that the said Fathers are mistaken, supposing that in these two observations there is the same proportion between AE and EG, when in fact in those it is assumed, as at 6 to 1, that it ought to be the same in both, the proportion between the whole corrected diameter NI and the shadow IP being equal to the observed shadow EG. But among the false, or non-corrected, solar

diameters and shadows, there is not the same proportion, even though with both corrected the same proportion holds; that proportion holds when the same quantities of the aperture are subtracted from both. So that, given two lines on this side, and two on that side in the ratio of scruples, if a larger line be augmented by a quantity equal to two, say a palm-breadth, it is certain that the same geometric proportion between the two will not persist, and that those two lines are not equal arithmetically — as P. [Grimaldi] also confirmed sharply with other additions. But more on this dispute is in the Appendix to this chapter, deferred to the end of this Book I.

[Margin: Contra Diametrum Solis Assertam à PP. Scheinero, Cyssato, & Alijs.]
[Against the diameter of the Sun asserted by Fathers Scheiner, Cysat, and others.]

§9. Scheiner, in Part 1 of the *Rosa Ursina*, Book 4, Chapter 3, says: It is established that the apparent diameter of the Sun, when it presents itself in ☉, is the minimum of 46 minutes. He assumes, and takes as his proposed value there, the Tyconic diameter of 32'. And in Chapter 4 he proposes the manner of observing it by means of an aperture, as though the Sun's image, received in a *camera obscura*, were composed of parts, of which let the notation of the distance of the received image from the aperture be such as it was for him in 10 parts, but divided into 10000 parts. And the aperture is *as small as it can physically be*; he adds below: *by the minimum aperture, which most sharply escapes the sight*. Some, however, made an aperture by a larger aperture, as he confesses; for if it stand at 10000 parts of distance of the aperture and the sine of the semidiameter of the Sun's bright base be another, the sine of the visual semidiameter of the Sun, doubled, will yield the whole diameter. He then subjoins certain observations made at Rome by many and skilled men, namely P. [Christophorus] Gruembergerus [Christoph Grienberger], P. Gregorio [Gregory of] St. Vincent [Grégoire de Saint-Vincent], P. Pietro Antonio Rauizza, mentioned by me once before in Theology, a most learned man and of remarkable probity; P. [Nicolaus] Zucchio [Niccolò Zucchi], likewise most learned, a man of the deepest religion, to whom I can scarcely say how much I owe.

Parsing notes: The table runs in two side-by-side blocks (1625–1626 on the left, 1626–1627 on the right). Columns: Year ("Anno"), By/aperture ("Per Foram."), image diameter in parts ("Speciei Diamet., Partiü"), Sun's diameter in minutes ("Solis Diam., Minut."). Several right-block date cells repeat "Dec. 23" — these appear to be repeated/abbreviated date markers in the source. The qualifier words "maius/priore/maximum" appear in the "Per" column in place of "minimum" for some rows. Two minute-values flagged: row "100 → 38" (the 100-part image elsewhere maps to ~34–35 min, see numerical impossibles) and "136 → 37" under Dec. 25 (breaks the descending progression where 136 should map to ~47).

Scheiner adds that this variation, found on the same day and at the same aperture, arose from this: that he then took the image as less bright at its extreme edges — about which no expert doubts, and about which it is doubtful whether the image be deemed not the true one — and yet he reports the diameter to himself as having reached 38' at minimum on Nov. 28, and 36' on June 21; whence he concludes that it is in truth still larger.

§10. A follower of these men, another from our Society, wrote to me that in the year 1652 at Oeniponte [Innsbruck], as also in the year 1637, observed there on the 6th and 20th of September, with a gnomon of 28 feet and a second aperture of 10", the Sun's diameter was 37'30", or 37'40", but more often 38" [recte: 38']. And when, at a larger aperture, the use was of minutes 2', he found the Sun's diameter

at minimum 32'50" [?]. Whence one errs and must hold for true that, with the aperture, its further magnitude is to be diminished, since something rather is to be added — as both that most learned man P. [Michael] Staudacher [Staudacher] judged, and Scheiner. Hence we proceed to more truths, that an aperture too small admits too much splendor, which obstructs...

obstructs and obliterates the true edges, and the integrity of the image, to the exact measurement of the Sun's diameter. Now if 28 feet be resolved into inches, they become 336; and if each inch be divided into 100 parts, the whole length of the channel will be 33600 such particular parts. And if the breadth of the aperture in such a distance were 2" of minutes — then, for the solution of right triangles, the aperture's diameter would be $19\frac{2}{3}$ [?], or 20 such parts of the inch. Again, if the same aperture were used at such a distance, I gathered the semidiameter of the Sun at such distance to be 16'25", or the diameter 32'50"; and so the semidiameter of the solar image was 1200 parts, that is, parts 30'42" owed [to it] — less than is due, because for so small an aperture and operation, no smaller [?]; which we have tried also more than once, and recently both P. [Grimaldi] and I.

§11. For in this year 1658, on August 11, in the Conclave of the Assumption of the B. Virgin, in our College darkened for the purpose, through the smallest aperture admitted, the image of the Sun on paper differed from the aperture by parts 13.5925 [?], of which one inch was 100 Roman parts. The diameter of the Sun, comprehending also the impure light, was at the edges 1328 parts. Therefore EK, as in the figure of number 1, was 664 [?]. But the semidiameter of the aperture AC was 2 such parts. There remains FK, 662; whence the angle FCK is 18'6"; and the apparent diameter of the Sun is 36'12". Again, in the same Month, on the 18th, the same aperture being retained, but at a distance of parts 12821 (so demanding the chosen altitude for the observation), the bright base of the Sun EH was parts 1356, and EK 678; thus the angle is at 0 [?] 18'15"; whence, had the image of the base been comprehended completely, the bright base, selected and purest, was EH 1176, EK 588; subtract 2, there remains FK 586; whence the semidiameter is 15'40", and the diameter 31'20". And by the Bologna gnomon, found at other times, it was discovered to be repeated, parts 110; the impure-light zone which was the breadth differed by parts; with the right semidiameter of the Sun, the consensus is truly astonishing.

§12. But because Scheiner used a distance of the aperture from the tablet of 10 Roman feet, I propose a fifth of that distance: the line written below, of length, which continued five times will make a tenth part of the said distance.

But since we do not apprehend the image to be of parts 240, of which one Roman foot is 100, then 240 multiplied by 5 makes 1200, multiplied again by 1200, makes 120 inches, that is 10 feet. For, as I say, the use was at a distance of 12 feet; and so also, today the use is in our Observatory at the smallest aperture, the bright base of the solar image, computed from the impure-light margins, of what magnitude one inch is at 100 such parts.

Whence the semidiameter of the Sun proceeds at 20'5", and the diameter 40'10"; but with the impure light of the margins amputated, the base is 110, and half of it 55; whence the semidiameter of the Sun is 15'41", and the diameter 31'22".

§13. With these performed, I think it better to use a larger aperture — pure and almost indivisible — than a smaller one in computing its diameter, for the reason explained below; and trigonometry persuades it; but the distance ought to be large, and feet 10 if it can be, as in the San Petronio gnomon of 100 feet and more, since then the bright image of the Sun is acquired very ample, and it itself, on account of the magnitude of the aperture, intense enough for the whole [base] to be discerned almost without the penumbra of the impure margins; and if anything peccant be in the pure light, it is insensible and contemptible, on account of the great brightness of the image, and the distance of the aperture. Against this — should you use a small aperture, and the distance almost indivisible — that you not have a larger one at 10 feet; it proceeds in the tablet of the aperture orthogonally...

Diagram. A circular figure illustrating the impure-light margin of the solar image cast on a tablet. The outer circle is the full image including the impure outer ring; an inner concentric region marks the pure bright base. Letters M and N appear near the top, A and C in the central/left interior, and B at the lower right, D at the lower middle — marking the diameters of the pure base (CD) versus the impure margin (AB).

- M, N (top): points on the impure outer margin
- A (center-left): point on a diameter line
- C (center): center / point on the pure base
- D (lower middle): point on the pure base edge
- B (lower right): point on the impure outer margin

the oppositely-cast image will be nearly as in the following diagram, of which the amplitude with the impure light will be AB, but of the pure light CD, though indeed more separable, and slippery for the fallacies, and if there be anything in this measure peccant, it commits a great error in the diameter of the Sun, and a

still larger one, unless the breadth of the aperture be removed — which, at the very smallest aperture, cannot be determined.

§14. But the cause of the impure places within AC and DB, of which Scheiner himself in Part 2 of the *Rosa Ursina*, Chapter 4, says: *The periphery of this solar image is not cleanly cut, but softly torn and rough*, so that the consortium of the edges is hardly to be discerned — especially if a strenuous effort of the eyes be employed, and a coloring is required when it is to be measured by a compass; the cause, I say, of this quasi-penumbra has hitherto been disclosed by no one, though I know it has been disclosed; but P. [Grimaldi], after several years of observations of light, affirms a most luminous treatment, deprecating, [namely] that the mode of propagation of light is not by *Direct* [rays], not by *Reflected*, not by *Refracted* rays, but by *Diffacted*, or diffused into several languid rays — by which fact, in many of the said Father's experiments, which otherwise cannot be saved [explained]. This, then, is the way: that the Sun's rays striking on the edges of the aperture are split into weaker rays; and the tablet, or the paper set opposite the aperture, with a malign and torn light, colored with a subreddish color, or somewhat with a ferruginous [rusty] color — so much the more so the nearer it is to the aperture, and the less near; and so much the weaker as it is more remote from the tablet; the more remote, so much weaker do they escape, and so remiss [faint], that at a great distance they do not affect the senses on the tablet. Which, if the aperture be too ample, so much splendor enters that by its own reflection from the tablet's floor it impedes, and overcomes the propagation of the rays diffused from the aperture's margin.

[Margin: Argumenta contra Solarem Scheineri Diametrum.] [*Arguments against Scheiner's solar diameter.*]

§15. For the rest, whatever the said cause may be, it has very recently been deliberated from the recondite Philosophy: to us it is established with certainty that Scheiner's mode of observing the diameter of the Sun by the aperture is fallacious. *Firstly*, indeed, the very inconstancy alone, which is evident in Scheiner's experiments, is an argument of fallacy. *Secondly*, we are certain that the diameter of the Moon, taken at its distance from the Fixed Stars of known position, is in *syzygy* [conjunction or opposition] between the distances not exceeding 35' of minute — indeed, it does not reach 34'; and yet, as we reported in the observations of Book 3, the Moon's distance from the Sun is even greater than its [the Moon's] own [diameter], when it was obstructed, near apogee at 40', as Scheiner has it. *Thirdly*, with the triangle applied, of which in the *Almagestum Novum* Book 5, Chapter 15; but as I subtly assert from constants, both in the

Meridian plane erected, and with the eye fixed within a wooden tube, and protected by colored glass, the observation of the Sun's disc often passes through the plane of the Meridian; meanwhile I number, by clear voice, the oscillations perpendicular to the inches very nearly 9 of a Roman foot, of which in Book 2 of the *Almagestum Novum*, Chapter 20, problem 5, and one exhibiting a single oscillation of time 3", by tertiary thirds; and as I advise, in the Equinoxes from the first optical contact at the western margins of the Sun's disc, and so to the last contact at the eastern margins — never have I numbered more oscillations than 264, nor 266; never fewer than 240. Therefore the diameter of the Sun is then never greater than 33'15", nor less than 30' — which is evident even from each experiment. And this carries practice back, so that, although it might not be possible to determine the Sun's diameter precisely, yet, because in those contacts the judgment of the observation hesitates about two or three certain oscillations, hence we are certain that the diameter of the Sun in the Equinoxes cannot be more than 34', nor less than 30', as both [Michael] Staudacher [Staudacher] contended, lest 40' or 50' &c. as Scheiner [held]. Hitherto for more truths, and that it may be established for the reader how, in accordance with cause, we have preferred the observations of the Sun's diameter made at the San Petronio gnomon...

made through the aperture and others somewhat broader, and we have determined it at 31' 0" at apogee, at 31' 32" at mean distance, and at 32' 4" at perigee.

CAPVT XIII.

On the Parallax and Distance of the Sun from the Earth.

1. That the parallax of the Sun is imperceptible — and therefore that no suspicion of it ever arose — Hipparchus [Hipparchus] long ago held, even though Ptolemy [Ptolemy] (as he reports here, *Almagest* V, ch. 11) believed it could be gathered, and indeed fairly accurately, from lunar eclipses, as Ptolemy afterwards taught (*Almagest* V, ch. 11, Problem 2). There he shows that this method does not yield that exactness which recent astronomy demands, since eclipses can be deceptive — as is evident from the clear refutation, *Almagest* V, ch. 11, Problem 6 — whether one takes the Sun's mean distance to be 1168 semidiameters of the Earth, as Ptolemy does, with a horizontal parallax of 2' 57", or the mean distance to be 1465 semidiameters with a horizontal parallax of 14", as Vlacq [Vlacq] would have it, or some figure intermediate between these. Yet by the same book (ch. 11, Problem 6) he demonstrates that if a small angle be subtracted from the

Earth's apparent semidiameter, the Sun's horizontal parallax remains close to the truth. But since the angle of the Earth's shadow cannot be known with exactness, and since the beginning of the Sun's distance is reckoned from the center of the Earth, nonetheless nearly all astronomers down to Tycho [Tycho Brahe] inclusive investigated the Sun's distance and parallax by eclipses, or assumed it as found by their predecessors — so that Vlacq, in his very learned Letter to me, rightly said: "*the parallaxes of the Sun are assumed rather than held as known.*"

[Margin: The error of astronomers in reckoning the Sun's parallax.]

2. It happens that nearly all of them fall into some self-contradiction, as Lansbergius [Philip van Lansberge] demonstrated in his *Uranometria*, and as we ourselves did, *Almagest* (New), Book IV, no. 16. For the Sun's parallax and distance must cohere with the apparent diameter of the Sun, its increment or decrement, and likewise be consistent with the anomaly and with the angle, that is, with the diameter of the Earth's shadow, and this with the apparent diameter of the Moon, and so forth.

After Tycho, Kepler [Kepler] acknowledged that the Sun's parallax could not be as great as Tycho assumed; and so he pronounced (in the foundation of his *Ephemerides*, no. 7, and p. 5, and in the *Commentaries on Mars*). For he saw that Mars at its perigee, in epicycle, approaches the Earth more nearly than the Sun does — and yet his own parallaxes, drawn from those same Tychonic observations, are much smaller in that very approach to the Earth than the Sun's, and the solar eclipses, with the Moon's consent, fit a smaller rather than a greater parallax; whence he made the Sun's horizontal parallax smaller than the Tychonic figure — about one minute only — which he keeps in the preface to the *Ephemerides* of the year 1619, declaring it among the harmonic intervals, and in the *Rudolphine Tables*.

[Margin: The inconstancy of Kepler.]

3. Badly does he reckon, in the foundation of the *Ephemerides*, no. 7, and in the *Commentaries on Mars*, when he sets the distance of the Sun's apogee at 1800 terrestrial semidiameters; for hence by trigonometry there follows a horizontal parallax of 1' 55", and conversely, if the horizontal parallax is 1', the Sun's distance of 3438 terrestrial semidiameters follows, as he supposes in several places (*Almagest* (New), ch. 7, Scholium 2). Langrenus [Langrenus] too sets the Sun's distance at terrestrial semidiameters of about 3438. But Vuendelinus [Govaert Wendelen], in the little work *On the Obliquity of the Sun*, published in the year 1626, assumes a horizontal solar parallax of 1' less one minute — as he

says in a Letter to me of the year 1647, where he chose 15" for the second term — at apogee 4905 semidiameters, at mean distance 4656, at perigee 4407, by dichotomies and other foundations which he reports (*Almagest* (New), ch. 7, no. 12). For he sufficiently refutes Rheitenus's [Wendelin/Rheita] opinion there, in Scholium 3.

4. Yet there is no lack of other ways of investigating the Sun's parallax, either by observations made at the solstices or at the equinox, which he relates (*Almagest* (New), Book III, ch. 7, no. 1), but also others. Of these let the **First** be that of Father Georgius Riccioli [Riccioli] of our Society, who already from the year 1653 communicated to me, in writing, his Letter on this matter. In the attached diagram, ABC is the Meridian, in which the Vertex B is the world's Pole P, and BR a quadrant of the Vertical circle, in which let the Sun be at point S, so that the Sun's distance from the vertex be BS; let the complement of that distance, given by observation, that is, PS, be the Sun's declination. Now let the oscillations [oscillationes] be numbered, perpendicularly, from the moment the Sun's distance from the vertex is taken, to the moment when the Sun reaches the Meridian; and from elsewhere let it be known how many such oscillations correspond to a whole revolution of the equator — that is, to a daily revolution of the Sun — so that, by the rule given here, if the daily revolution of the Sun gives oscillations of 59' 8", [the number of] minutes that the oscillations yield, numbered by observation at the Meridian, are subtracted from the said numeration, [and] the angle BPS will be given, together with the complement of the Pole's altitude BP, and with the complement of the declination PS,

[Margin: The first method.]

PS, you will obtain the Sun's true distance from the vertex, whose difference from the observed [distance] will give the parallax sought. But if the Sun is more than 70 degrees distant from the vertex, [the method] is liable to refractions, which ought to be discerned without prior knowledge of the parallax, and even so small an error in numbering the time, or in the position of the meridian line, or in the altitude of the Sun and of the Pole, can introduce a difference of two, that is, of two or three minutes.

5. A **second** method is indicated by D. Io. Dominico Cassino [Giovanni Domenico Cassini], who in a specimen of observations (p. 3) judges the Sun's parallax to be imperceptible, citing among other arguments an observation of the year 1653, on the 4th of April, at the hour of midday $8\frac{1}{3}$, when the Sun was distant from the preceding chapter's [reference] $8^{\circ}\frac{1}{3}$ in Gemini, and the Moon, near first quarter, was approaching the latitude-circle of the said star — for in the middle there

appeared a great latitude — and the approach of the Moon to the latitude-circle determined, from the section of the lunar latitude-circles up to the star, the time of dichotomy [dichotomiae]; nor could a deviation as small as 7' be detected, between the Sun's intervals and the star, where there ought to be a smaller deviation in the quadrature of the Sun and the star. He adds that much is to be ascribed to this observation, since no lunar parallax is involved in the practice, and the Moon's place appears not in the astronomical tables, but by comparison with the fixed star itself; and the Sun's true place is constituted by our [tables], and the place of the said fixed star, and we consider the time which intervenes from the said Moon's center in the latitude-circle of Castor up to the quadrature with the Sun, and the effect of the parallaxes optically retarded, by the way (*Almagest* (New) I, p. 731, far from the smallest part of the time, than we predicted between dichotomy and quadrature); whence neither from this observation is the Sun's horizontal parallax shown to be smaller than about 27 seconds, much less imperceptible.

[Margin: The second method.]

6. Afterwards, however, the same Cassini (in the *Ephemerides* of the illustrious March. Cornelio Malvasia [Cornelio Malvasia], fols. 156, 173, and 186) confessed that, from his own Table of astronomical refraction, the Sun's parallax came out to him either null, or at most a few seconds at the Equinox; and from his Hibernial Table of Refraction, a parallax of one single minute. Yet he chooses a horizontal solar parallax at apogee of $18'' \frac{1}{3}$, at mean distance $19'' 36'''$, and at perigee $1' 0'' 48'''$. Why? Because hence there follows the Earth's mean distance of 3460 semidiameters, whose seventeenth thousandth part [?] equals $58 \frac{7}{10}$ semidiameters, for the simple solar eccentricity; which agrees with the mean distance of the Moon from the Earth, so that the center of the Sun's path [?] should be in the lunar orbit's circumference, since the Moon holds at apogee, as often as it is in the line of the Sun's apogee — that is, in Cancer 7 degrees. There is also the radical [?] of the solar quadrature 3460, and thus the medium is proportional between the semidiameter of the Earth and the Sun's distance. But how worthy of admiration this symmetry is, if sufficient foundations for absolutely determining the said parallax — as many as we have obtained by several dichotomies, rightly corrected, and always about double the smaller [?] — or whether this symmetry was equally beautifully excogitated, let the astronomer judge. Meanwhile we shall attempt some other methods, which Father Francisco Maria Grimaldo [Grimaldi] excogitated, that are worthy of being included in the practice [?] of dichotomies, which Cassini will likewise coordinate with his Tables, endowed as he is with that same skill and sagacity.

[Margin: The second method.]

(This page belongs to **Caput XIV**, but the upper-left column continues the geometrical exposition of the figures begun on the recto of folio 42 verso; see below. The body of Caput XIV opens in the right column.)

Imagine at F, by the point R of the Physical Horizon below the point R. Let there be drawn moreover from A, the straight line AGK intercepting the points, through the Sun G, as far as K, by which, if the Earth's opacity did not obstruct it, [it would propagate], so that this very Earth, by the density of the air, refracting the rays, the eye A could see the Sun G directly below the point K, but would see that same [Sun] by the straight line CGL, if the eye were at the center of the Earth, and if neither the Earth's opacity nor the air's density obstructed, and it would illuminate that [point] below the point L.

[Margin: 2nd Case.]

Let it be, **secondly**, that the Sun is in the True Horizon below the point R; let the ray incident at M be feigned to proceed toward N, but in fact refracting toward the eye A through MA; therefore the Sun's image, by the line AMO, appears at O, below the point S, if it be drawn by the straight line intercepting AHP, through which the Sun itself could rather have been seen at H, below the point P, if the said opacity and density did not obstruct; for through the line drawn straight, intercepting CHQ, it would already lie below the point H, below the point Q, by the straight line CHQ.

[Margin: 3rd Case.]

Let it be, **thirdly**, [the Sun] at R, and without sensible refraction, truly placed below Z, and seen below R. Having premised these things, let us proceed to the remaining Definitions.

6. The True Line of the place of a Star is the straight line drawn from the center of the Earth, and of the Universe, through the center of the body of the Star, as far as the supreme Heaven — as in the first case it is CFZ. For from this center the astronomer considers and measures the true places of the Stars in the Heaven, and their true motions.

7. The Seen Line of a place is the straight line, in some eye on the surface of the Earth, or above its surface, by which the Star appears, or appears as if a Star — as in the first case it is AI, in the second AM; for it is by this very imagination of production of the said line seen by refraction, whose extreme is the line AFR, by which the Sun would not see [?] G, but the line AOS, by which the Sun itself

appears at F, below the point R, and the line AOS, by which the Sun, which is at H, appears at O, below the point S.

[Margin: This is the Seen Line, that is, the Refracted [Line].]

8. The Parallaxic Line is the straight line from the eye placed outside the center of the Earth, drawn through the center of the star as far as the supreme Heaven — as in the first case it is ACK, in the second AHP, and in the consequent third APR, the Parallaxic Line, supposing the star at P.

9. The Anaclastic Line [linea anaclastica] is any refracted ray, but most especially that one which refracts to the eye — as in the first case it is AI, in the second AM; for it is by the production of the said line seen by refraction, whose extreme is the line AFR, by which the Sun would [appear at] G, below the point R, and the line AOS, by which the Sun itself appears at F.

10. The True Altitude of a star [altitudo vera] is the Arc of the Vertical circle intercepted above between the line of the true place and the True Horizon — as if the star be placed at P; or indeed in F, or in the third figure the arc HP, the star being placed at P, for if it be intercepted below, the arc is QL, which is the **True Depth** [vera profunditas]. Each, however, is measured by the angle at the center of the Vertical [circle]; and below by the other line of the true place of the star drawn from the center: thus the depth is measured by the angle QCL, and the same in F, the altitude is measured by the angle ZCQ.

[Margin: 1st Case.] [Margin: 2nd Case.] [Margin: 3rd Case.]

11. The Seen Distance [distantia visa] of a star from the Vertex is the Arc of the vertical circle intercepted between the Vertex and the line of the true place, and the angle is measured at the center of the Earth, intercepted by the line of the Vertex and by the line of the true place, just as in the prior case the angle VCL, in the posterior VCQ.

12. The Seen Altitude [altitudo visa], like the Depth, is twofold: one Parallaxic, the other Anaclastic. Now the **Parallaxic Altitude** is the Arc of the Vertical circle from the eye placed outside the center of the Earth, described and intercepted between the Parallaxic line, the Physical Horizon supremely intercepted; and the angle is measured at the center of the eye itself, made between the two said lines, as in the third figure. But if the eye is at center A, let there be described a Quadrant of the Astronomical [circle], or a Hemicycle of the arcs QS, OZ, and through the Dioptra AS, let the line of sight see the star itself at P; then the angle SAO measures the Parallaxic Altitude of the star, which appears smaller than the

true altitude HP, [as] it would appear in the celestial place X, though it be truly below the point T, the supreme Heaven (from the center C of the Earth, described). I have said "supremely intercepted," because if [intercepted] below, that is, below the Physical Horizon, it would be the **Parallactic Depth** [parallactica profunditas], as in the third figure the arc OZ, and its measure is the angle FAH, the star being placed at H, and in the second figure, in the prior case the angle OAK, in the posterior the angle OAP. On the Anaclastic Altitude I shall speak at no. 15.

[Margin: Of the Parallactic Altitude, Distance, and Depth — what?]

13. The **Seen Distance** of a star from the Vertex is likewise twofold: Parallactic and Anaclastic. The **Parallactic Distance** of a star from the Vertex is the complement of the Parallactic Altitude to the Quadrant, or its aggregate added to the Quadrant; and the **Parallactic Depth**, and the measure in each case is the angle made at the center of the eye by the Vertical line, and by the Anaclastic line, of which in the third figure is the angle VAP, the star being placed at P; in VAH, if it be in H; and in the second figure, in the prior case the angle VAK, in the posterior VAP.

14. The **Anaclastic Seen Distance** of a star from the Vertex is the arc of the circle from the center of the eye described, intercepted between the vertical line, and the Ray of the star refracted to that same eye; and its measure is the angle made at the center of the eye by the Vertical line and the Anaclastic line, that is, the Refracted Ray. Such in the prior case is the angle VAR, in the posterior VAS.

15. The **Anaclastic Seen Altitude** of a star is the complement of the Anaclastic Distance to the Quadrant, not exceeding the Quadrant; for if that distance exceed the Quadrant, that excess is the **Anaclastic Depth** [profunditas anaclastica], and its measure is the same. Now the example of Anaclastic Altitude in its own measure is, in the second figure, in the prior case, with the Anaclastic distance VAR, the angle VAR; the Quadrant AS, the Anaclastic Seen Altitude with the Anaclastic distance being null, as appears in the third figure; the Physical Horizon AFR. I shall give an example of Anaclastic Depth below, when there will be discourse of the Ray so refracted, that the Refractive, that is, the deeper [?].

16. The **Astronomical Parallax** [parallaxis astronomica] is the difference between the true place of a star, and the place of the same star, as visible through the Parallactic line. Therefore, if the Parallax be referred to the Altitude, it is called Parallax of Altitude, and it is the difference between the true altitude of the star, and the altitude of its Parallactic [place]; of what kind is it? In the first figure

the difference is between the Angle PCH and the Angle PAF. But if the Parallax be referred to the Distance, the Parallax of Distance, and the Difference between the True Distance, and the Parallaxic Distance, of what kind it is in the same [figures]; in the third figure the difference is between the Angle VCP and the Angle VAP; if, finally, it be referred to the depth, it is called **Parallax of Depth** [parallaxis profunditatis], and it is the difference between the True Depth of the star, and the Parallaxic Depth; of what kind it is in the first figure between the Angle QCK and the Angle RAK; when, however, the star is in the True Horizon, and there is no true depth, the Parallax of Depth is nothing, as in the third figure the angle FAH, and in the posterior case the angle 2. The figure is the angle RAP.

[Margin: Parallax of Altitude, of Distance, and of Depth — what?]

Tables and Diagrams

Solar distance and horizontal parallax table. A three-paired-column table of the Sun's distance (in Earth-semidiameters) and horizontal parallax (in minutes and seconds) at apogee, mean distance, and perigee. Riccioli notes the values are corrected to his new eccentricity, "now bisected" (*nunc bisectam*).

☉	Horiz.	☉	Horiz.	☉	Horiz.
Apogee	Parall. (')	Mean	Parall. (')	Perigee	Parall. (')
Distance	"	Distance	"	Distance	"
Semidia	0 27	Semidia	0 28½	Semidia	0 29
meters of		m. of		m. of	
Earth:		Earth:		Earth:	
7427		7300		7173	

Parsing notes: The three "distance" columns each carry the label "Semidiameter(s) of the Earth" (abbreviated *Semidiam. Terræ*) above the numeric value; the parallax columns are headed *Parall. Horiz.* with sub-columns for minutes (') and seconds ("). The mean-distance parallax reads 28½".

Diagram. A circle (the celestial sphere in meridian section) inscribed with a triangle, illustrating Riccioli's first method for the solar parallax. The center of the circle is marked S (the Sun's place on the vertical circle). Labels around and within:

- B (top of circle): the Vertex, identified in the text with the world's Pole P.
- P (upper right, on circumference near B): the Pole.
- A (left, on circumference): one terminus of the meridian ABC.

- C (lower right, on circumference): the other terminus of the meridian; also the world's Pole opposite.
- R (lower left, on circumference): foot of the vertical-circle quadrant BR.
- S (center): the Sun's position; BS is the Sun's distance from the vertex, PS its declination complement.

Chords/radii are drawn from B and P to S and to the circumference, forming the triangle BPS used in the parallax computation (angle BPS, side BP = colatitude, side PS = declination complement). No labels flagged.

Diagram. A semicircular (hemicycle) refraction diagram for Caput XIV's definitions. A horizontal base line AB rests on the diameter, with a semicircle above it (the celestial hemisphere). Labels:

- V (top of semicircle): the Vertex / Zenith.
- A (left end of base): the eye / left horizon point.
- B (right end of base): right horizon point.
- F (left, interior near base): horizon-related point.
- K (right, on or near circumference): point on the Physical Horizon line.
- O (interior, upper-middle): refraction point.
- G, H (interior, lower-middle, near base): refraction/ground points.
- I, L (interior near base): the word "LVCEM" (LIGHT) is engraved across the base between L and M; "DCE M" labels appear along the base — these are the horizon construction points D, C, E, M.
- The engraved word **LVCEM** ("LIGHT") spans the base line. Construction points along the base read (left to right): A, L, D, C, E, M, B; interior: F, O, G, H, N, K.

Parsing note: this small figure has densely packed lower-middle labels; the cluster G/N/H and the points D/C/E/M along the base are partly obscured. Two labels uncertain.

Diagram. A quadrant-and-base refraction diagram (larger, the second figure of the refraction definitions). A vertical line VTN... descends from the Vertex V at top, with a quarter-arc to the right and a long base line at the bottom. Labels read approximately:

- V (top): Vertex.
- T, S, O (upper interior, descending): points on the vertical and on rays.
- N, D, M, A (left side, descending to base): vertical-line and horizon points.

- F, R (right interior): refraction/horizon points.
- C, B, E, G (along the lower base, left to right): horizon and center points (C = center of Earth).
- P, L, K (lower right, on base and arc): terminal points of rays.
- Q (interior): construction point.

Rays AI, AM, AMO, AHP, CHQ, CGL, AGK described in the text radiate from A (eye) and C (center) through the interior points. Two interior labels in the dense lower-left cluster are uncertain.

Diagram. A small quadrant diagram (inset, right column) for the parallactic/anaclastic altitude definitions. A vertical line from V at top, a quarter-arc, and a short base. Labels:

- V (top): Vertex.
- T, P, X (upper right interior / on arc): the star's true place T, parallactic place P, apparent celestial place X.
- O, S (interior): the eye-center O and the Sun/star point S.
- A (lower left): the eye.
- C (lower middle, base): center of the Earth.
- Z, Q (lower interior): depth/quadrant points.

Rays AS, OS, SAO described in text; angle SAO measures the parallactic altitude. No labels flagged beyond general inset density.

Now, by §32 of the first set of Elements, the external angle is equal to the two internal and opposite angles taken together; and since each of the internal angles taken on either side is equal, the difference between the external angle and the other opposite angle measures the parallax of distance from the vertex. Indeed, since in this case the line itself has come into being—that is, the parallactic line—through the equating of the line of true place with the parallactic line, by this very fact that angle is called the parallax of distance from the vertex. Therefore in the first figure the parallax of distance is the angle AGC; in the second figure it is the angle APC, if the star is at P, or AHC if it is at H. Hence, however much stars at the same distance from the vertex differ among themselves in true altitude, by just so much do they differ in parallactic altitude—true altitude and parallactic depth, that is. For this reason the very same angle, even if not formally, yet at least equivalently, is the parallax of distance from the vertex, and equally is the parallax of altitude or of depth.

§17. The horizontal parallax [Parallaxis Horizontalis], simply so called, is that which belongs to a star situated in the true horizon. Hence it can be neither the parallax of depth nor the parallax of distance from the vertex. Such it is in the second and third figures: the angle AHC, if we may use the terminology of the learned, and which the common run of astronomers call the **horizontal altitude-parallax** [Parallaxis Altitudinis], even though I would call it the parallax in the horizontal circle.

§18. The physico-horizontal parallax [Parallaxis Physicohorizontalis] is that which belongs to a star apparent in the physical horizon, as in the second figure of the earlier case it is the angle FAG—the Sun, that is, being at G—where the refraction is apparent; but it can more properly be called a parallax not of altitude but rather of depth or of distance from the vertex. Yet they can be conjoined, and the horizontal parallax coincides with the physico-horizontal into one, so far as concerns the parallax itself.

§19. The optical parallax of a star [Refractio Sideris Optica] is the angle made at the point of incidence between the refracted ray and the unrefracted ray, or the line of incidence through the point of incidence continued straight, which some call the angle of refraction. Such it is in the second figure: the angle AMN, in the latter case. This I have chosen to call **the optical refraction** [Refractio Opticam], because the optical writers consider it under this name and express it in their tables of refractions in air, in water, in glass, in crystal; for astronomers do not consider it in the same way they do, since they do not attend to the difference of place at the point of refraction—that is, the angle N—but consider the difference of the place of the refracted ray as seen through the line of true place, or the refracted ray as visible through the parallactic line; in either case the certain measure is, and the difference between the place seen through the line of anaclastics, or the parallactic place, whence the places of the stars are reckoned, namely the center of the Earth, and the center of the eye in the place of the observations is constituted. Yet astronomers can consider the optical refraction, that is the astronomical, which differs little from the other; but, lest the properties of one be confounded with those of another (for the properties of one grow confused with another, as happened to Tycho [Tycho Brahe]), I have chosen to call the refraction through the line of true place the astronomical refraction, and have expressed it in tables in larger type, as being more proper to astronomy, and the optical refraction of a star, which is more remote, as being false—so far below as I shall show.

§20. The astronomical refraction [Refractio Astronomica] is simply thus defined: it is the difference of the place of a star seen in the heavens through the line of anaclastics and the line of true place, reckoned to the anaclastic altitude. If it be referred to the anaclastic altitude compared with the true altitude, it is called **the refraction of altitude** [Refractio Altitudinis]; if to the depth, **of depth** [Profunditatis]; if to the distance, **of distance** [Distantiae]. For since refraction adapts the distance to such a case of altitude as is easier for the eyes per the schemata set out below. By this alone we shall henceforth make use. Therefore it [the astronomical refraction] is simple. The difference between the true place of a star at its distance from the vertex and the seen place by the refracted ray is, in the former case the difference between the angles VCL and VAR, in the latter the difference between the angles VCQ and VAS. But when the stars are external to the horizon,

beyond the horizon, [it arises] not from any horizontal lines, but from the line to be led by the eye, that straight parallel line to the line of true place. For the angle, indeed, as that parallel, and the refracted radius will make the measure of the astronomical refraction.

§21. The composite astronomical refraction [Refractio Astronomica Composita], namely from simple refraction and from the parallax for the diminished refraction, equated, or exceeded; as some pretend, [is] none in reality. For if the refraction be as great as the simple refraction, it is not composite with parallax; but to this on the contrary. If indeed the refraction be greater than the parallax would be, it does not produce two effects, but rather one effect alone of an optically-seen star, in which place beyond the meanwhile linear parallax, until the place from the center of the Earth is reckoned; and so elevating the star above the true place. Nor does elevating it optically above the line of true place, but if it produces in reality the sole effect; nor by elevating it optically above the star, more or less, or equally, than the parallax would have been depressed had it not been refracted; in this case the parallactic line does not obtrude itself upon the eye, nor for that reason does it pertain to the star in reality, nor that radius which afterward is refracted; and so the parallax in this case is not actual. Whence in the first figure the Sun being at G, it would be seen through the parallactic line AGK, under K; such a radius penetrates to A, the eye obstructing it, the opaque body of the Earth; refracted nonetheless at I, to the eye A; hence the Sun appears in line AIFR. Nor is the refraction elevated optically at K, in L, and at L in R, but rather at K, that is in R, or in line CL, to line AR, hence it is not composed from refraction and parallax previously corrected; and thereupon from simple refraction and from converting the distance of a star seen from the vertex into

true place, it suffices for the seen place to be added to the seen refraction, nor is the parallax inserted per the subtraction, as Astronomy through Tycho [Tycho Brahe] deceived itself. And if the refraction be less than the parallax would be, partly potential, partly actual; then to subtract the simple refraction and the residual parallax, by subtracting the seen place from the distance of the star from the vertex; but in this case the parallax itself is rather potentially seen, than actually parallax; and from the potential mere [refraction], inasmuch as the refraction is impeded.

§22. The horizontal refraction [Refractio Horizontalis] is thus defined: it is that which belongs to a star constituted in the true horizon, of which kind in the second figure is the parallax OAF, the Sun being at H.

§23. The physico-horizontal refraction [Refractio Physicohorizontalis] is that which belongs to a star apparent in the physical horizon, as in the latter case of the second figure, where the measure of the refraction contains the angle HCG. This nevertheless Tycho [Tycho Brahe] calls horizontal, and that one rather observes, because it is easier and because the moment is given immediately of that observation; nay rather it is the first apparition of the star in the physical horizon: but at the moment in which a star is in the true horizon, none is given by foreknown reckoning, because the demonstration is such that it itself does exact observations to institute. Thus in Tome 1, Prognosis, p. 102, I use the refractions and the seen altitudes of the observations, and earlier on p. 79 in the Table set out, nor is it doubtful both Lunar p. 124, and Fixed p. 280, the seen altitudes to estimate.

§24. The remaining Definitions, that we may pass over hereto as superfluous, namely of parallaxes, and of the refractions of right ascension, of declinations, of longitude, of latitude; since in this place we treat only of parallaxes, and of refractions in the vertical circle; nay rather the parallax soberly, and seldom in favor of refractions. The parallax also, and the subhorizontal refraction, or the superhorizontal—what indeed easily flows from these—if the situation of a star below the true horizon, or above.

Art. II. Some Propositions on Parallaxes in the Vertical Circle.

I. PROPOSITION. *Of a more remote star the parallax is smaller than of a nearer; conversely, of a more remote star from the vertex the parallax is greater than of a nearer—the rest being equal.*

§25. Since the angle measuring the parallax, namely that made at the center of the star, and having for its base the semidiameter of the Earth—

—of the Earth, which is also wont to be equal to the parallax, at an equal distance of stars from the vertex, is greater in the center of a nearer star than in the center of a more remote one, as being the external angle of the internal and opposite rectilinear triangle. But at an equal distance of the same stars from the vertex, the angle of the nearer is more parallactic to the vertex, until at the vertex itself it altogether vanishes; it suffices to describe a congruent figure, and forthwith the demonstration presents itself.

II. PROPOSITION. *For an eye elevated in the vertical line, the parallax is greater, the rest being equal, than for one less elevated.*

§26. Namely, the base of the parallax being opposite, it is greater, if it consist of a semidiameter of the Earth and of a greater height of the eye, than if of a lesser.

III. PROPOSITION. *The parallax of true altitude through the parallactic line, and the seen [parallax] of given equal altitude, are not equal—the rest being equal.*

§27. For at the same instant of time the same star cannot have the parallactic distance from the vertex seen, which would be equal to the true, since the seen is less than the true—as in the fourth figure the angle VAR is less than the angle VCR—and therefore the seen altitude is equal to the true. And in order that the seen altitude come out equal to the true distance from the vertex, it is necessary that the star be raised up so long until it becomes parallel to the line of the true prior distance, as in this figure the star, from R, ought in reality to ascend in S, and the parallactic line AS, parallel to the preceding true CR, so that the seen VCR, from the vertex distance VAS, comes out equal to the pristine true VCR, per §29 of the first set of Elements. But in such a situation the parallax ASC, per the first Proposition of this [series], will be less, and the parallax ARC greater; therefore the seen altitudes belonging to the equal true altitude are not equal to the parallax of the true altitude, but smaller, and so of the rest.

COROLLARY.

§28. The Table, therefore, of parallaxes serving for a given true altitude, does not serve exactly, nor in geometrical rigor, for the seen altitude—as to the quantity, equal as it lies; it serves nonetheless mediately by the artifice following, and immediately.

IV. PROBLEMATIC PROPOSITION. *From the Table of parallaxes of true altitude, to extract the parallax belonging to an equal seen altitude.*

§29. Seek in the aforesaid Table the parallax answering to the given seen altitude, just as if it were the true [altitude], and to it add the given altitude; and with the

aggregate produced by this addition seek in the same Table another parallax: that one will be the true altitude of the prior given seen one. For example: let the Moon be distant from the center of the Earth 52 terrestrial semidiameters, and let its seen altitude be 15 degrees; the parallax in the Table of parallaxes of the Moon answers to 15 degrees of seen altitude as 64'10". To this is added 15 degrees, which makes a true altitude of 16°4'10"; to this, however, in the same Table answers a parallax of 63'51". This, therefore, will agree with the seen altitude of 15 degrees; you will work the more subtly, however, by the Analysis of the triangle ACS. Given then CS, the distance of the star from the Earth, in parts of which the terrestrial semidiameter is AC; given also CAS, the complement of the seen distance VAS, to two right angles, the parallax ASC will easily be obtained, belonging to the seen distance.

[Center-column figure between §27 and §28; see metadata header below.]

Diagram. A quadrant figure illustrating the third proposition on parallaxes of true versus seen altitude. At lower left is the apex C (center of the Earth); a vertical line rises to the vertex/zenith V at top. From C a horizontal base runs to H at lower right, where the curved arc of the quadrant springs upward to V. The eye is at A, on the vertical line above C. Rays run from A and from C through the points R and S on the arc; AS is drawn parallel to CR. The interior point labels include S (upper, the raised position), R (lower position on the arc), and the triangle ACR / ACS construction.

- V (top): vertex (zenith)
- 4.fig. (label, upper right): figure number 4
- S (upper arc): raised seen position
- R (mid arc): position on arc
- A (on vertical line): the eye
- C (lower left apex): center of the Earth
- H (lower right): foot of the quadrant on the horizon

V. PROPOSITION. *The horizontal parallax is smaller indeed than the arc intercepted between the true and the sensible horizon; but in the Sun it is insensibly smaller, in the Moon scarcely sensibly, and almost negligibly smaller.*

§30. In this fifth figure the horizontal parallax is the angle AHC, per §17 of the Definitions; and FH, per the definition of sines, is the sine of the arc FH—that is, the sine of the arc intercepted between the true horizon CH and the sensible horizon; while the angle FCH, with the diagonal AI drawn, [is] between the equal parallels AF and CI, and the other CF; there is born the isosceles triangle COI;

therefore per §15 of the first set of Elements the angle OCI—that is FCI—is equal to the angle OIC, that is to angle AIC, but to the angle AIC, external per §32 of the first set of Elements, [it is] greater by the two internal and opposite [angles]; therefore the angle AHC is greater than the angle FCH, and the arc FH is greater than the horizontal parallax, that is smaller than that one.

Now, in order to compare at the same time the horizontal parallax and the arc FH, that is the angle FCI, by resolving first the triangle right-angled ACH, in which is given the side CH, that is the distance of the luminaries in semidiameters of the Earth, and AC, one semidiameter; wherefore the parallactic angle AHC will not lie hidden, deinde in the triangle FCI, given CF, but as the base, namely the distance of the luminaries from the center of the Earth, and FI equal to the terrestrial semidiameter AC; therefore the angle FCI will not lie hidden, measuring the arc FH. So that we may bestow upon Us the most subtle Logarithms, having assumed the minimum distance of the Moon from the Earth at 52 terrestrial semidiameters; that of the Sun, at the mean Tyconic [distance], 1142; and our terrestrial 7373: from which, the data being given, the horizontal parallaxes come forth, and the arc FH, as in the following Table.

Diagram. A quadrant figure for the fifth proposition on the horizontal parallax. The apex C is at lower left (center of the Earth); a vertical line rises to V at the top. From C a base runs rightward through B to H at lower right, with the quadrant arc curving up from H to V. The point F lies on the arc at upper right; A is on the vertical line; the diagonal AI and the parallels AF and CI are drawn, generating the isosceles triangle COI near the center. Labels B, I, H sit along the lower base.

- V (top): vertex (zenith)
- 5.fig. (label, upper right): figure number 5
- F (upper-right arc): point on the arc (sensible horizon)
- A (on vertical line, left): the eye
- C (lower left apex): center of the Earth
- B (mid lower base): point on base
- I (lower base, right of B): foot of diagonal
- H (lower right): foot of the quadrant on the true horizon

	Semid. of Earth	Parall. horiz. (I. II. III. IV)	Arc FH (I. II. III. IV)
☾ (Moon) at distance	52	66 6 39 0	66 15 8 0

	Semid. of Earth	Parall. horiz. (I. II. III. IV)	Arc FH (I. II. III. IV)
☾ (Moon) at distance	1142	3 0 22 0	3 0 22 5
☉ (Earth/Sun)	7373	0 28 18 0	0 28 18 5

Parsing notes: The table is in the right-hand column beneath the fifth figure. Three rows give the distance in terrestrial semidiameters (52 = Moon nearest, 1142 = Sun's mean Tyconic, 7373 = a third value), with the horizontal parallax and the arc FH each broken into four sub-columns (I/II/III/IV, presumably degrees/minutes/seconds and a further fraction). The leftmost two body-glyph rows are marked "in distantia." Values for parallax and arc FH agree closely in each row, confirming the proposition that the difference is insensible. Several fine digit-readings are uncertain at this resolution.

Therefore it is plain that the horizontal parallax is smaller than the arc FH intercepted between the true and physical horizon by an insensible amount in the Sun, and in the Moon to the utmost smaller by 9' for the most part; negligible.

VI. PROPOSITION. *Given the horizontal parallax, the true altitude of stars is forthwith given, when they are in the physical horizon; and therefore by the same the horizontal altitudes, apart from a discriminating sensible [quantity]; if nevertheless to the Lunar parallax the utmost nine seconds-fraction be added.*

§31. For the arc between the true and physical horizon is the true altitude of the physical horizon, which stars existing there have; but here it is given equal to the horizontal parallax of the Sun per the preceding Proposition, nay rather of the Moon increased by 9'; in equals indeed there is none, but in the stars themselves [is] a smaller parallax than they have at the same place, as is plain a fortiori. In Mars, however, in Venus, or in Mercury, although they have at perigee a greater solar parallax in reality, nevertheless the supposed distance of our Sun from the Earth, never have they a parallax of 3'; minutes, that is. Which nevertheless if they should have, as Tycho [Tycho Brahe] supposes of the Sun, it is plain from what has been said of the Tyconic [system], that they would be sensibly equal to the arc FH. Therefore no Planet, the Sun excepted, when it is in the physical horizon, is higher above the true horizon by more than one minute, and in the mean

—distance from the Earth, not to mention at apogee by more than 18 seconds, in whole seconds; the Moon however never there [is] higher than $60^{\circ}15'8''$. That maximum horizontal [parallax], which belongs to a star existing in the true horizon, since it is the maximum which is in the physical horizon, even though the discrimination in the Sun is insensible, and in the Moon does not exceed 9' seconds, as I said in Proposition 5: yet one could be used for the other.

VII. PROPOSITION. *The parallax of a star truly existing in the physical horizon is greater than the horizontal parallax; therefore it deserves, and is itself properly to be called, the horizontal parallax.*

§32. In the fifth figure of a Star existing at F, the parallax is the angle AFC, which is alternate to the angle FCI, [and] is equal, and this greater parallax AHC; therefore AFC, greater than AHC, see the preceding Demonstration. Nor is it inconvenient in a Star truly above the horizon to come out a greater parallax than not elevated, because in the physical horizon there is a parallax not of altitude but of depth, and truly it more depresses a star than the parallax of a star less elevated; that parallax in the sensible horizon does not depress more truly, that is below the true [horizon], but depresses more below the apparent horizon, and the horizontal parallax there depresses, that is below the horizon. But on account of the aforesaid greater [magnitude], it is nevertheless not unworthy of the name of the horizontal parallax, that the Tables of parallaxes use the true horizon, especially since it will presently be demonstrated to be the maximum of all parallaxes.

VIII. PROPOSITION. *The parallax of a star truly existing in the physical horizon is the maximum of all [parallaxes] of the same star elsewhere, but at the same distance from the Earth existing; and from the physical horizon both upward and downward the parallaxes continually decrease.*

§33. While I was attempting to demonstrate this otherwise, P. Francesco Maria Grimaldi [Grimaldi] suggested to me another proof, which is of this [matter]: In the vertical circle BVHP let there be the vertical line VP, and the astronomical horizon BCH, and the physical EAF, in which the eye is at A, if from the center of the Earth C, the straight lines CE, CF are drawn, which are equal to the semidiameters of this circle, there will be made the isosceles triangle CEF, and by §15 of the first set of Elements, with equal base, there will be equal parallaxes congruent to a Star placed at the extreme of the physical horizon E, or F, namely the angle AEC, and AFC, sit deinde [let there next be] a Star here in K, below the physical horizon, hence in F, above the physical horizon, [as far] as is the arc FK, so that through the eye A, led, it can fall to point K, and from there straight KI;

nam if to the same point K from the center of the Earth straight CK, and CI are led, there is born another isosceles triangle CIK, of which the parallactic angle at the base between equal will be AKC, and AIC; the rays at the chord KI are led, and to the chord EF, perpendicular CL, in the triangle indeed proper ACI, right-angled at L, base AC, per §18 of the first set of Elements, the maximum is the side CL; therefore the chord EF, [is] more distant from the center of the circle C, than the chord IK; therefore per §15 of the third [book of] Euclid the chord EF, [is] greater than IK; therefore the angle ECF, [is] smaller than the angle ICK, and therefore per §32 and §5 of the first set of Elements, the angles at the base EF are greater than the angles at the base IK; greater therefore the parallax F, and E, singularly, than the greater parallax at the inferior K. By how much, however, the point K below the point I, [is] superior, the point I, from the chord per chord EF, led to the point K is nearer the center C, and by so much the chord per chord ducta is nearer the center C, and so much greater, than EF, and that itself EF, of all [chords] which come from point C, led maximally to the center C, [being] distant, and so the parallax E, and F, of all the maximum, and the rest all always toward the vertex V, or toward the lowest point P, decrease continually.

NOTABLE COROLLARY.

§34. Falsely, therefore, has it hitherto been thought to be of all parallaxes the maximum, that horizontal one which belongs to a Star existing in the true horizon, since the maximum is that which is in the physical horizon, although the discrimination in the Sun is insensible, and in the Moon not exceeding 9' seconds, but I said in Proposition 5, one could be used for the other.

Diagram. A full-circle diagram for the eighth proposition (Grimaldi's proof) showing the vertical circle BVHP. The vertex V is at top, the lowest point P at bottom, on a vertical diameter through the center C. The astronomical (true) horizon BCH runs horizontally through C, with B at left and H at right. The physical horizon EAF is a chord above and parallel to it, with the eye A near its midpoint, E at left and F at right. The point K lies on the circle below the physical horizon (right side), with I a related point, and the perpendicular CL dropped to the chord EF. Rays radiate from A and from C through the labeled circumference points.

- V (top): vertex (zenith)
- 6.fig. (label, upper right): figure number 6
- E (upper left, on circle): left end of physical horizon
- A (center-upper): the eye, on the physical horizon

- L (near center): foot of perpendicular CL on chord EF
- F (upper right, on circle): right end of physical horizon
- B (left, on circle): left end of astronomical horizon
- C (center): center of the Earth
- K (right, below physical horizon): star position below physical horizon
- H (right, on circle): right end of astronomical horizon
- P (bottom): lowest point (nadir)

[Margin, beside §33: "Linea CH, serviat pro EAF, & omissa ab inesse." — The line CH may serve for EAF, and [is] omitted from being inserted. (marginal note, partly abbreviated; reading uncertain)]

—that maximum horizontal [parallax], which belongs to a Star existing in the true horizon, since it is the maximum, which is in the physical horizon, even though the discrimination in the Sun is insensible, and in the Moon does not exceed 9' seconds, as I said in Proposition 5: yet one could be used for the other.

IX. PROPOSITION. *The parallax of depth is smaller than the parallax of altitude equal in depth.*

§35. Let there be in this seventh figure a Star at K, [seen] from A; and therefore the parallax of altitude AKC, if indeed there be another star, or the same at another time in L, below the horizon toward BCH; given then the altitude-arc HK, there will be a parallax of depth ALC, per the definitions premised. Let CL be continued in M, and from A, to M, let the straight line AM be drawn; there will be made the triangle AML, in which the angle M is equal to the parallactic angle of altitude K, opposed to the same side AC; and the triangles ACK, and ACM, are similar, because besides the common side AC, the sides CK, and CM are equal, as being radii of the same circle; and comprehending under the side AC, equal angles VCK, and VCM, that is equal to the complements of equal altitudes, if indeed the angles MCB, and HCL, [are] equal at the vertex among themselves. And so in the greater triangle AML, the angle M, is opposed to the greater side AL, the angle however L, to the smaller AM. Therefore the angle M, and so that one which is equal K, which is the parallax of altitude, [is] greater than the angle L, that is the parallax of depth.

X. PROPOSITION. *The parallax of depth, [as compared with] the parallax of equal altitude in the Moon, is not smaller by more than 10" seconds-fraction.*

§36. For the maximum parallax of altitudes is that which belongs to a Star existing in the physical horizon, per Proposition 8; this, however, in the Moon is

as great as the vertical arc described through the center of the Moon between the astronomical and physical horizons; therefore the arc in the Moon proximate to it, per the said Proposition 5, [is the] minimum 66'. Of minutes 60' I now add to that—if so much be below the true horizon—added to this by 90 degrees: there will be made a triangle of which the angle, comprehended by the semidiameter of the Earth, and at the distance of the Moon from the Earth at the minimum, that is 52 terrestrial semidiameters, will be $91^{\circ}6'15''8''$. Therefore by the Logarithmic canons there will come forth the parallax of depth in such a minimum $65^{\circ}55''10''$; and therefore the minimum parallax of altitude [is the] maximum, not more than 66'. So that the same difference will scarcely be a single second, as will be plain by calculation. Wherefore in the Sun it can be held for insensible, and in the Moon scarcely and barely sensible.

Diagram. A full-circle diagram for the ninth and tenth propositions comparing the parallax of depth with the parallax of altitude. The vertex V is at top, on a vertical diameter through center C. The point M is at upper left, K at upper right (the star above the horizon), with A (the eye) just inside near the top. The astronomical horizon line runs through C to B (left) and H (right). The point L lies below the horizon (the depth position), with rays AM, AK, CL, CK, CM drawn from the center and the eye. The triangles ACK, ACM, and AML are formed.

- V (top): vertex (zenith)
- 7.fig. (label, upper right): figure number 7
- M (upper left, on circle): continuation point of CL
- A (center-upper): the eye
- K (upper right, on circle): star above horizon (altitude position)
- C (center): center of the Earth
- B (left, on circle): left horizon point
- L (lower, below horizon): star below horizon (depth position)
- H (right, on circle): right horizon point

Art. III. Propositions on Refractions.

XI. PROPOSITION. *A ray which falls more obliquely, or at a greater angle of inclination, is refracted at a greater angle, and equally if equally oblique.*

§37. Thus Vitellio [Witelo] Book 10, ch. 14, and Kepler in the *Paralipomena* to Witelo Book 1, ch. 4, Proposition 1, from the latter first by experiment, demonstrate; deinde a priori, and so received in Optics, let it have place as Axiom 2. The Axioms of Kepler in the *Dioptrice* [Kepler, *Dioptrice*]. Hence the refraction of an obliquely incident ray is greater than the optical refraction.

XII. PROPOSITION. *A ray returning from a denser medium, through the same point through which it entered, the refraction at the perpendicular [is] equal to the refraction at the perpendicular in the entry.*

§38. This is demonstrated by Alhazen [Ibn al-Haytham] Book 7, Proposition 34.

[Margin: Witelo [Witelo], Bk 10, Prop. 9; *Dioptrice* no. 10; Herigone in *Dioptr.* Prop. 1, etc.; likewise in [Kepler]'s *Dioptrice*.]

XIII. PROPOSITIO.

For a star, whether distant or near, the optical refraction is the same along the same line of incidence into the same point of the same dense medium.

[§39] Kepler expresses this same point in other words in his *Paralipomena* [*Paralipomena ad Vitellionem*], ch. 4, Prop. 4, when he says: "Between a thin light and a dense light there is no difference of refraction, other things being equal." And in this sense he adds in the appended note: "A greater quantity of light does not increase the refraction." For even though the ray from a more distant star is uniformly weakened in the course of its travel — being fainter, while the denser ray of a nearer medium resists more, with the result that it is more intensified — nevertheless this does not amount to more as regards the figure or the bending of the ray. The reason is that this quantity arises from the greater or fainter obliquity of incidence; and for a more distant star, and for a nearer one, the bending of the ray is supposed to occur along the same line of incidence, and hence at an equal angle of inclination. Therefore, by Prop. XI, the optical refraction of each is equal.

XIV. PROPOSITIO.

At the true vertex [zenith] the visible star is at a smaller distance, by force of refraction, when it is more distant than when the Earth is nearer — other things being equal.

[§40] With the other features remaining as described in Figure 2, let it now be so in this eighth figure that the Sun is at H and the Moon at G.

Diagram. A quadrant-shaped figure: a quarter-circle arc with a horizontal base line and a vertical line at the left, representing the celestial vault above the horizon. The vertical line at upper left carries V (the true vertex/zenith) at top, with S marked as a star near the top of the arc. Radii and refracted rays are drawn from points on the arc down toward the eye at the lower left. The base line runs along the bottom.

- V (top of vertical): the true vertex (zenith)
- S (near top of arc, with asterisk): a star
- M, L (on or near the arc): points on the celestial vault
- P, O, K (left region): intermediate points along the refracted rays
- A (lower left): the observer's eye (true position)
- F (lower left, near base): point on the base line
- C, G (along the base): G is the position of the Moon
- H (lower right, end of base): the position of the Sun

[The labels are small and several are crowded near the eye; readings P, O, K, L, M as best resolved.]

at the true vertex-distance VCGH, which is the same one, let a line parallel to it be drawn from the eye AF. The Sun's ray, refracted at the point K, then passing through HK, and entering at P, but truly refracted along KA toward the eye A — for from the produced line AK the Sun appears optically at the celestial vault in S, and so its distance from its visible vertex is the angle VAS. Now the Moon's ray at G cannot radiate toward K, because by Prop. XI its radiation occurs at a greater angle of inclination, and therefore the refraction is greater; thus the Moon's ray is refracted at AK, and likewise the Moon's incident line is the Solar line. The Moon will then be at N, where it is seen to be at a vertex-distance smaller than VCH — that is, the distance of the Sun. Then finally, since just as the Moon's ray, tangent to the sphere of the airy refraction, touches at the lower point because the Solar ray is higher: thus in this case the Moon's ray, tangent to the sphere of the airy refraction at the eye A, first enters the air; whereas the Solar ray first enters at the eye, striking it — therefore the Moon's ray and ray at the eye A, refracted at the lower point, say at L, and by that same refraction AL, the Moon appears at L; and so its visible distance from the vertex is VAL, greater than the Sun's VAS; and so for similar cases, the other features being equal, that is with the densities of the air the same, etc.

XV. PROPOSITIO.

At the same vertex-distance, the visible star, by force of refraction, is greater when the star is more distant than when the Earth is nearer — other things being equal.

[§41] In the eighth figure it will be apparent if they are not in the same vertical line; ...

at least diversely, by the same, or by an unequal refraction. The ray AK, with the Moon at M and the Sun at S, then by Prop. XII this same chapter falls in the same

line KH, where the equal and equally inclined refraction will occur, and the Sun will be at H and the Moon at N, and by the same force of each, the ray falls at K; therefore drawing the line CN, the Sun will be at S, true at its vertex-distance VCH, which is the Moon's nearer distance VCN.

XVI. PROPOSITIO.

The simple astronomical refraction of a star more distant from the Earth is greater in all other respects equal, than of a nearer one — provided the optical refraction is smaller.

[§42] For supposing the air to be of equal density, and the situation the same, if each is of equal force, the star's distance from the true vertex, as posited in Prop. 14, is smaller than the distance of the more distant star by the same Prop. 14. Therefore the greater difference between the visible and the true distance of the more distant star, and the visible and true of the nearer one — but in such a case the simple astronomical refraction consists in the difference, by Definition 20. Thus, as in Figure 8, with the stars positioned on the line CGH, the more distant luminary at VAF, the nearer luminary VAS, while the distance VAS falls short of the angle VAF (which is the true vertex-distance of the more distant star by the angle VCH) than the angle LAF (by which the visible Moon-distance VAL falls short of the angle VAF), the optical refraction AIO is greater for the Moon than AKP; and the Sun, on account of the greater Lunar ray.

But if the visible distance of each is the same, it is greater by Prop. 15. The true distance of the more distant star: therefore the greater difference between the visible and the true, the more distant than between the visible and the true, by Def. 20, the greater the simple astronomical refraction.

COROLL. I. AGAINST TYCHO.

[§43] [Tycho Brahe] is therefore wrong in his Tables of Astronomical Refractions, *Progymnasmata* Tome 1, pp. 79, 114, & 280. He exhibits the refractions of the Fixed stars as smaller than the Solar ones, and the Solar smaller than the Lunar, but from an altitude of 6 degrees not greater than the Lunar — when he ought to have exhibited them greater, as he did from the beginning of the quadrant up to an altitude of 6 degrees. Indeed because he confused the Optical Refraction with the Astronomical, he reckoned (doubtfully fearing) the more distant star's refraction to be greater than the Astronomical refraction. [Margin: Tycho's opinion false. 1, 2.] For thus they ring out on p. 280, where these are the words: "I judge that these refractions of the Fixed stars can be applied to the Planets too without inconvenience, since the difference is hardly perceptible, except that the

Moon, which we expose around the Sun, or some of these things somewhat greater, is liable to observation." He speaks of the refractions by that method he handed down on p. 91 — namely, by observing the difference between the true and the visible, the distance from the vertex; nor are they sufficiently coherent with parallax. And the refraction, simply compounded, since the method is openly to be applied as set out on p. 92, & that visible in practice p. 102. The Moon, being a simple star — if it had been composed of Lunar refraction out of the Horizontal Parallax, which is once around 23 degrees greater, the refraction would have made greater by one degree, which nevertheless he made not greater than 33 minutes.

COROLL. II. AGAINST KEPLER.

[§44] It follows moreover from Prop. 15 that Kepler's reasoning in his *Astronomiae Pars Optica* ch. 4, Prop. 4 is a paralogism [a faulty inference]. For in that Proposition, which he rightly stated: "Between a thin light and a dense light there is no difference of refraction, other things being equal," he deduced in the appended note: "A greater quantity of light does not increase the refraction." But when the rest are required to be equal, the distance from the vertex is greater, the astronomical refraction of more distant stars greater than of nearer ones to the Earth, by Prop. 14. And although he had earlier spoken of the Optical refraction, in the same proposition he applies the teaching to the astronomical, when observation repeats it; for it is in the air [that] Tycho Brahe handed down the refractions of the same stars of the Sun and the Moon, of which that lofty cupola has none.

[Margin: Kepler's error.]

which the perpendicular fell upon, for the Fixed stars and Planets, some of which are nearer to the Sun [than] others — Tycho ascribes the same to them, & soon: "In vain therefore is Rothmann, who supposes it to be the case, that diverse Fixed stars near the Sun, & Planets, would touch refractions: & however much Brahe in the *Progymnasmata* folio 280." The Moon's refractions are suspected to be greater, on account of its nearness; nevertheless folio 124 (which he afterwards wrote) the refractions, as I said, he found to be the same with the Solar. Therefore Kepler reckoned the refractions of stars to be equal in any whatsoever, at a distance from the Earth, which is true indeed if they are at the same distance from the true vertex, & in the same sense he says about the Optical refraction; but at the astronomical [refraction] it is false, since they are not at the same nor the true visible. Hence in the *Rudolphine* precept he said lastly about Tycho: "If perhaps (which he nevertheless suspected falsely) the altitude of the star from

the center of the Earth varies the cause, varieties would appear. I judge the refractions to be greater for that reason, because in computing them Tycho still applied the parallax too small. And indeed without the parallax the refractions ought to have been greater." Hence at last badly in the appended note of the same Prop. 4, Bk 1, *Optics*, ch. 4, he adds: "Nor does the refraction represent the Moon conjoined to a star, if it appears beyond a refraction-distance." And that this is false we shall show at once.

XVII. PROPOSITIO.

Two stars equally distant from the center of the Earth can, by force of Refraction, be represented as conjoined or nearly bodily, which, refraction set aside, appeared widely disjoined.

[§45] It is, as I said against Kepler, Bk 1, *Astron. Opt.*, ch. 4, Prop. 4, in the appended note. Let them be in Figure 8, the Sun at H, the Moon at N, in the same plane vertical, in which lie the rays of the Sun in the vicinity, but truly equal at vertical & at a smaller distance; whence if the aggregation of the semidiameters of both visual bodies, equal, radiating along an equally high line at the same point — equal, or very near, & equally high at the surface of the Air refractive, at the same point, or along an equally high refracted ray KA, will appear to the eye A, in the same line AKMS, equal, or higher, the Moon at M, & the Sun at S, & as to the visible Altitude conjoined, but as to azimuth or true latitude the Moon's image differs partly to the eye A, & nevertheless, if to the eye A, the line is drawn parallactically AN, & verum at the lower point, the distance is AH, where truly the distances are smaller, & per equal as if without refraction they were seen, & both, the Moon at a higher distance than the Sun. Hence one easily recognizes that two stars unequally distant from the Earth could appear conjoined, & conversely two stars unequally distant from the Earth, & conjoined, would appear, if without refraction seen, seen as disjoined by force of refractions.

XVIII. PROPOSITIO.

The eye on the Earth not at all raised, the Refracted Ray never represents the stars below the Physical Horizon, but only above it.

[§46] Because the Refracted Ray of this kind of place, either coincides with the Physical Horizon, or is above this horizon, & so represents the stars, or it is in this Horizon, or above, as it falls below this horizon, it does not penetrate the opacity of the Earth, nor does it reach the eye on the surface itself lying low.

XIX. PROPOSITIO.

The eye raised above the Earth, the stars can appear below the Horizon by force of Refraction.

[§47] It is proved by frequent experiment; for we have, from our Observatory, not from the eminent place, seen from the peak of the Paternal mountain [Monte Paterno] the Moon, & other objects below the horizontal line, instruments collocated for levelling appearing, nor do we doubt that, since their rays, as the air is denser, are inflected, refracted, & reach us, & this does the Moon move, that it is higher in the true horizon, since it can have a greater Refraction with a great parallax of its own; nor is it represented in the Physical Horizon, but above it. Let an example of this be in Figure 9, the Moon existing at H, ...

Diagram. A quadrant figure similar to the eighth: a quarter-circle arc bounded by a vertical line at the left (carrying V at top, O, A, C downward) and a horizontal base line at the bottom (running to F, L, H at the right). Internal lines show K and I as intermediate points; refracted rays run from points on the arc toward the eye region at lower left, illustrating how the Moon at H is represented below the physical horizon when the eye is elevated.

- V (top of vertical): the true vertex
- O, A, C (down the vertical, left side): points on the vertical / eye positions
- K (interior, upper): point on a refracted ray
- I (interior, lower): point on a refracted ray
- F, L (along the base): points on the base line
- H (right end of base): the position of the Moon

which, radiating into the point K, can be seen at L, by the refracted ray KO, verging downward: For the refracted Ray always represents the stars less distant from the vertex, than if without refraction they were beheld. And in this sense it always raises the eye, however much it verges downward.

By this occasion it is sufficiently advised that the eye below the surface of the Earth depressed — say in the bottom of a pit, a hollow, a ditch, a valley — by force of refraction some stars can appear there which without refraction could not appear.

XX. PROPOSITIO.

All the Fixed stars & Planets, the Moon excepted, when they appear in the Physical Horizon, are really below the true Horizon, by as great a depth as is the difference between their Parallax & their Horizontal Astronomical Refraction.

[§47, cont.] For from one part the Arc between the Astronomical & Physical Horizon of the Fixed stars is null to the sense, because they lack a sensible parallax; in the Planets, the Moon excepted, [it is] insensibly represented, because they lack a sensible parallax from their own Horizontal, by what is said in Propositions 5 & 6, nor does it exceed 1 minute, or the other [parallax], supposing the truer Solar distance from the Earth, of which we [treated] in the *Almagestum Novum* Bk 3. From the other part the Horizontal Astronomical Refraction of the stars, by Tycho's experiments and ours, does not exceed 1 minute 27 [minutes]; when therefore both are in the Physical Horizon, the distance from the vertex of the visible adds the horizontal Refraction of 27 minutes, & thence the Arc between the Horizons is so much, which is the residue from the subtracted parallax, since it itself is below the horizon. But if the Arc between the Horizons exceeds 2 minutes, the star will be below the horizon by as many remaining minutes as the residue is, when the parallax is subtracted horizontally.

XXI. PROPOSITIO.

When the Moon appears in the Physical Horizon, it is really between that & the Astronomical Horizon.

[§48] The reason is that the Lunar Refraction in that position is much smaller than the sensible Horizontal Parallax, not to mention the Arc between the Astronomical & Physical [horizons], the Horizon being intercepted. Therefore if then the refraction is added to the visible distance from the vertex, the true [distance] will become its distance from the vertex, larger than if the Moon were in the true horizon; but [it is] below, if it ought to be in itself, the distance of the visible adds so much as the arc by which its Horizon differs, which differs from the horizontal Lunar parallax 9' at its highest, by 2 seconds, by what is said in Prop. 5 & 6.

XXII. PROPOSITIO.

The visible distance from the vertex by force of refraction is not only smaller for the Moon, but for some others of the Planets, it can be greater than the True; yet it is always smaller, Visible, or Visible, by the parallactic line alone.

[§49] For the Moon in the apparent Physical Horizon, it is evident from the preceding Proposition; for the other Planets it is proved, because the eye can be elevated so far from the Earth that, the rays refracted, verging downward, may see the stars, as said in Prop. 19; yet nothing can be brought repugnant to it, on account of which the star at that moment could not be in the true Horizon, ...

[in the true Horizon], or above, in any case, the True distance from the vertex does not exceed 90 degrees; & nevertheless the Visible distance, by force of the refracted ray verging downward, will be greater than 90 degrees; otherwise it would not verge downward. As if, as in Figure 9, by the Refracted ray KO, the star which is really at H, appears at O, the Angle VOL is greater, than the angle VCH, smaller than the angle VOF, which is parallactic; & so as said in Prop. 19, the Refraction always raises: understand not the True visible [distance], but above the parallactic [distance], the Visible or beholdable distance from the vertex.

XXIII. PROPOSITIO.

To find the simple Astronomical Refraction of any given star by observing, the star's Declination & the Altitude of the Pole [latitude] being given.

[§50] This can be carried out in several ways, but the easiest & most exact is the one which, taking the Azimuth observed together with the distance of the star from the vertex at that very moment, by which the star's center appears in the determined Azimuth — which is evidently described by our Filar Triangle [triangulum filare], *Almagestum Novum* ch. 15, Prob. 8; & if it is located in the determined Azimuth, & is expected to be, ...

Diagram. A full circle (the celestial meridian/sphere) crossed by a horizontal diameter (the horizon line, with B, A at the left end and G, H at the right end) and a vertical diameter (with V at top and N at bottom). Near the center are points I, L, C, D, K marking the true and visible positions of a star and the triangle used in the construction. A curved line F at upper right and arcs descend toward the lower right, representing the refracted ray path.

- V (top of vertical): the true vertex (zenith)
- N (bottom of vertical): the nadir
- B, A (left end of horizontal diameter): points on the horizon
- G, H (right end of horizontal diameter): points on the horizon
- F (upper right): point on the arc / refracted ray
- I, L, C, D, K (central cluster): points of the construction — the true and visible star positions and the triangle vertices

and that the center of the star may arrive at its rising, or setting, & at the same moment another observer with the instrument may seize, splendidly to the minute, & some second of subdivision, the star's visible distance from the vertex. Furthermore in the Fixed stars there is no need to know the moment of time, since it suffices to know the day, because within one day their declination is not sensibly varied. But in the Sun it is expedient to make the observations on the days of the Solstices, in which the Sun's declination is insensibly varied — or at least in the Sun, & in the other Planets to be observed, either by clockwork [horologia], or by the Fixed stars, the more precise moment of time, so that the star's declination may be exactly computed.

These things accomplished, let it be so in the tenth Figure that the star first appears at K, but truly by force of Refraction it appeared at C, or wherever in the Physical Horizon BF, or wherever to the true place K, from the Mundane Pole P, let the arc PK be drawn, a portion of the circle of declinations; & from the Vertex V through K, [let] the semicircle vertical VN [be drawn], which gives rise to the spherical triangle VPK, in which the Azimuth observed is the Angle VPK, & the side PV the complement of the Altitude of the Pole [co-latitude], & the side PK the complement of the declinations Boreal, or the aggregate out of the declination Austral & Quadrant, if the declination be Austral, or Quadrant, if there be no declination: Therefore, three of these being given, by the Canons of Triangles, the side of the star's distance from the Vertex VK will become known, from which subtracting the visible VC, the simple Refraction CK will remain known.

But secondly, if the star at D appears by force of refraction below the horizon at L, drawing through it the vertical semicircle VN, & at the arc of declinations PD, the triangle VPD will be born, in which the Azimuth is known, the angle PV, & PD, the complement of the declination Boreal, or the aggregate out of the declination Austral & Quadrant, or Quadrant, from which the true distance from the vertex VD will become known, from which subtracting the observed, or visible VL, the Refraction DL will remain. Let it be on the contrary, the star at L, but it appears at C, ...

(for it is supposed to be seen as a greater distance from the vertex, than the true distance from the vertex is established from what is said above) then in the Triangle VLP, from these three given data commemorated, & applied to this case, the true distance VL will be given; from which subtracting it from the Visible VC, the Refraction CL will remain.

Nor does it stand in the way that the arc VLC, through which in this Figure the visible distance of the star from the vertex is represented, is the arc of a great

circle described from the center of the Earth; & nevertheless the visible distance from the vertex is captured by the surface of the air, where, however, since we do not indicate by such an arc, with the angle made in the center of the instrument, which in the highest Heaven we measure the visible [distance] from the vertex, we use a line from the center of the eye drawn by the instrument, & a parallel line as the True distance from the vertex. It suffices for us separately to find the true [distance], & without an arc vertical through the star drawn, to consider the visible place, or the image of the star, however far, from the eye into the infinite remote. Thus in Lunar parallaxes we use an angle made in the center of the eye & in a parallactic line, which we compare to a perpendicular line, & to a vertical line; & we compare an angle made in the center to a vertical line, & to a line of the true place. Thus in the Planetary Propositions where they use an anomalistic angle around their center in true motion — indeed in the form of the Equant, beyond the center of the Planetary orbit — because such an angle is not measured by the arc of the orbit, but by benefit of parallels, it is measured by the distance from the Apogee, in the highest Ecliptic infinitely, or however much, considered remote.

XXIV. PROPOSITIO.

Although the simple Astronomical Refraction of the Moon can be known without Parallax; & whether the Visible can be exchanged into the True, the True nevertheless cannot be exchanged into the Visible by force of one [refraction], any more than the Visible by force of one [can be exchanged] into the Visible by force of the other.

[§51] The first part of the Proposition is proved, because by Definition 20, the notion & usage of Astronomers received, this Refraction is nothing else than the difference between the true distance of the star from the vertex, & the visible by force of the refracted ray; but this, by Prop. 23, that is, by such praxis as is handed down there, can be known without parallax; therefore the praxis assigned to it does not need the notion of parallaxes. It is confirmed, first, because in this case the comparison is made between the true distance of the star from the vertex, & the true, or visible by force of the refracted ray; but between the true, & the visible by force of the refracted ray; & at the same moment at which the sensible Refraction occurs, the sensible Lunar parallax also occurs, greater than the refraction; the eye being in a suitable distance from the Earth or from the sensible parallaxes, it nevertheless does not raise the parallactic line, nor is it referred to in our case, but only made.

It is confirmed, 2, by example, & by the authority of Tycho, who in Tome 1 of the *Progymnasmata*, p. 124, exhibits a little table of Lunar Refractions, without including parallax; otherwise it would have had to exhibit the refractions not smaller than 85 [seconds]: established at 33 [minutes], namely, of pure Refraction, & of Parallax horizontal Lunar, which is once smaller, than 52', but it could be at most 33': & so of the others, & it likewise made the simple second part by these Propositions.

The third, & the fourth part, on the Commutation of the True into the Visible, or of the Visible by force of the refracted ray into the Visible by force of the parallactic line, is proved because then in the comparison there is not only the True with the Visible refracted; but the True into the Visible absolute, when however the Refraction is not greater than the parallax, or equal, as happens in the Moon; the Refraction does not raise the optical Visible so much, as the parallax depresses; turned therefore from the true distance into the Visible by force of Refractions, the star is seen higher indeed than in the absolutely depressed, it will be seen, since it is less by force of the residual parallax, but with the excess, since the Parallax as a whole conquers the Refraction, & by what excesses, the depressed effect operates. Therefore in order that the True may be turned into the Visible adequately, & absolutely, parallax will be needed, & much more if the visible is to be compared with the other Visible. Repeat here, what I said in Prop. 21.

Proposition XXV

For the remaining planets, which have a smaller refraction than parallax, not only can the simple distance from the vertex be known apart from refraction, but it can even be known apart from parallax — and the true distance can be converted into the visible distance, and the visible into the true (yet not into the visible anaclastic) by parallactic refraction alone.

§52. The first part is established as above, from what was set down in practice at Proposition 23. The second part is proved, and this second part follows from it: because in both cases — whether refraction acts alone, owing to a single refracted ray, without any regard for the parallactic line; or whether it acts together with parallax — the thing that has a smaller refraction holds simply, by the very fact that it is smaller than the refraction. But this is the simple true distance, and meanwhile it posits nothing in being, nor does it bring it about that the eye sees the stars truly parallactically, but only refractedly — yet merely refractedly. And although the eye placed beyond the center of the Earth — that is, above the horizon — sees the true [place], since the parallax of the stars, when

the distance of the star from the Earth is so great, is null or scarcely greater than the refraction, the parallactic line is so situated that it does not exist in the nature of things; rather it truly is not, nor does it furnish anything physically or optically, as I shall also show under number 21. Nor can it be conceived that there is here some conflict of contraries, in which refraction raises something upward by eight while parallax draws it downward by two, so that one should follow the elevation by only six. Rather, the refracted ray directs the visible star, and at that time the visible parallactic line, considered apart from this, is determined from the place of the star itself, when the refraction raises the ray; nor does it elevate the object more than it ought, so that it might be seen apart from parallax; and still it leaves a place for parallax, because this is the refracted distance. [The optical argument of this paragraph is densely compressed and partly conjectural in the reading. [?]]

Our discourse is confirmed when we descend to practice. Suppose, by Proposition 23, that the Sun's true distance from the vertex is found to be $84^{\circ} 30'$, but that it is observed by instruments as $84^{\circ} 50'$, and the refracted ray is certainly something not less than the elevation by some minutes, say $20'$; and it is not parallax, since [the deviation] from the vertex is some [?] $20'$; therefore the refraction will be $30'$. If, then, the minute of absolute true distance has been $84^{\circ} 30'$, and conversely, if 85° be taken, subtract $30'$ from it and the true distance of 85° will be left; and conversely, if 85° be given, subtract $30'$ and the visible distance of $84^{\circ} 30'$ will remain. [?] Most certainly, then, the visible refracted distance, when $30'$ is taken away, leaves the visible distance for the future. Nor does it matter for this comparison that there be a mutual conversion: the parallax does the work. [?]

But truly, if the refraction added $30'$ — for example, of one minute of parallax — the refraction would evade by $31'$, if the whole distance had been added to the visible; the true distance evades by $84^{\circ} 29'$, contrary to the supposition made. Nor would the comparison occur of the visible refracted distance, but of the visible-by-refraction (or the visible anaclastic) with the visible parallactic — in which sole comparison we grant the use of parallax. For then the visible refracted distance of $84^{\circ} 30'$, with $31'$ added, joined to refraction and parallax, results in the visible parallactic distance of $85^{\circ} 1'$. Most certainly, indeed, if the visible distance be diminished by $31'$, the visible anaclastic distance of $84^{\circ} 30'$ results. But the comparison declares nothing in astronomy, since, once that refraction is supposed known from here, parallax is no different than is usual, when it is the visible absolute distance that lies in the true distance from the vertex, and conversely the true distance is converted into the visible, or the absolute into the thing to be seen. [?]

We grant, moreover, that if anyone should cast into a Table that the refractions are composed of simple refraction and of a lesser parallax, and then proceed to convert the visible into the true and the true into the visible distance by subtracting the former refractions [and] that lesser parallax — I assert that that composition will be made in vain, since in practice it is to be dissolved, and simple refraction suffices.

Corollary

Against Tycho [Tycho Brahe], and the rest who were deceived in this — some of whom were even among us.

§53. It follows from the preceding proposition, rightly considered, that Tycho [Tycho Brahe] erred in the method of inquiring into Solar Refractions, in that, while he knew the parallax to be greater than he handed down (*Progymnasmata* I, p. 92), he said, when he treated of the Sun's elevation by a given observation: *It must be added — that is, that the Sun would incline more toward the horizon — and that Refraction emends nothing.* And at once he subjoins: *Thus we recognize the apparent elevation of the Sun, if it be wholly freed from parallax; but these [elevations], when the true altitude has been subtracted by computation in the same Azimuth, will give the sought Refraction.* These are trifles — nay, mere trifles, and the work of a depraved imagination. For refraction will be the difference between the True and the Visible distance from the vertex; that is, the greater between the true and the visible, which now acquires what is to be subtracted in withdrawing the visible from the true distance. Hence its composition out of parallax — either before the subtraction is made, since this can be had at once, or [out of] the addition of parallax. But let Tycho subjoin his method in the same place: *It does not escape notice — he says — that the third side represents Refraction in the circle of the verticals, to which nevertheless the addition of parallax comes; on which account the Sun appears lower [than it would] without this — for by Refraction it would appear higher, and on that account the Refraction is greater.* See in what manner Tycho estimated Refraction and Parallax to intervene, in reality, by a kind of quasi-conflict: so that, had Parallax not opposed, refraction in its working would have made a much greater [display] than is the image of the Sun, however large the latter appeared in reality. But this falls flat. For if there had been no parallax, on that account the Sun would have been in the center of the Earth, nor would there have been any Refraction in any place; but if, the Earth remaining, the eye [were] on the surface of the Earth, and the Sun were seen as high as $1^{\circ} 30'$, for example, while in reality it was as high as only 1° . And, by feigning the visible Sun seen by two eyes — by one a refracted ray, by the

other a parallactic ray that is wondrously not refracted — this would so move the eye that the Sun appeared less by one whole degree, namely 59'; by that much less is the refracted object, [yet] not because the prior eye sees the Sun higher. Whence it follows that there is no greater Refraction. For if there had been no parallax, on that account the Sun would have fallen [short]; nor would the Refraction have been greater than the $1^{\circ} 30'$ at which it had been seen as refracted and elevated, since in the first case it had been refracted and elevated. On that account, in the very thing Tycho already recognizes Refraction while the parallax is added — when you say, *it does not escape notice that the third side represents Refraction*; otherwise, if it were not refraction but part of refraction, it ought to have been named, for collecting the equation, not *Refraction* but a *part of Refraction*. Nor is that refraction of yours composed of an elevating refraction together with parallactic refractions partly, by one elevating so much as parallax had depressed; rather it would be from the other elevating above the true place of the Star, as I imagine.

Consequently, however, Tycho — after he had given, on p. 79, the Table of Solar Refractions composed of pure Refraction and parallax, and afterwards on p. 102 [given] both — is not consistent with it. But for the future, since our Tables of Astronomical Refractions are simpler, let us use the Rules set down above. Reread what I said under number 21.

Proposition XXVI

If the refracted ray be parallel to the line of the true place, the distance of the star from the vertex visible will be equal to the true distance from the vertex, and the difference between the visible-by-refraction and the visible parallactic will be equal to the parallax itself, the refraction ceasing; and then for the first time the refraction is astronomical.

§54. In Figure 11, let the star be at L, and the line of the true place CL, but the refracted ray AK; let the visible ray AB be equidistant from the line CL. Let the ray, on its refraction, fall along the line KL, and with the eye at O, let the parallactic line AL be drawn to L. I say that the visible distance VAB is equal to the true distance VCL, because the external angle [equals] the internal one by the opposite, on which account the straight line VC falls upon the two parallels CL and AB by the same angle ALC — that is, that the parallax is equal to the alternate angle BAL, by which

Diagram. A quadrant-shaped figure in the upper-left of the column. A vertical line rises at left from a corner; a horizontal base runs from that corner to the

right to point H. A quarter-circle arc connects the top of the vertical (V) to H. Within the quadrant, rays and chords are drawn from the lower-left corner (the eye/observer position) outward to points on the arc and to interior labeled points, illustrating the relation between the true place, the refracted ray, the visible ray, and the parallactic line.

- V (top of the vertical): the vertex / zenith point
- B (upper interior): point on the visible ray
- K (interior, left of center): point where the ray is refracted
- L (interior, right): the star's position
- C (lower-left corner): center of the Earth / observer base
- H (lower-right end of the base): horizon point

(angle) the visible distance VAB differs from the true distance VCL — that is, VAB differs from the visible distance, or visible parallactic, that is VAL. Lastly, if there is no difference between the true distance and the visible-by-refraction distance, by the definitions of number 20, all refraction will cease at that point, when first the parallactic line touches such a [point]. Yet there is no conversion; and so, if visible refraction cease, the visible distance evades equal to the true, as we shall say at Proposition 30, concerning the Moon. Hence the Table of the refraction of the visible altitude is not sufficient; one must proceed further, and a Table of Refractions must be constructed from the altitudes of the true distance from the vertex, congruent, or it teaches in what manner from the constructed visible Table others can be elicited; and then one must discuss when, [given] some star, the visible distance ought to be greater than the true, whether the refracted ray be in the physical horizon, or directed downward, or upward — and indeed it has hitherto not been demonstrated that, by the upward-directed refracted ray, the visible distance is always less than the true. These, then, are the matters.

Proposition XXVII

Of the Moon appearing in the Physical Horizon, the Visible Distance from the Vertex is greater than the True.

§55. For by Proposition 21, the Moon is then truly between the True and Physical horizons; therefore the True distance from the Vertex is less than a Quadrant, but the Visible is a Quadrant; therefore the latter is greater than the True.

Proposition XXVIII

Of all the planets (the Moon excepted) and of the fixed stars, in the Physical Horizon, the Apparent Visible Distance from the Vertex is less than the True.

§56. For by Proposition 20, the rest of the planets and the fixed stars are, in the Physical Horizon, truly below the True Horizon; therefore the True distance from the Vertex is greater than a Quadrant, but the Visible is equal to a Quadrant; therefore the latter is less than the True.

Proposition XXIX

Of the Moon above the Apparent Physical Horizon, the Visible Distance from the Vertex is greater than the True.

§57. For the Moon's visible distance is greater than the true, when it appears in the physical horizon by Proposition 27. Thereafter, if the Moon raises itself, [the distance] continually decreases until the Astronomical Refraction ceases (I speak of the perceptible sense), before which the Moon's Parallax in this case vanishes, and the visible has thus far persevered greater throughout the whole preceding and lower altitude, greater [than the true] with sensible Refraction. The sensible Refraction ceasing, the Moon is no longer seen by us through the Refracted Ray, which is diverse from the parallactic; rather it is seen through the Physical Ray, which is the visible parallactic Ray; but the eye, with the Vertical line, makes the angle of the visible distance, greater than the internal one, and by the opposite of the Triangle, the parallactic angle makes the true distance to be measured by the angle internal and opposite to the one mentioned. And so it comes about, until the Moon occupies the vertex [and] all parallax ceases.

Proposition XXX

Of the Moon existing in the True Horizon, with the eye elevated below the Apparent Horizon, the Visible Distance from the Vertex is greater than the True.

§58. For the True [distance] in this case is a Quadrant, [yet] the visible [distance] greater than a Quadrant, because it is seen by the downward-tending Refracted Ray, since it is not seen by the refracted ray coinciding with the physical horizon, unless it has ascended above the true horizon by Proposition 21. I said that this Proposition follows in this place, [namely] that, if no Refraction be supposed here, the Parallax thence will be something other than is usual, since the Visible [distance] is greater than the Visible absolute into the True from the Vertex; and conversely the True into the Visible, or what is absolutely to be seen, is converted.

Proposition XXXI

Of the Moon existing below the True Horizon, with the eye elevated below the Apparent Horizon, the Distance from the Vertex is greater than the True.

§59. The reason is, that in the ascent of the Moon to the True Horizon, the Astronomical Refractions are very great, nor do they cease altogether before the approach to the True Horizon; but if the visible distance of the Moon from the Vertex could be less, and afterwards, when the Moon is in the Horizon, the visible would evade greater, [and] could be made equal to the true, then, if the equal should evade the true, the Astronomical Refraction would cease — which is impossible.

Proposition XXXII

Of the planets (the Moon excepted) above the Apparent Physical Horizon, the Distance from the Vertex visible is greater than the True, so long as the Astronomical Refraction lasts as a sensible [quantity]; but the first sensible Refraction ceasing, the Visible is equal to the True, and thereafter [becomes] greater than the True, so long as the parallax lasts as a sensible [quantity]; yet it is always equal to the True when they lack a sensible parallax.

§60. Since indeed from the moment at which, in the physical horizon, the [planet] appears — in which the Visible is less than the True — before it become equal it always perseveres greater, when it cannot pass continually to a lesser and equal, unless it leap beyond the equal at the same time and in the same kind; and so it does not evade equal except when the first [moment of] the most parallel refracted ray, when the line of the true place ceases, and the visible distance evades equal by force of the refracted ray. And the refracted ray of Optical Refraction can indeed be remarkable, yet Astronomical [Refraction] can be so slight as to be insensible. Thence, the Star ascending, it is not seen by an ample [angle] through the refracted ray, which is sensibly diverse from the parallactic; rather there persists [a refraction], so long as the parallax lasts as a sensible [quantity], when the parallactic line with the Vertical line makes the angle external, greater, internal, and by the opposite of the parallactic Triangle, [it makes] the distance from the Vertex seen parallactically greater than the true distance, since that one measures the internal angle external; and the opposite as foretold. But in the Fixed stars, which lack sensible parallax, the Refraction ceasing, the Visible Distance is equal to the True.

Proposition XXXIII

Of all the planets (the Moon excepted) and of the fixed stars appearing below the Physical horizon, the Distance from the vertex visible is less than the True.

§61. For when they appear in the physical horizon, the visible is less than the true by Proposition 26; but it could before this have been greater than the true, [and] could before have been equal to the True; yet it could not be equal to the True except by the Astronomical Refraction ceasing, since it consists, by Definition 20, in the difference between the True distance and the refracted visible; because the refractions about the horizon, and in the ascent of the [planet] itself, never cease; nay, they persevere greater, until the parallax is external — neither is there obstruction to the elevated eye, which sees the Stars below the horizon, through the refracted ray below the horizon tending upward, and making with the vertical line a greater right angle; for never, however high it be elevated, will the distance of the refracted ray from the vertex be greater than the true — that is, that which we shall be about to teach of Mars at Perigee, of all [the planets], the Moon excepted, nearest to the Earth, in the following Problem.

Proposition XXXIV

Given the Distance of a Star from the center of the Earth, and the altitude of the refractive Air (in the parts of which the semidiameter of the Earth is known), and also the depth of the Star below the Horizon: to investigate the maximum distance of the [star] itself from the vertex from an eye placed within that Air, [the star being] visible at the highest by the Refracted Ray.

§62. Let it be: in Figure 12, A is the center of the Earth and of the circumscribed Air, the vertical terrestrial quadrant is BIC, whose semidiameter, or radius, is AI, and the Air's Refractive quadrant is OKD, whose Altitude is IK, the Vertical line is AV, and the Horizon is that in which Mars is at M, depressed by 1° , and therefore, the line AM being drawn to it, the

Diagram. A figure showing two concentric quarter-circle arcs in the upper-left of the column. From a lower-left corner (A) rise a vertical line and extend a horizontal base. The inner arc represents the terrestrial quadrant and the outer arc the refractive-Air quadrant. Straight rays are drawn from A across the figure to points on the arcs and to interior points, with a long oblique line reaching the lower-right (M, the position of Mars below the horizon).

- V (top of the vertical): the vertex / zenith
- O (upper-left, on the outer arc near V): point on the Air quadrant

- T (interior): intermediate point on a ray
- B (interior, near V): point on the terrestrial quadrant (BIC)
- K (interior): point on the refractive-Air arc (Altitude IK)
- L (interior, right): point on a ray
- A (lower-left corner): center of the Earth and of the Air
- C, D (along the lower portion / base): points where the arcs meet the base (terrestrial quadrant BIC; Air quadrant OKD)
- I (on the base, between A and the arcs): point on the terrestrial radius AI
- H (lower-right of the base): horizon point
- M (far lower-right): the position of Mars, depressed 1° below the horizon

angle of the true depth HAM is the degree of one [degree]; but Mars's ray, touching the Air at K in the Vertical KM, does not stand beyond the highest in the Air-elevated [region], because the altitude of the rising is the least IK, let it be BO, let it be admitted at the point of contact, which is OK, since AK and AO are equal, the Triangle AOK will be isosceles, and the angle at the base OK [will be] equal by Proposition 15, Book I of the Elements. Now if the ray be drawn down a little below the point of contact K, the air, [when] refracted, must be at the contact K, so near, that the more the refraction will be sensible, [the more] another OK, or how much lower it enters, by so much less highly will it be refracted, on account of the greater inclination of the incident ray, nor will the refractions pertaining to that contact O reach the eye, but they will fall there on the side toward B. The proposed thing now is to investigate the Angle VOK, the distance of the visible Star from the eye, that we may know which is greater or less than the angle VAM, the True Distance from the vertex, when we have assumed it as $91'$. And indeed at Mars's Perigee, since here, the Moon excepted, the planet at maximum accedes to the Earth, and hence judgment is taken concerning the more remote Stars.

Now indeed (as Book 7 of the *Almagestum Novum* [*Almagestum Novum*], Section 6, Chapter 1, [shows]), Mars's distance at Perigee from the Earth is the terrestrial semidiameters 247, and by our *Geographia Reformata*, the terrestrial semidiameter AI is 3690 Bolognese miles. Therefore Mars's distance at Perigee from the center of the Earth — that is, AM — is 871,630 miles of those, the Altitude IK, or the Air's refractive [height], at the most that it can be, being 50 miles; and so the whole AK is 3740 miles. In the triangle AKM therefore, having the rectangle at the point of contact K, Mars's Parallax AMK will be $1^\circ 28' 8''$; but let it be by abundance $1^\circ 30'$; therefore by 32, the angle of the first elements KAM is $89^\circ 48' 26''$; the angle KAH being removed, $88^\circ 18' 30''$; therefore the residue OAD, the complement of the angle OAK, [is] $1^\circ 30'$; and by the first elements of the

distance VOK, $90^{\circ} 10' 45''$, less than the angle VAM by $91'$, and the Astronomical Refraction by $18' 15''$, by which distance from O is less, if the [angle] be 50, [or] AK less by 50, if the Star be at M, and from the Earth greater; so therefore it is less, if these all concur, as in all the other Stars it comes about, the Moon excepted. By the same method, moreover, the same will be shown, if the Star be set below the True Horizon by several degrees.

For the Moon

§63. Let us now experiment in the Moon by the same method, and so: the distance of the Moon at Apogee AM, of the terrestrial semidiameters from the highest 70, the rest as above; so that, as above of Mars, the parallax AMK will be 50, approximately, and finally VOK $90^{\circ} 55'$, less than VAM, less by $5'$, as by Proposition 32; let it be of the Moon's distance from the Vertex $84^{\circ} 30'$; let there be added to it $11'$; the refraction is established at the Vertex $11'$. But from observations of Refractions about the horizon, the Moon's distance at Perigee being of the terrestrial semidiameters $11'$; let the parallax AMK be $66'$; and finally VOK $91^{\circ} 6'$, greater than the angle VAM, but by minutes more nearly $6'$; therefore the Moon's depth below the horizon is less than an integer degree, since

[Top of right column, continuing §63:] when first it appears refracted to the eye O, let us experiment what may happen in both cases of the Moon, namely at Apogee and Perigee, when it is in the True Horizon, in which we feign the Moon to be at A, the Moon's least parallax at Apogee AMK, let it be 50. The angle therefore KAO, [is] $89^{\circ} 10'$; and OAK [is] 50, the angle AOK [is] $89^{\circ} 35'$, and VOK [is] $90^{\circ} 25'$. But at the Moon's Perigee the maximum Parallax AMK, [if] it be $1^{\circ} 6'$, will be OAK, [a] degree $1^{\circ} 6'$, and AOK [is] $89^{\circ} 27'$, and VOK [is] $90^{\circ} 33'$. Wherefore, that the excess be safe by $30'$, [the] visible distance is greater than the true from the Vertex by some minutes; the Moon cannot exist below the true horizon unless [its] parallax be less, [and] the Moon's Apogee be refracted; but it appears refracted to the eye O, when, however, the Apogee [is] rather to be above that [horizon] by a few minutes. One must beware, lest these be feigned out of impossible cases of certain [stars]. It is enough that we have tried it, because perhaps it could happen at the eye O, since indeed out of so great an altitude of the eye we cannot observe, [and so] we cannot render these things more certain. Certainly, in the meantime, we presume that we can have the depth of the more remote stars [greater] than the Moon's, when first it appears to the elevated eye, unless [from] the thickness and density of vapors a horizontal [refraction] obstruct, [and] as much the refracted rays retard; nay, they do not appear, unless elevated above the horizon, which often [happens].

§64. Let us absolve, in the meantime, the Rules of conversion, which we began at Proposition 27.

Proposition XXXV

To resolve the conversion of the Distance of the Stars from the Vertex, both Visible into True and True into Visible from the vertex, and likewise of the Altitude absolutely.

I. Rule. Of the Moon, you will convert the Visible Distance from the Vertex into the True by first subtracting the Refraction [and] Parallax, and adding the residue to the Visible distance.

II. Rule. Of the Moon, you will convert the True Distance from the Vertex into the Visible by first subtracting the Refraction [and] Parallax, and adding the residue to the True Distance.

III. Rule. Of the Moon, you will convert the Altitude into the True by first subtracting the Refraction [and] Parallax, and adding the residue to the Visible Altitude.

IV. Rule. Of the Moon, you will convert the True Altitude into the Visible by first subtracting the Refraction [and] Parallax, and adding the residue to the Visible Altitude.

V. Rule. You will convert the Visible Altitude of the Fixed stars into the True by subtracting the Refraction from the Visible Altitude.

VI. Rule. You will convert the True Altitude of the Fixed stars into the Visible by adding the Refraction to the Visible Altitude.

The contrary must be done for obtaining the Distance of the Fixed stars from the vertex: for the Visible is to be added, and the True subtracted.

VII. Rule. You will convert the Visible Altitude of the other Planets into the True by subtracting the simple Refraction from the Visible Altitude. But if the Refraction be composed of Parallax, and that as in Tycho's [Tycho Brahe's] Solar [Table], subtract the greater Solar Parallax, and subtract the residue from the Visible Altitude; on the contrary, if the Parallax be greater, add this Refraction to it, and subtract the residue from the Visible Altitude.

VIII. Rule. You will convert the True Altitude of the other Planets into the Visible by adding the simple Refraction to the True Altitude. But if the Refraction be composed of Parallax, and that as in Tycho's [Tycho Brahe's] Solar [Table],

subtract the Solar Parallax from the Refraction, and add it to the True Altitude; but when the Parallax exceeds the Refraction, subtract this [Refraction] from the Parallax, and subtract the residue from the True Altitude.

It would be necessary, moreover, to have Tables of Refractions for the True Altitude, since they are wont to be made only for the Visible; and yet, by an artifice similar to that one which I have handed down at Proposition 4, the Refraction agreeing with the True Altitude can be elicited.

Proposition XXXVI

To investigate the Distance of a Planet from the center of the Earth, and hence its Parallax, supposing the altitude of the refractive Air (in the parts of which the semidiameter of the Earth is given) and the given true [place] of the Planet

A Supposition

[Margin: 65]

Let it be supposed here that the Fixed Stars stand so far distant from the Earth that they suffer no perceptible parallax, whether viewed from the center of the Earth or from its surface—and indeed not even from the surface of the refractive Air, since that Air is not raised more than about 50 Italian miles, indeed scarcely 20, above the dictated points. (On these matters see *Almagestum Novum* [Almagestum Novum] Vol. 2, Book 10, Sect. 6, Prob. 51.) Consequently the two straight lines drawn from any Fixed Star—one to the center of the Earth, the other to the surface of the refractive Air—are to be considered perceptibly parallel.

This being granted, in the following figure (which is part of the preceding figure, already set out), let the Sun stand, for example, at G, and the Fixed Star at F, as was said in num. 41. Let the visible incident ray be FGI, and so the two visible objects must lie at the same apparent distance from the vertex, that is, at the same angle VBI, since both are now brought to the Sun G along the straight line AG from the center of the Earth.

Diagram. A refraction construction repeating part of the larger figure from the previous chapter. A roughly horizontal baseline runs from A (lower left) to F (lower right), with intermediate points G and E along it. Above A rises a short vertical sequence of points K, V, B, H, O, I, with a curved arc sweeping from the upper-left points down toward F. The numeral "15" labels the figure at upper right.

- A (lower left): center of the Earth
- F (lower right): position of the Fixed Star
- G (on baseline): position of the Sun
- K, V, B (upper left, vertical): vertex / zenith line points
- H, O, I (upper left): intermediate refraction points on the incident ray
- "15": figure number

These things prepared: since in triangle ABI the refraction of the Air is given, together with the semidiameter of the Earth, the altitude AI, and the parts in which the semidiameter of the Earth AB is given, and since the apparent distance from the vertex VBI is given by observation, the angle ABI then becomes known, and by trigonometry its complement BAI is also found. By the same operation, since the refraction BIK has a known relation to the equal refraction of the Fixed Star, the angle AIK becomes manifest, and from its two right-angle complement we get AIG.

Next, since the observed distance of the visible Sun from the vertex is given at that moment, the true place of the Sun is given from the Astronomical Tables, together with its true declination, and from that, with the time before or after midday and the altitude of the Pole, the true distance of the Sun from the vertex VAG is found by trigonometry. Subtracting this from BAI gives the angle IAG; and in triangle IAG, in which the side AI is also known from the semidiameter of the Earth and the altitude OI, the distance AG—that is, the distance of the Sun from the center of the Earth—does not lie hidden. So if the refraction of the Fixed Star observable by Astronomers from the center of the Earth were the Optical Refraction... But these same Astronomers observe only the simple Astronomical refraction, namely the bare difference between the visible and true altitude of some Fixed Star, recognized through the altitude of the Pole, the declination of the Star, its azimuth, and the data; and in the Fixed Stars this is greater than in the Sun, as is plain from Prop. 15 and 16.

By another method we have no need, since this method supposes the true distance of the Fixed Star from the vertex to be already known, and yet it obtains the same visible distance of the Sun from the vertex; given which, first collect the angle ABI in triangle ABI, as above.

Next: since from the declination of the Sun and its azimuth, or from the time and the altitude of the Pole, the true distance of the Sun from the vertex VAG is given, and likewise the true distance of the Fixed Star VAF (if both are computed), the angle BAI becomes known, and likewise IAF. But since the Parallax of the Fixed

Stars is imperceptible, and the angle AIF is perceptibly nil, then IF and AF lie at the same parallel by the premised supposition; and therefore in triangle AIF the angle AIF, the complement of the known angle IAF to two right angles, and consequently the side AOI, without perceptible error, are given. Therefore in triangle AIG the two angles AIG and IAG are given, and the side AOI, whence the distance AG does not lie hidden. Finally in triangle ABG, since AB, AG, and the angle BAG are known, the parallax AGB becomes known.

[Margin: 66]

Proposition XXXVII

[Margin: 66]

To investigate the Distance of a Planet from the center of the Earth, and hence its Parallax, given the visible and true altitude of the Planet, as well as a Fixed Star which at the same moment, and at the same visible altitude as the Planet has or will have, and given the Altitude of the Air—provided that we first take the multiple refraction in the parts in which the semidiameter of the Earth is known, since not from a single but from a multiple Refraction the rays of the same Star reach the Air before they come to the eye of the observer.

This proposition is set down on account of the opinion that the Air around the Earth is suited for perceptible Refractions, not being of uniform density but of varying density and greater density near the Earth, yet not so much, nor uniformly throughout, except over some short span—for which the following diagram is given.

Diagram. A refraction construction. A horizontal baseline runs from A (lower left) through points C, E, N to F (lower right). At the left a vertical column of points rises from B up through D, P, O, M, V, H. Slanting lines and a sweeping arc connect the upper-left points to F and to the points along the baseline. The numeral "14" labels the figure at right of center.

- A (lower left): center of the Earth
- B, D, P, O, M, V, H (vertical at left): successive surfaces / refraction points of the Air rising toward the vertex
- C, E, N (on baseline): intermediate points
- F (lower right): position of the Fixed Star
- "14": figure number

With the Vertical line AV drawn from the center A of the Earth to the vertex V, let there be described from A the portions of the Earth's circles BOC, and of the Air the last refractive arc DIE, and the first refractive arc HMN—as great as the true distance of the Fixed Star from the Vertex requires, that is, the angle VAF, which is given. Then let the whole perceptible refraction—both of the Planet, suppose the Sun, and of the Fixed Star F—be at the same altitude of the Air, and at the same temper of the Air (as we required, if they are to retain the same distance from the vertex), incident at the same point, and through many intervening refractions of the Air: let the first ray FG, at M, where it first refracts toward the perpendicular AI, at P, where it concurs with the radius incident to the center EG, MK, which would necessarily make it fall toward EG (for if it touched only at the point of non-refraction, then IP would be shorter than DK). These things accomplished:

First, in triangle APG, AG and AI are given, consisting of the semidiameter of the Earth AO, and the altitude of the Air at the last refraction at I; and the distance of the visible Planet, and the angle VBI, the complement of ABI. Investigate therefore by the Trigonometry of Angles the angle BAI, from which subtract the true distance of the Fixed Star from the vertex VAF, and you will have the angle PAF, whose two-right-angle complement is the angle APF; and since the whole semidiameter of the Earth AB is not subtended at F by a perceptible angle, lest there be added an even greater quantity OP—of a thousand-some smaller fraction, scarcely 50 Italian miles, which makes the angle far smaller than 50 Italian miles—the angle augments F, if the angle is small.

Secondly: in triangle APG, if BAI, we subtract the true distance of the Planet from the vertex VAG, the known angle PAG; with which, since AP and APG, and the latter VAF, are assumed, the true distance of the Planet from the center AG is found; and from the difference, which is greater than AK, we investigate the distance of the Planet G; this AG, most close to the truth, with what difference is contemptible, as will appear if only you assume AI, in this manner AP, so great—as great as AK requires; the trouble, however, of this limited measure knows the true distance from the Earth, since it is certain that the difference does not reach the integral semidiameter of the Earth.

Method of observing for Propositions 36 and 37 in the Sun

[Margin: 67]

If an evening observation is made, await the Sun very near to setting, and with the instrument permanently set up, and showing each single second, take the visible altitude of the Sun's center...

[Margin: 68]

and at the same moment let another observe its Azimuth, and let him begin to number the time through the perpendicular oscillations until the moment of the noted altitude is reached, so that through the time of motion acquired by that movement, when subtracted, the time numbered may remain; the time at which the noted altitude of the Sun was observed will then be known. For from the declination of the Sun, agreeing at that moment, and from the known altitude of the Pole, the true distance of the Sun from the vertex for that very moment, when its visible distance from the vertex was taken, becomes known. Then await the following night, and for some of the noted declinations of the Fixed Stars, and to that selected by inspection of the Star-bearing Globe, the same visible altitude which the Sun obtained will be reached, whether in the same or in a different Azimuth; and at once at the same Azimuth take the time numbered as above, or acquire it.

[Margin: cum declinatione, & altitudine Poli visam Fixae distantiam à vertice — i.e. "with the declination, and altitude of the Pole, the visible distance of the Fixed Star from the vertex"] We, together with P. Grimaldi [Grimaldi], for taking the visible altitude of the Stars more subtly, made use of a water-level [libella aquatica], and with threads similarly parallel to the Horizon; and where we used it for taking the altitude of the Pole more exactly, in investigating the Azimuth of the Sun we made use of a thread-triangle set to the horizon at a right angle, expecting some noted Fixed Star at the same vertical plane—but the example may perhaps become clearer if the whole foregoing practice is observed; the highest utility requires it, nor a smaller utility in the calculations to be deduced from it. Moreover, the foregoing observation of the star appearing in the Horizon itself, since the Fixed Stars scarcely appear in it unless elevated above it.

Diagram. A schematic of the observing apparatus drawn horizontally across the page. At the left is a cluster of points labeled H, G, C, I, with O, R, S below and F, A at the foot, joined by short verticals to a long horizontal beam (the trabecula). At the right end is a second cluster M, D, Z (upper), K, S, P, R, N, T, B, L (lower), forming the eyepiece/pinnule assembly. Below the beam at the left a vertical drops to V, E, X, Y. A small auxiliary triangle with points a, g, h, b appears below the right portion. The figure illustrates the beam-and-pinnule (trabecula) instrument described in the adjacent text.

- AB (long horizontal): the beam (*trabecula*), 25 feet long
- H, G, C, I, O, R, S, F (left cluster): the pinnule and thread assembly at the head A
- FGHI, KLMN: the forked supports for stretching the threads
- OY, AC: perpendicular lines through the pinnule cylinder
- M, D, Z, K, P, R, N, T, B, L (right cluster): the eyepiece pinnule assembly
- V, E, X, Y (below left): plumb-line points
- a, g, h, b (auxiliary triangle below right): the thread-triangle for the Star

In the year 1656, October 10, upon the beam AB, 25 feet long, P. Grimaldi [Grimaldi] and I placed it nearly: a metal tube, whose convex lens was AC, & BD, of crystal, the same tube fixed beneath with iron screws, or orthogonally inserted into a red tube, or supported on the beam, so that water could not stand in either tube—continuous; upon the same beam were two forks FGHI, & KLMN, from which the threads could be stretched at once into the altitude of the water infused in the tubes, the crystalline water resting in its own equilibrium. At the head A of the beam was affixed a little cylinder OV, in which the perpendicular line OY ran, in which tube AC, through which the little cylinder of pinnules X could be moved up and down, so that it might stand at once in any position. These things prepared, by hand we frequently filled both tubes AB per both, until the water stood level in O & C, conserving the beam in a horizontal position, whence we knew the Sun to rise: soon, and the rising of the Sun extends us toward the thread QR, & ST, so that it was parallel to the horizon, and at once by its drawing it converges those forks in O, & in P, & is now in equilibrium at rest. Meanwhile the Sun ascended some degrees above the Horizon, & at the same situation, so that it might stand, P. Grimaldi observed the discus through the thread ST cutting the visible Sun bifariously, observing the impressions of the altitudes with the eye and the upper rib of the costume of the pinnules X, in V, collected; & the pinnules moving downward, until its upper edge with the thread ST concurred, beneath the Sun Z, situate at the same point V, in the extreme pinnules, P, in the thread ST, & Z, the center of the Solar discus. I however observed at the same moment by the sign given to me by P. Grimaldi: in triangle SVP, of whose latitude *ab* is the angle perpendicular, & cut at right angles at the horizon, converting toward the Sun thus, with the truth; thread *ab* would coincide in the plane of the horizon at the very narrow Iron Rule, *he*, which since about the center *a* it moves, & the thread *ac* affirmed superimposed at the head of the Iron Rule, the points below; & afterward most accurately we obtained the Azimuth of the Sun through some Fixed Star.

[Margin: The line RK, however, is produced from this V, so that it goes to P. —
Linea RK, inselligitur producta hinc visa, ac vt inde visa ad P.]

[Margin: 69]

But on the following night we awaited until the Lucida of the Aries reached from the center to the Azimuth designated through the thread-triangle *abe*, in which the Sun had stood in the morning, when namely in the same straight line stood the eye *b*, & two threads *ab*, & *ac*, & the center of the Star *g*; at once its distance from the vertex was taken, which is gr. 44. 24. beyond the perceptible distance of refraction. Therefore in the spherical triangle APV, with three known sides, namely AV, the distance of the Lucida from the vertex gr. 44. 24. & its Tycho[nic] [Tycho Brahe] declination boreal, which was then gr. 21. 49. 40. complement AP, gr. 68. 10. 20. & of the altitude of the Pole in our observatory the complement VP, gr. 45. 29. 50. Wherefore through Trigonometry it is examined; from this azimuthal triangle there comes out the azimuthal angle to this Star *g*, & the Sun in that situation remains, observed common AVP, gr. 104. 58. 50.

[Margin: 70]

From our and P. Grimaldi's [Grimaldi] Table constructed for the whole Year, under the altitude of the Sun gr. 4. 6. 13. below which the Sun was observed, it is given for hour 5. 6. 13. before midday on October 11, that is hour 18. 53. 47. after midday on October 10, & the Sun was very near it at gr. 18 ½. the time equated Tycho[nically] [Tycho Brahe] would then be 18.48. & since the moment of the observation in our Solar Tables above is settled, the true place is given gr. 18. 30. ½. & for that the mean Anomaly Sign. 3. gr. 11. 50. 29. but the true Sign. 3. grad. 9. 13. 17. for that place both of the Sun, & of the obliquity of the Ecliptic settled above gr. 23. 30. 20. it follows the declination of the Sun austral gr. 7. 16. 15. Therefore in triangle SVP, VP is given, & as above gr. 45. 29. 50. & PS constant from the quadrant, & the declination of the Sun, namely gr. 97. 16. 15. & the Azimuthal Angle AVP, num. 27. is found gr. 16. 0. whence per the laws of Triangles it is gathered the true distance of the Sun from the vertex VS, gr. 85. 19. 6. but at the visible it was gr. 85. 9. 47. therefore the Refraction of the Sun is Astronomical, & simple, gr. 0. 9. 19.

[Margin: 71]

The following night between the 12 & 13 of October, with the same serenity persevering, & with the temper of the air which had been on the preceding days, with the same instrument, of which num. 68, the little torches moved away, into the eyes however not running, but illustrating them, was awaited Aldebaran,

until it came to the same visible altitude in which the Sun had been, the Sun obscured by the Pinnule in its pristine situation at V, & a little after the trabecula was converted toward this altitude opposed in the same equal water; at once Aldebaran Z, was in a straight line VP, onto, whence it is Perpendicular oscillating numbered the time, until the distance of the Lucida of the Aries from the vertex was caught, which was gr. 54. very precise, & the time was found between the lapse of a minute...

of minutes 6'. 45". of which to the Equator are owed gr. 1. 41'. 15". which are to be referred. Meanwhile in triangle APV, with VP given, & as above gr. 45. 29. 50. & VA, gr. 54. & the complement of the declination of the Lucida of Aries, as above gr. 68. 10. 20. it gathers the angle to the Pole of the World APV, gr. 60. 23. 13". but the difference of right Ascension of the Lucida of Aries, & Aldebaran Tyconic [Tycho Brahe] gr. 37. 3. 44". and to this time, which added to the gr. 60. 23. 13". & the interval of time gives gr. 1. 41'. 15". makes for the distance of Aldebaran from the vertex example gr. 74. 13. 38". & VP, gr. 45. 29. 50". it gathers the True Aldebaran distance from the Vertex VS, gr. 85. 19. 22". for which moment, when found at the distance from the vertex seen so great, as much as of the Sun namely gr. 85. 9. 47". therefore of these the difference, that is the Refraction Astronomical simple of Aldebaran was gr. 9. 35". which is Tyconic [Tycho Brahe] gr. 10. 10".

[Margin: Refraction of Aldebaran — *Refractio Aldebarae.*]

[Margin: 72]

Let us now return to Figure 13, set out above, in which is given of the Sun the distance from the Vertex visible & true observed VBI, gr. 85. 9. 47". & its complement to two right angles ABI, gr. 94. 50. 13". & since the semidiameter of the Earth is taken for now AB, of German miles 1000. & AI, for the summit 1010. as much, however, as no one of expert Astronomers admitted, with *Almagestum Novum* [Almagestum Novum] Book 10, Almag. Nov. sect. 6. Prob. 51. we shall show the altitude of the refractive air not to be greater than 50 Italic miles, & about 20. to consist of this German 5. Nor is it needful that this be very true, & a small proportion between AB & AI; this being given, by Trigonometry we investigate the angle BAI, grad. 7. 30. 8". which subtracted from the distance of the Sun from the vertex gr. 85. 19. 6". leaves the angle IAG, gr. 77. 48. 58". the same with BAI, subtracted the true distance of Aldebaran, which num. 29. having got we were gr. 85. 19. 22". leaves IAF gr. 77. 49. 14". & therefore the angle FGS, will be 16". Since however from the very great distance of the Fixed Stars from the Earth the assumption of their parallax AFI, not to mention AFB, is imperceptible, & therefore AF, & AI, & at the same parallax, the parallax AGI

follows, in this final place 16". but in geometric rigor the third part of a scruple very small was the parallax of the Fixed Stars AFI, & even still smaller the parallax AGB, by example terrestrial estimated.

[Margin: 73]

But since it is certain there is not so great an altitude of the Air or first, until the last refractive, assumed the same AI, of German miles 1010. of which AB; 1000. for from this angle BAI, gr. 4. 30. 13". it follows the angle BAI, gr. 4. 30. 13". which subtracted as above grad. 85. 19. 6". & VAF, gr. 80. 45. 14". it relinquishes the angle VAG, grad. 80. 45. 1". & IAF, grad. 80. 45. 34". Wherefore the difference of these GAF, will be as above 16". & since only the Sun's parallax AG, by physical rectilinear parallelism AF, & IF, supposing, will rather be the same external angle AGI, so much greater than GAF, by however much you suppose in the third or fourth scruple of the parallax of the Fixed Stars AFI, & since it always happens, however much, you assume AI, if the Sun's Parallax within a second we neglect Thirds we choose, the distance of the Sun from the surface AG, nothing however will vary, with how much variation of the angle laterals AI, then of the variation of the angle IAG, & AIG. main in itself caused IAG, is gr. 4. 30. 13". in the second case IAG, is gr. 80. 45. 18". & IAF grad. 80. 45. 34". then AIF, or AIG gr. 99. 14. 26". from which it follows the interval of the Sun AG, of German miles 1259487. of which AI, is 1010. Finally if we assume AI, of German miles 1005. of which AB. for 1000. & the angle, ut supra ABI, grad. 4. 53. 13". varies, easily from the preceding method BAI, grad. 2. 38. 49. 24". so IAG, grad. 80. 40. 16". 36". & IAF gr. 12. 40. 32". 16". & AIG grad. 97. 19. 48. 24". always; AGI, 16". & AG, miles 11245. of which AI, 1005. of which AB, is one. Whence in triangle ABC, with AB, 1000. & AG, ut supra, & BAG gr. 85. 19. 6".

[Margin: 74]

it follows the parallax AGB, 15. 59". & horizontal 16". Hitherto we have hunted the parallax of the Sun together with the difference of it from the Earth distant, supposing the altitude of the refractive air, & at the same time the Refraction simply both of the Sun, & of the Fixed Star, but if we hunt only the parallax of the Sun, but of another Planet we inquire, the expedition will be in practice and below.

Proposition XXXVIII

[Margin: 74]

Given a Planet, & some Fixed Star obtaining the same Visible altitude, although unknown, & at the same diverse time obtaining it, the True altitude, for some moment of time, which they singly have at equal altitude visible; the same; the density of the refractive air remaining, there is straightway given the Parallax of the Planet, although the Parallax is imperceptible or unobservable, or observable, & given the data.

For the difference of the True altitudes of the Planet, & of the Fixed Star itself is the Parallax, which we inquire, if the Fixed Stars' parallax is indubitably nil; but at the same time it is supposed that, if at the same time it is observed, & its aggregate parallax, of the same difference, it constitutes the Parallax of the Planet, besides another calculus Geometric. Which that it become clear to the soul of the Reader, examine the figure 13. in which let be feigned to be in the same plane Vertical of the Planet G, & of the Fixed Star F, when both obtain the same Visible from the vertex distance VBI, & along the laws Anaclasticas; & in the same incident line FGI, there will be of the true distances from the Vertex differing the angle GAF, or therefore the parallax of the Fixed Star AFI, & the same surface, of the surface estimated, supposing imperceptible, & then the true angle AF, & IF, sole at the same surface AGI, in this very place 16". & since however the semidiameter of the Earth OI, ex dictis lib. 10. Almag. Nov. sect. 6. Probl. 51. not at the very greater miles 40. but at the very thousandth part of the whole AB, & Distance AG, & BG, & SG, are at the same equals; therefore the excess at the angle AGI, & therefore vel imperceptible, vel by example, vel more notable for AGB.

[Margin: 75]

We suppose however the observation of the Planet, & the Fixed Star to be made at the same night, or if the Planet at the Sun, made within at the same Distance of the refraction; & since that condition is judged not in itself in things estimated. Nor obstructs in any practice; that the Planet, when observed, has been in different vertical at the eo, in which it was; or shall be the Fixed Star, when the same, or perceptibly visible at the same altitude obtains, vel observed; & therefore it is, as if it were transferred to the same Vertical; but in this, two we suppose nil Astronomical, & Anaclastica to be denied known. First it is that all the Fixed Stars created are by God, vel credible at the same Vertical, & at the same center of terrestrial radiance; & at the same vertical at the points superficial of the air refractive at some equal, inclination at perpendicular; having at the same refraction posited at the same surface of the air density, & the same not only visible, but also true distance at the vertex. For in the foregoing num. 13. figure, if so you conceive the Triangle AFG, double to be, & one in one, the other in another

truly Vertical; if at the same Distance AF, on both; equal it is, & at the point I, equally high from the Horizon, equally as the arc EI, namely the angle IAE, & the radius FI, incident inclined at perpendicular AH, equally angle HIF, would have impressed at the same angle, the same at the truly; angle AIF, the complements of angles HIF, & at two right angles will be equal among themselves, & likewise; IAF, twins among themselves, & therefore the Angle F, among themselves, & not only F, the twins among themselves, but at the same sphere of the air at the terrestrial semidiameters AI, among themselves; therefore added an equal angle VAI, evades the distance from the vertex VAF, on both, equal. **Secondly we suppose**

at the moment at which some planet has been observed — as the Sun was in our example — that it could either be found in the same vertical circle (or one created by God in some way to be a fixed star), and direct from the center of the Earth, where it is sought, and shine to the same point; such a star would then have the same refraction and the same observed distance from the vertex. And since it would shine to a point higher than itself, namely to that point in whose vertical the other fixed star lies — when it would obtain a visible distance from the center of the Earth equal to the visible distance of the planet from the vertex — it would have an equal visible distance, and therefore would exhibit an equal parallax of the planet. For this reason, even if the two observations were not made at the same instant formally, they were nonetheless made equivalently, and so as if they had been made at the same instant.

Method of Observing for Proposition 38, in the Case of the Sun

[Margin: 76]

First, so that the error in the Sun's declination may be as small as possible, make the observation either at the solstice or as near to it as possible — because around the solstice the Sun's declination changes imperceptibly — taking the Sun's altitude with the kind of instrument we described above, or another, and observing the Sun's visible altitude. Note its astronomical (not optical) situation as to quantity; and let an assistant direct the cross-thread of the triangle of threads toward the center of the Sun, and hold it fixed there immovably. **Second**, on the night following, [observe] the chosen fixed star — a star whose transit falls at an altitude at least 20 or 25 degrees high, so that it reaches the same vertical above the refraction still sensible at that altitude — and at the very moment it arrives at the vertical plane marked out by the two threads of the same triangle, [measure] how great its greatest distance from the vertex can be obtained, with

all the subtlety attainable; for that is the complement of its declination. Then by trigonometry the azimuth in which the Sun stood will be obtained: this is the **common azimuth** — the one shared vertical, the sightline linking the Sun and the star — in which the Sun was. Therefore, since on the solstitial days the declination can be regarded as scarcely changing, and since by the clocks you will know the time when the Sun was observed, you have its declination free of error as to position; and from the complement of the declination just stated, together with the distance of the Pole from the vertex, trigonometry will yield the Sun's true distance from the vertex sought for that moment — namely the distance the Sun had before sunset, when it was observed. And so let the assistant observe at that prior moment, fixing the triangle of threads at the Sun's very center, but always holding it motionless, for the azimuth to be sought. **Third**, on the same night, the air remaining at the same temperature, let one wait until some fixed star — by inspection of the chosen globe and of its declination — comes to an altitude beyond sensible refraction, that is, at 20 or 25 degrees, and at the moment it reaches that plane [marked by the threads], let the most exquisite measurement of its distance from the vertex be taken. For from that, and from its declination — or from the complement of the declination, the distance of the Pole from the vertex being obtained — you obtain the common azimuth in which the fixed star itself stood; and, taking the declination of the prior fixed star as equal in altitude, with the adjacent side and the distance of the Pole from the vertex obtained, you will have the Sun's true distance from the vertex. This **ought to be greater** — the Sun's true zenith distance must come out greater than the apparent comparison derived from the unrefracted star, because refraction makes the Sun appear higher (with a smaller apparent zenith distance) by Proposition 9 [?] — and this difference will be the solar refraction to be applied as a correction (the source here prints "Parallax Solis corrigenda," "the Sun's parallax to be corrected," where the logic of the chapter requires *Refractio*, "refraction" — see anomaly), somewhat as said above.

[Margin: 77]

Proposition 39

Given the astronomical refraction of fixed stars lacking sensible parallax, the observed altitude of those same stars being agreed, and of the Sun, or of any planet, at the same observed altitude, and in the same density of air, azimuth, or declination, and at the same moment of time, together with the altitude of the Pole: the simple astronomical parallax of the Sun, or of that planet, is given — provided its simple astronomical refraction [is also given].

For the refraction having been subtracted from the observed altitude of the fixed stars...

their true altitude is had; and from the remaining data of the other planets, the true distance of the same from the vertex corresponding to the observed [distance] is had; and so the simple astronomical refraction, and the true altitude [are had]: finally, the difference of the true altitudes of the planet and of the fixed star is the parallax of the planet, by the preceding Proposition 38 — provided the true altitude of the planet comes out greater than that of the fixed star. From this it follows that, if at sunset, or at sunrise, the physical azimuth of the Sun, and above all the azimuth of the fixed stars, were observed, that observation could not have been made unless the difference of its distance from the vertex were known; and supposing the horizontal refraction, or the parallax, if the horizontal refraction of the fixed star is supposed to be that which suits it, the horizontal refraction of the fixed star would be that, which suits it — which is agreed upon in the very sensible point itself. The only doubt that can remain is whether the density of air was the same in place and time as that under which the refraction of the fixed stars was observed, and when the Sun is observed.

Probable Conclusions Concerning the Parallax of the Sun, for the Time Being

[Margin: 78]

First Conclusion. Through the preceding practice the parallax cannot be known with certainty, with that subtlety which more recent astronomy requires — so much so that this conclusion now requires the exclusion of an error of the very fewest seconds. For now indeed, from the lunar dichotomies, and the parallaxes of Mars, and others, by arguments we have come to know that the horizontal parallax of the Sun is much less than one whole minute. Although an instrument can be made so large, and the semidiameter of the divided circle could exhibit individual seconds — as the more learned teach (chapter 1, number 3 [?]) — yet so great are the errors in the division, and in the subdivision of the degree and minute, and in the placement, and in the use of the dioptra, and so on, and in the collimation toward the center of the star, and in the placement of the instrument itself, [even with] the most correct rectification and horizon-setting, that one can err by several seconds, or at the very least by single seconds in individual observations. Moreover, the said practice requires six points of astronomical elementary data, namely: the altitude of the Pole, the declination of the Sun, the observed distance of the same, the azimuth, or the observed declination, or the

moment of time of observation, and of these two the observed declination, or the observed azimuth; and so all things computed, however subtle the observation, can be collected from the errors, or from the errorlets, by more than 1 minute, more than 5 seconds. Furthermore, from the said data the same density of air is required, when the refraction of the fixed stars is observed at the altitude at which the Sun was observed, and so the fixed star with the Sun, neither the fixed star with the Sun, [whether] at once or just before, or just after, can be glimpsed; but by day, here by night perhaps it is visible; always the night is ambiguous, [as to] whether the air was denser by night than by day. Hence with such uncertainty it will be confirmed [in what is] to be said in the chapter following on the refractions of the Sun, and of the fixed stars observed by [Tycho Brahe], number 8.

[Margin: 79]

Second Conclusion. Since, however, through the preceding practices we have always found the horizontal parallax of the Sun less than 30 seconds, and have apprehended the same through several dichotomies, we therefore decided that it is not greater; and, as the more probable position, we have adopted and still hold it to be $19''\ 8'''$ (nineteen seconds, eight thirds) at Perigee, and $27''\ 8'''$ (twenty-seven seconds, eight thirds) at Apogee. (The source prints these as "19". 8"." and "27". 8".", with a double-prime on each figure; the leading double-prime on 19/27 is a compositor's reuse of the " sort for the thirds order — both values fall under the "less than 30"" ceiling the same sentence asserts. Note, however, that the apogee value ($27''$) is printed *larger* than the perigee value ($19''$), which is physically backwards — the Sun's horizontal parallax should be larger at perigee, when it is nearer; the Perigee/Apogee labels appear transposed. See anomaly.) We incline rather to the opinion of those who think it even smaller; but we do not acquiesce in those who contend that it is altogether insensible, so that the system of the Sun and its planets, together with the fixed stars, could be raised to infinity around it; but see the end of Chapter 13.

[Margin: 80]

Third Conclusion. However great the parallax of the Sun may be (at the same observed distance from the vertex, and of the fixed star, the same, the air being constituted), so much greater is the astronomical refraction of the fixed stars than the astronomical and simple refraction of the Sun, as is the parallax of the Sun. This is clear from Propositions 16, 38, and 39 together.

CAPVT XV.

On the Refractions of the Sun [De Refractionibus Solis]

[Margin: 1]

[Tycho Brahe] taught us the manner of observing the refractions of the stars in the preceding chapter, supplying what he himself omitted; but I am speaking of non-optical refraction, that is, astronomical and simple, which is the difference between the true and the observed altitude of a star, when the observed is greater than the true; and then the composite [refraction], out of this simple [refraction] and the parallax. Now indeed Tycho, in Tome I, *Progymnasmata* page 79, exhibits a Table of Solar Refractions from his own observation in the Danish Horizon; yet he confesses that these same [refractions] vary there in a less serene sky, and in different horizons, on account of the different temper of the air; and on page 94 [?] he affirms that the difference between them can be true; and on page 95, that the Solar refractions are observed on the day of the solstice, when the declination varies insensibly, and he exhorts that the visible altitude of the Sun be converted into the true, by the subtraction of the integral refraction; and on page 102, by example he teaches [this], and by the addition of the parallaxes. Afterward, on page 124, he exhibits a Table of Lunar Refractions in the circle of altitude, constructed by frequent experiment. Finally, on page 280, he produces a Table of the Refractions of the Fixed stars in the circle of altitude from his own observation, where he adds these words worthy to be noted, for the things to be said below: *"If, however, that mathematician [Rothmann] of Landgrave [William IV] in his Cassel [observations] should be shown to hold rightly, the refractions which he admits there for fixed stars are nearly double those [admitted] here — concerning which matter [see] in the volume of letters of our collection, [as he] indicates: But I should nonetheless believe that those observations attenuated the refractions of the fixed stars too much by some carelessness of his own. For Rothmann had written, as is had in the Letters of Tycho, page 29, that he had found by himself the refraction of the Fixed stars to be 5' 0" [?] at the altitude of 5° 18', and 2' 1" [?] at the altitude of 9° 42'. But Tycho's [refractions] of the Sun for the most part horizontal, 15', or at most 20', to which Tycho on page 65 responds, that he finds the refractions observed by himself to be nearly double in Denmark, than [those of] Rothmann at Cassel; and this rather [is to be] attributed to the incorrect observations at Cassel, than to the diversity of horizon. Again Rothmann there, page 81, says that the refractions of the Sun near the winter solstice [Bruma] are far greater than at other times of the year. And at last Tycho there, page 159, notes the refractions of Rothmann to be too small, and the twilights too great, [and that]*

these do not agree among themselves; for from the one it follows that the air is rarefied, but from the other that it is more turbid. But it would have been proper to inquire whether the refractions were observed at the same temper of the air, or rather at the same temper of day, [which is] very diverse around the rising of the Sun from that [air] around its setting." So far, summarily, concerning the general foundations of the Tyconic Refractions.

[Margin: 2]

Before we discuss these things, the triple Table of Tyconic Refractions, taken from the said places, must be set before our eyes, which stands as follows.

The right column of folio 57 carries the refraction table proper. Transcribed below as a pipe-table.

Refractions in the Danish Air, deduced by [Tycho Brahe] from his own observations.

Visible Altitude (Gr.)	Sun Refrac. ' "	Sun Refrac. ' "	Moon Refrac. ' "	Moon Refrac. ' "	Fixed- Star Refrac. ' "	Fixed- Star Refrac. ' "

44	0	6	0	5	—	—

Visible Altitude (Gr.)	Sun Refrac. ' "	Sun Refrac. ' "	Moon Refrac. ' "	Moon Refrac. ' "	Fixed- Star Refrac. ' "	Fixed- Star Refrac. ' "
45	0	5	0	0	—	—

Note on the Fixed-Star column: against altitude 22 the source carries the note "*Cessant hic Refract. Fixati, quia Tycho, vt fatetur pagin. 280. supra quartam viam refractiones ad sensum minores 4' ½ [?] insensibiles censet*" — "The refractions of the fixed stars cease here, because Tycho, as he confesses on page 280, reckons the refractions above the fourth course [i.e. above ~22° visible altitude] sensibly smaller, [and below] 4' ½ [?] insensible." A second marginal note opposite altitude 25–27 reads "*Ex repertis Solarib. minores 4' ½ [?]: Ideoq; ex Solis altitudinibus elicuit Fixarum Refractiones*" — "From the solar [refractions] found smaller [than] 4' ½ [?]: and therefore he elicited the refractions of the fixed stars from the altitudes of the Sun."

Parsing notes: the table has five paired (minutes/seconds) columns under three headings (Sun, Moon, Fixed star). Visible altitude runs 0–45° by single degrees. Several seconds-values in the lower altitudes are faint; the Moon-refraction at 40° (printed "25") breaks the otherwise smooth descent (39°→0'25", 40°→0'25", then 41°→0'20") and is flagged. The Fixed-star column terminates at 19° visible altitude (value 0'0"); cells at 20°+ are blank, consistent with the marginal note that Tycho deems fixed-star refraction insensible above the "fourth course."

[Margin: 3]

Not acquiescing, however, in these just causes, I wrote to Father Albert Curtius [Albert Curtz], to whom — by order of the Emperor — the manuscript of the Tychonic observations was delivered, that he might be the supervisor of their typographical edition, that he might not refuse to transmit to me those observations, by which (inasmuch as they were made in the summer solstice) Tycho had most especially, with great confidence, investigated the Solar Refractions — which he most liberally and most diligently provided, a most humane man, and of me most deserving, perfectly well: And these [observations], to be examined by the Reader by trigonometric calculation, if I have ever freely [erred] through carelessness, in good faith transcribed from his copy, I share.

Observed by [Tycho Brahe] at Uraniborg in the Year 1589, on the 11th day of June, [Old Style].

Measurement	Gr.	'	"
Meridian Altitude of the Sun			
Per quadrantem volubilem (by the revolving quadrant)	57	35	45
Per Chalybeum maiores (by the larger steel [instrument])	57	35	30
— or —			25 [vel]
Per Tychonicum (by the Tychonic [instrument])	57	35	45
Et per alterum (and by another)	57	35	50
Declinatio Solis per Armillas (declination of the Sun by the armillaries)	23	29	50
Subterraneas maiores (the larger underground [armillaries])	23	29	50
<i>Erat satis serenum</i> (the sky was sufficiently serene)			

On the same 11th [day], after noon, the following were observed for the Refraction of the Sun in the summer Solstice:

Declination of Sun by larger Armillaries (Gr. ' ")	Altitude of Sun by revolving Quadrant, or larger Steel [instr.] (Gr. ' ")	Azimuth of Sun from Meridian, in the West (Gr. ' ")
23 29 45 / 23 29 50 (<i>altero pinnac.</i> — by the other sight)	35 2 30 (<i>Volub.</i>)	80 40
23 29 45 / 23 29 40	33 22 30 (<i>Volub.</i>)	83 10

[Margin: 23 44] Then the Sun, on account of the Horizon of the observatory, could not be observed, nor could it be raised above the middle of its part beyond the horizon. It was around the horizon of medium thickness of vapors. [i.e.: at altitude 23°44' the Sun, owing to the observatory's local horizon, could no longer be observed and could not be elevated above the middle of its disk above the horizon; the horizon held vapors of medium density.]

On the 12th day of June, in the Morning:

Parsing notes: The 11–12 June observation tables present the Sun's declination as paired armillary readings (two sights / two instruments, transcribed here as "first / second"); these tables continue beyond this batch's page boundary. The left-hand 11-June table and the right-hand continuation are part of one descending series of solar altitudes (from ~35° down to ~1°30'); the 12-June morning table is a separate ascending series. Several seconds-values in the cramped gutter-side columns are faint and are flagged [?]; the declination second-readings cluster tightly around 23°29'–23°36' as expected for the solstice. Tables continue (catchword "Eodem" — "On the same [day]" — at foot of folio 58).

23	35	0							
23	35	50	4	30					

Parsing notes: the marginal notes in the azimuth column ("Today the air was clearer than yesterday") are interspersed comments rather than azimuth values; transcribed in place. The declination column gives paired readings for some altitude entries (the instrument was read twice). The instrument abbreviations — *Volub.* (Volubilis, the revolving instrument), *Q. minim.* (Quadrans minimus, the

smallest quadrant), *Chalyb.* (Chalybs, the steel quadrant) — are reproduced as printed beside their altitudes.

[Riccioli's analysis — right column, page 91]

[Margin: 4] From these data I selected the azimuths of the 12th, and the morning ones, because at that time the air was clearer, and because the solstice had occurred shortly after the middle of the preceding night. For this reason the morning declination of the Sun differed scarcely perceptibly from our maximum declination of $23^{\circ}30'20''$. I therefore chose the altitude of the pole at Uraniborg as $55^{\circ}54'40''$, the value I determined in my *Geographia Reformata*, Book 7, Chapter 21 (Proposition 23, Figure, and Triangle VPL). The complement of the polar altitude PVL is thus $34^{\circ}5'20''$, and the complement of the maximum declination LVP is $66^{\circ}29'40''$. From these, together with the azimuths, I derived trigonometrically the true distance of the Sun from the zenith, VL; and by comparing it with the observed (visible) distance, I obtained the refraction. But this often fails, because the computed true distance frequently comes out smaller than the visible distance, as can be seen in the following table.

[Margin: Tabula Cassini, etc.]

80 57	67	16	0	67	10	10	
85 25	64	24	0	64	21	35	

Parsing notes: the "Azimuth meridionalis complementi" column gives degrees and minutes paired in a single cell as printed. Several refraction-column cells are blank in the source (the computed true distance exceeded the visible distance, so no simple refraction could be entered); the fourth row's whole-degree cell shows a bullet/dot rather than a digit, transcribed as "•". See numerical impossibles below: row 6 (azimuth 63°40') shows a true distance (79°14'54") that breaks the smooth descending progression of its column.

From this it is apparent how unreliable this method by azimuths is, unless at the very same instant in which the center of the star reaches the vertical plane of the determined azimuth, the star's distance from the zenith is taken, with the instrument divided and positioned exactly. For it is more credible that the discrepancy arose from a fault in the observation or from an interval of delay that elapsed — though it is now neglected, as if not perceptibly obstructive — or from the trigonometric calculation, or from a sudden change in the air, or from a false polar altitude or maximum declination of the Sun, or from a scribe's errors in recording the figures. Perhaps several other observations of the many years that Tycho indicates in Tome 1 of the *Progymnasmata*, p. 79, will come to light, from which a fuller examination may be instituted.

[Margin: 5] Don Giovanni Domenico Cassini [Cassini] communicated to me the above-mentioned observations, having selected those of 12 June (the morning ones taken with the Chalybs quadrant), together with the declinations of each set of armillaries, and from them he collected the refractions written below — in each case smaller than those in the Tyconic refraction table. This agrees not

only with Rothmann [Rothmann] but also with Don Vincenzo Muto [Vincenzo Mutio], who observed in Hesse; for the latter observed much smaller refractions in Majorca than Tycho exhibits in his table.

[Cassini's refraction table — page 92 / folio 60]

Anno 1589, Iunij die 12, ex D. Cassini calculis. (In the year 1589, on 12 June, from Don Cassini's calculations.)

Parsing notes: the table has four field-groups — observed solar altitude; refraction from the prior armillary declination; refraction from the later declination; and the difference of the refractions. The second-minutes column of the observed altitude is mostly blank (whole minutes only); the fraction "44½" is printed in row 3. Several lower rows leave the "posterior declination" and "difference" cells blank. See numerical impossibles below: row 14 (altitude 2°26') and several adjacent rows do not maintain a strictly smooth monotone increase in the refraction columns.

[Margin: Contra Gassendus, etc.] Against this, Pierre Gassendi [Gassendi], at the close of the year 1632 and the beginning of 1633, having undertaken at Digne an investigation of the winter refractions, set it out in his *Commentaries on Celestial Matters* contained in Tome 4 of his Works — a specimen of which is in the small table here, and whose use is great parallax [*usus est Parallaxi multa magna* — i.e. the use of these is in matters of large parallax], and therefore the refractions of this kind are smaller.

Altit. ☉ Visa — Gr.	I	Refractio — I	II

40	9	0	0

Altit. ☉ Visa —

Gr.	I	Refractio — I	II
42	48		30

Parsing notes: the refraction values in this small table are erratic (e.g. $22^{\circ}16' \rightarrow 7'6''$, but $30^{\circ}28' \rightarrow 3'0''$ then $35^{\circ}11' \rightarrow 1'0''$), reflecting Gassendi's winter measurements as Riccioli reproduces them; transcribed as printed. See numerical impossibles below.

[Riccioli on Kepler and refraction theory — page 92, lower]

[Margin: 6] Kepler [Kepler], following the precept of the *Rudolphine Tables*, relates that he had observed nearly the same refractions in Bohemia as in Denmark; and he adds that the diversity of refractions can arise from different times — for at full moons, and on a day with abundant light, the air is rarefied for the most part, whereas at new moons, and in the depth of night, with the sky serene and clear, [it is denser]. Kepler, then (in Tome 1 of the *Progymnasmata*, p. 280), acknowledged that the lunar refractions ought to be corrected to make them larger; yet the solar ones he exhibits as larger in the same horizon on account of the excessive solar parallax added to the simple refraction. And nevertheless Kepler says the same thing in the *Astronomia Optica*, p. 123. Rothmann, from the secants of the Tyconic solar refractions, employs a minute of parallax for each [*utitur parallaxi minutorum 5'* — uses a parallax of 5 minutes]. He reformed Tycho's table at the end of Book X of the *Almagestum Novum*, prefacing it with many remarks worthy of note and with problems, both theorems concerning refractions and a calculation at the end of the same book. We added our own tables of refractions for the Sun, Moon, and Fixed stars from the solstice and equinox observations.

I confess, nonetheless, that I once acknowledged together with us nearly to consent in many points; afterward, however, having gained greater constancy both in his observations and in ours, I recognized how slippery this matter is — whether through the air's varying density around the Earth, arising not only from the ordinary causes of the year and the temperaments of the days (since the matutinal and vespertine refractions are greater than the equinoctial, and these in turn greater than the hibernal refractions, and the morning and evening ones greater because the air is then not parched by daytime heat but rather, beyond the ordinary, both at full moons and at the other lunar phases [is denser]).

[Margin: 7] *First, on the refractive altitude of the air* — how great it is, and whether it is perpetually the same in the same horizon — concerning which we

said a little in *Almagestum Novum*, sect. 1, lib. 10, at Problem 43. *Second*, on the shape of that same air, whether it is spherical or rather convex, and hence apt for varying the refractions along an elliptical [path] or otherwise. *Third*, whether the density of the more humid air conduces to augmenting the refractions more than the colder air, and whether on rainy nights, the sky being clear, [it is] denser than on less clear but more tepid nights. *Fourth*, whether the density of the refractive air is uniform or non-uniform and multiplex, causing refractions at the same moment. For it can happen that, although the individual refractions are smaller in less dense air than in very dense air, nevertheless because of the multitude of them arising from the non-uniformity of density, the rays that reach our eyes are refracted higher than we suppose. And so it is certain, or at least probable, that on the days when both we and Tycho and others recorded so great an inconstancy of refraction in their observations — apart from what could have been due to a fault of the observer or of the instruments — we obtained a greater refraction at one time, when we were expecting a smaller one.

For example, in the year 1656, on 19 August, when through a great level [*libella*] we had observed the Sun's vespertine altitude as $8^{\circ}23'16''$, from the time of meridian — 6 hours $23'47''$ — we derived the true distance as $8^{\circ}38'29''$. Hence the simple refraction was $15'3''$. But in the same year, on 11 October, in the morning, when from a double cause — that is, of the matutinal and autumnal seasons — a greater refraction would seem to be in prospect, nevertheless a smaller one was found, since the observed distance of the Sun from our zenith was $8^{\circ}45'47''$, and by the azimuth of the Sun verified against Lucida Arietis [α Arietis], the true distance of the Sun was found to be $8^{\circ}19'5''$; and therefore the refraction was $9'18''$. And so likewise on other days and at other times.

[Margin: 8] It is therefore best to abstain as much as possible from observations at the horizon, or those very near the horizon — or at least one still needs, in the same horizon, very exact observations of altitudes for an astronomy. For if there were none at all, the astronomical refraction tables of nearly all astronomers, ours and others', and especially Tycho's, would be useless in this kind of observation of many years, which he indicates were made [in] Tome 1 of the *Progymnasmata*, pp. 79 and 280. By the double method we use, *first*, in selecting the Tychonic refractions of the Fixed stars, and by subtracting the solar parallax, each person reckons the refraction to be as great as he would judge from Propositions 15 and 38. We there show, in equal visible altitude, the rest being equal, that the astronomical refraction of that star is greater, because the star's parallax is greater [than] from the Earth, and hence greater toward the Earth — inasmuch as the parallax of its own star is greater, [whereas] the Fixed stars lack

a sensible parallax, just as the Fixed stars [are] received [as being so far] removed from astronomers. But because Tycho, p. 280, indicates that from certain observations he had noticed the refractions of the Fixed stars to be about $4\frac{1}{2}'$ smaller than the solar ones, he therefore elicits the table of the Fixed stars from the solar one, subtracting $4\frac{1}{2}'$. Therefore by the surer method we elicit the Tychonic refractions of the Fixed stars from the solar ones, but corrected by subtracting the Tychonic parallaxes — in the middle distance from the Earth — and then by the simple refractions of the Sun, adding the solar parallax, [drawn] from the Tychonic [values], in order that we may have the truer refractions of the Fixed stars. We use our own solar parallax for the Sun; but for the Moon the astronomical refractions are stated to be somewhat smaller than the solar ones. Let the optical refractions be as in Propositions 14, 15, 16, etc.; for so it will appear that the refractions in clear and serene air cease around 30° of altitude, which is the middle opinion between Tycho and Rothmann. For Tycho, in the epistle on p. 108, and Tome 1 of the *Progymnasmata*, p. 91, judged that vapors around the horizon, which make the air thicker, are the chief cause of refraction; [these vapors] render the air denser, but not a proper and natural diversity between our air and the aether; and therefore [the refraction] ceases around 45° of [continued on next page]

altitude. Rothmann, however, conceded that it ceases around 20° , which Tycho granted for the Fixed stars. When, then, neither the air is so serene nor so still, there will be an inconstancy of refractions; no fixed law applies. And these things proceed to better [understanding]. Yet all the summer refractions are found to be smaller, and the winter ones larger, and on the same day the morning ones greater than the evening ones. See, therefore, the refractions [in] our tables.

[Margin: 9] After the foregoing, I found in the celebrated *Ephemerides* of Cornelius Malvasia [Marchese Cornelio Malvasia] — namely in the proem, fols. 155, 172, 173, and 186 — the new doctrine of refractions of Don Giovanni Domenico Cassini, who asserts from experience, certain in all transparent objects he has examined (both solid and liquid), that the refractions of the stars proceed by the same law of variety in different inclinations, although diverse in diverse bodies in the measure of [their] density; and from certain observations he derived, according to that law, a distinct table; and these he separated out into a horizontal solar parallax, the rest being refractions; and the visible solar parallax of horizontal vision he reduced to the first minutes, and to its refractions; and he corrected the polar altitude, even from the circumpolar stars formerly taken, and from certain solstitial observations he similarly corrected, compensating for parallax and refraction, [and] recognized that the same polar altitudes resulted,

and the solstitial ones that proceeded from the circumpolar stars. Hence he did not hesitate to say, fol. 175: "Wherever in a place by those solstitial altitudes I correct, it proceeds from the same elevation of the pole, which the Pole star's altitude furnishes; similarly corrected, it is deduced, the discrepancy never being any greater than in the observations themselves, which inevitably proceed by a discrepancy. For this reason he laid down that his refractions, wherever and at whatever time they are deduced under a clear sky, and from all those stars, the same altitude above the horizon possessing a visible [altitude], agree." *For neither* (so he says, fol. 172) *does any sufficient reason seem to support those who think, on account of the diversity of distances, that in the same altitude the refractions vary.* He asserts, moreover, that the refractions persevere up to the vertex, and finally, fol. 186, affirms: *that the ray of any [body], incident obliquely in the surface of the air at distances from the Earth, descends by refraction along its parallels.* And a little after: *that the altitude of the air is $\frac{6085}{10000}$ of the Earth's semidiameter.* These propositions he proves by no experiment, nor by an established foundation — I believe a proof of them [belongs] to an astronomical work, which he is contemplating; and therefore I have not yet departed from that refractive altitude of the air, of which I treated in lib. 10 of *Almagestum Novum*, sect. 6, at Problems 43 and 51.

[Margin: 10] Furthermore, I am not the only one at Bologna, but [also] Don Vincenzo Muto in Majorca and Rothmann in Hesse and Tycho in Denmark, who detected refractions even up to 45° of altitude; nor are these sensible refractions to be deduced from the Tyconic refractions of the Sun itself, if it is to be shown as above, by subtracting the very solar parallax. For at 14° of visible altitude the Tyconic solar parallax is at perigee 2'50", and the Tyconic solar refraction at the same point 2'50"; therefore at that place the simple refraction of the Sun ought to cease. But whatever may be the case from other observations, with the just cautions meanwhile I cannot — what I most desire — acquiesce, by the advice of friends and most illustrious men who say these things.

[Margin: Primo, etc.] *First*, given that the refractions which we experience in crystal, glass, water, wine, etc., we could distinguish [from] the refractions made in air — not the ray, for example, of the Sun entering glass would first have been refracted at the entry into our denser and thicker air; nevertheless these refractions are not those which astronomy requires, and the optical [refractions] are to be distinguished from the astronomical, as I taught at lib. 10, num. 19 and 20. *Second*, in Propositions 14, 15, 16, etc., we show that in the same altitude, whether visible or true, of stars more remote from the center of the Earth, the rest being equal, the astronomical refractions are greater — this is contrary to the

optical effects of Tycho and others, who confound [these]; for the optical [refractions], at fixed stars, rather than astronomical, assign refractions. *Third*, we show that the simple refractions of the Sun can be obtained without parallax, although these are smaller, as we show at Proposition 25; and therefore we refute Tycho at numbers 21 and 53.

Now indeed Cassini, in all examples, in order to obtain the true altitude of the Sun, adds the visible parallax, and subtracts the residual refraction; and if in his composition the refraction is simple [together with] the parallax, the same cannot be fitted to the Fixed stars, which lack parallax, as the visible parallax was [computed] above, said num. 21.

[Margin: 11] *Fourth*, near the horizon, in the Cassinian table, I do not see that headlong increment of refraction, in due proportion. For example, in his summer table, the refractions stand thus, where the greater is the difference of refraction degree 2 and 1; and the altitude, than degree 1 and 0; with this nevertheless requiring the opposite, the astronomical refractions [being] thus, and likewise in some others in the table — unless an error of the typography.

Alt. — Gr.	Refractio.		Differentia.	
	— I	II	— I	II
2	10	12	4	24
1	0	27	36	6
0	21	4		

Parsing notes: this small Cassinian summer-table excerpt is poorly aligned in the source; the columns (altitude; refraction; difference) overlap. The refraction value "27'36"" at altitude 1° is much larger than at altitude 0° or 2°, which is the inversion Riccioli is criticizing. Transcribed as printed; see numerical impossibles below.

The same equinoctial and winter [table], unless there be an error of the typography.

[Margin: 11] As for the retained solar parallax and the refraction of the stars in the Cassinian [table], and these being applied, in a few cases the same polar elevations result, [arising] not from a prejudged certainty (since we have the case of an insensible refraction of the Fixed stars beyond a degree of altitude), nor from prejudged certainty, [arising] from astronomical refractions of the Fixed stars taken in the polar altitude, the refraction of the Fixed stars exceeding 25° of altitude. And where the polar altitude or solstitial observations are deduced,

[their] refraction is ascribed only to the Sun, whether ordinary, or — as not rarely happens — extraordinary, or by a fault of some particular observation.

Caput XVI — De Constituendis Epochis Motus Solis

(On Establishing the Epochs of the Sun's Motion.)

[Margin: 1] Now in Chapter IV we had the true equinox of the year 1655 of Christ, at Bologna, on 12 September [in] the Gregorian style, at the hour after noon $18^{\text{h}}55'25''$. Hence the midday of 20 [September] [is at] hour $18^{\text{h}}55'25''$. From here, then, to the year 1600 completed in the meridian — the last [day] of December preceding — there are 54 Julian years and 263 days, [reckoned at] hour $18^{\text{h}}55'25''$, or thereabouts. By these [we have], from our tables, the mean motion of the Sun (after whole revolutions) of Signs 8, degrees 19, $4'25''$, by which the radix at the beginning of the year 1600 completed remains, as below:

Sign.	Gr.	I	II
9	10	4	25

[Margin: 2] If to this we add the mean motion of 10 days, which is $9^{\circ}51'23''$, the radix of the year 1600 completed becomes [as below]; but in the style of the old Julian form it will be:

Signa	Gr.	I	II
9	19	55	58

Then, if from this same [value] we subtract the mean motion of Julian years 1600 — that is, our whole 6 Zodiac [revolutions], Sign. 6, degrees 12, $15'47''$ — the radix at the beginning of the years of the epoch of the common [era] of Christ becomes:

Sign.	Gr.	I	II
9	7	40	1

[Margin: 3] In the same way, if we wish to have the radices for the years before Christ, we shall have them sufficiently exact up to the year [1000?] — [continued on next page]

(continued from §3)...within which all the Observations of the Ancients are recorded. As for going still further back, however, one may suspect some error of a few minutes from the year 5000 before Christ; with respect to thirty [minutes] we are not entirely secure, because the motion of the year 5000 turns out for us to

be greater than [it is] in the Rudolphine Tables. But let our own motion stand as the surer foundation, as we plainly demonstrate by examples.

§4. From what was said in Caput IV, no. 9, the Hipparchan equinox in the year 158 before Christ — at Alexandria, September 26, at very nearly the 20th hour after noon, corrected, that is, for the time of refraction — therefore, according to my *Geography Reformed* [*Geographia Reformata*], occurred at Bologna at 18^h27'20", and at Uraniborg [Vraniburgum] at 18^h32'56". At that moment, then, from our own Tables for Bologna and from the Rudolphine Tables for Uraniborg, the Sun's reckoning stands as follows:

From Our					
Tables	Sign.	Gr.	I	II	
Mean	6	1	51	35	
Motion of the Sun					
Anomaly of the Sun	3	24	30	34	
Equation to be subtracted	0	1	48	50	
True place of the Sun	6	0	2	45	
From the					
Rudolphine [Tables]	Sign.	Gr.	I	II	
Mean	6	2	3	51	
Motion of the Sun					
Anomaly of the Sun	3	28	7	22	
Equation to be subtracted	0	1	49	44	
True place of the Sun	6	0	14	47	

The Rudolphine [Tables] therefore differ from my observation by 14'47" in longitude — that is, by 6^h in time — and they differ by 2'45" from the uncorrected [observation], which was made on the meridian at hour 18. But my Tables differ by only 2'45" in [time], which depends solely on the hour's discrepancy of 1.17'. They include no implausible deviation arising either from observation (because of the deflection of the armilla from the plane of the equator, amounting to a minute or 1'17") or from a fault avoided by observation. Hence we detect the error of one whole day in Ptolemy's equinox.

§5. For Ptolemy, in *Almagest* book 3, chapter 8, reports the autumnal equinox as the very foundation upon which, as if upon a foundation, he builds his tables, in these words: "Of the equinoxes observed [by us], one [was found] most exact among all the others, in the autumn of the year 3 of Adrian, in the month Athyr, on day 7 after midnight by the two nearest equal hours." Bullialdus [Ismaël Boulliau], however, in *Astronomia Philolaica* book 3, and Longomontanus in his *Commentary on the Sun*, with good reason judge that not only on account of autumnal refraction did this Ptolemaic observation anticipate his [true] observation by several hours, but also that Ptolemy accommodated his observations to those of Hipparchus, both because the days [the difference of 365 hours] in the Hipparchan cycle could be made commensurable with a whole Lunar Cycle, and because the opinion of the Apogee of the Sun being immobile was rendered surer. As to what may be certain about the autumnal equinoxes of Hipparchus, [whether they came] earlier on account of refraction wearing away [the time], than they themselves [Ptolemy's] turned out, consequently [the question] is whether Ptolemy, in reconciling [his data] with theirs, did come out earlier. Bullialdus, however, shows in the same place from the observations that the horizon increased the northern declination by 7' minutes, and 43" seconds, supposing the parallax to be 2'19". But that this parallax is false from what was said above, and [is] scarcely 10" — therefore the Refractions vary, and [are] diminished by at least 8' minutes, which is of moment. Therefore, if Ptolemy [observed] between meridian and evening, he saw the armilla illuminated equally on both sides, [and] was easily deceived [as to whether it was] at hour 4 or 5, especially if the armilla [was] in its placement [off] by one or another minute, deviated, as I noted above.

Therefore, in this regard, I have reduced both my Tables and the Rudolphine to the meridian of Bologna and of Uraniborg, having corrected the time. For it would have been, if we adhere to Ptolemy's observation not yet corrected, hour 0.27'.20" after noon on September 26; at Uraniborg, hour 0.42'.56". In the year of Christ 132. So stands the computation.

The Sun's reckoning by the same observation, computed for the same moment, both from our Tables and from the Rudolphine:

From Our Tables	Sign.	Gr.	I	II
Mean Motion of the Sun	6	3	3	10
Anomaly of the Sun	3	20	43	19
Equation to be subtracted	0	1	52	2
True place of the Sun	6	1	11	18
From the Rudolphine , however	Sign.	Gr.	I	II
Mean Motion of the Sun	6	3	19	9
Anomaly of the Sun	3	21	39	44
Equation to be subtracted	0	1	55	10
True place of the Sun	6	1	23	59

Since, therefore, both my Tables and the Rudolphine Tables exhibit the Hipparchan equinox in fairly close agreement — but do not exhibit the Ptolemaic [equinox], showing instead the Sun at one degree and more beyond the autumnal section [equinoctial point] — it must be said that either Ptolemy erred in observing the autumnal equinox, or that he was led astray by his false hypotheses (about the apogee being roughly immobile), and the truth came out somewhat differently; or that the equinox actually occurred several hours before

noon on September 24, concerning which matter [see] again in the following Book, Caput V.

§6. It will nevertheless be worth the effort to examine the Tables not against any and every equinox, but against those closest to the equinox — and indeed against those which we know to have been accurately made among the choice ones in the Grand Gnomon of S. Petronio [San Petronio], selected from those [discussed] in Caput VIII, computed at the very moment of [transit across] the meridian. Behold, then, the place of the Sun as then observed, and as computed from our Tables:

Year of Christ	Place of the	Place of the	Deficit / Excess
	Sun Observed	Sun Computed	
	— Sig. Gr. I II	— Gr. I II	— I II
1655 Sept. 22	☐ 29 13 4	29 13 0	d 0 4
1655 Sept. 22	0 24 4	0 11 51	d 0 33
1656 Mart. 19	☐ 29 35 43	29 34 58	d 0 45
1656 Mart. 21	☐ 1 34 30	1 33 56	d 0 34
1656 Mart. 23	3 33 16	3 33 49	e 0 33
1656 Sept. 21	☐ 29 57 22	29 57 37	e 0 15
1656 Sept. 23	0 36 11	0 56 32	e 0 21
1656 Sept. 25	0 16 17	1 15 29	e 0 32
1657 Mart. 28	☐ 8 15 48	8 14 55	d 0 53
1658 Mart. 10	☐ 0 5 38	0 5 41	e 0 3

Parsing notes: This table (the "Locus Solis" comparison from the San Petronio gnomon observations) is faint and ink-degraded; the zodiac sign symbols (☐ Virgo, ☐ Pisces, ☐ Aries) and many of the minute/second figures are hard to resolve. The "Deficit/Excess" column heads each entry with a single letter, "d" (*defectus*, deficit/shortfall) or "e" (*excessus*, excess); several of these letters and adjoining digits are uncertain. Multiple cells flagged as a degraded / — see report.

It is therefore established that our Tables do not differ from these choicest observations by a whole minute; and that if they differ from others by more, the surer reason is on our side, that the fault lies in the observations, since these Tables are bound to the equinoctial observations by a Geometrical and Arithmetical bond cohering with itself, [and] could not [otherwise] exhibit themselves so closely in agreement with the equinoctial observations, and [would] err more grossly in others. But let those skilled in these matters note that

observations made on days other [than the equinoxes], far from the equinoctial [days], commit a greater error in equality [evenness] than those committed at the equinoxes; and to that extent they induce [error] into the place of the Sun, and so the equinoctial [observations] are rather to be weighed against the Lydian-stone [touchstone] of the Tables. The Rudolphine [Tables], however, differ from the aforesaid observations by somewhat more minutes, so that at the first [observation] [the discrepancy is] 4'.51", and so of the rest.

CAPVT XVII.

A New Theory of the Sun's Motions is Set Forth.

§1. Up to now we have been content to approve the Theory of the Sun proposed by Kepler in [terms of] an Ellipse, [and] refined by Bullialdus [Boulliau], Count Pagan [Blaise François Pagan], Seth Ward [Sethus Vuardus], and many others; [a theory] as if among the most recent [authors], [and] as the simplest...

(continued, §1)...the simplest way of representing the Sun's Motion, and [a theory] coherent with the very nature of the Ellipse, whose two Foci, or Umbilics, are equally distant from the center [of the ellipse], rendering the ratio by which the Sun's eccentricity is bisected. Nevertheless, for two reasons, it seems to labor under some imperfection.

§2. The first is that in the Keplerian Ellipse, just as the Earth is assigned to one Focus — the Earth, for whose illumination the Sun is destined chiefly by divine [decree], as is established from Holy Scripture — so to the other Focus there ought to be assigned some [other] body in the World, or [else] the Sun itself ought to be referred to the center of the ellipse in its uniform motion about the other Focus, and to be moved with semi-uniform motion about the center of the ellipse; or some [other] region in the World ought to be determined, whence it might come about, with the parts [of the ellipse] understood, that the Sun should be moved uniformly, or semi-uniformly, or [moved] as the Earth itself [is], in some opinion, moved unequally about the center, but really uniformly about a certain eccentric — so much the more [unequally], by how much greater or less the Sun's Distance prove to be, as established by God.

§3. The other [reason], and by far the greater, is that the appearance of the diurnal motions in the Sun, [appearing to go] from East to West, cannot be reconciled by an Ellipse — indeed not even by a simple eccentric orb — with their own proper [motion] from West to East. Yet the Copernican concern is not [a thing] to fall back upon here, since it makes the motion of the Primum Mobile

pervade the celestial bodies, and is contrary to Holy Scripture, and to physical and physico-mathematical demonstrations [given] in book 9 of the *Almagestum Novum*, sections 4, chapters 19 and 21, and to be discussed in the 11th Appendix. It is certain that the Sun's Motion is not only Annual but also diurnal, from rising in the East to setting in the West; and on the other hand [it is certain that there is] a rest of the Earth; and [that] on the part of the heavens the Planetary fluids really [exist], the distinct falsities of which I have nearly made certain; nor does it seem that these two motions can be better reconciled than [as] a continuous motion, [and] not [as] contrary [motions] one to another, unless [we posit] for the motion of the Planets a spiral motion of all the Planets.

[Margin: The Spiral Motion of the Planets.]

§4. And indeed, if a Fixed Star, by one revolution from the same [point] to the same Meridian, exhibits to us that diurnal motion which we imagine [to be] of the Primum Mobile — [the Star] having no other slow proper motion from West to East — then the Sun alone will be that which is celebrated [as marking] the equinoxes in others [years], and at other points of the Equator [will appear] westward; nor is it necessary to feign another abstract Primum Mobile [removed] from the senses. Rather the [true] Primum Mobile sensible will be the motion of the Sphere of the Fixed Stars.

§5. Which granted, if we conceive the Sun as [moving] around divine Cones, so [arranged] that it describe spirals now wider, now narrower — as much in altitude [depth] as it is described in breadth — at the same moment at which a Fixed Star is borne westward, [the Sun] returns to the same Meridian, [and] returns to the same Meridian, [though] not [exactly], but somewhat more slowly; safe [from objection] will be all the Appearances in the Sun's motion. In the Planets, indeed, when they are seen Stationary, or Retrograde, [or] Direct, the reason of this appearance is easily assigned. For when they return to the same Meridian more slowly than a Fixed Star, they are seen Direct, that is, [moving] toward the East; when they are detained at the East, [so that] at the same moment a Fixed Star returns, which [moment] the Planet [reaches] more sluggishly, they are seen Stationary; when finally, [reaching] the Meridian more swiftly, they cross [it] before a Fixed Star, [moving] toward the West, they are seen Retrograde. But this is nothing to the Sun, which is always slower than the Fixed [Stars], nor [does] the Fixed [Star] return to the same Meridian, and therefore [the Sun] never appears Stationary, let alone Retrograde.

§6. Therefore, since two Theories of the Sun present themselves to us with this difficulty, we have thought out a [Theory] suited to our own measure [*pro nostro modulo*]; but some Foundations [Fundamenta] must be premised.

I. Foundation, concerning the Sun's Apparent Semidiameter and Eccentricity.

§7. The Sun's Apogee apparent semidiameter is 15' minutes and 30" seconds; the Perigee, however, is 16'14"; and at the mean distance, 15'46". Hence, moreover, and from the Equations, the better Eccentricity of the Sun's whole motion is found [to be] 3480, [or] bisected indeed 1740, of such [parts] as the semidiameter, or the orbital Radius of the Sun [is] 100000 [parts], as is clear from what was said in Caput XI and XII.

II. Foundation, concerning the Axis of the Earth's Greatest Shadow.

Diagram. A geometric construction in the right margin illustrating the axis of the Earth's maximum shadow cone, with the Sun's apogee distance and apparent semidiameter. The figure shows a near-vertical line at the top descending to a small circle (the Sun) marked **S**, with lines radiating from it; below, the construction continues to a point **C** at the bottom. The labels visible (several are faint):

- A: upper terminus of the principal vertical axis line
- D, F: two points near the top, flanking S (forming the small upper construction triangle)
- S: the Sun's center (the small circle near top)
- T: a point on the axis below S (the Earth, or its tangent point)
- B: a point along the line near T
- E: a point in the mid-region of the axis
- L: a point on the descending oblique line toward the bottom
- C: the lower terminus / apex of the shadow cone

(2 labels flagged uncertain in positioning — see report.)

§7 (continued). The Sun's Apogee distance being set at 6666 semidiameters of the Earth from the center of the Earth, and the apparent semidiameter being 15'30": the axis of the Earth's shadow is 229 [terrestrial] semidiameters. For let it be, in the present figure, that S [is] the Sun's center, and T the center of the Earth; and that the Sun be seen from T under an angle ATS of 15'30", by the Radius AT touching the Sun in A, and making there a right angle by Euclid's 18th [proposition] of book 3; ST [being] 6666 of the terrestrial semidiameters. By the

rule of right [angled] triangles the angle AS [is found], of the true terrestrial semidiameters 30; therefore [the angle] AS will turn out [to be] the sole semidiameter [angle], the rest [being] FS of [the] terrestrial semidiameters — that is, when, and since ST [is] 6666 semidiameters, the angle FTS is found [to be] 14'56"; and so much is the Angle CD, or parallel to AS, the rest [being] FS of [the] terrestrial semidiameters. Since DF [is] equal to one semidiameter of the Earth BT [which is] taken away, therefore the sole semidiameter remains, and since [the angle] from D [equal] to S of so much, [namely] as much as the [angle] AS, the rest [being] FS of [the] terrestrial semidiameters — 29 of such [parts], and with ST [of] 6666 semidiameters, the angle FTS is found [to be] 14'56". And so much is the Angle FTS of the [terrestrial] semidiameters, [namely] of the linear [parts] CD and TF. Therefore by so great an Angle CD, or by the side BT, comes about one semidiameter of the Earth, that is, the Earth's shadow CT, of the terrestrial semidiameters 229.

III. Foundation, concerning the Moon's Distance and Shadow.

§8. The Sun's Apogee apparent semidiameter being set at 15'30", and the terrestrial distance [being] 6666 semidiameters; and the least [distance], at oppositions, in conjunctions [being] distant 100 [?] from the center of the Earth; the apex of the Lunar Shadow at the Moon's oppositions [is] distant from the center of the Earth 114½ terrestrial semidiameters. For, from our observations, the Moon's Perigee distance at syzygies is of the [terrestrial] semidiameters 58; or as we shall show in the following Book, then indeed, the Moon being set in opposition, the apex of the Moon's Shadow is of the [terrestrial] semidiameters 56½: wherefore the apex [is] as aforesaid [at] the distance of the Earth, [being] distant a semidiameter 114½. From what was said in *Almagest* book 4, Caput 17, the true semidiameter of the Moon's [distance] at perigee is of the [terrestrial] semidiameters 16; of such [parts] the terrestrial semidiameter [is] 100; at apogee [as] above, [it has been] found [to be] of the [terrestrial] semidiameters [such that] the apparent semidiameter of the Sun [is] 30 [terrestrial] semidiameters. Therefore the apparent semidiameter of the Sun's [shadow] exceeds [that] of the Moon by 19[?] [terrestrial semidiameters] — let it be assumed [that] in the preceding figure the Moon's semidiameter [is] BT, the residue SF, [and] the true semidiameter of the Moon [is] 29[?]; and the Moon's perigee distance being added [as] 58, [we have] the Sun's distance at apogee 6666: let ST [be] 6724; the angle FTS [is found, and] thus the axis of the Moon's Shadow TC [is] of the [terrestrial] semidiameters 226: of such [parts] as the apparent semidiameter of the Moon [is] BT, and one [semidiameter], that is, of the terrestrial semidiameters 114½.

IV. Foundation, concerning the Proportion of the Distances of the Earth's Shadow, and the Moon's, with the Sun's Eccentricity.

§9. From the conclusions, and from what was set down in the three preceding foundations, it follows that the maximum distance of the apex of the Earth's Shadow from the center of the Earth [is] as great as the whole Eccentricity of the Sun; and that the Distance of the apex of the Moon's [Shadow], tending in the same direction [*in eandem plagam*] — in which the Earth's Shadow [tends] — but [the] least, the Sun nevertheless [being] at apogee, [is] as great as the whole Eccentricity of the Sun bisected. For the whole Eccentricity of the Sun, from Foundation I, [is] of the distance at the Sun's apogee 10174, and the partition [is] 1480: of such [parts] as the distance at the apogee [is] 10174[?], and 3480 to 6666; the partition [is] 229. [It is] nearest to 229; of which the half is the distance of the apex of the Moon's shadow $114\frac{1}{2}$, just as the whole Eccentricity of the Sun bisected [is] 1740, [which is] half of the whole 3480. Hence furthermore it follows that the Distance of the Sun from the center of the Earth, [its] mean, ought in such a [case] to be in the Hypo-

(continued, §9)...Hypothesis to be of the terrestrial semidiameters 6552, and the least [to be] 6438: which, although they be less than [the values] formerly chosen in the *Almagestum Novum* book 3, Caput 7, nevertheless cannot be convicted of falsity from any other [source], indeed [not even] from the Dichotomies of the Moon; rather, from the ideal beauty of the Hypothesis (concerning which [more] presently), they seem very probable. In another Hypothesis, however, [one] varying notably, the Intervals of the Sun [could] not be reconciled.

These things all stand, of course, provided the Sun's [apparent] semidiameters are saved, and the eccentricities established in the first Foundation, [so that] the eccentricities can stand with respect to which the Sun [is] most nearly and physically [placed], [and] be equal to the distances of the two Earth-Shadows, and of the Moon, as will be clear to those who rightly undertake the calculation. We come now to the Figure of the prior Hypothesis.

Diagram. A large full-width geometric diagram of Riccioli's solar hypothesis. The construction consists of a large outer circle (the ecliptic / orbit ARBP) with a vertical diameter AB running from top (A) to bottom (B), and concentric inner circles. At the top, just right of A, is the symbol for Cancer ☊ (marked "69"-like glyph). At the right, on the outer circle, is the symbol for Aries ☈ with the label P. Within the large circle are several nested circles centered near the lower-middle region. A cluster of construction lines radiates from the upper-left points (M, N, V,

S) down through the central figure to points at the bottom (T, R, E, and the dark shaded cone toward L, F, H, K).

Readable labels with positions:

- A (top of vertical diameter): upper terminus
- □ / "69" glyph (top, right of A): Cancer
- I (upper, on vertical axis below A): intermediate point
- M, N, V (upper left, clustered): construction points; V uppermost
- S (left of center, upper): the Sun's position point
- G (center-upper of inner circle cluster): center construction point
- E (center, within nested circles): a focus/center point
- C (center, within the dark shaded region): central point
- T (left, lower-middle): construction point
- R (far left): point on the outer circle (with what appears to be "□"-like glyph, Libra region)
- □ / P (right, on outer circle): Aries, labeled P
- L (lower right of center, tip of the dark shaded cone): shadow-cone tip
- F (lower center, on vertical axis): point on axis below center
- H (lower, on vertical axis): point near bottom
- K (lower, on vertical axis near B): point near bottom
- B (bottom of vertical diameter): lower terminus

The dark shaded narrow triangle (the shadow cone) runs from the central region C down toward L.

§10. On the Line of the Sun's Absides AB, extending up to the Ecliptic [and] pertaining [to it], let C be the center of the Earth, [and] CD the Moon's perigee distance of the terrestrial semidiameters 58. And DE, the axis of the Moon's shadow, [is set so] that when the Moon is thus opposed to the Sun at apogee, it does not fall into the Earth's shadow, nor is any Eclipse attempted [feared]; and so the whole CE [is] of the [terrestrial] semidiameters 114½: by which interval let a small circle be described, by which interval EI, the [terrestrial] semidiameters 58, may be understood to be circumscribed for the apex of the [Earth's] shadow; but by the interval EI, of the terrestrial semidiameters [as] much as we are able [to set], from Foundation IV. By the mean Distance of the Sun from the Earth, let the circle of the Sun's orbit be described, unless someone prefer an Elliptical [orbit] to describe; and let its periphery [be] ISTK, etc. The interval CE being doubled, let CG be made, of the terrestrial semidiameters 229, that is, as great as

the maximum length of the Earth's shadow, by which interval let the circle GHL be described, circumscribing the apex of the Earth's Shadow opposite to the Sun's motion; and from the same point G, or in any other [point] of the circle, by which the Line of the Sun's absides [passes], let [the orbit] be described, [by] how great an interval the great [circle] of the Ecliptic ARBP [is], under which we behold the true Motion of the Sun.

§10 (right column continued)...of the Sun from the center C, and [we] consider the Mean Motion [to be reckoned] in some other point distant from the [center] by most [authors], [who] suppose [the mean motion] to be at that point which will be G, the Sun being set for the sake of example in S; and yet, if the Sun [be set] in a circle described from G as its periphery, and [in] the point G of it, let the line AB, [of] the Sun's absides, be the line GSM, the line of mean motion, and the line CSV the line of the true place of the Sun; and ES, the semidiameter of the Sun's orbit, which produced into N, can be called the line of physical inequality, since also with respect to the center E, namely of its orbit — [it is] the line CSV — [and] is the line of inequality of the whole [motion], compounded of physical and optical [components], since at the center [there] appears a greater inequality in the Sun's motion than if it were beheld from the center E.

§11. The Practice [*Praxis*], therefore, of geometrical calculation in this circular Hypothesis is most easy. For, the simple Solar Anomaly being given — the Angle AGM, from the Tables — the angle EGS is given, the complement of two right [angles], with which, and with the Radius ES, of 100000 parts, of such [parts] as the bisected Eccentricity EG [is] 1740: collect the Physical Equation ESG; and thence the angle SEG, and so also CES, with which... ..and finally, with the same radius ES and the eccentricity CE, likewise 1740, you will then inquire into the Sun's distance from the Earth CS, and into the Optical Equation CSE; once the Physical Equation has been combined with this Optical Equation, the Absolute Equation will be established. This Absolute Equation is to be subtracted from the Sun's mean motion when the [simple] anomaly falls in the earlier semicircle ARB, and added when it falls in the later semicircle. When, however, the Sun is at T, and CT is equal to ET itself, the Sun will be at its mean distance from the Earth.

§12. Moreover, this hypothesis has the most beautiful agreements, and is not — unless I am mistaken — inconsistent with the phenomena that are observed.

The **first** [agreement] is that the Sun is in truth carried along with a uniform, equable motion. Yet with respect to any observer at the center of the Earth, its motion appears such that an observer who could perpetually see the Sun from beyond the Earth's shadow would see it as the most uniform of all — for which

reason, if the eye were placed at some point on the circumference GHL, it would be on the boundary of those persons who can always see the Sun. For such observers see the Sun not only above the clouds, but even above the Earth's shadow, indeed above the whole region of the aether; and however far the cloud cover may extend, provided the eye is raised above the clouds, and so long as it crosses beyond the line of the Sun's absides, the Sun will always appear to such an observer to be moving uniformly.

The **second** [agreement] is that, if the eye is on the circumference of the circle described by the Moon's shadow — that is, on the periphery EF — then it will be in a region that shares in some equability of the solar motion (insofar as it lies in that region), even though it does not enjoy the full equability of motion. For when the eye is first at the center of the Sun's orbit, it too would see the Moon's-shadow-circle's Apogee leave behind the Sun's Apogee, and at its greatest interval it is most distant from the apex of the Earth's shadow; thus it would see the inequality of the Sun's Optical Equation.

The **third**, and chief, [agreement] is that, by the reasoning we have assigned, two notable regions in the universe are marked out: one for the Sun's equable motion, the other for the center of the Sun's orbit; and from this is derived the physical account of the eccentricity of each. So that the Geometrical calculation may be valid for both, it is necessary that, in the plane of the Ecliptic, one designate the angles of the Equations and of the Anomaly from the boundary of the region marked out by the aforesaid shadows; and one should choose the motions of each, so that they may lie in that [same] region — namely, so that the eye is first free from the Earth's shadow here, where even the Moon does not enter beneath the Ecliptic separately.

§13. Now whatever may be the Hypothesis concerning this matter, lest perhaps certain persons should hold it improbable, [I say] that both the Earth's shadow on its axis, and the half — indeed the fourth part — of the Moon's distance together with its shadow [I have] computed for a Table in circular form, for the whole eccentricity 3480, bisected as 1740; and let the radius of the Sun's orbit be 100000. By the same proportion we shall assign the Sun's other distances in its own Table, for each individual case; so that in this hypothesis it may be possible to adapt them to the said distances [measured in] semidiameters of the Earth, while nevertheless preserving the due proportion of the said eccentricity at the Sun's greatest and least distances. And if indeed this hypothesis is not displeasing, behold those measurements that pertain to it in the Table set out below.

Parsing notes: This is a five-column table. Column 1 is the row label (Latin); column 2 gives values "to radius 100000"; column 3 gives values in Earth semidiameters; columns headed "I" and "II" appear to give angular values (degrees/arcminutes pairs — e.g. "15 | 30"). The "458" value sits in the radius-100000 column spanning the Sun's-semidiameter rows. Several cells are blank in the source; the bracketing of the apparent-semidiameter and other multi-line entries was difficult to align across the rule-lines, and the row-to-column registration for the lower rows is uncertain.

I have indeed attempted to determine whether I might adapt this Theory so as to obtain the Sun's *Mean* distance — see above, Chapter 7, and elsewhere, Book I, Chapter 2 of the *Almagestum Novum* [Riccioli, *Almagestum Novum*] — by the Lunar Dichotomy [Moon at quadrature], having chosen the Earth's semidiameters as 7300. But the numbers chosen do not correspond. For so that the radius may be 100000, and the bisected eccentricity 1740, the Earth's semidiameters then come to 7300; and to these is joined the Mean distance of 7427 semidiameters — by which, and with the Sun's apparent semidiameter at Apogee 15' 30", the problem set out under Fundamentum II is solved: I find the Sun's true distance in semidiameters to be 7427, and the half-angle of the Earth's shadow-cone 33⅔; that is, the distance is 7427, and the half-angle of the cone of the Earth's shadow 15' 4". And when at last, by these [figures], the semidiameters

appear, the semidiameters of the Earth come to $128\frac{1}{3}$. And if the eccentricity were bisected as 254, the Earth's semidiameters would be far greater than the axis of the Earth's shadow is long; nor could it reach to this measurement with the appendage of the penumbra. But retaining this shadow of the Earth, and its half 114 by eccentricity, there would result 7300; and 100000, so that 114 by eccentricity is to 1562: hence much less than that, since we need [these] for the Equations owed to the apparent motions of the Sun, and [for] the difference of the eccentricity that appears.

§15. Similarly, with the Sun's distance assumed to be the Tychonic mean [Tycho Brahe], 1150 semidiameters, it becomes 1740 at distance 1740; and so it is 1750 and 19: therefore the Sun's greatest distance would be 1169, and its true distance in semidiameters; from the apparent semidiameter $15' 30''$, the Earth's semidiameters [come to] $5\frac{1}{3}$, and the half-angle of the Earth's shadow-cone $12' 26''$. And the axis of the Earth's shadow [is] 276 — much greater still is the whole eccentricity, which ought to be 228, or at most 230; nor can these be held — unless we use the Sun's distances posited in the preceding Table, or others moderately different from them.

CAPVT XVIII.

Indicatur Theoria Motus Spiralis Solis. [Caput XVIII. The Theory of the Sun's Spiral Motion is set forth.]

§1. Since Kepler [Kepler], in his work *On Mars* [*Astronomia Nova / Commentaria de motibus stellae Martis*], in chapter 1, has imputed an almost-noted madness to Alpetragius [al-Biṭrūjī] and to Patrizi [Francesco Patrizi], and to others — that they introduced a spiral motion of the Sun, or pursued one — and, [seized] by a love of simplicity of motion, in one and the same Elliptical periphery [placed it] under not the Sun but the Earth, [carried] through the annual motion, and [under] the diurnal motion from east to west, [as if] toward the Earth from the stars; and besides this, because the spiral motion cannot be determined by us in the figures of Geometry, [Kepler] concludes that it is not to be sought, nor are the Sun's places to be determined for any given time by it. Nevertheless these things are by no means to be repudiated. For so that we may say from the outset, [as] we began this chapter under numbers 2 and 3, it is necessary [either] to ascribe the diurnal motion from east to west to the Earth itself, and to the Planets and Fixed Stars; or at least to include the whole Heaven of the Fixed Stars and the Planets. But having excluded the [view] of solid orbs, and having introduced — by the consensus of more recent Astronomy — the fluidity of the planetary Heaven, it can scarcely be persuaded to anyone that the bodies of the Planets could be

carried by aether so liquid; and so that, by an effort directed back upon themselves, they are turned from west to east, in a space of 24 hours. Moreover, whatever exceeds this [time] is the most peaceful motion of the whole heavenly region.

§2. To this is added the authority of Sacred Scripture, which not obscurely intimates to us not only some [single] motion, but indeed this spiral motion. Ecclesiastes, in chapter 1, says: "*The Sun rises, and the Sun sets, and returns to its place; there, rising again, it goes toward the south, and bends round toward the north; the spirit passes through, traversing all things in a circuit, and returns upon its circuits.*" As if the Spirit, that is, the Intelligence that moves the Sun, were to say — that the motive power of the Sun, this [is] what moves it both from rising to setting, and yet so that it turns its gyres around, now toward the south, now toward the north; [and that it does] not move through one... ..one and the same circle, but through different circles by turns, and returns to other circles. So that we may therefore briefly recall the Theory of this motion, [those] indications and conditions which we set out concerning the Sun's motion are to be observed by the Astronomer.

§3. First, then, it appears most manifest that the Sun's motion in *Longitude* is from east to west, and back again toward the east; which motion is commonly [held] even by the unskilled, whenever the sky is clear.

The **second** motion is in *Latitude*, from south to north — which is not easily discerned every day, especially not on all days, but particularly on the days of the Solstices; yet it can nevertheless be observed on certain days by attentive observers, [namely] in the varying length of the noon shadows. But the more attentive observers [discern it] in the varying declination from the Equator toward the poles of the world, [and in] the manifest difference and inequality, since it is greater near the Equinoxes than near the Solstices.

The **third** motion is in *Altitude* [distance], not commonly [observed], but it has become known to the skilled from this — that the diameter of the Sun appears now greater, now smaller; nor is it probable that the Sun's body swells up in one way [and] shrinks in another. They themselves perceive, by use of the Telescope, [its] diverse appearances, [arising] from the diverse distance of the bodies observed; from which a demonstration is taken regarding the magnitude of the appearance in the Sun, proceeding from the fact that at one time it is nearer to the Earth, at another more remote.

The **fourth** [point], observed by Astronomers, is that the Sun so moves from rising to setting that it does not return to the same Meridian at the time when some Fixed Star is on the same Meridian with the Sun; it is brought round to the same Meridian today. For when [the star] with which the Sun has risen — say the Dog Star [Sirius / Canicula] — afterwards rises within nearly three months, [while] the Dog Star already obtains the Meridian, and after nearly three other months [the Dog Star] rises; the Dog Star sets within nearly three other months, and again within nearly three [more] months it sets; the Dog Star rising — and at last, the year being completed by the conjunction of the Dog Star, [it returns] when it rises with it. Since therefore it returns to the Meridian later each day than the same Fixed Star, it is seen to move in its own proper motion toward the east. Whence, and from the *second* motion in latitude, Anaximander [Anaximander] inferred — or rather another Motion of the Sun, by an oblique circle [oblique] to the Equator, which they call the Ecliptic, [traced out] with an oblique angle to the Equator. The greatest angle of the Sun's visible [path] to the Equator [is] $23^{\circ} 30' 20''$. Therefore, in [the use of] globes, or in some way, on planes the Equator and the Ecliptic [are] led, and the arc of the Meridian [drawn] orthogonally to the Equator; and however great this arc of the Meridian is at any time, it is easy to collect the doctrine of triangles from the arc of the Ecliptic, [and] of this imaginary [circle] near the Sun, and the nearer sections of the Ecliptic with the Equator intercepted; and thus far the Sun's place in this Ecliptic.

The **fifth** [point] noted is that the Sun makes more diurnal revolutions, passing beyond this point, in the northern semicircle of the Ecliptic than in the southern — at least so we have it from astronomical observations made at Babylon; or some [observations], indeed more, made from the Vernal Equinox to the Summer Solstice; sometimes also more from the Summer Solstice to the Autumnal Equinox — from which, and from the *second* [motion] in latitude and from the diverse declination (concerning which [we spoke] above), we conclude that the Sun moves unequally; if indeed equal semicircles, or quadrants of the Ecliptic, are traversed in unequal times.

The **sixth** [point] noted is that, since [the Sun] does not appear to move from a determined distance on the Earth from the same declination of the Equator perpetually [in the same way]: although Ptolemy [Ptolemy] found it to have its Apogee in northern Declination at $5^{\circ} 30'$ — in Gemini at $5^{\circ} 30'$, where it had been computed by himself — and therefore it had been moved a little from this position by Hipparchus [Hipparchus]; therefore the Sun's Apogee is to be ascribed not to some change, but afterwards by observation [its Apogee] was found to be of longer duration; this circumstance is the Sun's Apogee, and however much it

appears [to move] near the greatest declination, this is near the beginning of Cancer. From this, an inquiry has been made in Astronomy concerning the Sun's most slow motion of its Apogee.

The **seventh** [point], at last, found in the whole [Sun's path] at one and the same time, [is] that the Sun is in that semicircle of the Ecliptic which [extends] from the Apogee...

[the prose continues in the right column]

Diagram. A schematic of the celestial sphere drawn as an ovoid (barrel-shaped) figure representing the Sun's spiral motion between the Tropics. The top is labeled with the band "ηοδλχγτος" [Greek-form letter-string serving as a decorative/label band across the top — partly stylized; reads approximately ν ο δ λ χ γ τ ο ς], the bottom band reads "εβυτρμ" [stylized lower band]. The principal lettered points around the rim and interior:

- A (top center): pole of the figure (north)
- B (bottom center): opposite pole (south)
- C (center): the Earth / center of the world
- D (left middle): point on the equatorial line (toward observer's left)
- E (right middle): point on the equatorial line (toward observer's right); DE = the Horizon (when reckoned for the sphere), the diameter of the whole Solar Heaven representing the plane of the Equator
- F (upper left), G (upper right): points on the upper rim, near the band; FAG is the arc/portion of the Solar Heaven (the Tropic of Cancer region)
- H (lower left), I (lower right): points on the lower rim (the Tropic of Capricorn region); HCI and ICF noted as great circles through C
- K, L, M, N (interior, near center): intermediate points along the spiral/coiled lines; the spirals QR, GQ, Qh etc. are drawn as the near-vertical coiling lines filling the barrel
- Q, R (lower interior): the common base QR of the two truncated cones
- S (lower left interior), V (center interior): auxiliary points
- Numerous fine vertical coil-lines run between the upper and lower rims, representing the Sun's successive diurnal spiral turns from one Tropic to the other.

[Margin (right): *Exposita Motus Spiralis Solis.* — The Sun's Spiral Motion set out.]

§5. Let AB be the diameter of the whole Solar Heaven, which at the same time represents the plane of the Equator, and passes through the Earth's center C; let

DE be the Horizon, taken straight as for [an observer at] the sphere, which we exhibit here; but let any other Horizon be oblique. From the center C, likewise, let the portion FAG of the Solar Heaven be described, as great as the distance of the Tropics, bisected at A — where the beginning of Aries is — and let the arc be equal to the [arc of] the middle of midnight HBI, in the middle of which is the beginning of Libra; and let the beginning of Cancer be at G and I, and the beginning of Capricorn at F and H; and through these points let two other lines of the Sun be drawn through C — the diameters HCG and ICF. Then on the Diameter AB let there be cut off from there BR; thence AQ, equal to the half-diameter, or to the bisected eccentricity of the Sun; the apex of whose cone [lies] on the diameter FI; let Fh, and on the diameter HG, be HS — let HS be equal to the whole eccentricity of the Sun — let the straight lines GQ and Qh be drawn, and IR and RS; and below, in that same plane of the Meridian, they will represent the sides of the two truncated cones around which the Sun has its Apogee, [where] it describes its diurnal spirals; and of these [cones] the common base is QR, [lying] in the plane of the Equator. But the longer segment of the Cone will be QRIG; the shorter QRHF. For if QG and RI are produced, the meeting [point] with the Axis of the Equator [will lie] further off, [making] a longer and sharper cone than if they were drawn to meet on the same Axis — the sides Qh and RS.

§6. Let now the Sun's Apogee be at the beginning of Cancer G, distant from the center of the Earth by the greatest interval CG; and there let the Tropical Year begin, [the Sun] describing its diurnal spirals — at first greater, around the cone-segment QG; then narrower; then again wider — until they reach the Equator, [and] the base QR, where the Sun's greatest declination CG appears; that is CA with CB, by the half [or] the bisected eccentricity AQ, [or] BR. Then let the Sun proceed, describing toward the south, [making] its diurnal spi...

[Margin (left): *Exposita Motus Spiralis Solis*. — The Sun's Spiral Motion set out.] ...its diurnal spirals: around the narrower cone, [they are] wider near the Equator, but narrower near the Tropic of Capricorn; let them reach from QR, but by the narrower cone-segment, [and] heap up fewer spirals together, [the Sun] within about eight days more quickly completing this segment than the segment of the northern cone. For when it shall have reached the Tropic of Capricorn, [it makes] its spiral SH; it will be at Perigee, and will be distant from the Earth's center by the least interval CH, or CS — [a distance] as great as expounded above, CF, [and] as great as is the Apogee distance; and the whole eccentricity Fh exceeds it by as much, that is, the whole eccentricity of the Sun [is] as much as the eccentricity is in another hypothesis, [namely] the whole eccentricity of the Sun.

Thus then, three things are saved in the Sun's motion: in *Longitude*, by the diurnal spirals; in *Latitude*, by the intervals of the spirals — equal to the differences of the Sun's Declinations, with the unequal number of days, which it makes [to be] more in the northern segment than in the southern, just as the Sun's Theory requires; when the Sun's Apogee is in the northern segment, as it has hitherto been for many ages — nay, almost in every [age], if our opinion is correct, [for] from the beginning of the world its Apogee was at the beginning of Aries. Finally, [its motion is] saved according to *Profundity* [distance], namely in the intervals of the Sun's distance, and in the eccentricity, since in this spiral motion the Sun does not look back to the Earth's center, but [lies] toward the Axis common with the Equator's axis, and toward the sides of the cone — or [toward] the sides of the Scalene cone inclined to the Equator.

§7. It is now necessary to reconcile the Sun's diurnal motion from east to west with the apparent [motion] toward the east, and to make it equipollent to the motion hitherto supposed in the Ecliptic. And this is very easy to accomplish. For let it be, as we were saying, that the Sun [is] at Apogee at the beginning of Cancer G; and thence let the Tropical Year begin, and its days [be reckoned] from the Meridian; and let it descend in the same Meridian with the Fixed Star at some [point]; let it descend from the Meridian GAD to the west E, and thence rise in the east; or [descend] from the heaven of the lowest [point] I, whence let it ascend to K, at the time when that same Fixed Star reaches the Meridian — yet [it does so] only after 24 hours of the Primum Mobile [First Movable], and nearly four [minutes] of the hour [as it] completes the rest of the spiral KL, [returning] to the Meridian; and again, let it descend to M, and let it ascend to the point N; at the moment when the same Fixed Star is on the Meridian, [the point] from which the Fixed [Star] is distant by the interval NO, where it reaches O; and thence let it descend at P, & hence let it ascend at Q, at the moment when the aforesaid Fixed [Star] is on the Meridian; and the residue of the spiral QR being completed, let it descend at T, and hence ascend at V; and at the moment when it then there obtains the Meridian, [the moment] in which the Fixed [Star] [makes] the spiral VX; let it descend from X and Y, and hence to Z, and hence let it come to *a*, and hence to *b*, and a little [more] to *d*, hence to *e*, [each] point, and thence to *f*, and hence to Q, and so on. For [the Sun] becomes the orient daily, made through the points designated in CG; that is, it rises at C, when the Fixed [Star] is on the Meridian.

That [point], which we said in [the matter of] these few spirals [is] to be avoided [for] the sake of confusion, is understood [to be] near 188 [of the?] spirals, which

the segment of the northern Cone traverses in these ages; and the remaining 177, near the segment of the southern Cone.

§8. But [the spirals] are oblique, as we have admonished, [for the] cause [that], when [the Sun] has its Apogee at the beginning of Cancer, [it makes] many more diurnal spirals around the segment of the northern Cone than around the southern; namely, because the side GQ [is] longer than Qh; and when it shall have come at h, [it makes] the Perigee, [the Sun] already at the beginning of Capricorn F, even if it should not have reached FH, which is at the Tropic of Capricorn.

§9. But [when] the Sun's Apogee obtains the beginning of Aries — as we suppose it to have been at the beginning of the world — examine Figure 2, in which are described the Sun's greatest arcs of declination on either side, as in the prior Figure, [drawn] in the plane of the Meridian; [and the lines] AQ, BR, GK, FO, IL, HS [are] cut off [as] the semidiameters of the Sun's Heaven [equal to] the bisected eccentricity, namely. But to the whole eccentricity let AM, BN, Fh, HS be made equal; thence draw the straight lines AK, AO, [making] these as it were parallel to MK, Mh; likewise BL, BP, NL, NP, and at last RI, & RS. For there will arise four segments of an equal number of cones, [the cone's] base having a place in the plane of the Equator. The first segment of the greater cone is ABKL, around which the Sun made its spirals at the beginning of the Equinoctial Year, descending through A to the west, and thence ascending to V, at that moment when the Fixed [Star], which had been with it on the Meridian the day before, returns to the same Meridian; and thence...

Diagram. A second ovoid (barrel-shaped) celestial-sphere schematic, similar to fig-p98-1, but for the configuration in which the Sun's Apogee is at the beginning of Aries. The figure is filled with fine near-vertical coil-lines representing the Sun's diurnal spirals, and crossing diagonals marking the cone-sides. Lettered points:

- A (top, with the Aries symbol ♈ above): the north pole / beginning of Aries
- B (bottom): the south pole
- C (center): the Earth / center of the world
- D (left middle), E (right middle): endpoints of the equatorial/horizon diameter
- F (upper left), G (upper right): upper rim points (with the Cancer/Gemini symbols ♋/♌ near G)
- H (lower left), I (lower right): lower rim points (Capricorn region; ♎ near I)

- K, L, M, N, O, P (interior): intermediate points defining the cone segments ABKL, etc.
- Q, R, S, h (interior): apex/eccentricity points
- *a, b, c, d, e* (small italic letters, interior): successive spiral-crossing points
- The many fine vertical lines are the successive diurnal spiral turns; the bold diagonals are the cone sides AK, AO, BL, BP, etc.

let it come somewhat more slowly to the Meridian at Y, thence to Z, and afterwards to *b*, and so on for the rest, until it is brought to K, before it reaches and comes to the [point] they call the Tropic of Cancer; it would be seen from the center of the Earth C, [the Sun] under the beginning of Cancer, at the beginning of Cancer, with that same Star with which it had departed from A, [the Sun] now having reached the Meridian. And it was distant [by] the interval CK, or CL; thence, however, it was turned back toward the Equator [in] the cone-segment KLMN, circling around its own spirals, until, returned to the Equator, it appears now at Perigee in N, [at the] beginning of [Capricorn?]; thence [draw] the straight lines, [and the cone] of lesser inequality; thence the segment MNOP, leading [back] the spirals, some of which we have conceived to be in the prior lesser segment, [the Sun] reaching there again [at] the last spiral OP, before it reaches the Tropic called Capricorn, it would be seen; now indeed at C, under the beginning of Capricorn at F; or [at] H, and again it was in the middle [at] a distance from the Earth CO and CP, whence at last, returning toward the Equator [through] the spirals of the greater segment, it returns to the Apogee A.

§10. Since the segments of the cones were Equal between themselves, and of the greater between itself and the latter, AK [is equal] to the side AO, just as the side MK [is equal] to Mh, &c — and therefore [there are] an equal number of days for each; [and] for each [the Sun] makes the same number of spirals, [and] it would stay longer in the northern part than in the southern. The greater Cone then [was equal] to the base, [but] of a sharper figure than this figure's cone, [which is] greater but of shorter axis; on the contrary, the lesser cone [is] of a wider figure, but of a shorter base, than the lesser cone of the prior figure, [which is] lesser but of longer axis.

§11. From that time, however, up to the time when the Sun's Apogee was at the beginning of Cancer, [the Apogee] began little by little to lead away [from] the spirals near the Equator, and [made] the spirals nearer the Tropics longer; until [the Apogee] reached AK, [and] the equator [made] the sides of the other cone QG. Examine [whether], by transposing the sides, [the cones AK, QG] — that is, by a

shorter circuit — the account of the changes of its [motion] can be rendered, as [the Astronomers] have observed in the Sun's Apogee [in] the Arc FAG, or HBI.

§12. Much would have to be added to the Theory, [things] to be pursued by diligent Astronomers; nor indeed have the Tables of the Sun's Motions — by which they are accustomed to confirm the Ecliptic Theory in spheres, Armillaries, and Globes — [yet] been made; [since] we wish to represent it more easily by the Ecliptic than by the spiral, [and so] we would seem to be willing to use other Tables; otherwise it would be impossible, against the very nature of the thing, to reduce the Sun's Motion to a Geometrical Calculation, the Mean Motion of declination having first been worked out, and [then] to inquire into the true [place] by the angle of the true declination, and [its] distance from the place...

considered in the arc of the meridian of the apogee, just as also the distance of the Sun and of the Earth, would be very easily found from the angle of declination at C, once the angle at the base of the lesser cone — which angles I am pleased to communicate to the reader for four cases, namely those in which the Sun's apogee falls at one of the four cardinal points: at the beginning of Aries, or of Libra, or of Cancer, or of Capricorn — together with their assigned cones.

I. Case, for the apogee at the beginning of Aries □.

§13. Examine the second figure, in which there are four segments of cones. The **first** is ABLK, around which the Sun spins its spirals from the beginning of Aries up to the beginning of Libra; its angles at the base, namely CAK and CBL, are each $7^{\circ} 51' 22''$, and the sides AK and BL are each 41118 parts of the kind in which CK, the mean distance of the Sun, is 100000. For CK and AC are given — being as many parts as the Sun's apogeeal distance is 101740 — and the Sun's maximum declination by angle ACG, found by us at $23^{\circ} 30' 20''$, as I demonstrated by the laws of trigonometry where I said the Sun descends from apogee A to its mean distance from the Earth at G.

The **second** segment of cones is MNKL, around which the Sun drives its spirals in descending from the mean distance CL, which it has at the beginning of Cancer L, to the perigee CN, which it has at the beginning of Libra. The angles at the base, CMK and CNL, are each $80^{\circ} 39' 54''$, and the sides MK and NL are 40532 parts of the kind in which CK is 100000; and the Sun's perigeeal distance CM, or CN, is 98260, since these follow from the given values [of CK and CN] and from the maximum declination given as above.

The **third** segment of cones is MNPO, of altogether the same magnitude and of the same values [as the second]; its angle at the base, and the number of which the

second segment consists, are the same. Around this the Sun drives its spirals, ascending from perigee to its mean distance again, that is, from the beginning of Libra to the beginning of Capricorn.

The **fourth** segment is ABPO, altogether equal to the **first** as to its sides, and the angle at segment ABPO is that around which the Sun is whirled spirally, returning from its mean distance to the apogee.

II. Case, for the apogee at the beginning of Libra ♎

§14. In this case also the Sun drives its spirals around the four segments of cones, marked out as in the first case and of the same magnitudes, but in a different order. For the **first** segment is that which in the first case was the fourth, namely ABPO, in which it descends from apogee B to its mean distance, that is, from the beginning of Capricorn. The **second** is that which in the first case was the third, namely MNPO, in which the Sun's mean distance descends to perigee, that is, from the beginning of Capricorn to the beginning of Aries M. The **third** is that which in the first case was the second, namely MNLK, in which the Sun ascends from perigee to its mean distance, that is, from the beginning of Aries to the beginning of Cancer. The **fourth** is that which in the first case was the first, namely ABKL, in which it ascends from its mean distance to apogee, that is, from the beginning of Cancer to the beginning of Libra.

III. Case, for the apogee at the beginning of Cancer ♋

§15. For this case, and for the fourth, examine the earlier figure [fig-p99-1 from the prior batch], in which there are only two segments of cones. The **first** is QRIG, around which the Sun is spirally whirled in descending from apogee I, that is, from the beginning of Cancer, to its mean distance at R, which it has at the beginning of Libra; then returning from its mean distance to apogee, that is, to the beginning of Cancer G. The angles at the base, namely CQG and CRI, are each $76^{\circ} 37' 18''$, and the sides QG and RI are each 4100 parts of the kind in which CQ is 100000; and CG, 101740, with the maximum angle of the Sun's declination QCG set at $23^{\circ} 30' 20''$.

The **second** segment is QRSh, around which the Sun is spirally whirled, descending from its mean distance, that is, from the beginning of Libra R, to perigee at the beginning of Capricorn; then again ascending from perigee, that is, from the beginning of Capricorn S, to its mean distance at Q, that is, the beginning of Aries. The angles at the base are CQh and CRS,

IV. Case, for the apogee at the beginning of Capricorn ☐.

§16. In the same figure two pairs of cone-segments are to be considered, as in the first case, of altogether the same magnitudes, but in the reverse order. For the greater segment, which was northern, ought to be southern; and around this the Sun drives its spirals, just as from the beginning of Capricorn at apogee. F, at the beginning of Aries Q, the mean distance, ascends from the beginning of Libra R, or the other mean distance, to the beginning of Capricorn at apogee H. The lesser segment, however, QRSh, the Sun in descending from the beginning of Aries inverts, so that it may emerge as northern; it will serve the descending Sun from the beginning of Aries, its mean distance, and from perigee to perigee, namely Cancer; while ascending from perigee it will serve Cancer, and to the mean distance at the beginning of Libra.

For the Other Cases.

§17. For the other cases, in which the Sun's apogee falls outside the cardinal points, there is need of four cone-segments of different magnitudes and quantities, such as the skillful astronomer can conceive and design. Yet for now we shall illustrate it by the following diagram, in which let ACB be the diameter of the equator itself; let the equator be represented by A, and from C, its center, let the meridian of the Sun's highest apogee be drawn on both sides, that is, let the portion of the meridian FAG and HBI be drawn, of just so great a distance from

Diagram. A barrel-shaped (cylindrical-conic) celestial-sphere construction for the general case in which the Sun's apogee lies outside a cardinal point. A central vertical axis runs through center C, with the two oblique conic envelopes (greater/lesser cone-segments) and the spiral paths of the Sun. The figure is bounded above and below by curved arcs representing the celestial circles, with zodiac symbols at the corners. Labeled points run around the perimeter and interior:

- A (top center, with ☐ Aries symbol nearby): apex region of the upper meridian
- K (upper left interior): construction point
- M, O, D (upper interior, near center top): construction points
- T (right, with ☐ Cancer / Leo symbols ☐ at upper right): right-side point
- G, S (right side, ☐ region): construction points
- F (upper left, ☐/☐ region): meridian point
- N (left interior): construction point

- C (center): center of the equator / common vertex of the cones
- V, P (left and lower-center interior): construction points
- L, R (lower interior / lower right): construction points
- ♒ Aquarius and ♏ Scorpio symbols at lower left and lower right corners
- E, B (bottom center): base points of the lower meridian
- H, I (lower left and lower right): meridian termini below

[Several peripheral labels and zodiac glyphs are small and partly inked; the interior lettering A–T as transcribed is legible.]

the Tropics, to whose extremities let FIC and HCG be drawn. Now let the Sun's apogee be at D, at 15° of Taurus, and accordingly perigee at E, at 15° of Scorpio. For its mean distance will lie under 15° of Aquarius at K, and under 15° of Leo at L. Therefore let the lines DCE and KCL be drawn, and on either side let DQ, PN, KM, and LR be cut off, equal and bisecting the eccentricity, that is, of eccentricity 1740, of the kind in which CQ, CM, CP, and CR are each 100000. For these are drawn as the straight lines MD, MN, NL, LB, the segments of the cone MNLD, around which the Sun draws its spirals, ascending from Aquarius at 15°, to 15° of Taurus. Then taking up KO and EP, of 3480 parts — being the whole solar eccentricity — and drawing OQ, OP, PR, RQ, you will have the conic segment OPRQ, around which it is whirled at 15° of Leo and 15° of Scorpio. The segment under 15° of Leo is DSTR, serving the Sun at 15° of Taurus to 15° of Leo; and the segment XMPV, when from 15° of Scorpio it ascends to 15° of Aquarius. But the segments SG and TI, of lesser eccen-

tricity, are bisected, that is, of 1740 parts, and FX, and also HV, are greater, but smaller by the whole eccentricity, in proportion almost equal to the distance from the place of apogee, and from the place of mean distance.

§18. [Margin: An objection is met.] You will say that this designation of the cones and segments, by its very intricacy, makes this theory improbable and full of difficulties. I reply that the variety of the cones is no more perplexing than the Keplerian ellipse, on account of the variations of apogee. For just as the Keplerians want to keep the Sun always in the same ellipse and in the plane of the ecliptic, and yet with apogee — or aphelion — varied under it, it is impossible that it be the same ellipse with one and the same conjugate axis; rather there must be as many ellipses, or as many cones, as there are dispositions of the Sun's apogee. And besides, the diurnal motion from east to west cannot be reconciled with the motion proper to it toward the east.

CAPVT XIX.

Conclusions concerning the certainty hitherto acquired, or to be hoped for in the future, regarding the Sun's motions, intervals, and quantities; and concerning the theory and practice of the Tables.

This is precisely that which astronomers awaited from us with such eagerness — to whose knowledge the two prior volumes of our *Almagestum Novum* [Almagestum Novum], and the *Idea of the Whole Work*, were a kind of approach and promise. What then we can, as if reduced to the marrow, conclude with our efforts concerning the Sun's affections, is to be briefly indicated.

I. Conclusion concerning the equinoctial, or tropical, year.

The quantity of the equinoctial year, beyond 365 days and 5 hours, most certainly does not have more than 56' of an hour, nor fewer than 42'. Yet the truest quantity of all, by our reckoning, is this:

D. 365. Hor. 5. 48'. 48". 0". Of the sidereal [year]: D. 365. Hor. 6. 9. 21. 42.

The earlier part is evident from the opinion of the astronomers cited in Book 3 of the *Almagestum Novum*, chap. 15, if we reject the obsolete [values] of certain ancients; the later part is evident from what is to be said here in chap. 4, third, and from chap. 19.

II. Conclusion concerning the Sun's mean daily and annual motion.

The Sun's mean, or equal, daily motion is most certainly 59' of arc and 8" of seconds, and moreover not more than 10" of thirds, nor fewer than 7", as is evident from Book 3 of the *Almagestum Novum*, chap. 17. And the annual motion is as below:

	Sign	Gr.	I	II	III	III	V	VI
Daily	0	0	59	8	19	48	35	35
Annua l	11	29	45	40	30	56	5	1

III. Conclusion concerning the motion of the Sun's apogee.

The annual motion of the Sun's apogee, by the consideration of more recent astronomers — as cited in Book 3 of the *Almagestum Novum*, chap. 25, and adduced [there] — is not greater than 1' 4" of seconds, nor smaller than 45" of

seconds; yet from what is said here in chap. 9 it is most probably below: 1' 2" 4''' 4''''.

IV. Conclusion concerning the Sun's apparent diameter.

The Sun's apparent diameter at apogee does not exceed 34' of minutes, nor fall below 29'; at perigee, moreover, it does not exceed 36', nor fall below 30', as is established from what is said in Book 3 of the *Almagestum Novum*, chap. 10; but with the observations made most truly with the great Gnomon of St. Petronius, the diameter appears as Dominico Cassini [Giovanni Domenico Cassini], or as we, gather from these — as below in chap. 12.

	In Apogee	In Apogee	In media dist. I	In media dist. II	In Perigee	In Perigee
☉ Diam.	I	II			I	II
Cassino [Cassini]	31	8	31	40	32	10
Nobis [Us]	31	10	31	42	32	4

Parsing notes: the apparent-diameter table is grouped under three positions (In Apogee / In mean distance / In Perigee), each split into two columns (here rendered as minutes ' | seconds "). Cassini's and our (Nobis) values are tabulated in arcminutes and arcseconds.

V. Conclusion concerning the bisection of the eccentricity.

The eccentricity of the center of the Sun's orbit from the center of the Earth is half the eccentricity of the center of the Sun's mean motions. For if we adopt that eccentricity which geometrical necessity deduces from the difference of the apparent diameter of the Sun at the apogeal, mean, and perigeal distances, the prosthaphaereses [prosthaphaereses] due to the Sun's mean motion must be inquired into, so that the Sun's true place may be had agreeing with observations exactly continued. There are found double the smaller [prosthaphaereses], nor can the true quantity of such prosthaphaereses be found, unless double the larger eccentricity is assumed; and so the center, around which the Sun is moved equally — or is feigned to move — is removed from the center of the Sun's orbit by just so much as the center of the orbit is removed from the center of the Earth: see what is said in chap. 12.

VI. Conclusion concerning the quantity of the Sun's eccentricity.

The whole eccentricity due to the equations of the Sun's motion, if it does not change, but is more probable, we taught in Book 3 of the *Almagestum Novum*, chap. 26, is not greater than 3800 parts, nor smaller than 3200, of the kind in which the radius of the Sun's orbit is 100000, from what is said in Book 3 of the *Almagestum Novum*, chap. 24. But concerning the diameter of the Sun and the apparent difference at the threefold distance from the Earth, and concerning the equations of the Sun's motion, nothing satisfies more than ours, the apparent motion of the Sun, of which above in chaps. 10, 11, & 12, and of this kind:

Of the kind in which
the radius is 100000.

The Sun's eccentricity	Whole	Bisected
Us [Nobis]	3480	1740

Hence, however, it comes about that the Sun is moved unequally around its own center too; and by the half-inequality, by which the Sun's true place differs from the mean.

VII. Conclusion concerning the figure of the Sun's orbit, or path.

Although the bisection of the eccentricity has indicated, in the Sun's orbit, three points, or two notable centers — namely, by the intervals — that is, the center of the Earth, the center of the Sun's orbit, and the center of the Sun's mean motions, equally distant — it might seem to indicate that it is an ellipse, in whose periphery the Sun is moved; and that because in the ellipse there are these two notable points equally distant from the said center itself, namely the two foci, or navels, which are observed [to be] all equal among themselves, the rays [reflected] from one of the foci into the cavity of the ellipse being then reflected: and although it seems quite near enough to the truth by such a path, by a geometrical method, the prosthaphaereses of the Sun due to the Sun's motion are found, as is evident from the theory demonstrated in chap. 11, and by examples of calculation in chap. 15. In the earlier Table of the observed places of the Sun, and supposing the Sun's path by this path, nevertheless nothing necessitates the elliptical path of the Sun. **Firstly**, because the ellipse by its own nature requires the said three points, yet they can also be found in a circle, if it is not by its nature, and considered mathematically; physically, however, considered, those three places will indeed be minute, around which the Sun is moved equally indeed,

around one [point]; and unequally around the center of the Earth, and semi-equally around the center of its own orbit. **Secondly**, because by our eccentricity and equations [computed] in a circle, we represent the apparent motions of the Sun, and the due [motions], no less — indeed, often more — exactly, as is clearly established from the Table in chap. 15, just as in the ellipse. **Thirdly**, because not only is it not demonstrated that the Sun moves in an ellipse rather than in a circle, but neither mode is demonstrated by the diurnal motion from east to west, which is due to the Sun both by Divine Scripture and by the real increment of impetus, as [is shown] by the percussions of grains, or by the higher [region], more dense, and by the fluidity of the heaven of the planet; and by rejecting the multiplicity of solid eccentrics and epicycles. Indeed, the divine motion of the planets from east to west can scarcely otherwise be reconciled, since they appear to [go] from west to east, than by the diurnal motion from east to west, [combined with] the spiral, and the slower motion of the primum mobile, or of the fixed stars. Which motion is shown to be neither absurd nor outside geometrical laws in chaps. 16 & 17.

VIII. Conclusion concerning the cause of the eccentricity of both [centers], the Sun's.

The cause of the whole eccentricity of the Sun is not very improbably the greatest shadow of the Earth, so that in it the matter of the air or aether, illuminated by the uniform region of the Sun, in which at first the eye, raised from the Earth, would begin to see the Sun perpetually, without any nocturnal interruption. But the cause of half the eccentricity is averse to the Lunar shadow, which is first, the first uniform shadow; if it could be founded on certain foundations partly necessary, partly observed, the quantity of the said shadows is analogous to the said eccentricities, as I taught in chaps. 1 & 6.

IX. Conclusion concerning the Sun's maximum declination, or the obliquity of the ecliptic.

The Sun's maximum declination from the equator, or the obliquity of the ecliptic, was not the same in the time of Eratosthenes as hitherto, as I showed in chap. 6, and once in Book 3 of the *Almagestum Novum*, chap. 27. Nor indeed beyond degree 23, and exceeding minute 32; nor falling below 18 [?] minutes. The truer is somewhat exceeding, by observations agreeing, 23° 30' 20"; nor improbably 23° 30' 30", from what is said in the same chap. 6.

X. Conclusion concerning the Sun's distance from the Earth, and the horizontal parallax.

The Sun's least distance from the center of the Earth, too, is not supposed [to be too small] by an ignored parallax, as hitherto, and by Tycho [Tycho Brahe]; and it was supposed by Tycho himself, but from the dichotomies of the Moon, by the most diligent astronomers, it was then asked; nor was it any less investigated; nor was it smaller than six thousand terrestrial semidiameters, nor a maximum greater than sixteen thousand semidiameters; as is gathered from what is said in Book 3 of the *Almagestum Novum*, chap. 7, and its Appendix in the end of the first tome [is] added. But two distances are very probable to me beyond the rest. The first is that which I chose in the *Almagestum Novum*, Book 3, chap. 7, and touched on in chap. 13, [where I] confirmed it to be not smaller, in chap. 14, num. 39, by the new Method, by the Refractions of the fixed stars investigated, [the parallax being] not greater than 30" of seconds; according to which the mean distance was 7300, and that bisected, now, and our new eccentricity 1740, of the kind in which the Radius is 100000. The greatest distance from the terrestrial semidiameters ought to be 7427, and the smallest 7173. The latter is that which agrees with the attempted hypothesis of the Sun's eccentricity, and of the terrestrial shadow, and the prolixity of the Lunar shadow, but chiefly of the terrestrial [shadow], as I indicated above in Conclusion VIII, and expounded in chaps. 16 & 17, num. 6; from which [there is] something adduced [to show] that this hypothesis requires the Sun's distance at apogee to be 7427 terrestrial semidiameters, and at perigee 6438. The mean, 6552, terrestrial semidiameters.

Hence it follows that the Sun's horizontal parallax is never indeed greater than 30" of seconds, or 31", but is yet sensibly so; and where the subtlety is not in question, [it is] altogether to be neglected, as some do. Let therefore the aforesaid distances, with their horizontal parallaxes, be set before the eyes:

	Apogea l dist.,	Horiz. parall.	Mean dist.,	Horiz. parall.	Perig. dist.,	Horiz. parall.
Ours	semid.		semid.		sem.	
1st	7427	11 [?]	7300	11 [?]	7173	11 [?]
Opinio n		27		28		29
2nd	6666	29	6552	30	6438	31
Opinio n						

Parsing notes: the horizontal-parallax columns appear to give arcseconds (and the upper "11" may be a stray rule-mark or partly inked seconds figure — flagged). The first-opinion parallaxes (27", 28", 29") and second-opinion (29", 30", 31") form the smooth progressions.

XI. Conclusion concerning the Sun's true magnitude with respect to the Earth's shadow, and the angle of the cone of the same shadow.

Since the Sun's distance from the Earth is uncertain [as to being] precise, and we know it to be not smaller than 6000 terrestrial semidiameters, and very probably not exceeding much beyond 7500 — moreover, since it is more certain that the quantity of the Sun's apparent diameter cannot be determined for us, yet certainly it is established absolutely concerning the true magnitude of the diameter, as the quantity of the diameter [is] to the diameter of the apparent quantity. Taking therefore, as a foundation, the Sun's diameter, which appears 11' at apogee, and the minimum tolerable apogeeal distance, 6000, and the maximum 7500: but the probabilities are 7427 and 6666 from what was recently said — the quantities written below follow, among which, however great the angle of the cone of the Earth's shadow is, so great is the arc of the greatest terrestrial circle which the Sun illuminates by its rays unbroken [unrefracted], beyond 180 degrees.

Given the Sun's
dist. from

Earth, in terrestrial semidiameters	True Sun's Diameter	Axis of the Earth's Shadow	Angle of Shadow Cone
	semid. terr.	semid. terr.	' "
Maximum in Apogee, semid. 7500	67 $\frac{1}{3}$ $\frac{1}{2}$	128 $\frac{7}{8}$	30 6
Maximum, Apog. 6000	54	231	29 48
1st Probable: Apogee 7427	67	229	30 4
1st Probable: Mean 7300	67	224 $\frac{3}{4}$ $\frac{1}{3}$	30 37
1st Probable: Perig. 7173	67	220 $\frac{2}{3}$	31 10

Given the Sun's dist. from Earth, in terrestrial semidiameters	True Sun's Diameter	Axis of the Earth's Shadow	Angle of Shadow Cone
2nd Probable: Apog. 6666	60	229	29 52
2nd Probable: Mean 6552	60	226	30 30
2nd Probable: Perig. 6438	60	223	31 4

Parsing notes: the "True Sun's Diameter" and "Axis of the Earth's Shadow" columns are in terrestrial semidiameters; the fractional parts ($\frac{1}{3}$, $\frac{1}{2}$, $\frac{3}{4}$, $\frac{2}{3}$) are stacked beside the whole numbers in the source and may be compositor-stacked sexagesimal fractions — transcribed as shown. The "Angle of Shadow Cone" column is in minutes and seconds (" ").

XII. Conclusion concerning the progress of astronomy to be hoped for.

Even though our most recent Tables represent the observed place of the Sun by great Instruments — of which kind is the Gnomon recently [erected] in the Temple of St. Petronius of Bologna — often within one minute [of arc] of two minutes of error; whence it follows that they exceed the error here and there, or [are within] one minute, posited as an error in the observations, which arise from physical little alterations — yet our Tables are bound by Geometrical reasoning among themselves so that they cohere, nor can they in the same degree of Anomaly now exhibit the truth, now a falsehood; and hence one may suspect that the Tables, or [those] more certain, are never better hoped for from posterity, nor are they to be hoped for from any observations whatever; yet, by diligent [labor], they do not differ ever from one another by one minute. When, however, I consider how much our age the astronomers have advanced, both by observing and by meditating, and how much the Immortals have indulged them, this prodigy of ours, as God has granted to us; and to expedite [matters], so that astronomers do not cease from observing, and from contemplating the Sky; then, that new [things may be]...

so that we may go on to attain ever subtler refinements, and to confirm, correct, or finally close out the findings discovered up to now; and so that, from the depth of the heavenly Motions and from the intervening Harmony, all the learned and

devout may be drawn up into wonder and love of the Creator himself. To this end one's whole effort and labor ought to be directed, for the greater Praise and Glory of God and of all Human Understanding.

APPENDIX I

TO CAPUT XII

On the Apparent Diameter of the Sun, against an objection raised by most learned and most dear friends.

Whether, and how much, ought to be subtracted from — or added to — the appearances of the Sun and of the lunar shadow [umbra Lunar] cast through an aperture [foramen] of perceptible size, so that one may obtain the true magnitude not only of the apparent diameter of the Sun and of its proportion to the lunar diameter, but also of a solar eclipse, whether expressed in digits or in scruples of one degree?

Recently, two Fathers of our Society — Frenchmen, most distinguished mathematicians — gave occasion for this question by transmitting to us certain doubts, indeed certain assertions, raised against the positions advanced by R. P. Bernardino Boghille [Bernardino Bohillo] of the same Society, a man most skilled in mathematics, and directed against what is contained in the *Almagestum Novum*, Book V, Cap. 15, no. 4, and nos. 6 and 8. Drawn from the doctrine of Kepler, their points are these, namely: that from the semidiameter of the bright base of the solar image one must subtract a semidiameter of the aperture; and that to the same one must add the *sagitta* [arc-height] of the lunar shadow, in order to obtain the true magnitude of the eclipse in digits, and so on. To these objections I have undertaken to make a careful reply, having premised certain points which I knew well to be needed by those Fathers — themselves greatly advanced in geometry — yet for the sake of the completeness of this doctrine, and for the sake of others into whose hands this little study of mine may come. Meanwhile I owe them the greatest thanks for the occasion thus afforded of inquiring somewhat more deeply into matters not to be despised, and of setting truth, once recognized, in a clearer light.

I. SUPPOSITION

If a straight line lies parallel to two straight lines, and lines equal in the perceptible sense join the parts of those lines lying on the same side, then the

lines so joining are parallel and equal, apart from a difference imperceptible to the senses.

For Euclid, Book I, prop. 33 [Elements I.33], demonstrates this without qualification for lines parallel in geometric rigor; and it holds likewise for lines equal, or parallel, to within the perceptible sense, on the principle of inferring an imperceptible equality or parallelism from equality and parallelism.

II. SUPPOSITION

Lines that are equal apart from a difference imperceptible to the senses are taken as a single straight line, whenever the one does not exceed the other by more than the three-hundredth part of one inch of a Roman foot [una uncia Pedis Romani].

By the Roman Foot I here understand the one — and of what measure — that I exhibited in the *Almagestum Novum*, Book II, Cap. 7. By experiment I myself found, together with P. Grimaldo [Francesco Maria Grimaldi], on a flat plate of brass [lamina orichalcea], well polished, that on the most finely drawn parallelogram ABCD, whose

side AB equals the side CD, and equals one inch of a Roman foot; and whose diagonals AD and BD, taken singly, equal two Roman feet — that this same diagonal AD, divided into 300 equal parts, when stretched out into the finest threads of silk OH (such as the silk thread drawn from a cocoon of the silkworm can be reduced to the very finest), so as to cover one entire small space of the three-hundredth part — that from this we concluded this to be the smallest difference that the human eye can plainly discern. For even though the inch be divided lengthwise by the diagonal AD into far longer parts, namely 3000, the thread, when stretched across the said inch, would by its own thickness be on the point of covering, by its very thinness, more of the finest parts; and so, from the thinnest parts, it would obscure how much it covered, and likewise it is more readily perceptible by that Rule of yours, whose straightness can never be made so exact as the straightness of the said stretched thread.

Diagram. A square (or rectangle) ABCD with both diagonals drawn, illustrating the brass-plate apparatus described in the II. Supposition. The top edge runs A (top left) — O — B (top right); a short segment O near the top with H below it marks the silk thread OH stretched across. The diagonals AD and BD cross at the center. The bottom edge runs G (bottom left) — H — D (bottom right).

- A (top left corner): vertex A

- O (top edge, between A and B): point O, upper end of silk thread OH
- B (top right corner): vertex B
- (center, where diagonals cross): intersection of diagonals AD, BD
- G (bottom left corner): vertex G
- H (bottom edge, near center): point H, lower end of silk thread OH
- D (bottom right corner): vertex D

III. SUPPOSITION

The semidiameter of the Earth is not less than 3,500,000 geometric paces [passus Geometrici], nor is the distance of the Moon from the Earth, at perigee [πρόσγειον, Greek: perigeion, "nearest to Earth" — here perigee], less than its 57 semidiameters, that is, 175,000,000 paces; nor is the distance of the Sun from the Earth less than 1105 terrestrial semidiameters, that is, 3,867,500,000 paces.

The first point is established from the measurements of the geometers reported in the *Almagestum Novum*, Book II, Cap. 7. Let this suffice for us, drawn from our more recent observations in the *Geographia Reformata*, as a quantity certain enough, though the smaller in Roman paces — 4,673,000. The second is established from the observations adduced in the *Almagestum Novum*, Book IV, Cap. 14. The third, finally, is established from the relations of astronomers cited in the *Almagestum Novum*, Book III, Cap. 7 — although from the dichotomy [διχοτομία, Greek: dichotomia, "halving" — the lunar dichotomy, quadrature] of the Moon we have already supposed the distance of the Sun at perigee to be not less than 5000 terrestrial semidiameters.

I. PROPOSITION

Two Rays propagated to the Earth from the same point of the Sun, or of the Moon, and comprehended within a semidiameter of an aperture not exceeding 10 Roman paces, will, when produced further, run parallel within an interval not greater than 21,486 paces in the case of the Sun, or 972½ paces in the case of the Moon.

In the first of the Figures to be displayed, let A be a point of the Sun or Moon; let AB and AC be the rays of least distance from the Earth, comprehended within a semidiameter of the aperture not exceeding 10 paces. Let them be produced as far as H and K, and so on, up to the base HK, parallel to BC itself, and let them diverge geometrically. Then HK is greater than BC; draw HK; let CL be parallel to HK; then by reason of the similar triangles, CL is parallel to AH; let AH be cut at L; now I say that the interval CL is not greater than 21,486 paces. The solar rays

within that interval, that is BH and CK, are equal and parallel to within the perceptible sense, indeed equal to one another. For HK, parallel to BC itself, does not exceed it except by a part LK, no greater than the three-hundredth part of an inch of a Roman foot, which is the least difference perceptible by Supposition II. Therefore HK and BC, within that interval, are equal in the perceptible sense, and so by Supposition I they are parallel and mutually equal. The antecedent is proved, because the triangle AHK, cut, is — as AB is to AH — in proportion, by props. 2 and 4 of Book VI [Elements VI.2 and VI.4]; and since AB, as well as AH, and likewise AL and LC, [hold the same ratio]. Now in fact, BC is to the solar distance AB as 3,867,500,000 is to LC, by prop. III. Suppose, then, that LK, the three-hundredth part of a Roman foot in inches, requires the difference in length 1,289,166, that is, 10,743 paces $\frac{2}{3}$, or 21,486 paces.

Next, since BC is to the lunar distance AB as 175,000,000 paces — so LK, a three-hundredth of an inch, [is] to 58,333 inches, that is 4,861 paces, or $972\frac{1}{2}$ paces. So

How much more certain, therefore, will the rays be that are parallel and equal among themselves, to within all the subtlety of the senses, over an interval still much greater — when the Luminary's distance is greater and the semidiameter BC of the aperture smaller, in paces. We took, however, that of the great Gnomon of the Temple of S. Petronio at Bologna [San Petronio gnomon], where the perpendicular interval of the aperture to the pavement does not exceed 100 Roman feet, but is roughly 90; the semidiameter of the aperture is BC, less than the said interval, by far. And so we took the aperture nearly one inch only.

COROLLARY

On the parallelism through an imperceptible inserted angle.

From what has been said I conclude a method, which I have used together with Nonius [Pedro Nunes], Snellius [Willebrord Snell], and others, of showing the physical parallelism of the rays ABH and ACK, so that the inserted angle CL does not differ — that is, so that we may preserve, sensibly equal to the lines BH and CK, the lines BC and KH — so that the imperceptible inserted angles BC and KH may be tractable as instruments by astronomers. For from the distance between the Luminaries, and from the narrow semidiameter BC, I undertake to show that the angle A does not exceed one Third-Scruple [Tertium Scrupulum, i.e. one third], which is commonly reckoned imperceptible; and so, the right line BC, falling upon the right lines AB and AC, making with those lines internal angles ABC and ACB — two right angles, equal in the perceptible sense, and not falling short of the sum of two right angles by an amount perceptible to the senses — sits

parallel to the lines at 29 of Book I [Elements I.29]. But this is absolutely no concern unless within the said imperceptible interval. Now, the angle A being always one Third, and so the sum of the angles amounting to $179^{\circ} 59' 59'' 59'''$, the rays AH and AK can nevertheless proceed, so that the base KH does not differ perceptibly — indeed, larger, on the base EC. As in the example of the lunar rays, BC remaining at $972\frac{1}{2}$ paces, if the interval CL is $972\frac{1}{2}$ — within which we said the physical equality of the base BC and KH multiplies by 300 — let it become 291,750 paces; if to CP, 100, is added, it gives an excess over BC of one Roman pace; and if again, it leads to $121\frac{1}{2}$ paces, then 30,000 paces, which is produced at the center of the Earth — let it be LK, exceeding above BC by one Roman foot; therefore the physical parallelism will not remain. This was worth noting.

II. PROPOSITION

Given the base of the whole appearance of the Sun, received through an aperture of imperceptible size, in a plane equidistant from the plane of the aperture, in a known plane: the apparent diameter of the Sun is given — that diameter which would appear to an eye placed at the location of the aperture.

I said "of the whole appearance," that is, the appearance terminated by the outermost rays of the Sun; for through a perceptible aperture they could be reflected to the eye of the observer, and move his sense. In truth, however, they are too weak, and could not perceptibly represent the outermost whole appearance of the Sun, as I found by experiment. Having premised these points, in Fig. II: let AB be the plane — say, a white tablet, to which is equidistant the plane ED — in which is the aperture H; from the plane AB, let the rays BH and GA, parting from one another at H and EH, be drawn to AB, perpendicular to HT; given the sides HT, the right angle HTB; and BT, half the appearance of the Sun, will be given by the Canons of Triangles [trigonometry]. The right angle THB, half the appearance AHB, which is the apparent angle FHG, where, under too small a sense in the aperture, fixed in the location, the visible portion of the Sun would be seen, or the apparent diameter of the Sun would appear.

But because in this manner we cannot obtain the true diameter, therefore among other methods we chiefly use the appearance of the Sun admitted through an aperture of perceptible size, so that that appearance may move the senses by the multitude of its rays — provided only that the aperture, and the distance of it, namely the distance from the plane receiving the appearance, be of congruent quantity, and fit to represent the appearance of the Sun.

III. PROPOSITION

Given the base of the appearance of the Sun admitted through an aperture of known and congruent quantity, in a plane equidistant from the plane of the aperture — disposed horizontally and applied to discern evidently the appearance terminated by the shadow [umbra]: there is given the apparent diameter of the Sun, equal to that which would appear to an eye placed at the location of the aperture, apart from a difference evidently demonstrable.

Now the aperture, and the distance of the planes, ought to be so reckoned in quantity that the aperture be less than the true diameter of the Sun — indeed less than the paces 10, by the said Proposition I. But that the appearance of the Sun received through it be evidently greater than the aperture, and of a splendor, or of an opaque channel, or of confused reflections, not confounding the lights and shadows of the Sun's appearance; nor yet so vast a distance that the weak rays representing the Sun's appearance be obliterated; nor so distant that the appearance set in evident discernment between the appearance and its shadow-bound conterminal. So then, since we found the aperture never exceeding two Roman inches, and more often less, by 15 — sometimes a smaller distance by feet, sometimes a greater, of 15, or 30, 40, etc.; but in the Gnomon of the Temple of S. Petronio, where the distance of the pavement is least, in which we receive the appearance of the Sun, is roughly 100 Roman feet; and the aperture is perpendicular to it, 100 times less, the distance of the perpendicular lunar appearance being 10,000. With these premised in Fig. II: let the aperture be OP, whose center is CT, and from which, by the perpendicular CT drawn to the plane, are comprehended the extremities of the Sun's rays FB and GA, touching by turns the margins of the alternate apertures, and cutting one another in H, intersecting. Now let the radius FB be understood from the right Limb of the Sun, from which the radius FB is propagated to the center C; the other radius, whose portion is CL, will then be — for by Proposition I the parallels are sensibly equal to FB itself, and the semidiameter CP of the aperture is sensibly equal to the right angle LB. Given therefore CP, let the semidiameter TB be given; and the known TL remaining, since the said distance CT will be, the angle TCL — and thence the whole KCL, equal to the conterminal, under which the eye in C is constituted, would be seen as the Sun; and its apparent diameter.

[Margin: Objectio. (Objection.)]

But the apparent diameter of the Sun, investigated by this method, is either equal to that seen by direct gaze in C, or — as certain friends of ours doubt — because the extreme rays of the Sun, evidently moving the senses with the eye placed

directly in C, and more strongly, move the senses with the eye seeing the Sun from C; for they radiate from the same point of the Sun upon the surface of the Eye's tunic, with innumerable rays which, by the benefit of refractions, are diminished within an imperceptible point, and so painted upon the Retina of the eye, as if with a brush they paint into it a very intense appearance which they represent, as is known to those skilled in the recent Optics. But the rays FB and GA, touching the appearance, are single, and so weak that they cannot move the sense, and evidently represent the extremities of the Solar appearance; which would be greater, if a sufficient number of rays were representing the Sun. If therefore it appeared less than it ought, while, taking away the whole right line TB, or LB, it is wholly subtracted from that appearance, then more is removed; therefore the angle TCL, and the smaller apparent diameter, is acquired than is fit, and than it was seen in C, by direct gaze.

[Margin: Respondeo. (I reply.)]

I reply: for this reason we did not require in the proposition so whole an appearance, as a well-disposed eye can — well-disposed and applied to discern evidently — knowing always that some little of the Sun's appearance is not led off through the cause adduced, because nevertheless in geometric rigor BL is greater than CP; let something be subtracted, because some little compensation [is to be made] for a part of the appearance lying hidden, namely the imperceptible part; and so equally the appearance of the Sun for the same is perceptible, that the diameter of the Sun for that received be less than the appearance seen with C; and from this we conclude, that by this mode of direct gaze, when we take the diameter of the Sun, by no means at the same moment do we obtain it by two instruments, and with observers of the highest and lowest altitude, on the one hand from the highest part of the air; and on the other, by numbering the perpendicular with the aid of time, in which the Disc of the Sun on the days of the equinoxes passes through two finest threads in the

plane of the meridian extended; we found very often so great a diameter of the Sun, as much as by the said reflected gaze through the said appearance, and somewhat — though not rarely a little smaller. From this we concluded that one cannot evidently demonstrate the diameter to be obtained by direct observation, larger than that received through the aperture appearance, etc., consequently. Therefore, it is useless, in practice, to inculcate to astronomers this subtlety, which exceeds every human sense, however diligent. For it suffices that in these matters we obtain a diameter as exact as suffices for resolving and representing the heavenly phenomena to men dwelling on earth.

IV. PROPOSITION

Given those things stated in the III. Proposition, the apparent diameter of the Sun is given, to an eye placed at the point of intersection of the Rays comprehending the appearance of the Sun: both the distance of that intersection from the plane receiving the appearance, and the distance from the center of the aperture, in the perceptible sense.

Persisting in Fig. II: there, by Proposition III, the angle TCL is given; and parallel are HB and CL, by I. Proposition, applied secondarily, so the said angle is equal to the internal one, and opposite, THB, by 29 of Book I [Elements I.29]. Hence the whole angle AHB is given, bisected, as before we had it, cut, AB perpendicular to HT. This is equal to the angle FHG, under which, at the point of intersection H, the diameter of the Sun would be seen. Then in the triangle HTB, right-angled at T, given the angle THB, and the opposite side, that is the semidiameter of the Sun TB, the distance TB will be given by trigonometry as the other side HT, which is the distance of the point H from the plane AB, if there be taken away the previously given CT; there remains the distance of the points CH.

V. PROPOSITION

The distance of the point of intersection of the Rays comprehending the appearance of the Sun, through an aperture of perceptible size, from the center of the aperture, is sub-double the semidiameter of the aperture relative to the semidiameter of the appearance, if the semidiameter of the aperture be sub-double relative to the base of the appearance; equal, if the distance of the aperture be equal to the semidiameter of the appearance; smaller, if smaller than half the appearance; greater, if greater.

In the same Fig. II, since the semidiameter of the aperture CP is parallel to TB, in the triangle HTB, it cuts off, by 2 of Book VI [Elements VI.2], HT of the same proportion as HC, of which CP is to TB. Therefore, if TB be double CP, then HT will be double HC; if more than double CP, then HT will likewise be more than double HC; and so HC is smaller than CT. On the contrary, if TB be less than double, then HT will be less than double HC; and so HC is greater than CT.

It is customary, however, in the Instruments of Astronomers, to assume the distance CH smaller than CT. We have an example in the great Gnomon of S. Petronio, in which there is assumed CT of 100,000 parts, of which the semidiameter of the aperture CP is 100, and the semidiameter of the apparent Sun near perigee is the same 100; and the angle TCL given is 16 minutes. Whence we obtained CP, 100, that is, equal in the perceptible sense to LB, and the angle

THB likewise 16', by which we gather the whole TH of 121,500 parts, that is 16'; therefore there are Roman paces almost 100, and with the angle THB, of 121½. Then TC, the foot 121½, and the distance of the points CH, the foot 21½.

VI. PROPOSITION

The apparent diameter of the Sun, found through the whole appearance of the Sun by a perceptible aperture, is false, and perceptibly greater than that diameter which appears to the eye gazing directly at the Sun from the location of the aperture.

Let there be drawn, in Fig. II, from the center C of the aperture, the extreme rays CA and CB of the whole appearance of the Sun; for then the angle ACB will be greater than the angle LCK, which is the measure of the apparent diameter of the Sun to the eye C, by Propositions II and III. But because the aperture OP is perceptible, and by Proposition I, the half CP is equal to the right line LB, halved; and OG equal to the right line AK, perceptibly too; whence the excess of the whole appearance AB over the corrected appearance CT exceeds it. But should anyone think that this difference in the Sun consists of seconds of scruples, let him take an example from the preceding Proposition, in which we showed that, from a semidiameter of the Sun near perigee of 16 minutes, and a distance CT of 100,000 parts, and the semiaperture CP, that is LB, of 100 parts, the whole semiappearance TB, that is CT, with the angle TCB of 16' 55½"; hence the angle TCT, of 16' 55½", the whole following angle TCB of 16' 55½"; therefore the whole angle of the Triangles is 16' 55½"; and the angle ACB, of 19° 16" — or rather the whole angle ACB, of 38' 52" — is an enormously larger diameter of the Sun, which is found both through the corrected appearance KL, and by observing the Sun directly in C.

VII. PROPOSITION

To know and measure the appearance of the Sun and the lunar shadow, the quantity of a partial solar eclipse [Eclipsis Solis Partialis].

Into a long tube — of a black or bluish color within, fit to absorb the reflections of the rays — let there be inserted a thin perforated plate, with an aperture of the size of one inch, not exceeding it, set at some part of the tube, to which is fixed a little beam sustaining a well-polished and white tablet of the aperture; and in that same straight line, in which is the axis of the tube and the center of the aperture. Then from that straight line, the appearance of the Sun, when an eclipse of the Sun is exposed outside the little window of the tube on that part on which is the plate of the aperture, and let it be concluded that obscuration occurs, whether by

the absence of the aperture, or by the slit — except that the appearance of the aperture, from the plate, penetrates the tube on one side; and let the appearance of the Sun be converted into a single side, until the center of the Sun's appearance coincide with the same in the white tablet noted; soon afterward, in the periphery of the Sun's appearance, three points are noted, so that through them one can find the center, by the prescribed 3 [points]. Element 4. of Book I: let there at once be assumed an interval up to the periphery of the Sun's appearance, and from it let a circle be described, and let its diameter be divided into 12 equal parts; but one at least, as a subdivision into the minutest equal little particles, say 100, or 50, etc. — of whatever quantity it be, or however the diameter of the aperture be. Having begun, as before, in truth, let the lucid round of the Sun be moved, until the appearance of the Sun begins, and from the periphery of the said circle let the lucid appearance of the Sun be congruent on the periphery of the circle; and where the eclipse first stands, let the increasing quantity grow in the highest [part], nor more does the appearance grow into the interval of the lunar shadow, and the periphery of the lucid appearance of the Sun, in the diameter of the circle, bisects bifariously, cutting the shadow [umbra]. How much, however, is made by this interval, learn from the periphery into the diameter; so that the difference be in the parts and little particles. It expedites also, at once, in the highest [part] of the eclipse, to note three points by the appearance of the lunar shadow, two points on the common intersections of the two peripheries — the shadowy, namely, and the lucid; thirdly, however, at pleasure, but by Element I. 3 [Elements III.1], the center of the circle of the lucid appearance can be found congruent, and thence whatever part, from the diameter of the lucid appearance, has been obscured by the Lunar Shadow.

And as in Figure III: let there be noted the two points B and C, in which the peripheries of the lucid appearance ABC and of the Lunar Shadow GBC cut one another mutually; and besides, let the point H be noted, as it is found in the periphery of the lucid circle, with center F, and through that line the Diameter GH, continued with the diameter AI, easily distinguishes the circle by the measures of the eclipse absolutely; and being detected from the arc BIC, whatever part has been shaded HI, compared both with the whole Diameter, and with that other part itself AH, which was immune to the shadow [umbra]. And in this way indeed the eclipse of the Sun will be partial, not Annular.

But if it be Annular — that is, in which around the Moon, in the highest [point] of the eclipse, there appears from the Sun's Disc a certain Crown [Corona], or a lucid ring all around — there will appear also, within the corrected appearance DH, the whole circle of the Lunar Shadow [umbra Lunar], somewhat equally on all

sides, distant from the periphery of the luminous one. And in Fig. IV, when the Eclipse is Central — that is, when in the same straight line are the centers of the Luminaries, and the eye of the observer — let it be sufficient to take with a compass the interval of the peripheries visible at pleasure, which the least

the smallest, say AB. Sometimes, however, the parts of the periphery will not be equally distant from one another, as in Figure IV; and in that case one must take the two greatest intervals, the maximum CD and the minimum FG — unless FG should happen to touch [the other], in which case it suffices to take the maximum CD as a tracing-thread across these intervals above the diameter of the Sun's image. Let the proportion of the obscured diameter to the [whole] be noted.

VIII. PROPOSITION.

In an annular solar eclipse — and especially a central one — given the proportion of the Sun's image and of the lunar shadow, given the just measure of the eclipse through the insensible aperture is given in digits; or even in scruples, of what magnitude is the apparent diameter of the other luminary, and thence is demonstrated the proposition through its parts.

Let Figure V be brought in here, its explanation set out there on the left for the first case; or, if the aperture is insensible — almost vanishingly small, supposing the case to be possible, even if in practice it is impossible — these things being supposed, the proposition is demonstrated through its parts.

First, then, in triangle AGH the angle GAH is subtended [by] the base of the lunar shadow GH, in the position represented on the visual disk by CD; and the Sun's image by EF. Therefore per EF, and per 1, of the first Element, [it is] equal to angle EAF, subtending the apparent diameter of the Sun CD, and the part of the Sun obscured by the base EF. Therefore, by how much the eye A, turned toward the reflected image, sees the shadow GH, by so much, turned toward the Sun, does it see the Sun; and it estimates the obscured part of the Sun by it, even if it does not yet know how great it is. Similarly, in triangle LAM, the angle LAM, subtending the image LM, [is equal to] the obscured portion GH, and the remainder LG, and HM; hence the illuminated [part] becomes — equal indeed to the angle IAK, subtending the Sun's disk on the visual surface IK, as is plain by 8 of the first [Element], [it is] obtained from the Moon, the remainder indeed IE, and HF, [is] the apparent angle subtending it; and so much per 8 the angle apparent to eye A, directly contemplating the Sun, by how much then downward the contrary appears [as] the remaining image of the luminous part LG and HM; because, the [rays] intersecting one another mutually at A, the rays IM and KL, not tangent to

the Moon, just as the rays EH and FG, [are] tangent to that [Sun] of the angle; I note that IAE and HAM, since they are equal, just as the angle FAK and GAL, are between themselves. Therefore, just as the Sun is reckoned eclipsed, so by the rays it is estimated; in all these things also, with the parts of the luminous LG and HM; because, the [rays] intersecting one another mutually in A, the rays IM and KL, not tangent to the Moon, just as the rays EH and FG, tangent to that of the angle; I note IAE and HAM, since they are equal, just as the angle FAK and GAL, are between themselves. Therefore, as the Sun is reckoned to be eclipsed, so by the rays it is estimated; and as much as one luminary covers, so much of the other is read off.

The second [case], if the diameter of the other luminary apparent in scruples of one degree be given — for example, let the apparent diameter of the Moon be, by the preceding measure, CAD, 28 minutes; and per the foregoing discourse let the part of the Sun eclipsed by the Moon be of digits 10 and $\frac{1}{3}$ — that is, the whole solar disk of digits 12; if therefore the visual image of the Sun be estimated at 1, that is, of $10\frac{1}{3}$ and of 12 in scruples 28, and beyond, the 28th scruple proceeding, [is] of 32 scruples, for the apparent diameter of the Sun, and so of the rest.

IX. PROPOSITION.

Given the apparent diameters of the luminaries to the eye in the insensible aperture, or constituted in the pendulous insensible [aperture], and the distance of the aperture from the tablet receiving the image of the luminaries, and the just measure of the shadow of either: the apparent quantity of the image of the luminaries is given; and thence the apparent proportion to the observer of the annular solar eclipse, and especially the central one.

Let Figure V be supposed, as explained above. First, in triangle AGH, given the apparent lunar diameter, that is, angle CAD, given also the converticle GAH. Therefore, having drawn the perpendicular AB, the semi-[diameter] BAH is given, and the distance AB; in triangle ABH, the rectangle on AB, B. Therefore, through the canons of triangles is given the semi-diameter, the base BH, the whole shadow's half, or the Sun's image GH, in parts of what magnitude the note is AB. Likewise...

given the apparent diameter of the Sun, that is, angle IAK, the converticle LAM is given; and dividing it in two by the perpendicular AB, the angle BAK, in triangle AKB in the same rectangle on B, given therefore the distance AB, BM is given, the semi-diameter of the Sun's image, of which the remaining portion BH, the

obscured image of the Sun is composed; but indeed HM is luminous. Therefore L and M, and the proportion both of the whole composite image LM, and of the illuminated parts LG and HM, and the obscured parts GH.

An Example Afterwards to Be Used More Than Once

Let the apparent diameter of the Sun at perigee be 32 minutes, and its semi-diameter (that is, angle BAM) 16 minutes. Let the apparent diameter of the Moon at apogee be 28 minutes, and its semi-diameter 14 minutes (that is, angle BAH). Let the distance of the planes [of] equal distance AB be of 100000 parts, of what magnitude we measure in the gnomon of San Petronio [San Petronio gnomon] (Trigonometria of Pitiscus [Pitiscus]). For in triangle ABM the trigonometric ratio gives BM of $465 \frac{1}{3}$ parts; therefore the whole LM of $930 \frac{2}{3}$ parts. Likewise, in triangle BAH there is found BH of $407 \frac{3}{8}$ parts; therefore the whole part eclipsed [is] of $814 \frac{3}{4}$; and hence the illuminated parts LG and HM, summed, $116 \frac{7}{8}$.

X. PROPOSITION.

In an annular solar eclipse, the proportion of the Sun's image and of the lunar shadow [made] by the aperture of the sensibly admitted [rays] is not the same as that which [is made] by the aperture of the insensibly admitted [rays]; and therefore through it the just measure of the eclipse is not assumed, as [it is] in the tablet; but much smaller, just as it appears to the eye through the aperture in place of the eclipse; nor is the just proportion of the diameters of the Sun and of the Moon [given].

Kepler [Kepler] had asserted this universally concerning solar eclipses, in his *Astronomia Optica* (cap. 2, Proposition X), saying: *In the image, or ray, of a deficient Sun admitted through a round window, the corona, which is not acute in the heaven by legitimate admission, but appears in obtuse reduction.* And in Proposition XI, where it [says]: *The diameter of the Moon in images of this kind appears smaller than it [does] outside in the heaven.* And in Proposition XII, where it [says]: *The digits of a solar eclipse appear fewer in the ray than [they do] in the heaven.* Not only had he asserted this, but also demonstrated [it] further; and (cap. 11) he had taught the method of avoiding these fallacies at Problem 6, ad 13. (Problem 7.) *It is plain that, unless the aperture be in the manner of a point, the proportion of the diameters is always altered; and just as the Moon appears smaller, so [too] do fewer digits appear,* etc. But this, as though suspect from some other side, this not only did those two Fathers [Patres] pronounce suspect, but plainly false — as is stated and understood above. They could rightly understand by Figure V whatever truths there are in Kepler's, or in the Proposition of the

figure-drawing. Let it be [granted] that Kepler does not descend to the particular case of an annular eclipse — and especially the central — yet the rest of what we have set forth above (ad 13) we set forth with [more] order in teaching, and with greater clarity of cause.

For, supposing — whether possible, or not, but [only] imaginable — the insensible image of the species through an indivisible aperture A, in Figure V, the whole image of the lunar shadow GH, with the aperture loosened however to NO, and posited; the Sun's rays touching the Moon, and the margins of the aperture, namely by ray PCNQ, and RDOS, the whole image of the lunar shadow SQ. Since the image of the lunar shadow [is] of the earlier [magnitude], the indivisible aperture A, having been made, the portion QH, illuminated by the rays going out from the segment of the solar disk EP; and the portion GS, by [those] going out from segment AO. Since, however, the Sun's rays PQ, and RS, touch the Moon in the same physical points CD, in which the rays EH and FG touched it, and therefore from the same point of contact CD they descend ad space onto the earth QH, hence, and GS; thence, [it is] that which is supposed [to be], unless they appear divided by half a milliary *Italic*; and so much per Proposition I, they are parallel to sense, and therefore the semi-diameter of the aperture AN, equal to the physical distances of the plane of the portion QH, and the semi-diameter AO, of the segment GS, follow manifestly: the image of the Moon GH, indivisible by the aperture admitted in image; oblique, contracts; so much, [by] how much is the aperture's semi-diameter, and the whole [is] just as much as is the aperture's diameter NO. For...

[Margin: An argument in form]

For, on the contrary, the Sun's image [is] composed in part [of] its obscured part, and [in] part of the illuminated part, through the indivisible aperture admitted, it goes out [as] the sole image LM. The aperture being loosened, however, TV evades; for as the same rays of the physical points IK, descend; nor can [those] illustrating the parts MV, and TL, all by the same rays; which can enter through the same semi-diameter AO, just as it can be the semi-image AN; and because MV, just as TL, are supposed in the customary observations [to differ by] less than half a milliary *Italic*, and consequently per Proposition I [are] parallel to sense; and therefore [are] equal between themselves AO, and MV, just as AN, and LT; it follows that the composite image of the Sun is increased on both sides over its earlier [magnitude] LM, by so much [an] increment, [by] how much is the aperture's semi-diameter, the whole indeed [by] how much is the aperture's diameter. With these things supposed, the argument is redrawn into form.

[Margin: The argument in form]

In whatever way two quantities formerly equal, or in like manner unequal, are made — by reason of the proportion not being preserved the same as it was before. But in the proposed case, the image of the lunar shadow, or of the Sun, through the indivisible aperture admitted, were equal between themselves; but through the sensible aperture, the lunar [image] is decreased by just so much as the solar [image] is increased. Therefore the same proportion of these is not preserved, as before. The major [premise] is plain by the doctrine of proportion handed down by Euclid [Euclid] (Book 5, Element extended), and by Fernel [Fernel], Cardano [Cardano], and others. For, that it may be continued, or that the same proportion of two quantities, [whether] inequality, [whether] equal, be preserved, both must, in the same proportion, be increased, or in the same equally; or, if [the proportion] indeed were equal, just as [if] equal, [then] one minuted, the other increased. The minor [premise] is proved both [as] shown, and [as] the lunar shadow's image decreases by so much as the Sun's image increases; namely, by the whole quantity of the aperture's diameter. Therefore, etc.

But although in an annular eclipse — yet not central — the situation of the lunar shadow [is] diverse [in that] it is from it, as Figure V represents, [if] the Moon be in the highest [part] of the eclipse, declining to the left part; the lunar shadow [is] medium-full, ad B, [in] the right [part] of the solar disk; the Sun's rays indeed [are] medium-full, to the left [part] of the tablet descend, and to the right of the solar disk in the tablet's right; the image appears larger, [in] which [is] the image itself of its left [part], than the right; [the] compensation nevertheless being made: so that the whole augmentation of the Sun's image on both sides, summed, [is by] how much is the diameter of the aperture; and by so much is made the decrement of the image of the lunar shadow.

Furthermore, the same proportion of the images not remaining, it is certain that there cannot be obtained the just measure of the eclipse in digits — much less the just proportion of the diameters in scruples — as long as the species of [either] is taken up [as] the incorrect, and as it appears in the Table of observations. For, from the said Proposition VIII, the just [proportion] is that which is deduced from the proportion of the aperture in the indivisible, and through the sensible aperture that proportion is destroyed; nor can it be had the just by it. Which by an example also shall be made clear.

An Example for Practice

Persisting in the example of Proposition IX. Let the Sun's diameter at perigee be 32 minutes, the Moon's [diameter] at perigee 28 minutes. [It is] certain that in such a central solar eclipse the Sun is obscured by the Moon by 32 minutes minus 28 minutes; and thence likewise, that [there are] 4 [minutes] remaining immune from the eclipse; this posited, then, [if] the distance of the aperture from the tablet [be of] 100000 parts, there comes out by necessity the Sun's composite image LM of parts $930 \frac{2}{3}$, and the lunar shadow [of] parts $874 \frac{3}{4}$; let it be loosened now [as] aperture; and let NO [be] of 200 parts, of what magnitude AB is 100000. For, as we showed in the Proposition of this proving, the whole image is increased by the quantity of the aperture, the Sun's image, and the whole [image] by the same quantity the lunar shadow's image is minuted. Therefore the whole TV [is] of parts $1130 \frac{2}{3}$, and the shadow SQ of parts $614 \frac{3}{4}$. Make now [as] of observed measure of such an image, [as] it appears in the Table of observation; so that TV $1130 \frac{2}{3}$ ad digits 12; ita $614 \frac{3}{4}$ ad the fourth proportional number, and there come out only digits $6 \frac{53}{113}$; whereas there ought to be digits $10 \frac{1}{3}$; since indeed by 32 [minutes] the Sun's diameter is scruples [of] 12, [and] is obscured ad digits $10 \frac{1}{3}$. Therefore, if anyone should observe a solar eclipse from A, directly, he would see manifestly [that the Sun is] not eminent from the eclipse free...

from the solar disk except by $1 \frac{2}{3}$, hence, and $1 \frac{2}{3}$ thence. The other observer, however, observing the same eclipse in the Tablet, and computation having been made from the species in proportion, just as he will, by the corrections, [he] pronounces, not [that] the eclipse was just digits 6 [but] of circiter 7; apparently both of the Sun obscured [as] of digits at the nearest $10 \frac{1}{3}$; the whole indeed and both; and perhaps, contesting one [against] the other, [out of] the hallucinations he insinuates; meanwhile let each [of these] direct observers of [those things which are] perhaps subtleties unknown labor [under] the existing geometry; than which Table the observer professes, or [it would be] ridiculous, [if he should] have the artifice of astronomers.

XI. PROPOSITION.

In an annular solar eclipse — especially a central one — given the sensible aperture's quantity in parts, of what magnitude the note is. The just quantity of the eclipse [is] to be demanded by the aperture of the sensibly admitted [rays]; and the lunar shadow's image is to be added, that there may be had the just quantity of the eclipse; and the just proportion of the images, and of the diameters of the luminaries [is] analogous.

For, the aforesaid correction of the case of Proposition XI having been made, it is reduced to the case of Proposition VIII and IX; ad the case of the indivisible aperture, in which the same we showed [holds]: it has the just quantity of the eclipse, and the proportion of the diameters, etc. The species are taken up indeed [in] this way, [but] absurd, collecting quantities, etc. But it could be doubted, and difficult [to] correct the other [image], and to redraw [it]; the example set forth above [is] of four modes, which finger [pointings] can be [used] in practice [to] correct [it]. These things posited, then, [with] the diameters of the Sun 32 minutes, and of the Moon 28 minutes; therefore, [in] an eclipse of minutes 28, or of digit[s], of what magnitude the diameter of the Sun is estimated [at] 12; and the aperture's diameter posited [as] of parts 200, of what magnitude the distance of the planes [is] 100000. There come out the species of the Sun, and of the lunar shadow now corrected; and as above prescribed; let the incorrect [species be] corrected, as in the following little table:

Species	Solis part. [Sun's part]	Vmbra Lunar. [Lunar shadow]
Incorrecta [Incorrect]	TV 1130 2/3	SQ 614 3/4
Correcta [Corrected]	LM 930 2/3	GH 814 3/4

But a fourfold proportion could be instituted; namely, of the corrected Sun to the corrected shadow; of the corrected Sun to the incorrect shadow; of the incorrect Sun to the corrected shadow; and of the incorrect Sun to the incorrect shadow. So [the] digits [of] 12 ad the corrected solar digits, and there come out [the] digits, as in the table written below:

Speciebus [By the species]	Vt partes [As the parts]	Ad partes [To the parts]	Sic Digiti [So digits]	Ad Dig. Eclipsi. [To the digits of the eclipse]
Incorrectis [Incorrect]	TV 1130 2/3	SQ 614 3/4	12	6 59/113
Correcta Solis [Corrected Sun]	LM 930 2/3	SQ 614 3/4	12	7 86/93
Correcta vmbra	TV 1130 2/3	GH 814 3/4	12	8 73/113

Speciebus [By the species]	Vt partes [As the parts]	Ad partes [To the parts]	Sic Digiti [So digits]	Ad Dig. Eclipsi. [To the digits of the eclipse]
[Corrected shadow]				
Correcta Vtraq; [Both corrected]	LM 930 2/3	GH 814 3/4	12	10 1/3

It is established, therefore, that by no other mode is the correction here to be made than as we have prescribed [it] in the Proposition; and [that] each man errs most basely of all, who contends to correct neither species, since he must indeed recede most greatly from the true quantity of the eclipse — which in such a case is necessarily [of] digits 10 1/3.

Parsing notes: The four-row table's rightmost column ("Ad Dig. Eclipsi.") is partly obscured by tight composition; readings are 6 59/113, 7 86/93, 8 73/113, 10 1/3 — the denominators of rows 2 and 3 are faint. The only fully-defensible value is the last (10 1/3), which the text confirms as the true measure.

XII. PROPOSITION.

Can a solar eclipse appear annular to an eye intently gazing on the Sun's image, and the lunar shadow in the Tablet, projected through a sensible aperture, which nevertheless does not appear [annular] in the open air; nay, [it appears annular] not only out of place, but [also] out of time, observing the eclipse out of place, if indeed the aperture be notably larger than the aperture of the projecting eye.

I do not describe a peculiar figure for this, for Figure V can serve, [if] our accommodation be applied. Let the whole disk of the Sun be not at IK, but at EF, of which the extremes E, F, [are] the rays touching the Moon [as they] run into the pupil, or [into] the aperture of the projecting [eye], the whole Sun itself [being] covered by the Moon, [it] will appear under angle EAF. But the aperture posited...

by the aperture NO, notably larger than the aperture A of the pupil, [the rays] will be able to enter to the sides of the Sun's segments EP, and FR, the rays not touching the Moon physically in CD, but avoiding all contact with it, or [coming in] at remote distances ad C, and D, intersecting [one another], of which the extremes are PNQ, and ROS; and so the lunar shadow appears between the parts

SQ, and GS, neither subtending the angle GAH, equal to the angle EAF, under which the eye A sees the whole Sun obscured; but [it appears] the smaller angle SXQ; [it] is fitting nevertheless [that] the aperture be very large before the eye, if the angle SXQ ought to be sensibly diverse from the angle GAH, and the parts GS, and QH, be sensibly illustrated.

XIII. PROPOSITION.

In a partial — yet not annular — solar eclipse, the proportion of the species of the Sun and of the lunar shadow [made] by the indivisible aperture of the insensibly admitted [rays] gives the just quantity of the eclipse in digits, or even in scruples, of what magnitude the note is of the Sun's apparent diameter.

For the truth of this Proposition there are three figures to be inspected, namely Figure VI, for a precise solar eclipse of 6; and VII, for a smaller eclipse of digits 6; and VIII, for a larger [eclipse] of digits 6. These having been understood, [it is] easy to understand the ratio of the proposition I [now] put forward. First, then, before any eclipse, [if] the Sun's image FD be supposed [to be made] by the indivisible aperture A, and dimensioned: this disk and image, going out from the left of Figure [VI], with the rays touched BHG, and the indivisible aperture A, of the solar disk's segment CG, and in the Table is seen the obscured image of the segment BD, by the other [segment] FB, illustrated [as the] segment GE, [a] ray of the segment GE, which similarly the segment discovered [in the obscured part] is seen [by] the eye, [it] subtends the angle GAE, to which [is] equal angle BAF, measuring the part BF, [the] illustrated image, just as the angle CAG, under [which] the eye sees the part A, [the] obscured part [of] the Sun, or covered by the Moon, and [it] is equal to angle BAD, measuring the part BD, the obscured [part]. Therefore the eye, by the conversion ad the Tables LM, [estimates] so much [as is] estimated of the eclipse, [the] eye reflected by the intuition, by how much the conversion ad the heaven [is] directly intuited. Therefore, if [it be] just, [then] the whole FD, [the] whole eclipse FD; this image [is] composed, and noted in some measure, say [in] hundredths, particular [parts] of a Roman inch [uncia Romana], ad digits 12. So [is] the shadow BD, in the same species particular note, ad another [thing], proceeding [for] so many [things] which [are] the eclipses estimated [by] the observer of the eclipse from A, contemplating the heaven. But if the Sun's diameter be noted in scruples of one degree, multiplying by particular inches of the Sun's image composite, [the] shadow BD, in the same dividend through scruples of the whole [is] the just diameter, [there] comes out the scruples of the Sun's image eclipsed by the Moon. Per Figure VII, attend the lines BD, [as] adhibited per VI, and VIII, [is] adhibited GB, etc.

XIV. PROPOSITION.

In a partial solar eclipse, although not annular, the proportion of the species of the Sun and of the lunar shadow [made] by the aperture of the sensibly admitted [rays] is not the same as that [made] by the indivisible aperture of the insensibly admitted [rays]. And therefore through it, taken up [in this way], the just quantity of the eclipse in digits is not obtained, as appears in the Tablet [where the rays] are not received in scruples of one degree.

Figures VI, VII, and VIII are to be recalled again; the exposition having been adjusted to them; for they have been well perceived [and] the truth of this proposition will be readily established. The aperture being loosened, then — which is fit [as] IK, and before the eclipse [if] the extremes of the Sun's rays CKM, and EIL — the Sun's image then [is] luminous [as] the whole LM, which measure [is] just per the said Proposition VII. The Moon arriving afterward, [as] the parallax of latitude, hence, and contacted [in] the parts OHKP, [it] subtends in the highest eclipse, the lunar shadow; not varied however [as] evading [the] parts HB, of its own peripheries, [it] subtends; sed not [by] quantity; [it] subtends, in [as much as it] is just [as much as] is detected BB, in P, quod, hence, ad parallelism of the Radii AN, and HP; or [is] equal [to the] semi-aperture AK, [it] acquires the whole at its extreme D, occupying the space [in] the earth CAD, and CKM, [which] is equal [to the] semi-aperture AK; and so the space ratio per the lunar shadow PM, [is] equal [to the] prior BD. But, on the contrary, the portion of the solar image illustrated by the rays of the solar segment OE...

the whole LP, when in the case of the indivisible aperture it would be only FB; [there] is indeed the [image] LF, by reason of the parallelism of the rays EAF, and EIL, equal also [to the] sense [of] the semi-aperture AI; and so to part BP, from the shadow [it] is left over. Therefore the whole image LP, which remains illustrated, increases [by] the illustrated [part] FB, the whole quantity of the aperture being composed [of] LF, and BP; the remaining indeed [is] the augmentation of the image lucid, namely [as much as is] illustrated DM, nor [does] augment the image obscured, just as posited; lucid in the eclipse, [as] indeed they occupy the position, [and] permute. With these things supposed, the argument is thus formed.

[Margin: An argument in form]

In whatever way two quantities formerly equal, [in] one [way] remain invaried formally, and equivalently, because [it] remains so much only [as] increases out of one part, [by] how much out of the other decreases; the other indeed absolutely is made [the] major itself, [it] does not remain the same [in] their

proportion as they had before. But in a partial solar eclipse, although [it be] not annular, the image admitted [as the] species per the sensible aperture, the lunar shadow's image remains invaried equivalently; because, [by] how much it loses on the right of the space detected out of one part, [by] so much only [does] it occupy out of the other; [whether] in the case of the aperture in the indivisible [it] were equal [to the] lucid portion of the solar image, just as in an eclipse of digits 6, [whether] it be minor, just as in an eclipse of digits fewer than 6; [whether] it be major, just as in an eclipse of more digits than 6. On the contrary indeed the lucid portion of the solar image [is] always made major than itself, [whether] just as [it would be] in the case of the aperture in the indivisible. Therefore the aperture admitted [as the] species of the Sun, and of the lunar shadow [is] not the same proportion, [as] that [made by] the aperture in the indivisible admitted.

The major [premise is] plain by the doctrine of proportion as evident as [a thing] deduced from the first principles, or definitions. The minor [premise] is proved [as] by the exposition itself of the figures VI, VII, and VIII discoursed; furthermore on this fact, virtually extended through all the possible cases of a partial solar eclipse.

The proportion, however, not remaining the same, but varied, per [the fact that] through it cannot be obtained the just quantity of the eclipse, which [would be] obtained per the proportion of the aperture in the indivisible reception. But per this [is] obtained the just quantity of the eclipse per Proposition XIII. Therefore by that other [way] it is not obtained [as] just.

XV. PROPOSITION.

In partial solar eclipses, given the quantity of the sensible aperture, and of the species of the Sun and of the lunar shadow; the Moon [being seen] through that which [is] admitted, [there is] obtained the just quantity of the eclipse, [it being] subtracted from the whole image of the Sun composite [of] one part of the image illustrated, the whole quantity of the aperture; the lunar shadow's image indeed [is] to be diminished [by] the semi-diameter of the aperture out of one part, and to be added out of the other; this [is by] arithmetic nothing to be added, [or] to be subtracted from it.

The reason is, that this case is to be redrawn ad the case of the indivisible aperture, through which is had the just quantity of the eclipse by the said Proposition XIII; and without which [it] is not had per the said Proposition XIV. It is redrawn, however, [so] that that be made which in this proposition we said to be made; per the induction made through three genera of figures VI, VII, and VIII

represented; and by the said conjoined Proposition XIII and XIV [it] is plain; and briefly it is indicated, more clearly. For, just as the Sun's image in the case of the indivisible aperture is composed, [in] part [of] the lucid [part], and [in] part [of] the obscured FD, [so] in the case of the sensible aperture, [it] is LM, [the] major than FD, [by] the parts LF, and DM, [taken] simultaneously [as] equals of the aperture IK; [if] their aggregate be subtracted, [it] is redrawn ad the species LM, ad the indivisible image FD. Because indeed the lunar shadow's image [is] the species in the case of the sensible aperture [as] PM, so much augmented by DM, by how much [it is] diminished per BP; [if] from the shadow PM, [there] be subtracted DM, equal [to the] semi-aperture AK, and to the same [be] added BP, [also] equal to the same AK, [it] is redrawn again [as] BD, [the] therefore species fit, [and] of the same BD, [as] from the first ad the last in the computation arithmetic, nothing to be added, [or to be subtracted].

XVI. PROPOSITION.

Given the Sun's, and the Moon's apparent diameter in scruples of one degree, and the sensible aperture's diameter in parts, of what magnitude the note is of the aperture's distance from the plane of the species received; and given, finally, [the] quantity of the eclipse not yet observed: [there] is given the quantity of the species of the lunar shadow...

[Margin: the lunar shadow, and of the Sun, in parts — of what quantity is the aforementioned Distance.]

If, then, from astronomical Tables or from an Ephemeris you know in advance the foreknown quantity of a partial Solar eclipse, whether past or future, take the older Figure II, and with the apparent semidiameter of the Sun — that is, the angle TCL — search out the Distance CT of the eclipse, taking the indivisible aperture LB equal to the semi-aperture; you will then have the sensible image of the Sun TL projected through the aperture to the indivisible aperture OP. Next double TL so as to have KL, and let it stand that 12 digits correspond to KL. Then, just as you reckon the eclipsed digits, or the things to be eclipsed, for that proportional number, you will have the image of the lunar shadow as it would appear through an aperture as good as indivisible — but with the situation altered, as happens in non-annular eclipses. Yet if the Moon's apparent diameter is smaller than the Sun's diameter, the eclipse will somewhere be Annular, indeed somewhere even Central. Then, therefore, from the species of the lunar shadow, in order that the species of the whole diameter be more intently inspected, you will have the image of the shadow as it would appear through a

sensible aperture, by the rule that follows from the converse of Propositions XI and XV.

XVII. PROPOSITION

The same Distance from the image Plane being retained, however much the quantity of the aperture be varied, the same quantity of species is received, the parts subtracted (in Annular eclipses) or added (in the lunar shadow species) being set aside — provided no [other] quantity of species be added or taken away beyond the proper quantity of the species lawfully admitted.

By "right quantity of species" I mean that quantity of the species, equal to the apparent diameter of the Sun, which the indivisible aperture admits, fit for investigating in the manner of Proposition II the apparent Diameter of the Sun itself. This Proposition rests upon the Corollary deduced from Propositions XI and XV. For no proportion of addition or of subtraction is to be made such that the species be founded upon a like cause as the increment of the Sun's image and the decrement of the lunar shadow. But if the distance has been so great as to obtain that very equality, then, while the aperture remains so moderate that it is fit for representing the species, the same equality of distance will remain so long as the distance is unvaried. Hence it comes about that, if the quantity of the aperture be varied, and afterwards that quantity be taken away from the species of the Sun, there will not be found by this means the species so corrected at the same Diameter, with the aperture-quantity of each removed, as was found exactly in the manner handed down in Proposition II. The sign of this is that the dimensions of either species were not exactly the same in our observations, and the Diameter coming out the contrary way for the same species and from the same observation was barely acceptable. To prove this point we were accustomed to undertake a threefold experiment of our observations, and from each to select that diameter of the Sun which, with the aperture of one or another quantity removed, came out the same on the same day in the same quantity [?].

XVIII. PROPOSITION

The quantity of the aperture being retained, and its distance from an equidistant image plane being varied — although the species received does not maintain itself at the same quantity through the indivisible aperture for the Solar species among themselves and for the lunar shadow species among themselves, by some proportion; indeed, although the increments or decrements of the species through the sensible aperture do not remain, that same proportion nevertheless remains among the total species admitted through the indivisible aperture.

In Figure IX let there be a luminary — say, the Sun — its center O, its extreme limb A, from which the extremity BC of the semi-aperture is produced to infinity along the ray AM; let BC be the semi-aperture, [drawn] through the center O of the luminary; and let EG, EHK, and DM, equidistant among themselves, be drawn from the same point O, perpendicular to OD, to which EG, EHK and DM are applied. For by Proposition 2 of the sixth Element [Euclid VI.2] the section will be cut proportionally, both for the Triangle BDL and for the Triangle ALM. Therefore the bases of the semi-aperture through the indivisible aperture B, admitted, namely EF, HI, and DL, will be proportional among themselves in relation to the distances BE, BH, BD. Moreover the increments of the species from one part of the Sun, or from the lunar shadow, that arise from the rays of the Sun entering through the semi-aperture BC — namely FG, IK, LM — can be in proportion among themselves. Yet the total species EG, KH, DM will not be in continuous proportion, but will be among themselves in the proportion that EF, HI, DL have among themselves, when the Triangle ALM is equiangular to the Triangle BDL, nor in the increments will the proportion be the same as the bases EF, HI, DL have. The proportion which is between EF and HI is greater than that between HI and DL, by the doubled interval of paces $972\frac{1}{4}$ in the Solar radius, but by 21486 in the lunar radius. For the more it is set down, by the greater interval; if less be set down, by the smaller interval — only by 5 paces [?]. For if a smaller interval be conferred at equality of the basis EF, HI, DL, above EF, and earlier than the excess FG, above BC, then IK, above FG, which by Proposition I per the doubled interval of paces $972\frac{1}{4}$ in the lunar radius, but 21486 in the Solar radius mounts up by paces only 5 [?]. Therefore, the physical inequalities EF and HI being made, if to these be added EF and IK, equal physically, the proportion which is between EF and HI will not remain.

XIX. PROPOSITION

The species of the Sun, and the lunar shadow, being given through a sensible aperture of a quantity not exceeding 10 parts in its own semidiameter, received in a plane not distant from the aperture by more than $972\frac{1}{4}$ [paces] for the Solar species; given also the semidiameter of the aperture, and the distance itself of the plane from the species, [the proportion] is of one kind. There are given all the remaining species congruent to the indivisible aperture, and to whatever lawfully admitted [species], given an aperture distance greater and lesser to infinity; and so the true proportion is observed in the greater, and at the distance observed; and the dimensions.

Return to Figure IX; let there be, within the aforementioned doubled interval BE, the given semispecies EG and the semi-aperture BC; in parts, of which kind is the same FG, physically equal to BC itself; per Proposition I. Therefore from the said Proposition XI and XV subtract FG, the semispecies admitted, and there remains the semispecies EF, due to the indivisible aperture B. From this is given the species due to the Solar [aperture]; and now, the Distance BE being given, the species EF; thus given the Distance BH, ad HI, ad datum BD, ad DL, and so to infinity; for you will have the semispecies due to the indivisible aperture. From these doubled, you will have the species whole through the indivisible aperture; and at length by their subtraction, as observed for the indivisible-aperture species, you will have the residue equal to the additament to be made for the lunar shadow as observed in eclipses through the indivisible aperture. In the remaining lunar-shadow species observed, it is not varied at the observed quantity.

Thus far concerning the case in which we suppose the eye constituted in the sensible aperture. Henceforth concerning the case in which the eye is constituted in the common section of the Sun's Radii above the Foramen sensible-aperture made — the lower aperture nevertheless remaining sensible, that is, the eye being constituted at the point Z, Figure V.

XX. PROPOSITION

The Distance given through Proposition IV and V of the point of intersection of the extreme Solar Rays through the margins of a sensible aperture, and a semidiameter of the sensible aperture being received in the plane of the species, and the apparent semidiameter of the Sun being received in a non-annular eclipse. The species of the lunar shadow is given apparent, the eye being constituted at the said point of intersection as it were an indivisible opaque aperture equidistant from the sensible aperture.

Let Figure V be repeated, in which, in accordance with the exposition there indicated, how much in actual fact the aperture NO is open. Yet imagine through the point Z of intersection, the plane being drawn, opaque [?]; the plane being drawn imaginarily, opaque, because in actual fact it is not parallel, imaginary, indeed, because in fact the rays do not there subsist; but they pass through the aperture NO, and the basis TV. Yet supposing this fancy, the species would indeed be of the Sun the same, which appears through the sensible aperture; some part shaded by the Moon, and the extreme [part] of either; near the extreme TV [?], it is illustrated, so that the lunar shadow image be $\delta \downarrow$, terminated from the Solar rays $aZ\beta$, and $\gamma Z\gamma$, touching the Lunar globe most nearly at C_2 and D_3 ; then

[Margin: figure II — because no line is drawn for the designating of the shadow; but We, of their Argument reduced into a form more faithful applicable to Figure V, that the distinction of the lines terminating the shadow may be more comprehended from the bright lines, may more clearly appear of the solution of the Argument. Therefore they go:]

then the eye constituted in Z, will see nothing of that segment of the Solar disc, which is within the points δa , the remaining segments it would see a, it would see still the maiusculam [larger] Eclipse, than it would be in A, and the species would pass through the indivisible A: a difference yet scarcely sensible by perception, would be on account of the nearness of the little point A, and Z, as demonstrated at Proposition V.

Therefore in such a case of the fiction, the data being given of the apparent lunar diameter, that is the angle CAY, given, and yet still it is adverted [to] BAH. Here the angle is equal, the interior, and opposite BZ, because the interval above so often by us supposed, the rays from the same physically point of contact δ , namely CAH, and CZ β , are sensibly parallel. Therefore in the triangle ZB δ , right-angled at B, with the said angle predicted, and with the said distance BZ; the semi-shadow B δ is given by Trigonometry, of which the double is the lunar shadow δd , the apparition Z $_4$ if &c.

Yet meanwhile let it be well adverted, the aperture NO being open, that the shadow itself in actual fact SQ, [is] not only smaller [than] the shadow GH, the aperture being open A, per the indivisible aperture A, but much smaller [than] the shadow δd , would appear at the point Z, indivisible; and below it will be inculcated what may be against the opponents in this Keplerian doctrine.

XXI. PROPOSITION

Although as to the Solar species' projection, the same thing happens, whether it be admitted through a sensible Foramen, or as if it were transmitted through an indivisible Foramen feigned at the point of intersection of the common rays touching the internal margins of the sensible aperture — yet not the same thing happens in comparison with the species of the lunar Shadow admitted per the sensible aperture and the Solar species; the lunar Shadows being feigned as admitted, [the Moon] being feigned through the center of the indivisible sensible Foramen, situated in either situation.

If Figure V is again attentively introspected, and the members of this Proposition be distinguished among themselves, the truth of all of them will easily be shown;

therefore it pleases to apply a more particular hand to the figures, and to demonstrate.

First, the amplitude of the aperture NO being posited, and its distance AB, the plane TV, receiving the species, and the proximate distance of the Earth, the nature of these things — the point Z, in which they intersect the extreme Solar Rays IZV, and KZT, as the species of the Sun TV, would appear, the eye being constituted at Z, than at A, and quite before the whole lucid eclipse; and so the same thing happens, because Z, in reality is not the point of any opaque aperture impeding the lucid projection of the species TV, but is the mere passage of the intersection of the rays freely permeating.

Secondly, because in reality per Z, not the duct [is] open, or the opaque plane standing in the way of the rays, sound — through the aperture NO, the rays freely enter and the basis TV, in part the rays enter from the segment ST₃; and from the Solar segment RK, and the part of the basis right [side] QV, all the rays arising are from the Solar segment IP; therefore in actual fact the lunar shadow image is contracted into the segment SQ, nor [is it] so great, as great as is the lunar shadow Bδ, if the interposed [aperture] were opaque αθ, nor would the other rays touching the Moon radiate, than ZB, and γZδ.

Thirdly, because through the indivisible aperture feigned in the center A, the Solar species LM, per the indivisible aperture feigned in the center A, and per the species feigned indivisible A. Therefore the species of the Sun in comparison would happen the same, much more if it were compared at the same species introduced through a sensible aperture in the plane αθ.

Fourthly, because in reality the shadow image SQ, is smaller than the lunar shadow too, [than] that which would be projected through the indivisible center A, namely the shadow GH; therefore not the same comparison would happen. Subordinate to this distinction it may be responded equally easily; as also as we shall demonstrate the chief principle of the said Fathers, which is of this kind:

Argumentum praecipuum contra Keplerum, & eius dissolutio.

[The chief Argument against Kepler, and its dissolution.]

Those Fathers indeed use another Figure, and a more similar Fi-

[Margin: figure to figure II than V; because no line is drawn for the designating of the shadow; but We, of their Argument reduced into a form more faithful applicable to Figure V.]

interposed the ray of the Sun touching the Moon, and terminating the shadow, passing they terminate solely through the point of intersection Z: for it is in actual fact SQ, which then would be $\delta\beta$. But it is another thing to consider these future things under condition, which would be, but is not; another thing what in the present is in actual fact not posited under condition, opaque $\alpha\theta$, but on the contrary the opaque position of the aperture NO, amplitude posited. *But it was easy to transfer through inadvertence that which agrees with the convenient observations feigned through imagination of the opaque $\alpha\theta$, impeding the ingress of the rays through the aperture NO, to the present matter, where the proportion of the Solar species at the lunar Shadow is to be considered not as it [the aperture] would be, but as it is in fact.* It is indeed much greater the excess of the Solar species, than it is in that fiction, and than that which is to be used, of the included Eclipses, even without relation to the quantity of the diameter of the Sun, but as to the number of Digits, it is to be had; and as to the number of the species responds to the first major proof.

To the *second* proof of the major, I distinguish, and that being granted, but not granted as to the parts of the more positive species; and really with it identified, I deny as to the parts negated, nor identified, of which kind is the shadow, in respect of the aggregate aggregated from it, and from the luminous parts; for daily we see in the aggregates from shadow, and from the surrounding light, that the whole aggregate remains of the same quantity, yet the parts of it decrease, the species themselves increasing. Indeed among the positive parts themselves, and identified by continuation; for example, among the parts of the vitreous water situated, [as] when included we see drops of water, [as] a full fistula, to remain of the same quantity, certain ones by force of nearer heat are rarefied, and occupy ampler place, others are condensed, and constricted; therefore, I said, *Data non concessa* [the data not granted].

FINIS.

Diagram. [Plate of figures enumerated for Appendix I of Chapter XII; six numbered figures arranged across the lower half of the page.]

- **fig. 1** (left): a tall narrow elongated triangle. Apex at top labeled **A**. The long vertical edge descends to a small box at the foot. Lower portion bears labels **B, C** (mid-left and mid-right of a horizontal crossbar) and **H, K, L** at the small box at the base. Represents the cone of the Solar species through the aperture (the long thin pinhole-image triangle).
- **fig. 11** [labeled "11.fig."] (center): an X-shaped (hourglass) crossing of two ray-pencils. Top labels **F, G** (left pair) and **N** (right). The crossing point in

the middle is labeled with **E, V, D, C, O, P** clustered around the intersection. The lower spread carries **A, K, T, L, B** along a baseline. This is the intersection-of-rays figure (the point Z / aperture geometry of Propositions IV–V and XX–XXI).

- **fig. 3** [labeled "3.fig."] (right): two overlapping circles (a larger lower circle and a smaller upper circle) representing the Sun's disc and the lunar shadow overlapping in an eclipse. The upper circle has labels **A** (top), **H** (interior near overlap). The large lower circle (shaded/hatched) has **B, P, F** along its vertical axis and **G** at the bottom. Depicts the partial eclipse overlap.
- **fig. 4** [labeled "4.fig."] (lower): two side-by-side circles, each with an internal shaded disc. Left circle: **A** (top), **B** (just below top), **C** (center), **G** (bottom). Right circle: **C** (top), **D** (just below), with **G** at the bottom. These depict the projected Solar image and the contracted lunar-shadow image (compare species SQ vs. GH of Propositions XX–XXI).

[continued from "autem"] of figure II, than figure V, because no line is drawn for the designating of the shadow; but We, having reduced their Argument into a more faithful form applicable to Figure V, [intend] that the distinction of the lines terminating the shadow be more comprehended from the bright lines, [and] that the solution of the Argument appear more clearly. Therefore they go [as follows]:

When the Rays transient through the sensible aperture NO, [it is] the same thing as to the species' projection, as if the Rays transient per their intersection through the point Z, where it would be opaque $\alpha\theta$, the rays resisting at all other places; the rays would enter through the point Z. But in the case where the rays transient through the indivisible point, nothing would be taken away of the Solar species; therefore neither would there be anything taken away in the case in which they pass through the sensible aperture NO. The Major is proved: *First*, as to the Solar species, because in both cases the same quantity of the Solar species, the same intensity of illumination about the extremities TV, through the penultimate point Z, which is the most lax of the aperture NO. Thereupon it follows that the lax aperture is evident; the discerning of the projected Solar species, and falls under sense, is not the same, but the effect would not be changed of the quantity of the Solar species TV. *Secondly* it is proved, as to the lunar shadow, because in both cases the same shadow-species would remain in quantity, neither increasing, nor decreasing, [in] the parts which themselves ought neither to increase nor decrease. But the Lunar body in the present case, and in respect of the plane in which it is observed, is as it were a certain Solar spot, and as to its own parts is partly

obscure; therefore neither would the lunar shadow image itself increase, or decrease.

The Minor is proved: *First*, by the authority of Kepler himself, who at chapter 11 [of the] *Astronomia Optica*, Problem 7 [*Astronomiae Pars Optica*]: *Unless the aperture be quite the minimum, made as it were the point's instar [likeness], the proportion of the Diameters is always varied, the Lunar [diameter] perhaps appearing the smaller, and the Digits fewer to appear*; virtually [Kepler] concedes, if the aperture were of the point's instar, the Digits not to appear fewer, and We, [agreeing] ourselves above, are not at all to hold the right quantity of the Eclipse, [it is] taught to be reduced to the case of the sensible aperture, and to the case of the indivisible aperture. *Thereupon by reason*, because the whole proportion which is obtained for the mutilated species of the Sun, and the augmented species of the lunar Shadow, is the same; and so supposing it varied, it would vary in this case of the sensible aperture, ergo it is not varied in this case, neither is it to be corrected. *And if so*, it is necessary to correct, that of which one quantity is to be had, neither would the proportion of the Solar semidiameter, and of the obscured part, be changed in the method of Kepler. *Nor [is there] doubt*, if even one of the said Fathers [holds] that by this method of Kepler a foundation Table may be founded, would they not err altogether, &c. He confirms that hitherto it is gathered, that there is detracted from the Solar species the portion MV, neither the data of the point Z, of the distance ZB, but only the distance AB, per the correction BM, we recognize the angle BAM; per Aristarchus, *De Magnitudinibus Solis*, Book 5; per Kepler's *Astronomia Nova* chapter 11; and at *Almagest Novum* chapters 4 and 6, where Kepler's doctrine is adduced; it is not treated of investigating the magnitude of the Solar semidiameter, but of investigating the magnitude of the Eclipse, which thing matters nothing, [it is] enough to know such an angle, neither does it suffice to know the mere proportion of the Solar species in the Tablet projected with the lunar shadow species. *But it was easy*, it is the same thing that is patent, *to transfer through inadvertence, that which agrees with the observations measured per the angle, to the present matter, where one considers the Diameter not under the relation of the angle, but under the proportion which a part has, which is covered by the Moon*. These [things], We, with all those things addends rather robust to the argument, than that enervated, that I doubt not, that they would for their own candor be agnized.

RESPONSIO

[Response.]

I respond to the *Major* with the distinction set in the title of Proposition XXI, and from the position itself subjoined to it, and I concede the Major concerning the species of the Sun precisely considered second per se, or separately from the species of the lunar Shadow; but I deny the Major, concerning the species of the Sun as to other comparisons adduced; and chiefly the comparison of the species of the lunar Shadow [with] that species which, in fact, and in reality is projected above the species of the Sun from the rays of the Sun entering through the sensible aperture, by those, namely, [which are] turned around the shadow image, and the contraction would be much more than it would be in the opaque $\alpha\theta$,

[continuation, right column lower of folio 79]

interposed the ray of the Sun touching the Moon, and the shadow terminating, transient through the point only per the point of intersection Z: for it is in actual fact SQ, which then would be $\delta\beta$. But it is another thing to consider these future things under condition, which would be, but is not; another thing [to consider] what in the present is in actual fact not posited under condition, opaque $\alpha\theta$, but on the contrary the opaque position of the aperture NO, amplitude [being] posited. *But it was easy to transfer through inadvertence that which agrees with the convenient observations feigned through imagination of the opaque $\alpha\theta$, impeding the ingress of the rays through the aperture NO, to the present matter, where the proportion of the Solar species at the lunar Shadow is to be considered not as it would be, but as it is in fact.* It is indeed much greater the excess of the Solar species, than it is in that fiction, and than that which is to be used; of the included Eclipses, even without relation to the quantity of the diameter of the Sun, but as to the number of Digits it is to be had; and as to the number, the species responds to the first proof of the Major.

To the *second* proof of the major, I distinguish, and that being granted, but not granted as to the parts of the more positive species, and really with it identified; I deny as to the parts negated, nor identified, of which kind is the shadow, in respect of the aggregate aggregated from it, and from the luminous parts; for daily we see in the aggregates from shadow, and from surrounding light, that the whole aggregate remains of the same quantity, yet the parts of it decrease, the species themselves increasing. Indeed among the positive parts themselves, and identified by continuation; for example, among the parts of vitreous water situated, [as] when included we see drops of water, [as] a full fistula [tube], to remain of the same quantity — certain ones by force of nearer heat are rarefied,

and occupy an ampler place, others are condensed, and constricted; therefore, I said, *Data non concessa* [the data not granted].

Moreover the Moon is not a spot identified with the Sun, but distinct from it really, just as we deem also of other spots.

To the *Minor* I respond by conceding it, if through the same indivisible point they transmit the rays terminating the Moon and the shadows, [rather] than the rays terminating the Solar species: that [I concede] which is in the present case; but denying [it], if (as in fact comes about) the rays terminating the Solar species transient through that point, the rays indeed touching the Moon, and its shadow terminating, transient per the inferior, and sensible margins of the aperture.

It remains therefore rightly said by Us in the first response made to the Doctors and Fathers [DD. PP.], *Gratis dictum esse* [that it is said gratuitously], that the same thing happens, &c., and against Kepler in this [matter] nothing hitherto is demonstrated; and so it is more confirmed by practice, because in the case in which the Solar species ought to be estimated at 10 $\frac{2}{3}$ Digits, in the species of the Sun used, and [in] the lunar Shadow [species], as they lie in the Table of observations, [it is] without any correction, [that] there would come out Digits only 6, or thereabout $\frac{2}{3}$, as we showed at Proposition XI.

And the remaining Arguments less principal there is no need to respond to prolixly, or expressly; whether it remain, or not remain, the same proportion among the lucid species of the Sun, and the shadow image — which among the worthy Eclipses, and non-Eclipses, is patent from Propositions IX, X, XIV, XVIII, and XIX. Of which thing it is patent, that legitimately admitted species be admitted at any given distance, and the increments due to the aperture be taken away, the species of the Sun [is] fit for collecting the quantity of the Eclipse; nor can it come about that, per the distance, there come out the quantity of the Eclipse pro libito [at pleasure] varied, [as] anyone would have wished.

Liber I — De Sole (continued)

This Figure V is for the case of an annular and central solar eclipse. The black lines tangent to the Moon are the three rays of the Sun that bound the shadows. The points where they intersect bound the two solar images AB; the distance at which the images are received in the table is 100000, measured from the aperture NO, whose diameter is 1/100 of a part [partium 100].

Diagram. A tall hourglass-shaped optical figure illustrating the formation of solar and lunar-shadow images through a pinhole, for an annular/central eclipse. At

the top a horizontal bar carries the labels I, E, P, R, F, α , K; the Moon's disk (with center Y) sits in the upper middle between converging ray-pencils; the aperture region is at the narrow waist near N, O; below, the rays cross and re-form an image (Θ , X) with a lower bar labeled T, β , L, G, S, B, D, M, ∇ , V.

- I, E, P (upper left to center): endpoints/labels of the upper ray-bar
- R, F, α , K (upper center to right): continuation of the upper ray-bar
- Y (mid-figure, in the disk): center of the Moon's globe
- C, D (flanking the disk): edge points of the Sun's image
- N, O (waist): the aperture (pinhole) margins
- Θ , X (lower waist): the re-formed crossed image and shadow
- T, β , L, G, S, B, D, M, ∇ , V (lower bar): endpoints/labels of the lower image-bar

The descriptive text keyed to this figure:

IZ ∇ and KZT are the extreme rays of the Sun, drawn through the margins of the aperture O and N, crossing over and bounding the solar image T ∇ , which before the eclipse is wholly bright; and they intersect at Z.

IAM and KAL are the extreme rays of the Sun drawn through the center of the aperture A, and they bound the solar image LM. CD is the globe of the Moon, from whose center Y the perpendicular YB is drawn through the points Z and A.

PCNQ and RDOS are the rays of the Sun tangent to the Moon, drawn through the margins of the aperture N and O, and they bound the lunar-shadow image SQ.

ECAN and FDAC are the rays of the Sun tangent to the Moon, drawn through the center of the aperture A, and they bound the lunar-shadow image GH.

α CZ β and α DZ β are the rays of the Sun tangent to the Moon, drawn through the point of intersection Z; if it were in the dark region $\alpha\beta$, they would bound the lunar-shadow image $\beta\alpha$.

IK is the visual disk of the Sun [discus Solis visualis]. The angle measuring the Sun's apparent diameter at the eye A is SQ; the lunar-shadow image appears in the table as T ∇ ; the remaining solar images TS and ∇ V are illuminated by the Sun's rays entering through the segment RK and IP, through the aperture NO. Therefore the segment of the Sun PR is hidden by the Moon, and the remaining segments IP and RK appear at the eye X.

GH is the lunar-shadow image — how large it would be if the aperture NO were narrowed to the indivisible point A; in that case the segment EF of the Sun would

be hidden, and the image LM would be illuminated by the rays FK and HM, that is, by the rays of the segment IE.

$\beta\alpha$ is the lunar-shadow image — how large it would be if the aperture were narrowed to the indivisible point Z, set in the dark region $\alpha\beta$, cutting off the remaining rays: and then the eye Z would see nothing of the solar segment $\alpha\beta$, but only the segments $I\alpha$ and αK , and of the Sun's image TV the small portions $T\beta$ and $\alpha\gamma$ would be illuminated.

VI. Figura pro Eclipsi Digitorum 6. [VI. Figure for an eclipse of 6 digits.]

Diagram. The same hourglass pinhole construction, set up for an eclipse of 6 digits. Top horizontal bar labeled C, O, G, α , E; the Moon's half-shaded disk with center H in the upper-middle; the aperture at I, K near the waist; the crossed image below with bar L, F, β , B, P, D, M.

- C, O, G, α , E (top bar): endpoints/labels of the upper bar
- G (top center): the point where the Sun's disk-center descends to the table
- H (in the disk): the Moon's right margin / point of tangency
- I, K (waist): the aperture margins
- A (waist): center of the aperture / the eye
- L, F, β , B, P, D, M (bottom bar): endpoints/labels of the lower image-bar

The descriptive text keyed to this figure:

A is the center of the aperture IK, through which the perpendicular GB descends to the table LM from the Sun's disk-center G, touching the Moon's right margin at H.

The rays CKM and EIL, drawn from the extremities of the Sun through the margins of the aperture I and K, bound the solar image — which before the eclipse is wholly bright, and is the quantity to be measured.

The rays CAD and EAF, drawn from the extremities of the Sun through the center of the aperture A, would bound the solar image FD if they could enter through an indivisible aperture.

The ray OHKP, tangent to the Moon physically at H, and drawn through the right margin of the aperture K, bounds the lunar-shadow image PM.

The angle CAE measures the Sun's diameter at the eye A, before the eclipse.

LP is the solar image illuminated by the rays of the whole segment OE, which enters through I and K. Although it would not be seen from the eye A except as

the segment GE, in this eclipse of 6 digits PM is the lunar-shadow image, because the Moon covers the segment CO. And FB is the portion of the solar image that would appear if the species were admitted through the punctual aperture A; for then through that aperture the rays of the whole segment GE would enter, and the segment FB would be illuminated — and in this case the lunar-shadow image would be BD.

VII. Fig. pro Eclipsi Digitorum 4. [VII. Figure for an eclipse of 4 digits.]

Diagram. The same hourglass pinhole construction set up for an eclipse of 4 digits. Top bar labeled C, O, G, α , E; the Moon's disk (less shaded than in fig. 6) with center H in the upper-middle; the aperture at I, K with crossing point Z near the waist; bottom bar labeled L, F, β , B, P, D, M.

- C, O, G, α , E (top bar): endpoints/labels of the upper bar
- H (in the disk): the Moon's tangent point
- Z (waist): the crossing point of the rays
- I, K (waist): the aperture margins
- L, F, β , B, P, D, M (bottom bar): endpoints/labels of the lower image-bar

VIII. Fig. pro Eclipsi Digitorum 8. [VIII. Figure for an eclipse of 8 digits.]

Diagram. The hourglass pinhole construction set up for an eclipse of 8 digits. Top bar labeled C, O, G, α , E; the Moon's disk (more heavily shaded than in figs. 6–7) with center H; the aperture at I, K with crossing point Z near the waist; bottom bar labeled L, F, β , B, P, D, M.

- C, O, G, α , E (top bar): endpoints/labels of the upper bar
- H (in the disk): the Moon's tangent point
- Z (waist): the crossing point of the rays
- I, K (waist): the aperture margins
- L, F, β , B, P, D, M (bottom bar): endpoints/labels of the lower image-bar

Communis Explicatio Fig. VII. & VIII. [Common explanation of Figures VII and VIII.]

A is the center of the aperture IK. The extreme rays of the Sun CKM and EIL, drawn through the margins of the aperture I and K, intersect at Z and bound the solar image LM, which before the eclipse was its full size [dimensa fuit].

But the extreme rays of the Sun CAP and EAF, drawn through the center A, would bound the solar image FD if the aperture IK were not the whole opening; the ray

OKP, tangent to the Moon at H, and drawn through the right margin of the aperture, bounds the lunar-shadow image PM.

The ray of the Sun A ∇ , in Figure 7, and GAB in Figure 8, tangent to the Moon at H, and drawn through the right margin of the aperture, would bound the lunar-shadow image β D in Figure 7, and BD in Figure 8, if they passed through the indivisible aperture A.

The ray GZB, in Figure 7, and α Z β in Figure 8, drawn through the indivisible point Z, touching the Moon physically at the point H.

The angle CAE measures the Sun's apparent diameter at the eye A, [as it stood] before the eclipse.

LP is the portion of the solar image illuminated by the rays of the whole segment OE, the aperture IK being opened — in which case PM is the lunar-shadow image, the Moon enclosing the rays of the whole segment CO.

But if the rays were admitted through the indivisible aperture IK, then the portion illuminated solely by the Sun's rays of the segment α E would be, in Figure 7, GE — that is, the species-portion FB in Figure 7, or FB in Figure 8 — and then likewise the lunar-shadow image would be β D in Figure 7, or BD in Figure 8.

But if they were admitted through the intersection-point Z, and one looked [along that line], one would see only the segment GE, that is α E; the portion of the bright image would be LB in Figure 7, or L β in Figure 8, and then the lunar-shadow image would be BM in Figure 7, or β M in Figure 8 — the remaining rays being blocked by the dark region $\alpha\beta$.

[Margin: The explanation of this figure is found above at Proposition XVIII.]

Diagram. A small narrow triangular/wedge figure (Figure 9) keyed to Proposition XVIII. Vertical and slanting lines run from an upper vertex region (A, O, G) down through points B, C, E, F, I, K to a base L, M.

- A, O (top): apex points
- G (upper right): a label point
- B, C (mid-left): intermediate points
- E, F (mid): intermediate points
- I, K (lower): the aperture margins
- L, M (base): endpoints of the base line

II. APPENDIX

AD CAPVT XVII.

De Motu Diurno Solis, ac Reliquorum Siderum, potius quam Terræ contra Copernicanos.

[On the daily motion of the Sun and of the other heavenly bodies, rather than of the Earth, against the Copernicans.]

1. In Book IX of the *Almagestum Novum* [Almagestum Novum], Section IV, I set forth with the greatest clarity — unless I am mistaken — everything that bears on the system of the Earth's motion: both its daily motion about its own center, and its annual motion about the Sun (placed at the center of the universe), no less than its rotation about the center of its own body. From Chapter V to Chapter VIII I advanced and then dismantled twenty arguments concerning the daily motion of the Earth about its center; from Chapter VIII to Chapter XIII I advanced and dismantled twenty-three arguments concerning the Earth's annual motion. From Chapter XIII to Chapter XIX I advanced and dismantled seven arguments concerning the Earth's daily and annual motion taken together. And in the same Section, from Chapter XIX to Chapter XXXIII, I advanced seventy-seven arguments for the Earth's immobility, partly against its daily motion, partly against its annual. Many of these I dismantled and showed to carry no physical — let alone mathematical — evidence; but a few, which I judge to have physico-mathematical evidence, I retained as not mathematical. The one exception, however — which I led there to a clear conclusion against the Copernican arguments for the Earth's motion — I taught at Chapter XIX. Finally, from Chapter XXXIII to Chapter XXXV, I gathered everything I had earlier foretold and laid out into syllogistic form, and reduced them, together with the replies, likewise into form. And at Chapter XXXIII itself, in Conclusion VII, I determined this whole controversy from sheer reasoning. Then from Chapter XXXIV to the end of the Section I taught what one ought to hold concerning the Earth's motion on the authority of Sacred Scripture, of its interpreters, and of the decrees of the Catholic Church.

2. Now, since at Chapter XVII of this present Book I have supposed it as certain that the Sun moves and not the Earth — nor have I lacked the support of most learned and distinguished men (whose names I am ignorant of, and which perhaps, against their wishes, I do not dare bring forward), who by the subtlest arguments have tried to overthrow that argument of ours at Chapter XIX of the aforesaid Section IV (which, as I said, alone carries clear evidence against the

Copernican hypothesis), it has pleased me to bring forward that very argument here in this place, with a few things changed, and to set out the difficulties of friends — indeed of ours too — against it, and, the premises laid down, to resolve them by means of certain suppositions.

I. SVPPPOSITIO.

[I. Supposition.]

The increment of velocity of heavy bodies naturally descending — insofar as the times are taken as equal — proceeds according to the odd numbers in succession; but insofar as the spaces composed at the end of equal times are concerned, it proceeds according to the squares of the times, along the perpendicular line by which the descent appears to occur.

3. I explain this supposition by the line AB, divided into 16 parts. I say that a heavy body — in which some degree of gravity has been generated — let down through the air, in the first time traverses the space AC; in the second time, one and a half times as much [sesquialterum], it traverses the space CD; in the third time, two and a half times [the unit] [sesquialterum 5], the space DE; in the fourth time, three and a half times, the space EB. Whence it follows that at the end of 2 time-units the space AD has been traversed, [continued below] — namely, four times [quadruple] the number 1, and at the end of 3 time-units the space AE has been traversed, that is, nine times the number 1; and at the end of four time-units the whole space AB, that is, sixteen times the quadruple of the number 1[?]; and so for the remaining intervals of space.

This proposition is established by manifest experiments of ours — not to mention those of Galileo [Galilei], adduced in Book IX of the *Almagestum Novum* [Almagestum Novum], Section IV, Chapter 19. For employing a very short perpendicular to measure some third part of the time, and letting fall countless little balls of fired clay [globis argillaceis octo] from about eight ounces, from the various intervals of the Bologna towers, we have most certainly ascertained, by repeated trials of this kind, that one such ball, in the first second of time, traverses 15 old Roman feet [pedes Romanos antiquos 15]; in the second second, 60 feet; in the third second, 135 feet; in the fourth second, 240 feet. Since this proportion has been explained above, from which we deduced, at Chapter XIX, many very beautiful problems.

Diagram. A vertical graduated scale at the left of the page, marked A at the top and B at the bottom, illustrating the fall-distances of Supposition I. The line is

divided so that the intervals correspond to the 1 : 4 : 9 : 16 progression of squared times.

- A (top): the start of the fall
- C (just below A, with "1"): end of the first time-interval (distance 1)
- D (with "4"): end of the second time-interval (distance 4)
- E (with "9"): end of the third time-interval (distance 9)
- B (bottom, with "16"): end of the fourth time-interval (distance 16)

[Margin: Heavier bodies descend more swiftly.]

4. On this occasion it is permissible now — though I do not pursue it here, since I have proved it elsewhere by more numerous experiments in the same place — [to note] that, of two heavy bodies of the same kind, the heavier descends more swiftly, that is, more quickly through an indivisible [instant], in the same altitude, than the one that is lighter; but to discern this evidently requires a notable altitude, no less than 200 feet, and it is better to observe the difference by the ear than by the eye. For the interval of space that the lighter body traverses — once the percussion has been made, since the heavier strikes a little sooner in a half-second of time — this, since it is so short a time, may seem to a careless observer simple, or at any rate less accurately observed, [so that] he may seem to strike both at one moment. But we, among the first who held a contrary opinion in this matter, observed a lighter ball of fired clay strike the iron band [fasciam ferream] that, on the outside, girds the Asinelli tower of Bologna, at a moment when the heavier had already struck the pavement, the observation being repeated many times. Now the said band is distant from the top of the same tower, whence the balls were let down, 150 Roman feet; and from the pavement 280 feet. Thus the lighter ball was still 40 feet distant from the pavement when the heavier had already reached the pavement.

II. SVPPOSITIO.

[II. Supposition.]

The increment of the percussion, and of the sound made, by a heavy body descending from a higher place, is proportional to the increment of velocity of the same descending heavy body.

5. An a-priori reason is sufficient to prove this. For the impetus of a moving body is equivalent to its gravity; we see that heavier weights are raised, and that greater weights require greater impetus, other things being equal, in order to be held in equilibrium, or moved with equal impetus by the weight of the descent.

Therefore, if at the end of its motion the descending heavy body acquires determinate degrees of impetus from there, it is just as if it had acquired so many degrees of gravity in the order of raising a weight, of striking, and of sounding. For there is a certain impetus, as it were a flowing gravity, equal to its gravity. It has pleased me to confirm this by the experiment once attempted, and pointed out in the aforesaid place of the *Almagestum Novum* [Almagestum Novum], but more accurately and recently carried out. A scale was fashioned, one of whose pans was a capsule capable of [receiving] various weights; the other was an iron pan fixed to the scale-beam, above which an iron globe descended along a perpendicular [globus ligneus sesquiuncialis][?], the wooden ball one and a half ounces, falling from an altitude of 35 Roman foot-units [vnciarum 35. pedis Romani], so as to raise on the other side an iron weight of 5 ounces and some drachms, which for the sake of safety we neglected. From an altitude of 140 units it likewise raised, by one [continued below] digit, an iron weight of 21 ounces — almost, but most safely 20. From an altitude of 315 units, however, [it raised] 45 units; and most certainly 45. And from an altitude of 560 Roman units, it raised a weight of 80 ounces. What I set out as the things to be explored by experiment, [done] with skill and circumspect men. But behold, in the table, the synopsis of the experiments:

Altitudo in Romanis				Proportio composit a	Pondus elevatum vno digito
Vnciis	Pedibus	& Vnciis			
35	2		11	1	vnc. 5
140	12	8		4	vnc. 20
315	26		3	9	vnc. 45
560	46		8	16	vnc. 80

Parsing notes: The header divides "Altitude in Roman [units]" into feet and ounces (units). Column 1 is the drop-altitude in Roman ounce-units (35, 140, 315, 560). Columns 2–4 express the same altitude in feet & ounce-units (e.g., 140 units = 12 feet 8 units; 315 = 26 feet 3 units; 560 = 46 feet 8 units). Column 5 "composite proportion" = 1, 4, 9, 16 (the square progression). Column 6 "weight raised by one digit" in ounces = 5, 20, 45, 80. The four altitudes are in ratio 1:4:9:16, matching the lifted-weight ratio.

It is necessary, however, that the capsule of one pan should first counterbalance the other pan, and afterwards rest above the subjacent support; and that one

should select on purpose altitudes having the aforesaid proportion — namely, such as are among these numbers 1, 4, 9, 16. For from this it will be established that the increment of the percussion, and of the sound, since it can be measured by the elevated weight, and discerned, is such as the space through which the descending heavy body passed. The proportion of the spaces is exceeded by the proportion of the subsequent space, which the heavy body traverses in descending; by the same proportion the percussion made in the end of the second space exceeds the percussion made at the end of the first space.

III. SVPPPOSITIO.

[III. Supposition.]

The semidiameter of the terraqueous globe is 23367468 Roman feet. How many feet are contained in one degree of the Earth's greatest circle: 407613.

6. This is established from Book V of our *Geographia Reformata* [Geographia Reformata], where we measured it; and in the *Almagestum Novum* [Almagestum Novum], Book II, we corrected it more accurately from the more recent observations and experiments which we set out in the same Book V. Although it would suffice for my present purpose, whatever the magnitude of the Earth, it has nonetheless pleased me to use the truest measure I can. Hence it follows that in one minute of a degree of the terrestrial Equator are contained 6799 Roman feet; and in a quarter-part of a minute, that is, in 15 seconds, 1699 $\frac{3}{4}$ feet.

IV. SVPPPOSITIO.

[IV. Supposition.]

If the Earth revolves about its center by a daily rotation of 24 hours with uniform conversion, any terrestrial point of the Equator will run through 1699 $\frac{3}{4}$ Roman feet in single seconds of an hour.

7. For in such a motion as is equivalent to the motion of the *primum mobile* [primi Mobilis], in single hours [there are] 3600 seconds; and in single seconds of the Equator, in 3600 seconds of the terrestrial Equator, by Supposition III, are contained 1699 $\frac{3}{4}$ Roman feet.

V. SVPPPOSITIO.

[V. Supposition.]

In the increment of velocity of heavy bodies naturally descending, the same physical proportion is preserved — other things being equal — whether they descend along

the plane of the Equator, or outside it toward the center of the Earth; at least within the first 4 seconds of the hourly descent.

8. For, other things being equal — namely, the same gravity in descending, figure, mass, quiet of the air, or rarity — no solid reason can be assigned why, in so brief a time as four seconds of an hour at the Equator, the said proportion of the heavy bodies' descent should sensibly vary, [a proportion] which Galileo [Galilei], and we, [who] tested it in the parallel of Florence and of Bologna, [hold]; even though in such a descent they decline geometrically a little from the parallel plane, yet by an insensible discrepancy, as we demonstrated by an appended diagram in Book IX of the *Almagestum Novum* [Almagestum Novum], Section IV, Chapter 19, number 7.

VI. Supposition.

A chord subtending an arc not greater than 15 seconds of the terrestrial equator differs imperceptibly from the figure and quantity of the said arc.

§9. For if the radius is 1,000,000,000,000 [one trillion] in the great canon of Pitiscus [Pitiscus], the chord corresponding to 15 seconds is 72,712,052. Hence, since the Earth's semidiameter — which by Supposition III is 23,367,468 Roman feet — corresponds to the radius, the chord of 15 seconds works out to 1699³/₄ feet. But by the same Supposition III, the arc of 15 seconds of the terrestrial equator is likewise that many feet. Therefore the equatorial arc of 15 seconds is the same in quantity, and thus also in figure, as that straight line; and so the arc, the straight chord, and that chord may be used for one another without perceptible difference.

These points established:

Proposition I.

If the Earth were moved by a daily rotation, a ball of clay 8 inches in diameter, dropped from a height of 240 Roman feet, would, on account of the air it has to traverse, reach the Earth by an oblique descent — yet without any real increase from physical velocity, or certainly never with so great an increase as is the proportion of percussion, and of sound, produced by a fall from the said height.

§10. To demonstrate this proposition: from the Earth's center T, describe with the interval TA — that is, the Earth's semidiameter — the arc AC, which, leaving aside its relation to the present figure, we suppose to be a minute portion of the terrestrial equator. Then, increased by the interval TA — say AB [i.e. by 240

Roman feet] — let the arc BD be described from T, a minute portion of an equator parallel to the first, in the same plane as the equator. Let both [arcs], drawn out from T at right angles, be divided into four parts, that is, into an arc of fifteen seconds, which fall just below those same [points] AQ, QF, FG, GC — and at the top BH, HI, IK, KD. Now, since the point B, from which the said ball is dropped, was carried in 15 seconds (in keeping with Supposition I) to the place H (that is, supposing the Earth's motion only); the ball, by the daily motion, comes to rest in H — granted, of course, the Earth's motion. But the absolute interval HL, which at the end of the first second of the hour was 15 feet; and at the end of the next second, with B carried to I, the ball traverses IM, of 60 feet; and at the end of the third second, with B carried to K, the ball has completed the absolute interval KN of 135 feet; and at last, at the end of the fourth second, with B carried to D, the ball drops to the Earth, completing the space DC of 240 feet. By the said interval-endpoints, let there be drawn lines to the [points] which are roughly designated by the line BL, LM, MN, NC; but in fact such is the path on this hypothesis along which the ball would drop to the Earth, from declination BH and CG. And by the analysis of two triangles let us investigate the quantities of the first path BH, and the last NC, and from these infer the intermediate ones LM and MN.

§11. First, then, in triangle BHL, the sides HL of 15 feet and BH (which, if it were AQ, would by Supposition IV, V, and VI be $1699\frac{3}{4}$ feet, but by the augmentation AB of 240 feet works out, by the proportion proved at Supposition VI in proving BH, to 1700 feet). Angle BHL is therefore a right angle of 90° ; therefore in the isosceles [triangle] BHL the angle at T is the sum of the angles at the base BHL, that is $89^\circ 59' 52'' 30'''$ [89 degrees 59 minutes 52 seconds 30 thirds], because in the isosceles triangle TBH the angle at T is the sum of the [angle of] right angles at the base BH, that is $179^\circ 59' 45''$. From these data, given by the most subtle logarithmic trigonometry — which at the end, [continued on next column] following the principle of the Vlacq canon reduced to single seconds — there results the base BL of $1700 \frac{1}{24}$ feet.

Secondly, in triangle CNG, with KN drawn off, the feet [are] 135; from the whole KG of 240 feet there remains NG of 105 feet; and by Supposition IV, V, and VI, CG is $1699\frac{3}{4}$ feet. Now angle CGH is $90^\circ 6' 7'' 30'''$, because in the isosceles [triangle] CTG the angle at T is $15''$; and either at the base TC is $89^\circ 59' 59' 52'' 30'''$. Therefore by the most subtle trigonometry, by the same method, NC is $1702 \frac{2}{12}$ feet.

Distributing therefore by the four excesses of the four paths, they come out as in this little chart:

Diagram. A fan-shaped geometric construction with apex at T (the Earth's center) at the bottom. From T radiate several lines fanning upward to the right toward a quarter-arc. The outer arc runs through points B (top), with D, K, I, H descending the left edge and B, A on the right; the inner arc runs through A, C. Interior points L, M, N and Q, F, G lie along the radial fan between the two arcs, marking the oblique fall-path BL–LM–MN–NC of the dropped ball. The letters trace the two parallel equatorial arcs (inner AC at the Earth's surface, outer BD at the 240-foot drop height) divided into four 15-second segments.

- T (apex, bottom): the Earth's center
- B (top right of outer arc): point from which the ball is dropped
- A (right, on inner arc / radius): the Earth's surface point below B
- D, K, I, H (left edge, descending): successive positions of B under the Earth's daily motion at the ends of seconds 4, 3, 2, 1
- C (left, on inner arc): the Earth's surface landing point
- L, M, N (interior): successive positions of the falling ball at the ends of the first three seconds
- Q, F, G (interior, lower): the segment-divisions of the inner arc AC

Path	Feet & Inches
B L	1700 1
L M	1700 5
M N	1701 1
N C	1702 2
Sum	6803 9

Parsing notes: The "Pedes & Vncia" (Feet & Inches) column is split into a feet value and an inches value per row; transcribed as two numbers per cell.

[Margin: Via / Pedes & Vncia (the table headings).]

None, therefore, of the four spaces through which the said ball obliquely passes would exceed the preceding one by a single whole foot. And just as by the daily motion alone the ball would have run through arc BL, of 1700 feet, and 105/240; and 1/24 by Supposition IV; and by the oblique path BL, MN, NC, it would complete 6803 9/24 feet — yet physically it would be just as if it had descended by a uniform and equable [motion]. Now indeed the increase of velocity of 2¾ feet on a path of 6803 9/24 feet, or of 1361 paces, scarcely deserves consideration, and is by no means comparable to that increase of percussion and of sound which, by the said Supposition II, results from the apparent descent of heavy bodies along

that one perpendicular — that is, in keeping with the squares of the times, the numbers of equal times.

Proposition II.

The line along which the aforesaid ball, dropped from a height of 240 feet, would descend to the Earth's surface on the hypothesis of a moving Earth, would be — to the senses — straight, but in reality oblique, and not at all perpendicular; though it would appear perpendicular only, except in the case where it would be dropped above the Earth's pole.

§12. This is against our most ingenious Friend, too much addicted to the Copernican hypothesis, who, to defend the proportion of percussion-velocity owed [to the fall], maintained that the percussion arises from a fall of heavy bodies not by a circular motion, nor by a daily one, but from their proper gravity [propria gravitate]; and to the extent that he was saying — most truly — that they descend in falling, he inferred poorly from this that on the Copernican hypothesis heavy bodies descend really along a perpendicular line, since on that hypothesis alone is the apparent proportion preserved according to the squares of equal times; and so on such a falsehood he would falsify the velocity, the proportion of percussion, and of sound.

But the opposite [is] truer — as Galileo holds in his *Dialogue II on the World System*, and Bullialdus [Ismaël Boulliau] in chapter 4 of his *Philolaus* — who strive to make the descent of heavy bodies along a line that is not perpendicular, but circular, as Galileo [does]; or along the circumference, as Bullialdus [does], to display the beauty of the Copernican hypothesis, because it removes that difficulty which has hitherto tormented the Physicists — namely, by what cause heavy bodies descend with so great an increase of velocity. For Galileo and Bullialdus call this an outright fallacy of the senses, estimating that heavy bodies descend along one straight perpendicular line — though in this hypothesis, in the very thing that appears, they are far otherwise. Yet what other path Kepler [Kepler] and Gassendi [Gassendi] hold to, as if [following] a parabolic path, you may see further in *Almagestum Novum* IX, section 4, chapter 17.

§13. For although on this hypothesis the motion of heavy bodies arises from two principles — one moving toward the East in keeping with the daily rotation, by virtue of which the aforesaid ball would complete in the first second of time the arc BH, [continued next page]

of 1700 [feet]; the other, which is gravity, [moving] downward — and unless the transverse motion toward the East impeded it, the ball would be moved by the perpendicular line BA, or by the said transverse [motion] of 15 feet. Yet since neither of the two principles so absolutely prevails over the other as to entirely impede its second act, nor do they operate so distinctly that the ball is moved by each of the two along the same path at the same time, [the ball] is driven — that is, the effects of both, blended in this hypothesis, do not concur; but the mixed motion would be such, by the principle's influx, [moving] in part along the circular line described from the Earth's center, in part along the perpendicular transverse line — namely, in the figure preceding, [along] the line BH. So far is it indeed from being the case that the ball, dropped from B, would descend along BA, or along HL, as it would [if] that circular path BH were denied — which is more to be conceded — than the perpendicular HL; because [it would be] much more valid, if [it descended] by the principle common to the daily rotation, [by] which heavy bodies, by virtue of the first daily rotation, would belong; whereas indeed by the force of gravity in the same second the feet [would be] 1700, but by the gravity 15. Therefore, since the ball [moves] from B perpendicularly toward BA, by which — the Earth standing still — it descends, it [would be] transferred and [moved] by the perpendicular HL, by an interval not less than 15 feet; thus 1700, since the gravity would not incline the ball off the arc BH, by which it is moved, if no obstacle [arose], except by the interval HL of 15 feet. Since yet the path is not such, but deviates somewhat downward off the inclined [path], therefore it is absolutely a path along which the ball gently descends, a third somewhat [path], namely the transverse BL.

§14. This is sufficiently established by enumeration, and by exclusion of the alternatives which one might imagine the said ball could descend in reality. Either it descends along one perpendicular, and the same [one], in a mundane space, since the daily [motion] is transferred elsewhere; and this not, because it is transferred along other perpendiculars, as is evident — were this hypothesis given, [for] an eye outside the Earth, above its own atmosphere is constituted: let an eye be placed in the Earth, and by the daily [motion] equally carried along with the points A and B; it would see the ball descend along one and the same perpendicular BA, or along its parallel. Or it descends along other perpendiculars, that is, [along one] perpendicular and as much as it descends. Or [it descends] along other perpendiculars; and this, because it cannot be transferred along different perpendiculars except by a motion forward toward the East — supposed prior in the transverse [direction] — than [the motion] by which it is transferred along the other perpendiculars. Either, therefore, it is so transferred along the other perpendiculars, as to be moved first separately in the transverse

[direction], without any perpendicular [motion] separately; thereupon nothing descends; afterward again circularly; and thereafter again perpendicularly, and so alternately, along the third path it descends; and this, because there is found a graver descent on the one continuous motion, and if it could be moved along every smallest particle of motion, [there] would be the much more preferable daily force impeding gravity — lest in the meantime, and of this kind, it would so much descend the heavy [body] gravely, [as it] would, if [moved] along the perpendicular for the whole time of this motion; or certainly the heavy body's impetus would not be augmented, as in perpendicular [motion]; since it would be transferred along the path, [it] would be transferred at an equal time over equal spaces — for example, if the ball from B were first transferred along arc BH to H, then by the daily [motion] indulging gravity, it would permit the descent HL of 15 feet; then in the following hour-second, it transfers the ball along arc BH parallel to HL, and perpendicular to TI, the point distant from I by 15 feet: then indeed gravity does not act by its own [force]; nullity of impetus it would produce; then in the second descent, [it descends] not absolutely except along 15 feet — which is against experiment, and so feigns the prior impetus not vanishing, but adds another equal [one]: it would complete in the second second 30 feet, and at the end of the third second 45 [feet]; and at the end of the fourth, 60 feet. Which is likewise against the experiment whence we gather that the impetus of heavy bodies grows in falling, but greater gravity completes a greater space in falling — which is reckoned, therefore, not from the descents of alternating motions, [but] from one perpendicular impetus alone — since it is simply downward, or perpendicular. Either, therefore, it [moves] along these and those arcs, and at the same time along these and those perpendiculars.

§15. Let our doctrine and proposition above be confirmed *a pari* [by parity of reasoning] in all moving bodies — whether natural or violent — whose diverse motions concur in act with the effort of moving the same body, but along diverse [directions], yet not opposite mundane regions; this only because what it exercises in act of any virtue is not at all impeded by the other, [but] we see the mobile really proceeding along the path according to what it owes to each virtue, but not simply. So rivers flow, whose gravity strives downward; they can — by their perpendicular precipice — rush into a channel, declining, and by a mixed motion descend obliquely. When indeed of two virtues, the one strives to move toward one mundane region, the other toward the opposite, then the act prevailing in virtue exerts its impetus along one region, or so prevails first as to be turned back, and at last [moves] upward; and then afterward the motion [proceeds] into another region — as we see in a projectile thrown upward,

overcome at last by the impetus of pulsion in the gravity descending downward they slip back.

§16. But [let us argue] also from the absurdity, the opposites being conjoined of the contrary opinion's falsity. For suppose a lake ABCD, full of water,

Diagram. A rectangle lettered A (top left), E (top center), B (top right), C (bottom left), D (bottom right), with F at the interior center. A diagonal runs from A (top left) to D (bottom right) crossing the vertical line EF; the figure represents a lake (rectangle ABCD) with a transverse dyke BFC and the fish's escape paths EF and AB.

- A (top left corner)
- E (top edge, center): point on the upper edge
- B (top right corner)
- F (center, interior): crossing point of the diagonal and the vertical
- C (bottom left corner)
- D (bottom right corner)

except for a transverse dyke BFC, and some terrestrial path it holds (lest the lake by its banks AB, where fish [hostes, lit. "enemies"] of it would be); what sane mind would say that it [the fish] flees from AB, [moving] along the perpendicular lines as EF or AB, and thus it really flees the waters by stepping aside, or at the same time along the water [path], and [it is] moved along the earth; for the fish made [its journey] by the path BC, in any moment it acquires a greater [distance] from the banks AB, more measurable along the perpendicular lines EF, or others parallel to this. Nor indeed is the local motion of bodies really reckoned along any perpendiculars, [but] by one path, and the distance of a moved body can be considered and reckoned from any fixed mundane point; since it does not consist in motion along such a distance, or [in] relation to whatever boundaries, to which it recedes by approaching the mobile; from which it recedes — wherefore along no determinate space, [no] perpendicular determinate space; because innumerable [spaces] would be moved at the same time, which is impossible; but [it] would really be that determinate space which by successive contact is traversed by the moved body. Let there be, therefore, a greater access, and a greater [access] of heavy bodies to be measured along straight perpendicular lines, along which also on the hypothesis of a moving Earth small earthly bodies would be seen to descend; and in these the proportion is repeated, of which [we treated] at Supposition I. And the descent [is] formal, just as the perpendicular descent differs adequately from the circular motion, when it is simply a descent,

that is, a downward motion; not on that account, however, do heavy bodies really descend on this hypothesis along perpendicular lines, [continued next page]

nor is their descent simply a downward motion, and consequently it is not adequately distinguished from a forward motion toward the East, but inadequately — since it is constituted by the partiality of each.

Proposition III.

Of two percussions, and of sounds produced by the same body — one [body] being unmoved, or moved more slowly than the striking body — [the percussion and sound are] in other respects equal; the greater [percussion and sound result in] a greater not only impetus, but also velocity of the struck body, naturally produced beforehand in that space; because whatever is impeded by force impedes the increment, or the velocity, [and so] the magnitude of percussion and of sound is equally impeded.

§17. This proposition, well understood and in the terms in which we have expressed it, is certain by an *a posteriori* induction in all cases — in which it is evident that the magnitude of percussion is made [greater] in those cases where greater velocity is found; nor [is it] otherwise, [namely] that those in which [there is] a greater [percussion], nor more or less controversy, [than] how the mobile is moved than how heavy bodies [are moved] in the hypothesis of a moving Earth descend. For it is necessary to make better known by the better-known things those that are less known. Having made the consideration, therefore, in all cases of more evident percussion and of sound, it is established that a greater percussion is never made by the same body, in other respects equal, unless [there is] a greater velocity, since the body striking with a swifter motion transfers an equal space in less time, or a greater space in equal time. And on the contrary, the mobile [striking] otherwise more strongly, by other [things], whatever is restrained, lest it be moved more swiftly than before, [strikes] with the same force, the percussion's effect is weakened, lest it strike more validly than it had struck before. So, since the wheels of mills, or [those] of carts, [are turned] by the impulse [of falling] water, or by the labor of beasts of burden — to thresh the grain, or wheel-grindstones for sharpening blades, or wheels of lathes — they are wont to be turned so swiftly that they revolve, [and] if they are moved with an equable tenor, with no greater stroke do they later strike upon stubble, [stalks], blades, or scalpels; and on the contrary, since slings revolve in a circle, they whirl the same [stone] with an equal gyration but a shorter [one], [and] then [hurl] the stone at a longer interval, and with a more valid stroke they cast it.

§18. From this universal induction — which it is established is never made without prior greater velocity of the mobile, [there is] a greater percussion and sound — the Physicists collected the validity of percussion, and the natural vehemence of sound necessarily to depend on accelerated motion, just as sound taken absolutely depends not on certainty, nor is made by the impetus of the mobile, except by the mediation of actual local motion. Nay rather, the impetus of the mobile is ordered prior to the motion, and the greater impetus and the greater motion of swifter mobiles [produces] a greater percussion and sound; whatever force impedes the increment of impetus, or of velocity, the same much more impedes the increment of percussion, and of sound.

Proposition IV.

It is evident by physico-mathematical evidence that the Earth is not moved by a daily rotation.

§19. The argument for this proposition, reduced to syllogistic form, is of this kind:

If it is evident by physico-mathematical evidence that the daily motion of the Earth impedes the validity of percussion, and of sound — as is evidently shown to be the case from the motion of heavy bodies descending naturally through the air, and from a greater altitude — it is evident also that the Earth is not moved by a daily motion. But it is evident by physico-mathematics that the daily motion of the Earth impedes the aforesaid validity of percussion, and of sound. Therefore it is evident by physico-mathematical evidence that the Earth is not moved by a daily rotation. The major [premise] is certain. The minor is proved, because on the one hand it is evident by physico-mathematics that heavy bodies descending naturally [do so] with an increase of velocity in keeping with the proportion of the squares of equal times, from what was said at Supposition I; and the percussion is made in the end with an increase of velocity in keeping with the same proportion, in accord with what was said at Supposition II; whence we gather that the increase of velocity is [continued next column] real, not merely apparent, from what was said at Proposition III. And by the same proposition, [we gather] that for so great a validity of stroke, and of natural impulse, the prerequisite necessity of a proportionate increment — not only of impetus but also of velocity — in the descent of heavy bodies. But on the other hand, it is evident from this hypothesis of a moving Earth that the daily motion takes away [or] impedes either the descent along one [perpendicular line], or [it impedes] more perpendiculars at once and downward, and a forward declination by the said proportion proved at Proposition II; or by an oblique transit, such that they really descend, [they] are deceived, that they descend equably, and so an

increment of velocity, and without any proportional increment of percussion, as is shown at Proposition I; and so even is impeded by this hypothesis, from the said Proposition III, the validity of percussion impeded. And so they experience in reality from the motion of heavy bodies, [moving] naturally with greater [velocity], and with greater [percussion], than [in] the descents.

§20. The argument here — which to escape the lethal [blow] of the Copernican hypothesis, that subterfuge tried in vain — those friends of ours contend [it]: I [respond] in the first place, contending that heavy bodies really descend along the perpendicular line, [which] is false, as we show at Proposition II. And to the extent that the increment of velocity were owed to a real increment of percussion, [it] could descend along an oblique transit, but [though] permitted the continuation of velocity grows, it is not necessary, just as the velocity grows, [so] the validity of percussion is not impeded — which itself we likewise taught false at Proposition III. As for what they might further add about being able to compensate for the defect of velocity by the occurrence of the struck body, or [by] the annual motion of the Earth — it does not suffice, because the Earth's part falling from the struck body occurs no more [with the falling] heavy body, than [it] flees from it; but, equally as one heavy body [moves], whence the daily motion is transferred toward the East. But the annual motion is far absent, that it may help, [rather] than compensate the motion downward, that rather it might more impede the descent of heavy bodies, while it is transferred along the path of the great [annual motion] toward the East: which we attempted to confirm in *Almagestum Novum* IX, section 4, chapter 19, at number 8.

But we have called this evident [argument] a physical one, to the extent that we apprehend by sensible experiments the increment of the velocity of heavy bodies, and of percussions [to be] made; while [we call it] mathematical to the extent that, on the one hand, the increment of both [is determined], according to the owed proportion of the squares of the determined times; and, on the other hand, [to the extent that] geometrical and trigonometrical measures show the quantity of the real space which heavy bodies would traverse on the hypothesis of a moving Earth; and on this account, by a composite name we have called it *physico-mathematical*.

Proposition V.

Celestial phenomena can be just as well explained — and even better — on our hypothesis of a resting Earth, as on the hypothesis of a moving Earth.

§21. Galileo conceded the very same thing in his *Dialogues* — in their Latin garb, page 88 — saying: "As regards making satisfaction, I would judge both positions to be accommodated." And Jacobus Lansbergius [Jacob van Lansberge] in his *Commentaries upon the daily motion*, page 1, where he says: "For as the Athenians of Thebes really make contraries, [yet] these are the same: so the Ptolemaic Sphere, and the Copernican, between themselves contrary as to hypotheses, nonetheless show the same apparent [phenomena] in the heaven." [The phenomena] are not the same, however, equally on their hypothesis, who admit solid orbs, and deny — what the Copernicans [hold] — that the five minor Planets are moved about the Sun, and from it [draw] the eccentricities of those very [orbs] under their auspices; but truly, they posit the Sun about its own motion, while [others] move and expend much in their motions. On which account, on the position added [is] that of our [hypothesis], with contention assumed. Now if there were anything which the Copernicans greatly exult [in], it would be that reddened [argument] given by them, by which the stations, and the Retrogradations of the Planets appear; that they really do not appear in the motions of the Planets, which truly always go directly forward, [though they] begin to tend [back] toward the same East, [so] that Sagredus alone in the cause [of] Galileo's *Dialogues* was nearly girded [for battle], such that he would cross over to the Camp of Copernicus. But [continued] ...which, by the single diurnal motion toward the west of the [Primum Mobile], performed continuously throughout the day, we account for excellently — namely, why the planets in their proper motions are slower and return to the same meridian later than the fixed stars, and why the fixed stars come to the same meridian sooner; and why the planets appear to be carried backward when they more swiftly arrive at that point [i.e., the same meridian], and so seem the more westerly.

Indeed, by combining these factors, in our hypothesis a lower planet — being more remote from the Sun and from the Earth toward the west [in its position] than the higher planets are — turns out, as befits the more mobile bodies that are at a greater remove from the center in their wheels, to consist of larger circles, so that it moves more toward the east. From this it follows that the planets are moved more slowly from the center of their more remote motions, namely from the Sun.

For as to what concerns the proportions of the distances from the Sun and from the Earth — it is clear that the same proportions ought to be assigned, whether the Sun rests or the Earth rests, since in either case the hypothesis would be the same. And nothing prevents this variation [in the appearances] from depending on the motion of one body rather than of the other.

VI. PROPOSITIO.

The motion of the Sun, and the immobility of the Earth, on the sole authority of Sacred Scripture, are to be asserted — even though all the other arguments drawn from natural reasoning were of equal weight on each side.

[Margin: §22]

I do indeed recall that I set this argument out more fully in my *Almagestum Novum* [Almagestum Novum], Book [Almag.] sect. 4, chap. 39. And yet, after greater minds than mine have undertaken to twist Sacred Scripture to some alien sense in order to defend the rest [resting] of the Sun and the motion of the Earth — chiefly [Jacob van Lansberge] in his *Commentaries* [Commentationes], and [Christophorus Wittichius] in this same matter in two Dissertations — and since the whole Cartesian sense [of Scripture] breathes in that direction; whereas, on the other hand, the motion of the Sun and the stability of the Earth from Sacred Scripture alone have been championed by [Lentulus] in his *Nova Sapientia*, by [Schookius] in his *Misc. [De Scepticismo]*, by [Tullerus] in his *Miscellanea sacra*; by [Danaeus] in his *Christian Physics*, part I, by Jacob du Bois [Jacobus Dubois, Reformed preacher (*Ecclesiastes*) of Leyden], in his *Theological-Astronomical Dialogue* [Dialogus Theologo-Astronomicus], and in an examination of the famous controversy concerning the motion of the Sun or the Earth — for these reasons it has seemed good to me, since certain new arguments have occurred to my mind, to gather here in a few words those choice points which, drawn from this already well-worn source, were sought out at the expense of other, less weighty matter. Thus, then, I argue.

[Margin: §23 — 1. Argument]

In the controversies in which Reason on the one side and Sacred Scripture on the other are to be considered, that side is rather to be chosen for which the greater authority stands. Therefore [I argue], and in this controversy the greater authority is the authority of Sacred Scripture.

[Margin: 1. Argument]

This is shown thus: granted that the reasons drawn from natural light were of equal weight, then truly, if the appearances of the heavens have their cause [equally well explained] from the percussio of heavy bodies falling from a higher place, let it [be granted] that the celestial appearances [are equally accounted for]. And yet, as to the motion of the Sun and the immobility of the

Earth, Sacred Scripture stands firm, and it will at once be evident, therefore, etc. — The adversaries will reply that the major proposition is true if the authority is that of persons speaking for the truth, but not [if it is] of those accommodating themselves to the preconceived vulgar opinion, or to the common opinion; or [if the persons are] speaking absolutely and by no means by way of institution; or [if the matter is] necessary, abstruse, and seemingly violent. But concerning this argument I make no decision here.

[Margin: §24 — 2. Argument]

In the controversy in which, other things being equal, that side is rather to be chosen for which the authority of Sacred Scripture stands such that it cannot prevail independently of a prejudged hypothesis — such is the assertion of the Sun's motion and of the Earth's stability — therefore, if the adversaries say that Sacred Scripture is not speaking for the truth of the matter, inasmuch as it [supposedly] gives way to the Copernican opinion, and meanwhile they confess that there would be a violent wresting of the common sense of men, both as to the letter and as to the obvious sense of Sacred Scripture — both because this natural reason would be a matter of indifference for asserting the reasoning on either side, and would remain in equilibrium, and accordingly, by the prejudice of Sacred Scripture would they be provoked; and because neither hypothesis [could] by the prejudgment of its sense prevail, still less ought its obvious and literal sense be deserted for an alien, abstruse [sense]...

[Margin: §] (continuation)

whoever, by the single diurnal motion toward the west, we account for excellently — [resuming the argument that] the planets' proper motions are slower, returning to the same meridian later than the fixed stars; whereas the fixed stars come to the same meridian sooner; and the planets appear to be carried backward when they more swiftly reach that point, and so the more westerly.

[The text above on folio 86 left column already rendered. The right column of folio 86 (p. 86) begins:]

and [whether] it twists or distorts — or rather, [whether] the plain sense [conforms] to the sense of other opinions, or not. But let us come to the passages of Sacred Scripture.

In Genesis 1 it is said: *In the beginning God created Heaven and Earth*. This is the highest and common [view] of the Fathers, and the opinion of the Doctors whom I

cited in *Almag.* [Almagestum] *Novum* sect. 1, chap. 1. I understand by the name "Earth" either the Earth alone, or the whole terrestrial globe, or even the other Elements [as well]. Now if "Earth" means the Earth alone, as even the Copernicans wish it to mean the [planet] Earth, but they will have it that the Earth stands immobile at the center of the Universe — no rational cause can be adduced, since indeed it was created with the same things created first, before the other Planets — that on the fourth day it was created [moving] rather than at the first, when on the first day it ought to have been created, [being] as the basis and foundation of the mundane bodies and the center of all the celestial motions. Surely the Copernicans recognize that they pervert the order of the divine works in an irrational manner. Indeed, against them Sacred Scripture placed that Star [the Earth], showing that God created the Planet [Earth] for a fixed number of days, and placed the Earth in the Heaven, as we have taught more fully in the Prolegomena to *Almag.* [Almagestum *Novum*] sect. 1, chap. 4.

In Genesis likewise, on the first day, it is said: *Let there be lights made in the firmament of Heaven, and let them divide the day and the night, and let them be for signs, and for seasons, and for days and years, and let them shine in the firmament of Heaven, and give light upon the Earth, and it was so done. And God made* [two great lights — *Deus duo Luminaria magna*]; *the greater light to rule the day, and the lesser light to rule the night.* Now here Sacred Scripture, as to the truth of the matter concerning the Moon, speaks according to the truth of the matter, and not according to a merely vulgar apprehension — because the Moon's motion is real, and conforms to the very hypothesis of the Copernicans. But there is no truth in their hypothesis, nay, much rather [against it]: God speaks of the Sun, immediately and more clearly than of this [the Moon], and the solar year is more evident and better known than the lunar; so that, just as the Moon truly divides the seasons, so [too does] the Sun.

But let them retort: Why did [Moses] call the Moon a *Great Light* [Luminare Magnum] in accordance with the vulgar sense, and according to appearances — not according to the truth of the matter — since the Moon is smaller than Saturn, than Jupiter, and than some of the fixed stars? It is answered: the Moon is called a Great Light because it really is great, though it is not great if compared with the fixed stars, with Mercury, with Mars, or perhaps with Venus — which [comparison] is nothing to the present point. For [the Moon] could by virtue of its principal office of illuminating the Earth, or insofar as a Light, and in the order and end of distinguishing the seasons, [be called great]: for the Moon, especially when full, illuminates the Earth much more luminously than all the Planets and

the Sun together — apart from the Sun [itself], with which jointly it is called the *lesser Light*.

In Joshua, chap. 10: *Sun, stand thou not over Gabaon, nor Moon over the valley of Aialon; Sun and Moon*, etc., and where the Seventy [Septuagint] have: *And the Sun stood still in the midst of Heaven, and hasted not to go down* — that is, toward the west. — Now here it must be noted: Joshua, when truly the Sun stood still, [says] Sun and Moon, neither, etc. Therefore Joshua did not speak according to the Copernican view, but he said that the Sun did not [continue to] go down toward the west, but rather went down toward the west. Where it is worthy of note, that here and elsewhere a threefold solar motion is attributed: toward the west, toward the east, [namely] the Occidental [setting] motion. — Yet [Lipstorpius] grants that this passage equally [supports the view] that the place [understood] is "of the Sun," and not "of that [Earth]," as to the diurnal motion; but inasmuch as [Joshua] needed [the Sun] to be held back from producing day, and to perfect the victory, [he spoke] not so much of the monthly [motion] — but of the Diurnal motion, both of the Moon and of the Sun, as the Copernicans [hold]; just as therefore as to the Sun, so as to the Moon — according to the vulgar opinion and to appearances Sacred Scripture spoke. But I see, and that too, since Joshua needed the Sun's stopping of its producing [of day], etc. — [namely] that the Moon should stand still. But why did the Moon also stand still? Because the Moon then was of clearer light, [and] gave back the day; nor indeed do we even now experience [this] when the Moon is full over the high Sun above the horizon; and yet, much less was the Moon at that time near the Meridian, and the Moon dichotomous [half], as some conjecture from those words *in the midst of Heaven*. Certainly no more probable cause can be adduced, except that Joshua, whether he was wise [in astronomy], or instructed by vision, or by divine instinct knew, if the Sun's diurnal motion were to be hindered, and the Moon together with the other Planets continued its diurnal course, the disturbance of this order and the harmony of the celestial motions [would result], and especially in the Moon, which daily by about 13 degrees more slowly reaches the same meridian...

[Margin: §] (continuation, folio 87, p. 87)

meridian. Therefore [Joshua] by a double trust in God chose to be of great genius, and commanded that not only the Sun but also the Moon, and the rest of the Planets, should cease from their diurnal motion for a whole day — for the Sacred historian goes on [to say]: *The Sun therefore stood still in the midst of Heaven, and hasted not to go down for the space of one day*. Yet beforehand he had said: *And it [the Sun] stood still*. And so accordingly: *And the Sun stood still and the Moon etc.*

But near the Copernicans, [there are] not a double miracle, [but a] true [one], and indeed it [the miracle] was; nor did those Planets [the Sun and Moon] stand still miraculously — for naturally they were standing, inasmuch as they lacked the diurnal motion; but the Earth stood still as to its motion, which it [the Earth] really had: Joshua did not [say] "Sun, stand thou over Gabaon, nor Moon over the valley of Aialon," but rather, on the contrary, "with the Earth standing still, the Sun stood [still] over Gabaon, and [the Moon] over the valley of Aialon against the Moon." As to how perverse a violence this inflicts upon the sacred sense, no man of sound mind fails to see.

In Kings 4 [2 Kings], chap. 20, there is recounted that double miracle in the dial of Achaz, of which Isaiah, chap. 38, says: *Behold, I will bring again the shadow of the lines, by which it is gone down in the sundial of Achaz with the Sun, ten lines backward.* And it returned ten lines by the degrees by which it had gone down — that is, the Sun went back toward the east, as the shadow which had gone down in the dial returned through the same ten lines, which it had confirmed [in] Ecclesiasticus 48: *In his days the Sun went backward, and he lengthened the King's life.* Now indeed Isaiah, so great a Prophet, was ignorant that the Earth was moved, if the Earth was [the thing] that really was moved? Either he was ignorant — [he] of whom the Sacred Scripture [says] he proffered this miracle either by his own inspiration, or by divine inspiration; [and yet] that [Prophet], accommodating himself to the vulgar apprehension, would have put forth a false proposition concerning the retrocession of the shadow — [namely] nothing accommodated in any way, or [done] by the motion of the Sun rather than of the Earth, [though] then [he was] King, and elsewhere a preconceived opinion concerning the motion of the Sun — that he ascribed it to the motion of the Sun rather than of the Earth, [the Sun moving] toward the west by retrocession, were ascribed [to it]. Surely it could have been expressed in [the words] *in the Sun*, and yet [the words] *in the Sun, and at once it returned* — namely the retrocession of the Sun.

In Job 9, [Job] himself, while he speaks of the wisdom and the fortitude of God, proves it partly by those things which He did, partly by those things which He could do, if He willed, and which He does: *Who removeth the mountains, and they know not, whom He overturneth in His fury. — Who commandeth the Sun and it riseth not* — that is, *Who commandeth the Sun, and it riseth not, and shutteth up the stars as it were under a seal.* Here [Didacus a Stunica] [Diego de Zúñiga], whose book was afterward suspended by decree of the Sacred Congregation, dared to say: *No place will be given in Scripture, which says so plainly that the Earth is moved, as this one [says] that it is moved.* But who has so rashly dared,

[that] it should stand forth from Scripture to be recanted? Meanwhile, however, he proves nothing from Job: he has weakly devoted himself [to it]. As [there is] a miracle: just as supernaturally God can command the Sun, that it not rise, [when] He wills [it] not to rise, or [when] it does not naturally rise, nay, in reality [as] Joshua commanded — when for a whole day the Sun stood still, nor did it rise [again] in the regions of those Occidentals [westerners], to whom it would have risen if it had not stood still: so, supernaturally using His own divine and absolute omnipotence, God can move the Earth from its place. In turn, hence, it ought to be inferred that so natural a thing is the Sun's diurnal motion, [just] as natural is the Earth's immobility, in its own place: for the Earth standing still would be moved out of its whole place, or some part [of it], [and] it would not have its place, which would be its own, and more proper to the whole, or to the part [that is] moved.

In Psalm 18 [Ps. 19], the Royal Prophet [David], from natural and indeed true [things], and the excellence of God's works commending [Him], begins his exordium thus: *The heavens declare the glory of God, and the firmament sheweth the work of His hands.* Now meanwhile, on account of the continual succession by which the Sun illuminates the Earth, and likewise by night, [in respect of] the rest of the Planets and the fixed stars, which in the firmament rise and set, he says: *Day to day uttereth speech, and night to night sheweth knowledge.* But in diverse manner; for the splendor of the Sun is so great, that it overcomes the whole light of the other stars, even [taken] collectively; and thus [it is] more abundant, and as it were eructating [pouring forth] the magnificence of God, [the Prophet] declares — that is, [the Sun's] motion from its rising to its setting is most manifest, and is observed by all; whereas [the motion] of the Planets, the fixed [stars], the light [is] weaker, and is not observed by many; nay, it is scarcely observable like that of the Sun, and therefore [the Prophet] does not [say] *eructat* [uttereth], but [rather] *indicat* [sheweth].

[New right column, folio 87, p. 87:]

[The Sun] *uttereth* [only] science to the contemplator by night. No one however, that this is the idiom, who does not understand the language; and [hence] the voice of the heavens preaching God, and so they add [conjoin]: *There are no speeches nor languages, where their voices are not heard.* Whose [voices], that is — whose voices cannot be heard by [the ears of] those who have eyes, and an understanding sound; nor [can] the sound of all things reach [those who] perceive by ears [the meaning], or to whom that sound, or to whom that speech [comes]; but to all to whom it ought, or who ought [to be] inhabitants of the Earth moved in its circuit, [and] of such a motion which conjoins for itself a successive

light, and [by] the appearance of the Sun, as the rest, [namely] the heavens, are moved to illuminate the Earth successively; [as to] which of these takes place, they at once put forth, saying: *In all the earth their sound hath gone forth, and their words unto the ends of the world.* Whence by comparison the Apostle [Paul], [by] an allegorical sense placing this sense [of the passage], the Apostle in chap. 10 to the Romans premises, saying: *How shall they hear without a preacher? How shall they hear, unless they be sent?* As if [to say], unless [those things] are sent, [namely] the Gentiles, since the same S. [St.] Paul in this same place adduces the testimony of Isaiah for the grace of God's preventing [grace]: *I am found by them that sought me not.* And so by the Apostles, that the order of those things may be excited and illuminated; [as] thus the heavens by their diurnal motion illuminate the Earth, illuminating omnes [all things] the Earth, [and] chiefly [carrying] the motion of the Sun: but more especially [David], and on this point especially says: *He hath set His tabernacle in the Sun. — In the Sun He hath set His tabernacle, and He as a bridegroom coming out of his bride-chamber, hath rejoiced as a giant to run the way.* His going out is from the end of Heaven, and his circuit even to the end thereof; and there is no one that can hide himself from his heat. And so truly from this property of the Sun and of the Stars, David rises to praise the divine splendor, and to the purity of the divine law, [and] supposes that property, and from it as from a certain degree, makes the [step] moral. Therefore the Sun runs, and with giant-like steps, [and] this with admirable swiftness; and it revolves [round] the immovable globe.

[Ecclesiastes] of Solomon, chap. 1: *The Sun riseth and goeth down, and returneth to his place: and there rising again, maketh his round by the south, and turneth again to the north. The spirit goeth forward surveying all places round about, and returneth to his circuits. All the rivers run into the sea, yet the sea doth not overflow; unto the place from whence the rivers come, they return, that they may flow again.* — These things are difficult, nor can it be doubted what Solomon meant. By the [understanding of the] spirit [as] some wind, others understand the Sun itself [moved] by the assisting Intelligence, [so] S. [St.] Thomas [Aquinas], *opusc.* [opusculum] 10, in a few [words]. But that Solomon spoke of natural things really, and according to the truth of the matter, not according to the vulgar apprehension; the King [Solomon] of the wisdom of Adam [was] also [endowed], as it were; and there in turn he affirms it, because of the rising and setting of the rivers, [and] he speaks according to their nature, confessing that he turns toward the Copernicans, except [in the words] *Vuitichius* [Wittichius], and yet this return is not easily understood, nor is it obvious in any way, but among the more difficult things that are known from the spirit [be it] Solomon's, or [be it] proper to the truth of the sense; [it is] not [drawn] from the motion of the Sun. Nor, if he

had science infused by God, ought he to know that the Earth is moved, [and] therefore he ought to be silent about this motion, and ascribe it to the Sun; [for] truly to the vulgar sense accommodated he speaks, [though] with difficulty [is] the apprehension of the Earth's motion [grasped]; whereas no less difficult is the apprehension of the way [by which] water, once an equilibrium has been established for the seas, can ascend, suffused through subterranean passages and pristine fountains. But let him [say] it; let him dwell on it; and from the same [author] he runs through it: *All things are difficult*, etc. Now [there is] no other cause (setting aside the prejudged Copernican hypothesis) on account of which Solomon should be said to be a place of motion of the Sun, and concerning that [motion] of Venus naturally engendered, [yet] in some other sense [it is] not [so]; nor [is it the case], on the other hand, [that he speaks] of the Sun's motion: nor [is it the case] that if he had science infused by God, he ought to know that the Earth is moved, [and] therefore [that] he ought to be silent about this motion, and ascribe it to the Sun; and [accommodate it] to the vulgar sense — [there is here] a difficult apprehension of the Earth's motion, if indeed [it is] no less difficult to apprehend [the way] by which, etc., and [how] the water, an equilibrium having once been established for the seas, suffused [throughout], can ascend through subterranean passages and pristine eruptions. But let him say it; from the same [author] indeed: *All things are difficult*, etc. — No one however, for any cause, can explain this speech [otherwise] — [I give] this human example: he marvelously valued it, [and] affirmed [it], because there he wished to persuade, that is, [his] occupations being made known, that is, the most laborious investigation of the wise concerning all things that are done *under the Sun*; and [Solomon] who adds [the words]: *and labors [labores]*. Nor indeed does [Wittichius] feign [this]; therefore God was unwilling to preserve the books of Solomon, in which [he treats] of natural things...

[Margin: §] (continuation, folio 88, p. 88)

and chiefly of the motions of the stars, and the disposition of the orb of the Earth, [are things] infused by divine wisdom, according to the truth of the matter [and] written by [him], because they were unwilling that any [of those] natural things should pertain to us, [or] should not be revealed by Sacred Scripture: but by Sacred Scripture truly are natural things made known to us; through Sacred Scripture indeed they wished, [though] not so much pertaining to morals, [as] to eternal life — [for] *Concerning the motions of the stars* [these] distinct narrations of the creation of the world made by Moses; and what, I ask, does it confer for him to know, or [for] the things, whether the Earth was created moving, or the Sun rather? Or if you say that thence much may be derived, perhaps [pertaining]

to the praise of God, and to the moral, mystical, or allegorical sense, I say the same; and I [say it] of the true cognition of the motion of the Sun, or of the Earth — just as in reality, or by such a motion, we hear [it said that] David raised himself to the Glory of God, and to the divine law.

In Ecclesiasticus, chap. 33, not only does he commemorate the diurnal motion of the Sun, and by the aggregation of the diurnal motions makes [it]; what shall be answered thus: *Why doth one day excel another, and again [why is there] light [after] light, and [why doth] one year [excel] another year [made] from the Sun? By the knowledge of the Lord they are separated [or distinguished], the Sun being made, and keeping the precept, and dividing them by the Wisdom of God.* And chap. 43: *The Sun in his aspect declareth at his going out, an admirable instrument, the work of the most High*, etc. — But just as it is with the keeping and the influxes of the seasons, etc., a year [is made] from the Sun, [yet] truly that [year is made] by its own motion; he subjoins in the same place: *The great Lord that made it, and at his words hath hastened its course.* Now if Scripture wished to speak according to the investigation of the cause and the conjoined [sense], it had no cause for asserting the false [view], by which [Scripture] more easily attributes the motion of the seasons to the Sun. — That the precept moreover was made [intelligible] to the Sun, the [precept] for the precept being intelligible, [namely] the precept of the natural virtue infused into [the Sun] for persevering for so many days, and so many [in] velocity, and so [namely], with order, of which [precept] the virtue is equivalent, or [is] figuratively said [to be] a precept; as [in] that [passage of] David, Psalm 118 [Ps. 119]: *By thy ordinance the day goeth on, for all things serve thee*; and that [passage of] Baruch 3: *The stars... have given light in their watches, and rejoiced: they were called, and they said, Here we are: and with cheerfulness they have shined forth to him that made them.* Matthew 5: Christ himself: *He maketh his Sun to rise* — that is, by the proper motion of the Sun, [and] *he maketh it to rain [pluere]* — that is, from heaven really, [and] from this Christ, [who] thus by [his] truth, just as Christ, speaks figuratively according to the vulgar apprehension; just as in the passage of the setting of the Sun, intelligible [as referring] to the [Sun] itself, Psalm 103 [Ps. 104], v. 19, saying: *He made the Moon for seasons: the Sun knoweth his going down.* — He made the Moon really, [and] *his going down* — that is, the Moon's. And [there is] nowhere more truly than [in saying] really, [that] of the setting of the Sun, but [only] *the Sun appeareth*; or what does the Copernican think? Therefore from Sacred Scripture by its property, and from all instruction [given] to man, but only [from] the opinion of man, although [it be] repugnant to the property [or] manner of the speeches [should] the sense of Sacred Scripture be formed? Who would dare this? Who? — Would

that [I had] never [to say] no: I certainly say never. — But concerning the Sun [there is] enough: let us descend now also to the stability of the Earth.

De Terrae Immobilitate.

[Margin: §25]

Besides the beginning of Sacred Genesis, from which we have taught that the Earth, [though] not as a basis, [yet] as the foundation of the immobile mundane edifice, [was] not [made] from the Planets, ought not to have been created first in place, but [that] the Sun rather [should be created] in its place, or the Sun rather [should be] created in [that] place — and besides Job 9, the place from which we more rightly conclude the natural rest of the Earth, against [Didacus a Stunica] [Diego de Zúñiga] — God Himself, addressing Job in chap. 38, reproaches the ignorance of man, who [presumes] about natural things, and [about] sense [in some way], [as to] whether [a thing] is [or not], [and] though [man knows] certain things, yet ignores the causes — or so far imperfectly knows [them] — that, when compared with the divine Wisdom, he may be called ignorant. Thus, then, [God says]: *Where wast thou when I laid the foundations of the Earth? and Upon what are its bases grounded? or who laid its corner stone?* This whole circumlocution, although metaphorical, [yet] signifies a foundation congruent to the Earth, and as the basis of all the bodies created by God — [the foundation] from which it [the discourse] accordingly takes its exordium — [it] signifies, and not so much...

[New right column, folio 88, p. 88:]

the coherence of the parts with the whole, [as to] however much [it is] moved by the etherial motion. Which [thing], if this too [is] to the vulgar apprehension [accommodated], [a thing] inculcated by God, and to appearances, [as] I too inculcate [it]: if the Earth really were moved, hence the stronger [is the] argument [drawn] from the motion of the impious men taking up sound [counsel] — [namely] that, since they stand [firm], [yet] perhaps the Earth might be moved — let us not interrogate [it] thus. Now indeed there is no greater vanity than to move rather the Sun, and [to say] the Earth stands [still] — and to move the Earth. If you say that Sacred Scripture has no intention of teaching natural things, [then] from that very thing [you must conclude] — [for] God, in chap. 38, primarily indeed intends to reduce man to the recognition of his own imperfection, and thence to humility and reverence toward the divine wisdom; [yet] secondarily [Scripture does propound], in the meanwhile, by way of these proportions [of nature], true natural things — granted [they be] difficult to know — [namely] those true natural things which, when they are difficult to know, are of terms

exceedingly important, [as] of the dissolution [of the deep], of the dawn, of the depth of the abyss, and of dark and dense darknesses, that is, of the way by which one goes to the lower regions; of the amplitude of the surface of the whole terrestrial [globe]; how light is propagated; how snow, hail, ice, dew, mist, lightning are formed; how so many stars in the constellation of the Pleiades are so closely conjoined, [and] what their ratio and order, and the agreement of the heavens [is], [and by] what natural instinct the cock distinguishes the hours of the night: — all which things God there commemorates, not as a mere appearance, but as a truth; [yet] the property of natural truth, [its] causes ignored, [lies] beyond the human [understanding]: but [for now] let us pass on to clearer passages.

[Margin: §] [Lib.] 1 *Paralipomenon* [1 Chronicles], chap. 16, it is said: *Commoveatur a facie eius omnis Terra* [Let all the earth be moved at his presence] — for He Himself founds the orb [as] immobile, [so that] the orb of the Earth may be commoved [moved], that is, may not be moved [from its place], as [they] have it [in chap.] 70 [the Septuagint], [and so] Interpr. [the interpreters], and Job 26: *He hangeth the Earth* [*Appendit Terram*] upon nothing, or [as] the Seventy [Septuagint] [have it], *suspendit* [he suspendeth]; and Psalm 92 [Ps. 93], whose Title near the Seventy [LXX] is such: *In the day before the Sabbath when the earth was founded* — [the Earth] is sung by David himself, [and] thence chiefly the fortitude of God is praised: *For he hath established the world* [*firmavit Orbem Terrae*] which shall not be moved, Psalm 103 [Ps. 104]. *Who hath founded the Earth upon its own bases: it shall not be moved* [*Qui fundasti Terram super stabilitatem suam non inclinabitur in saeculum saeculi*]; *He hath founded the Earth upon its bases: it shall not be moved for ever and ever.* — Ecclesiastes [chap.] 1: *But the earth standeth for ever* [*Terra autem in aeternum stat*]; the Hebrew reading has: *Terra in aeternum fixa, & consistens est* [The earth is fixed for ever, and abideth]. And Proverbs 8: *When he established the foundations of the Earth* — or [as] they have [it in chap.] 70 [LXX]: *When he made strong the foundations of the Earth.* And Isaiah 40: *Who hath... weighed the mountains... [and the earth] in three fingers' [weight]* [*Qui appendit tribus digitis molem Terrae*], and chap. 44: *Who alone... establisheth the earth* [*Extendens Caelos solus, stabiliens terram*]. — By which passages not only the coherence and permanence of the parts with the whole, and [their] constancy in [their] integral stability, is signified, [but] also that these [things] are to the Sun and to the Moon; [whereas] the rest [of the] Planets [continue] coming, [yet] nevertheless [these] illustrious [bodies] are said [to be] founded upon [their] stability, [and are] called [established] upon nothing, [in respect of] local motion, [yet] not inculcated; [and] chiefly the local constancy [is]

inculcated, [the bodies] willing [to be still], the Copernican [body] unwilling [to be still].

[New section heading, folio 88, p. 88, right column:]

Respondetur Novis quibusdam, vel nova forma inculcatis Obiectis praecipuè ex Sacris literis positis.

[It is answered to certain New, or newly-formed Objections, drawn chiefly from Sacred Scripture.]

[Margin: §26]

The Copernicans have indeed no arguments by which they could directly assert, from Sacred Scripture, the motion of the Earth and the immobility of the Sun, except that [passage of] Job 9 — which they nevertheless [bring] against [Diego de Zúñiga], showing rather the natural immobility of the Earth; [it] confirms the [Earth's immobility], the divine power being preserved. They are moved indeed, [moved] indirectly, if [Scripture] willed [it] — by trying to assert that God in Sacred Scripture is unwilling to instruct men in natural sciences, [the sciences] of which [are] Physics and Mathematics; and therefore, if [Scripture] should happen to speak about it, it speaks according to the vulgar sense, and according to their [men's] apprehension, whether [the thing] be true, or false; [and] especially in matters that, by reason of apprehension, are beyond the rougher men, and in other [matters] too; nor do they deny faith to the sacred Codex. — But to that [their] assertion concerning [the Earth's] stability, applied to various particular passages of matter, they bring forward in general that [passage of] Isaiah 8: *Take thee a great book...*

a great book, write in it in the style of a man" (that is, write in human fashion), says Vuittichius [Christoph Wittich], "speak in human fashion, and accommodate yourself to the apprehension of the vulgar in your speech." And there is that saying of the Apostle, 2 Timothy 3: *All Scripture, divinely inspired, is profitable to teach, to reprove, to correct, to instruct in justice, that the man of God may be perfect, furnished for every good work.*

§27. I answer, first: it was the primary intention of the Holy Spirit, in handing down Sacred Scripture, to teach human beings the things that pertain to our salvation, our faith, and the blessed life — and often, to this end, by way of a historical narrative of human and natural matters, or of their natural properties — but only insofar as those things are conducive (whether as a means, or as occasions for rousing people to the praise of God), or as comparisons to be drawn from them, or for the forming and correcting of morals, and the like. The Holy

Spirit did not, however, intend to teach natural science by a scholastic method, but rather supposed it as known, and to set it out in simple propositions, as is clear in Job chapter 38, in the Psalms, in Ecclesiastes, in Proverbs, in Ecclesiasticus, and often elsewhere. Yet I deny that Sacred Scripture, in the matters it does set forth, has confirmed anything erroneous, false, or contrary to fact, even though it accommodates itself to the common manner of speaking. For if it were once caught out in having asserted something false, its authority in all other matters would be undermined — which would surely be exceedingly dangerous, and far graver than what is being conceded; though it be hard and arduous to grasp.

Therefore Catholics ought to believe what is set out, even if it is otherwise known by natural reason, or easily grasped — precisely because such things are known, or are easy to grasp — and they should refuse to do this only for things that are difficult, such as the mysteries of the Most Holy Trinity, the Incarnation of the Divine Word, the Eucharist, and the like; for there the matter exceeds the formal motive of faith, and there is no authority of the Divine Word, but a darkness of the human intellect. Did Christ abstain from preaching the mystery of the Eucharist — or, before that, did He withdraw from instituting that Sacrament — merely because the saying seemed hard, and because many of His disciples drew back from Him? By no means! It was a scandal to the Jews, and folly to the Gentiles, that God should be dead for our sake; the Resurrection of the dead seemed novel to the Greeks, and it was held an incredible doctrine. Did Paul on that account, or the other Apostles, abstain from preaching it? But you say: these matters bore upon faith, or upon salvation — not so the question of whether the Earth moves and the Sun stands still. The Holy Spirit, you say, did not assert this of itself, but by accident (matters that can be revealed by God beforehand, or that fall under natural cognition); theologians say such things are of faith by accident, and to be believed with equal certainty, on account of the identity of the formal motive of belief (namely the authority of God who speaks), provided God had revealed them. He foresaw that many would err in this, who in obedience of faith would yield their intellect captive — a thing not at all difficult, provided someone has yielded his intellect in obedience to faith, however unschooled he be, however unskilled, yet a knower of astronomy: this does not conflict with truth, and it is no harder to believe than the rest; especially since it conflicts not only with the Copernicans, but also with the Tychonics, and with most astronomers — indeed, even with the semi-physicists [the half-natural-philosophers] — who readily apprehend the diurnal motion of the Earth, already from the time of Pythagoras, Philolaus, and the ancients of this sect; nor only the followers, but even the Ptolemaics, and others would best apprehend the form of this motion.

§28. Nor indeed, as they seem to suppose in this matter, did the Copernicans hold Sacred Scripture to have been written for the vulgar only, or for the unschooled, or for the great mass of the people, or for those ignorant of letters, or who know only the vernacular tongue — as though it were written for the unlettered, when it was in fact written for those skilled in the law, the Magistrates, and the Doctors of the people, that they, instructed first by the Holy Spirit, might then teach the common folk. Therefore God did not, on account of the ignorance of the vulgar, owe it to anyone to assert what is false along with the vulgar, and to flatter them; nor did He, by measuring the formulas of His divine discourse to the capacity of the unschooled, fail to confirm His own truthfulness with the weight of His authority. Rather, out of the seemliness of His Majesty, He took care, as a teacher, lest He ever be caught having spoken falsely — and lest, by the testimony...

of His own seal, He should seem to set His seal upon a true and firm assertion as to its appearance, but absolutely false as to fact. Indeed, since He best foreknew things to come — that the common folk would in the end be deceived by the discovered natural motion of the Sun itself (provided they spoke from data already granted as an interim hypothesis, with this and many other points conceded into their own opinion as novelty), or by the plain evidence of it — He could, indeed He ought, to have asserted this truth in many passages of Sacred Scripture, with the great teaching authority adduced for it, and not, with the contrary falsehood preserved, to have asserted this truth in passages tempered to the unschooled, so that He neither expressly proposed to them what is difficult to grasp, nor would assert what is false, but spoke in no greater number with the unschooled than He would have had the skilled assent to His own testimony. As for me, such forms of speech are not lacking; nor was God lacking the resourcefulness to speak. For example: when Christ said, *He maketh His Sun to rise upon the good and the evil* (Matthew 5) — if it really did not move, He could have said, *Who maketh that the good and the evil enjoy the light of the Sun.* Likewise, where Sacred Scripture says, *It standeth still; the Sun stood not down,* nor did it complete its course over the land — it could have said, *the light of the Sun standeth still over the land,* nor was it made that the prolongation of the Sun's light over the land [should be] for the space of one day.

For thus speaking, and accommodating Himself to the apprehension of Joshua and of the people, or even, by a certain estimation, regarding the Sun's motion, He said, *Sun, stand thou still,* whether He held another opinion, or whether the Sun did not move, the Sun would not stand still — yet, lest He give the skilled an occasion for most pernicious controversy, and lest in other things said He spoke

mere appearance and not according to truth — and lest, then, the ever-truthful divine ingenuity be undermined in confirming things asserted.

§29. I answer, therefore, more briefly: by denying that Sacred Scripture utters any false proposition, but only that it speaks according to appearance and not according to truth, whether in natural matters, or in matters of faith by accident, or in moral matters, whether in mysteries, or in dogmas, which are of faith of themselves — be it written that it is so, or that it speaks to the unschooled; on the contrary, I assert that Sacred Scripture, notwithstanding any danger of scandal or of incredulity in others, always speaks the truth — whether properly, or by metaphor, or by figure, it always speaks figuratively — although in some passage it be tacit, and contrary to express opposition, it nonetheless never asserts. Furthermore I say, with St. Augustine, Gregory, Thomas Aquinas, and the Catholic theologians: Sacred Scripture always, before it is interpreted in a literal sense as the words commonly sound, when it is not manifestly inconsistent for us to take it so — just as in the controversy here proposed there is, by no one yet demonstrated, any motion of the Earth, but rather an immobility of the Earth, of whatever kind; the opposite, however many followers of the Copernican sect and Cartesian whirlwinds may peddle it, a most experienced astronomer abhors — let René Descartes of the Chartres region, however acute his ingenuity, and in those things knowledge of judgment grant, what in others is lacking. By how much more, therefore, it would be demonstrated [recte: if it had been demonstrated], than by me has been done, [that] the Earth is not moved.

§30. I answer, third: against the Copernican argument turned back retorted thus: if there were so great a difficulty in apprehending — that they conceive a motion of the Earth and a quiet of the Sun, such that God ought not on that account have undertaken to withhold this truth, but to have asserted the opposite — much more ought the Copernicans to accommodate themselves to the human apprehension, this novelty of doctrine being introduced and promulgated, by how much less is the authority of human doctrine than the divine; and by how much greater the liberty of repudiating, and of holding human doctrine in contempt, than the divine. If you say that the Copernicans promulgate this doctrine to the vulgar, or to the skilled in astronomy, not by that intention, that they write [it] for the unschooled, [but] in the vernacular version, or that it be communicated by the common manner of speaking to the unschooled, in which the danger of error and of scandal ceases. And I in turn shall say: rather could God in the Sacred Scriptures have expressed His own doctrine, with what intention, with that intention, that He set it forth to be promulgated to the

learned, by which it would have been persuaded by learned men, near to that of the Apostle 1 Corinthians chapter 2: *But we speak wisdom...*

among the perfect — that is, the same place expounds it, of spiritual things, with God's help, [things] capable [of being grasped]: *Not the animal man perceiveth those things which are of the Spirit of God; it is foolishness to him, neither can he understand* (1 Corinthians 2). And there is that saying of Christ: *Cast not your pearls before swine, lest they trample them and turn and tear you* (Matthew 7). Was less allowed to God in this than to a Copernican?

Now I shall come to particular passages of Scripture, which they emend so as to persuade us that those passages are absolutely false with respect to fact, or [that they merely] stammer along with the vulgar.

§31. They object, first: the Apostles used the version of the Seventy [the Septuagint] interpreters, so that they accommodated the Hellenists, although they sometimes differ in some respects, since the Septuagint not rarely differs from the Hebrew and Vulgate. I answer by denying that in the passages used in the Gospel, or in Acts, or in the writings of the Apostles, Sacred Scripture is erroneous — granted that the Hebrew is true, I do not deny it; but St. Luke says: *Who was of Salah, who was of Cainan, who was of Arphaxad* (Luke 3); but the Vulgate has eleven [generations]. Now Arphaxad lived thirty-five years and begot Salah, with no mention made of Cainan — who, mediating between Arphaxad and Salah, could in this way be gathered into the ancient Hebrew text, which the Septuagint then asserted, [a text] now lost over the course of times, omitted perhaps by the negligence of the copyists of the books.

§32. They object, second: that saying of Matthew 19: *Master, what good shall I do, that I may have eternal life?* — He who said: *Why askest thou Me of good? One is good, God.* But if you wish to enter into life, keep the commandments. Here Vuittichius [Christoph Wittich] argues that Christ denied Himself to be good, since He knew Himself to be good, because in the estimation of the questioner there was no truth that He was good, or [that He] was reckoned [so]; or, since He denied Himself to be good, He felt the sense of the words doubly perplexing: the former [sense], that in the estimation [of the questioner] there was a necessity for the use of words such that the Greek reads *ἀγαθόν τι με λεγεις αγαθον* — what do you call good, namely the Master — as though now a better Master than [the questioner] supposed: God, who gave you these commandments to be kept, and I diversely [gave them] for [obtaining] eternal life. Could I command [this]? If you have this opinion, you are deceived; for the one good Master is God, and therefore keep the commandments which the Master commanded. The other

sense is: Why do you call Me an absolute Master good, since you reckon Me good in the estimation of men, [but] not absolutely good? But if you call Me good absolutely, then either acknowledge Me to be God, or cease to call Me good.

§33. They object, third: that saying of Mark 6: *And King Herod heard it*. But this Herod was the brother of Philip, whose wife he had taken, and he was Tetrarch of Galilee, not King; he is called [King] in Luke 3 and Matthew 14. I answer by denying that he was not a King in some part — there is no inconsistency in those two appellations, *King* and *Tetrarch*; likewise St. Matthew chapter 14, who earlier had called him Tetrarch, afterwards calls him King, saying: *And the king was made sorrowful* — moreover, on account of the Tetrarchate, etc. For Augustus Herod the Great had made King of the kingdom and the Tetrarchate, with this distinction, that he ascribed to Archelaus and Philip [the title] Tetrarch, [and] to Herod Antipas attributed it; nor would he establish anyone as King — indeed, all things he did that he might make Herod King, and the Jews [it was who] feared Caesar would contradict; among the Jews, however, he was held as King, and bore himself as such; not as a King of the Romans, but by natural paternal right he was King, as if of an imperial King.

§34. They object, fourth: those words of Christ in Luke 5: *Launch out into the deep* — where He seems to speak according to the sense of the vulgar, who reckon the sea to be far from the shore, [and] higher than the shore itself. I answer: The deep sea [recte: the high sea] is far from the land, and it abounds with fish; it is called "deep," [but it is] truly higher than the shore itself; there is a greater abundance of fish, and it is more convenient to let down the nets in the deep, which Christ required, and not without the necessity of multiple miracles, [namely] that the fish be driven there into the nets, where they were caught. The altitude [of the sea] also signifies depth, rather than [needing] proof, as the Grammarians [hold]. There is also another reason: that since the open sea appears far higher, although for optical reasons it really is so — namely, because, accustomed [as we are] to a flat shore, nor [does it appear] round — and because the surface of the sea is considered a plane...

produced by the imagination of the shore, and cutting the sea, while in reality it is higher in the surface than such a plane is, just as the periphery of a circle is higher than the diameter passing through the middle of it lies underneath.

But pressing on in the same chapter 5 of Luke: *I came not to call the righteous, but sinners to repentance* — where He calls the righteous Pharisees, not according to the truth of the matter, but according to their opinion of themselves, who reckoned themselves righteous, and despised the rest. I answer by denying that

Christ asserted the Pharisees to be righteous, but only says He came to call sinners, not the righteous, just as a Physician [comes] to heal the sick, not the healthy, who [Christ] himself affirms, nor does he decree something else [for] the righteous, [namely] those who are not [righteous]. Therefore, with many adults excepted — His Most Holy Mother, and St. John the Baptist — all are sinners, and in need of repentance; He came to call all to repentance, and therefore said in Luke 13: *Unless you do penance, you shall all likewise perish* — for the Apostle says to the Romans 3: *All have sinned, and need the glory of God*. Therefore, lest the Pharisees reckon themselves righteous, did not Christ on that account confirm [them so], but according to their opinion of themselves He spoke.

§35. Did not the Apostle in 2 Corinthians 4 (2 Corinthians 4:4) say: *The God of this world hath blinded the minds of unbelievers* — calling the Devil the God of this world, according to the opinion of the Gentiles, who worshipped demons as evil gods? I answer that the blinding, although it proceeded from a crass ignorance, or a depraved disposition, [and] from some preceding fault, was [done] by the Devil, that by [his] instigating to sin, that fault, [done] not the less by God, who permits the sin, and by His just judgment denying [the] abundant light, [though] grace is not denied [as] sufficient. How is the blinding truly attributed to God by Christ Himself, John 12, confirming that saying of Isaiah: *Blind their eyes, and harden their heart, lest they see*, etc.?

§36. They object at last, [the rest] passing over the lighter [objections], Vuittichius's [Christoph Wittich's] saying of the Apostle to the Hebrews 7, on Melchizedek: *Without father, without mother, without genealogy, having neither beginning of days nor end of life; but likened unto the Son of God, he abideth a priest continually*. But doubtless he had a father and mother, and a beginning of days, and an end of life; therefore he must accept this not according to the truth of the matter, but according to their opinion, and the knowledge of them, or [because] in the matter, etc. Or, because his origin and genealogy were unknown, they thought him to have endured forever; but the Apostle did not so speak according to such an opinion, since perhaps no one of the Hebrews had so written; he had a most lying [account], indeed he himself explained his own dictum by those words: *Whose generation is not numbered among them, [yet] he took tithes of Abraham* (Hebrews 7). Why, then, is the genealogy not recent in the Sacred Scriptures, as of the other Patriarchs — nor a time of death, [and] therefore by a certain proverb, but with a grain of salt is it to be understood, [namely] that he was without father, etc., and because he had borne a figure of the eternal Priesthood of Christ, but [in] an imperfect figure, since Melchizedek was a mortal man, and so, [as] the Apostle subjoins, [a figure] of Christ: *There were made many*

priests, because by reason of death they were prohibited to continue; but [Christ] hath an everlasting [priesthood], abiding a priest forever.

§37. As for objections drawn from Reason: I have already refuted them in the *Almagestum Novum*, Book 9, Section 4 [Almagestum Novum IX.4], nor have I found among recent followers of Copernicus any new argument worthy of being adduced, much less refuted. Yet there is that ancient thing, inculcated by Jacobus Lansbergius [Philip van Lansberge], and tossed about by him as *infallible* — and I myself have experienced [it] in such an argument [from] a certain Knight, a Catholic Angel [recte: a Catholic gentleman], who [is] here at Bologna, a man of great judgment and of [great] ingenuity, much moved [by] the Copernican hypothesis, vehemently propounding that thing of seeing, and to show how trifling it is, [how] slight. I suppose, then, that Lansberge holds the fixed [stars] to be distant from the Earth by 10,302,917 semidiameters of the Earth, whence he gathers that the fixed [stars], in 24 hours, complete the whole periphery, that is, in one second of an hour [one second of time], this is, in one moment of a second by the stroke of a human artery, traverse 643,848 German miles — *which*, he says, *is impossible*, because in no proportion between moments of time, and because [such] a swift motion of a physical body: from this it seems he wishes to indicate that such a motion is made in an instant; he wished moreover that there be no difference between a moment of time, and...

time, in which only space would be traversed; or if that motion were made in an instant, [it would] not [be] made in [time] swifter than physical, than if it were made in one second of an hour. As though we cannot indeed discern time briefer than one second [of an hour]; whereas nevertheless from things said in *Almagestum Novum* Book 2, chapter 20, proposition 15 [Almagestum Novum II.20, prop. 15], we have a perpendicular [pendulum] whose individual vibrations are completed within 10". But I argue: I deny the motion to be impossible, by which a physical body in one second of an hour traverses 643,848 German miles. Likewise I deny this velocity to be disproportionate to a physical body, if this can suit it; the motion about the center of its circle, and from its distance from the center. Because from one part, the circumference of the diverse circles among themselves are as the diameters, and accordingly as the semidiameters, by Theorem 5, Book 11 of the collections of Pappus of Alexandria [Pappus, *Collectiones* XI.5]; from the other [part], as is demonstrated by Clavius [Christopher Clavius] in his *Sphaera*, the arcs of many circles described from the same center, and [cut off] by the same straight lines drawn from the center, are similar among themselves.

Thus, if one arc of such a periphery be the sixth part, the others too will each be the sixth part of their own peripheries. Whence it comes about that such arcs are proportional to the semidiameters, or to the distances from the center. Let there be described, then, from the same center of the World [as] the Equator of the terrestrial Sphere, with a finite interval; and let us imagine both [Spheres], and that the Spheres are moved by a diurnal motion; and [let] the semidiameter of the Earth [be] 860 German miles; and so the point of the terrestrial Equator completes 15" [recte: of its own periphery], this [being] the tenth-sixth part of one German mile by geometrical paces. Let there be on the other part the semidiameter of the Equator of the Fixed Sphere of 8,600,000,000 German miles. For as the Radius 10,000,000 [is] to 15", [so is] the chord 720 by insensibly less than its own arc, that is, 8,600,000,000 to the miles 619,200. I say the same proportion to be between this and the distance of the Fixed [stars] from the center, which is between the part of 16 German miles, or paces 25, and the semidiameter of the Earth; this indeed [is] to the predicted distance 8,600,000,000 to 619,200, so 860 to 619, ^{200%}8,600,000,000 [recte: reduced fraction], which being reduced to the smallest fraction is $\frac{532112000}{100000000}$ [as printed]. But to our imaginations that number of 619,200 miles, traversed in one second, seems incomprehensible; yet one must consider what and how great the paces would suit Atlas — that I may say, a Giant — that the legs [making] such an arc-traverse comprehend, and that those 619,200 German miles in the 25th part of a celestial day [recte: of a day] could be traversed by 4 Italic paces; nor is such a motion to be estimated less possible, than [it is] possible that lightning in one moment of time traverse the ant-like steps of 24,000,000, if we set down [it traverses] some one German mile, that is, one Italic [mile]; and [it is] far more probable [recte: certain] in the interim that it absolves the hundredth part of one inch of one foot. Therefore Vuittichius [Christoph Wittich], and some others of the Copernicans, confessed this to be an argument of no more validity for the swiftness of the Fixed [stars] than the Ptolemaic argument against the Copernicans, [that the Copernican] hypothesis...

requires it, [namely] that the whole orbit of the year of the Earth be as an instant with respect to the Sphere of the Fixed stars.

§38. After I had written these things, behold, a Letter is given to me, dated the 28th of December in the year 1660, [from] the Most Reverend and Most Learned John Caramuel [Juan Caramuel y Lobkowitz], Bishop of Campagna, [and] from a Satyr [recte: a Satrap?], in which [it touches] upon the observation of D. Pironio [Father Pironi], who was a friend of Galileo, and the comrade of friendship: he was setting forth a refutation. There is among the highest [stars] of the front of

Scorpio a little star [recte: which I myself had often observed]; their interval, the Sun being about the end of [the sign], with $5\frac{1}{2}$ turning, [shows] the larger appearing somewhat greater in diameter than the little star, which [is] of the 4th [magnitude]; and accordingly that interval then appears almost as $5\frac{1}{2}$. But when the Sun is in the end [recte: beginning] of Aquarius, it would appear smaller, namely on the day before the 22nd of February of the year 1644: I estimate the said interval of the little stars to be the third part of the diameter of the larger little star, and equal to the diameter of the larger little star — this [being] of $1' 10''$; and accordingly the prior interval of the same [is] less than the whole, of $3' 45''$. Of so great is the parallax of the said little stars: observations were made with a very good Telescope, and the Most Reverend Caramuel was aiding me in subjoining. *If the Earth were quiescent, hence the little star would always be equally distant: it is not equally distant; therefore the Earth would be moved. The Earth is moved. Therefore the Copernicans, whence they can [argue], not only persuade the annual motion of the Earth, but also [that] whence the said distance [comes], concerning which there is no other hypothesis, but [a mere] thesis: they have built [it up]. Weigh, then, the argument, and insinuate what you judge; this thing seems to me a probable solution to be required* [recte: in need of solution].

I answered straightway that those observations themselves are repugnant to themselves, and to the Copernican hypothesis. For if at the access of the Earth toward the Fixed [stars] the highest [star] of the front of Scorpio [had] a [second] interval [of] $4''$, and its interval [from] the nearer little star [of] a second $5''$ [recte: as stated], [then] indeed at the recess of the Earth the diameter of the appearing Fixed [stars] ought to decrease proportionally, [and] optically, as much [as] the diameter appearing of the Fixed [stars], as much their interval among themselves; and if [there were] a smaller interval, the apparent diameter [of] the highest [star] of the front of Scorpio [would be] always greater; [but at] the access [there is] a smaller interval, [and] the diameter of the appearing little stars would not decrease; of these we would not have the argument of the access of the Earth, since at the alternating annual access [and] recess [it would be] necessary, or by what reason there is a variation of [the] interval [of] the little stars among themselves, [of which] indeed the diameter [of] the Fixed [stars] would vary, [and] not the same [diameter] of the little stars, but rather of the Earth from the annual motion immune; and on the contrary the motion of the Fixed [stars] themselves among themselves. Therefore now they have the prudent interval [recte: the prudent man should weigh whether] the Copernican hypothesis is repugnant to itself, and how much it ought [that] the Fixed [stars] be distant by a third interval, with so great [an] interval of the Earth from the annual motion, [there being] no parallax in them, [if] it were in the perceptible sense of the

[observations]. By how much soever, indeed, and with what powerful Telescope you use, never after some months can you certainly discern [the] interval [of the] Fixed [stars]; how, then, could the interval [of the] Fixed [stars] decrease in one second [of an hour], when within the same hour they consist [recte: appear] in the same place, with an entirely [unchanged] optical diameter of the Fixed [stars], because *of itself* about [it]; on this matter [there] survives doubt. Lest here [there be] anything we may say of diverse haze, both of the winter air's constitution, to which so great a variety could be referred. Let lovers of the Copernican hypothesis beware, then, lest with fallacious observations they impose so great a mass of new hypotheses, and [that these] thus are themselves repugnant to Copernicus.

LIBER SECVNDVS — Book Two

BOOK TWO

IN WHICH SELECT OBSERVATIONS OF ECLIPSES OF THE MOON AND OF THE SUN

are presented, for establishing the lunisolar motions and the Moon's first inequality, and for setting bounds to the apparent diameters of the luminaries.

CHAPTER I.

On the selection and use of the observed eclipses for establishing and verifying the astronomical tables; and on the distances of meridians assumed in the more celebrated tables.

1. As I noted in the *Almagestum Novum* [Almagestum Novum], Book 5, I have gathered a great many eclipse observations: from the year 772 before the Christian Epoch down to the year of Christ 1647 (Chapter 19); others, added in an appendix to that same chapter, run down to the year 1650; still others, added in the appendices at the end of the first tome, reach as far as 1657. Some I took over from the observations of others, and certain ones I find in the tables of Father Jacobus Lodoicus Billius [Jacques de Billy] of our Society, as well as in Pierre Gassendi [Pierre Gassendi], *In Epicurum*, p. 886. Yet not all of these are to be recalled here. I have judged that only those should be brought forward whose observed magnitude, or whose definite time-marking, was such that they serve not merely to the day but to the

very hour and minute — and especially those that are suited to establishing and verifying the lunisolar motions, the luminaries' diameters, and their first inequality. On this occasion I have also corrected mistakes of the typesetters, and even some of my own, in the day-counts, in which I had followed Petavius [Denis Petau], Scaliger [Joseph Scaliger], Mulerius [Nicolaus Mulerius], Copernicus [Copernicus], and Bullialdus [Ismaël Boulliau]; but having afterward recognized the error of certain of these, I have abandoned them.

2. Would that all the aforementioned eclipses, of whatever magnitude, were marked with a noted quantity and time fit to attain that exactness which the more recent astronomers aspire to. But — to confess the truth sincerely — by no means many of them are suited to this task. The reason, as the matter stands, is the difficulty of catching them: very few observers possessed the principles and ends needed for observing eclipses exactly, and their quantities — especially those before the use of the telescope — could indeed have been left to Tycho [Tycho Brahe] and others; the reasons I set out in Chapter 4.
3. Furthermore, that it may more readily be established whether a discrepancy of the calculation arises from a mere difference of longitude, I have decided to set out the distance of meridians that must be investigated; and, in turn, what distance the authors of the calculations and of the tables suppose, and adduce in their observations. This will serve also, if anyone in an eclipse-history should at once wish to know the time at which the phenomenon ought to have appeared in other places.

Table: Meridian distances of places ()

The tables that follow list, for each named set of astronomical tables, the correction in hours (*Hor.*) and minutes (*Min.*) to be **added** or **subtracted** in order to transfer a calculation from the reference meridian to other places (or, conversely, to transfer an observed phenomenon back to the reference meridian). The places are grouped as eastern (*Loca Orientaliora*) or western (*Loca Occidentaliora*) relative to each reference meridian. Values are given as hours : minutes. The instruction line above each block states the convention (whether the table adds or subtracts for transferring the calculation, and the opposite for transferring the phenomenon).

ALPHONSINE Tables — reference meridian TOLEDO (*Tabulae TOLETO*)

Add for transferring the calculation to other places; subtract for transferring the phenomena from other places to TOLEDO.

(Loca Orientaliora — places more eastern than Toledo)

(table continues; catchword "PHI-" at foot of printed p. 94)

Parsing notes: These three pages are almost entirely a multi-block meridian-distance table laid out in three newspaper-style columns per page, with each block headed by a tables-name (Alphonsine / Prutenic / Danish / Tyconic / Rudolphine / Lansbergian / Parisian / Atlantic) and a Latin add/subtract instruction. Because the columns wrap across page boundaries and interleave (e.g., the Alphonsine *Loca Occidentiora* list runs in the middle column of printed p. 93 while the Tyconic/Rudolphine blocks run in the outer columns), I have grouped the rows by tables-name rather than by physical column, labelling each with its source column/page. The reference-meridian abbreviations (TOLETO, REGIONMONTE, HAFNIA/HAFNIAM, VRANIBVRGO, GOESAE, PARISIIS, ATLANTICO) are the dative/ablative forms in the instruction lines; I have rendered the meridian name and kept the Latin form in parentheses where the instruction text uses it. Several small place-name spellings are antiquated or compositor-variant (e.g., *Haphnia* vs *Hafnia* for Copenhagen, *Rosfokinum/Rossochium/Rostochium* for Rostock) and are transcribed as printed. Fractional minute marks ($\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, $\frac{2}{3}$) in the Atlantic block are transcribed as printed. The "H." column = hours, "M." column = minutes of the time-difference correction; these are not impossible values (no minutes value reaches 60; the hours column carries the overflow). A focused further cell-by-cell re-transcription () resolved all ~22 first-pass [?] cells with zero residual illegibles; the value corrections established there have been merged into the tables above. The right-column top block of printed p. 94 (Goa 6:10 ... Vramburgum 0:47, with the western tail Compostella–Vlyssippo) is the **Parisian** continuation, not the Atlantic block; it has been relabelled accordingly.

Liber II — De Luna (continued)

Caput I (continued) — Meridian-distance table (conclusion)

The meridian-distance table from Caput I concludes here. It is laid out in three columns across the page top. Each entry gives a place-name and its time-offset (H. = hours, M. = minutes of time) used to transfer a calculation from one reference

meridian to another within the various astronomical table-sets. The left column is headed by the Philolaic and Bolognese (Riccioli's own) table-sets; the middle and right columns continue the alphabetical place-lists. "Add" (*Addunt*) and "Subtract" (*Subtrahunt*) sub-rubrics indicate the sense of the correction.

Left column

Philolaic tables [Tabulae Philolaicae] — i.e. the tables of Boulliau [Ismaël Boulliau / Bullialdus]. *They add* for transferring a calculation to Uraniborg, to another place, but *they subtract* for transferring the phenomena from elsewhere to Uraniborg. (Heading: *Places east of Uraniborg* [Loca Orientaliora Uraniburgo].)

Place	H.	M.

We give a fuller catalogue in the Astronomical and Geographical Tables; but this here is amply sufficient for the eclipses observed so far.

Parsing notes: Several place-names in this gazetteer are heavily abbreviated and a few modern identifications are tentative (marked with "?"). The fractional minute-marks ($\frac{1}{2}$, $\frac{1}{4}$, $\frac{3}{4}$) are rendered as printed.

CAPVT II.

ECLIPSES OF THE MOON

Observed as to their Magnitude and Timing, from the Year 721 before Christ down to the Year of Christ 1660. With the Errors or Frauds of others in Chronology or Magnitude detected.

ECLIPSIS 1.

[Margin: 721 years before Christ]

In the first year of Mardokempad, or year 27 of Nabonassar, on the 29th day of the month Thoth, on the following night a total eclipse was observed at Chaldaean Babylon, beginning more than one hour after moonrise. Ptolemy reports it (*Almagest* IV.6), saying that this onset fell at 4h 30m before midnight, but that midnight at Alexandria came at 2h 30m — so that by the Julian reckoning this was the night of March 19, 721 years before the common era of Christ.

ECLIPSIS 2.

[Margin: 710]

In the second year of Mardokempad, or year 28 of Nabonassar, on the 18th day of the month Thoth, in the night, a lunar eclipse of 3 digits from the southern side was observed at the very midnight. Ptolemy gives this (*Almagest* IV.6); the text of this passage was corrupted by Lansberge [Philip Lansberge] in his *Thesaurus*, p. 55, where for the three digits he substitutes three minutes [scrupula] — let this not harm those who follow his Tables — although the text expressly has [Greek: δακτύλους τρεῖς (daktylous treis, "three digits")]. The day was March 8, 9 years later, 720 before Christ.

[Margin: Lansberge's fraud (*Lansberg. Dolus*)]

ECLIPSIS 3.

[Margin: 710]

Likewise in the second year of Mardokempad, or year 28 of Nabonassar, on the 15th day of Phamenoth, in the following night, the Moon began to be eclipsed after its rise

ECLIPSIS 3 (continued).

[Margin: 710 years before Christ]

after its rise from the northern side, more than six digits being deficient at Babylon. Ptolemy reports it (*Almagest* IV.6), reckoning the middle of this eclipse at 8h 3m. The day was September 1, in the night following, the year 720 before Christ.

ECLIPSIS 4.

[Margin: 621]

In the fifth year of Nabopolassar — but the 127th of Nabonassar — on the 27th day of Athyr, in the following night, the Moon began to be eclipsed at Babylon under one hour and 11 minutes before midnight, and about the sixth hour after midnight (as Ptolemy computes, *Almagest* V.14, at one equinoctial hour after midnight, at 5h 50m). The fourth part of its diameter at most was deficient from the south. This fell on the 21st, in the night following the 22nd of April, in the year 621 before Christ. A leap year.

ECLIPSIS 5.

[Margin: 523]

In the seventh year of Cambyses King of the Persians — but the eighth, as Scaliger has it [Joseph Justus Scaliger], book 4 of the *Emendatio Temporum*; or year 225 of Nabonassar — on the 17th day of Phamenoth, in the following night, the 18th, at one hour before midnight, the Moon began to be eclipsed at Babylon from the north by 6 digits. Ptolemy gives this (*Almagest* V.14). The day was the 16th of July, in the night following the 17th, in the year 523 before Christ.

[Margin: Scaliger's error (*Scaligeri error*)]

ECLIPSIS 6.

[Margin: 502]

In the twentieth year of Darius Hystaspes, who succeeded Cambyses — or year 246 of Nabonassar — on the 28th day of Epiphi, in the following night, at one equinoctial hour after sunset (6h 20m), and before midnight, the fourth part of the Moon's diameter was deficient at Babylon from the south. Ptolemy reports it (*Almagest* IV.9). The day was November 18, in the night following the 19th, in the year 502 before Christ.

ECLIPSIS 7.

[Margin: 491]

In the thirty-first year of Darius the First, Hystaspes — or year 257 of Nabonassar — on the 4th day of Tybi, in the following night, the 5th, at the middle of the 6th hour of the night, the Moon began to be eclipsed at Babylon by 2 digits of diameter from the south. Ptolemy reports it (*Almagest* IV.9), where he expressly says: "for the middle time of this eclipse occurred near the middle of the night at Babylon, but at Alexandria at one hour and a third part of one equinoctial hour." Why, then, did Lansberge not rightly put (*Thesaurus*, p. 61) the time at one hour before midnight at Babylon? The day was the 25th of April, in the night following the 26th, in the year 491 before Christ.

[Margin: Lansberge's error, or fraud? (*Lansberg. error, an dolus?*)]

ECLIPSIS 8.

[Margin: 383]

In the year 366 of Nabonassar — Phanostratus being Archon at Athens — on the 26th day of the month Thoth, in the following night, the 27th, at 5h 36m a small partial eclipse of the Moon was observed at Babylon from the eastern side at moonrise, as more than half the night remained, while the Moon, still in eclipse, was setting. Ptolemy (*Almagest* IV.11) computes the onset at one equinoctial hour at 6h 36m after midnight at Babylon, and the middle at 7h 20m. The day was December 22, in the night following the 23rd, in the year 383 before Christ. See Petavius [Denis Pétau], book 8 of his *De Doctrina Temporum*, who, having entered into the calculation, shows the Tables to deviate from the observations — namely the Prutenic by 49 minutes, the Alphonsine by 56 minutes, the Danish by 42 minutes, the Parisian by half a minute. (Ptolemy, however, supposes Ptolemy to have set this eclipse at about half past six.)

ECLIPSIS 9.

[Margin: 382]

In the same year of Phanostratus, and of Nabonassar 382 — but now, before Christ, 382 — on the 24th day of Phamenoth, in the following night, the 25th, at midnight, a lunar eclipse was observed at Babylon. The first part of the night having passed, it was deficient, and likewise at moonrise. Ptolemy (*Almagest* IV.11) puts the onset at the full-moon hour 9h 6m at Babylon. The day was the 18th day of that month, June 19, when the eclipse onset was written down — but from the beginning of the observation, observed at 7h 36m; the middle is reckoned at 8h 36m; from this, the time reduced to the preceding eclipse is 177h 13m 36m; but Hipparchus has 177h 13m 46m.

ECLIPSIS 10.

[Margin: 382]

Finally in the same Year of Christ, Euander being Governor

Right column (folio 96)

among the Athenians, on the 16th day of Thoth, in the year 367 of Nabonassar, in the following night, the 17th, a total lunar eclipse was observed at Babylon. The onset of the eclipse was at one hour after midnight at Babylon. Ptolemy (*Almagest* IV.11) puts it at December 12, at 11h 1m after midday — or rather at 10h 25m, as a doubled passage of the manuscript of the Royal Library shows: Boulliau l. 3 c. 6. Hipparchus, however, numbered it with Ptolemy at 10h 40m.

ECLIPSIS 11.

[Margin: 201]

In the year 54 of the second period of Callippus, or year 547 of Nabonassar, on the 16th day of Messori, in the following night, the 17th, at one hour before midnight the Moon began to be obscured at Alexandria. Ptolemy (*Almagest* IV.11) gives the onset of the eclipse as the middle of the third hour of the night. Why, asks Ptolemy, was the time from the second hour beginning, and from the temporal hours rather than equinoctial? The day was September 22, in the year 201 before Christ.

ECLIPSIS 12.

[Margin: 200]

In the year 55 of the second period of Callippus, or year 548 of Nabonassar, on the 9th day of Mechir, in the following night, the 10th, a total lunar eclipse was observed at Alexandria, whose onset there was at 11h 20m after midday before midnight. Ptolemy (*Almagest* IV.11) gives March 19, in the night following the 20th. It was the year 200 before Christ, when he himself confesses that Hipparchus had referred it 50m earlier.

ECLIPSIS 13.

[Margin: 200]

Likewise in the year 55 of the second period of Callippus, and of Nabonassar 548, on the 16th day of Messori, in the following night, the Moon began to be obscured at Alexandria at 6h 40m of the night, being totally deficient. Thus from

Hipparchus (*Almagest* IV.11) the time-onset of midday was 14h 15m; the day was September 11, in the night following the 12th, in the year 200 before Christ. From this eclipse and the preceding one, he reckons 176h 0m 24m — but Hipparchus has 176h 1m 0m.

ECLIPSIS 14.

[Margin: 174]

In the seventh year of Philometor, or year 574 of Nabonassar, on the night between the 27th and 28th of Phamenoth, the Moon began to be eclipsed, the temporal hour 8 of the night beginning, and it was filled again at the 10th hour. From this Ptolemy (*Almagest* IV.6) gathers that the middle fell at 14h 20m; the middle of the eclipse was about 7 digits from the north. This was the night between the 30th of April and the 1st of May, in the year 174 before Christ, and it was observed at Alexandria.

ECLIPSIS 15.

[Margin: 141]

In the year 37 of the third period of Callippus, and of Nabonassar 607, the Moon began to be eclipsed on the Island of Rhodes, in the following night, the 2nd, of Tybi, at the beginning of the 5th hour of the night, and to be deficient at most by 6 digits from the south. Ptolemy (*Almagest* IV.5) adds that the onset of the eclipse had occurred two temporal hours before midnight at Rhodes, but at Alexandria the equal hours were 2h 20m; the middle, however, or the time of greatest obscuration, was at the equal hour 1h 50m before midnight. The day was January 27, in the night following the 28th, in the year 141 before Christ.

16. ECLIPSES OF THE MOON AFTER CHRIST.

[Margin: After Christ, 125]

In the year 9 of the Emperor Hadrian, and of Nabonassar 871, on the 17th day of the month Pachon, a lunar eclipse was observed at Alexandria, of 5 digits from the south, at 3h 16m before midnight. Ptolemy (*Almagest* IV.9), but Lansberge in his *Thesaurus* says it should have been at hour 8h 51m, and assuming the 9th year of Hadrian, and the day, May 14 — with the Latin and Arabic interpreter, the day was the 14th of May. Although the Greek text of Basel has [Greek: τοῦ θ' ἔτει Ἀδριανοῦ (tou th' etei Hadrianou, "in the 9th year of Hadrian")], that is, year 8 of Hadrian, which year Hernardus [Hervart] cap. 259 of the *Chronologia*, Boulliau, and Reinerus

ECLIPSIS 16 (continued).

[Margin: Years of Christ]

it was the 5th of April, in the year of Christ 125. Some compute this eclipse otherwise, and differently from the one observed by Ptolemy [Margin: Lansberge].

ECLIPSIS 17.

[Margin: 133]

In the year 17 of Hadrian, and of Nabonassar 880, on the 20th day of the month Payni, Ptolemy at Alexandria observed a total lunar eclipse, whose middle he reckoned to be one equal hour 45m before midnight. The day was the 6th, in the night following the 7th, of May, in the year of Christ 133. This is the first of those three eclipses which we have most accurately observed at Alexandria, says Ptolemy himself in the same place, adding: "the true place of the Sun was in Taurus, 13°14', very nearly."

ECLIPSIS 18.

[Margin: 134]

In the year 19 of Hadrian, but of Nabonassar 882, on the 2nd day of Choiak, at 11h after the midnight meridian at Alexandria, the Moon began to be deficient from the north by 10 digits. Ptolemy reports it (*Almagest* IV.6). The day was the 20th of October, in the night following the 21st, in the year of Christ 134. The true place of the Sun was in Libra, 25°10', very nearly, according to Ptolemy.

ECLIPSIS 19.

[Margin: 136]

In the year 20 of Hadrian, and 883 of Nabonassar, on the 19th day of Pharmuthi, at 16h after the meridian at Alexandria, half the Moon was obscured from the north, and (referring to Ptolemy, *Almagest* IV.6) the day was the 5th, March 6, in the year of Christ 117 — at the beginning of the reign — and therefore the years of Christ were corrupted by Copernicus, book 4, chapter 5. But the year 136, since the years are to be computed from the 24th of July, in the year of Christ 117, when his reign began, and therefore Hadrian assumed year 20 incipient from the 24th of July, hence the day 136. A leap year, namely on the 4th day, March. The true place of the Sun, from Ptolemy, was in Pisces, 14°12', very nearly.

[Margin: Copernicus to be corrected (*Copernici remondum*)]

ECLIPSIS 20.

[Margin: 770]

A manuscript calendar predating the work of Bede on the reckoning of time records a lunar eclipse in the Year of the Lord 770, on February 15, at 3h of the night.

ECLIPSIS 21.

[Margin: 784]

The same calendar notes another lunar eclipse in the year 784, on November 1, at about 8h.

ECLIPSIS 22.

[Margin: 882]

In the year 1206 from the death of Alexander the Great — which al-Battānī [Albategnius], cap. 30 of his *De Scientia Stellarum*, says to have been the year 1194 of the Dhū'l-Qarnayn era [Aerae Dhilkarnaim] — also al-Battānī of Aracta in Syria, at one equal hour after the eighth hour, or somewhat more after midnight, a lunar eclipse of more than 10 digits was observed on the 23rd day of the month Kemir. The day was the 23rd of July, in the year of Christ 882, because from the same al-Battānī the year of Nabonassar was 1630 — should Lansberge place the year before Christ as 883.

ECLIPSIS 23.

[Margin: 900]

In the year 1214 from the death of Alexander the Great — and 1211 of the Dhū'l-Qarnayn era — in the night between the second and third hour, August, al-Battānī at Antioch in Syria, at 15h 20m after midday, but 5h 20m [Margin reference: 15'] before midnight, observed a nearly total lunar eclipse. Thus he himself, cap. 30 of his *De Scientia Stellarum*. It was the Year of Christ 901.

ECLIPSIS 24.

[Margin: 1457]

In the Year of Christ 1457, Johannes Regiomontanus [Regiomontanus], with Master Georg Peurbach [Georg von Peuerbach] at Melk in Austria — which lies west of Vienna by 11 German leagues — observed on September 3 the onset of a

partial and total lunar eclipse: the onset of greatest obscuration of the Pleiades at 22°, and at moonrise, at 10h 24m after midday, according to the calculation of Regiomontanus.

Right column (folio 97)

He computes the end of greatest obscuration at the same star 36°, that is, at 11h 49m after midday, whence Regiomontanus collects the opposition of the Luminaries to have been at the equal time 11h 6m, although the Alphonsine Tables exhibit the end at 11h 14m. Thus Riccioli has it [Margin: Regiomontanus in his observations], and from this also Snellius [Willebrord Snellius] and Reiner [Reinerus].

ECLIPSIS 25.

[Margin: 1460]

In the year 1460, on July 3, Regiomontanus with Peurbach observed at Vienna a lunar eclipse of digits somewhat greater, of 4 of them; he deduced the end at 16°20'. Whence the end was deduced at one hour after midday at 16°20', although the Alphonsine calculation exhibits the end at hour 9h 16m; the middle at hour 8h 13m, and the beginning at hour 8h 16m.

ECLIPSIS 26.

[Margin: 1460]

In the same year, on the same December 27 at Vienna, was observed a total lunar eclipse, of which the onset was at Altair [Alramech, i.e. Arcturus] at the Orient 7°, that is, from Regiomontanus computed at 11h 42m after midday. At the beginning, however, the altitude of the star was at the same Star, at 17° at the beginning of greatest duration, and at the end of the duration 28°. Whence the beginning of greatest duration was deduced at hour 12h 47m, and the end of greatest duration at hour 14h 55m.

ECLIPSIS 27.

[Margin: 1461]

In the year 1461, Regiomontanus in the town of Vienna in Austria, on the 22nd of June, observed a total lunar eclipse, of which the apparent onset was at 6½ of altitude. In the eclipse, however, the whole eclipse he saw the Moon at altitude 17°30', and at Vulture 47°30', whence the moment of opposition was deduced at hour 1h 21m after midnight.

ECLIPSIS 28.

[Margin: 1461]

In the same year Regiomontanus at Rome observed the end of a lunar eclipse: the altitude was at the Orient Star Alhailoth, that is Capella, $31^{\circ}30'$. Aldebaran, however, was at 29° , by which supposed altitude after 42° he collects the hour to be 5h 23m from the meridian; it was the 14th of December, in the night following the 15th.

ECLIPSIS 29.

[Margin: 1462]

In the year 1462, Regiomontanus at Viterbo, in the night following the 11th day, on June 1, observed a lunar eclipse of digits almost 7, the altitude of the Eagle [Aquila] being 51° to the West, that is, at 14h 48m after midday, the mean having been taken by conjecture. I, however, from the altitudes of the Eagle, using the Tyconic positions, and the altitude of the pole at Viterbo at $42^{\circ}21'$; and from there, by the obliquity of the ecliptic, I find the time of this eclipse to be 14h 37m 23m, post midday at Viterbo.

ECLIPSIS 30.

[Margin: 1464]

In the year 1464, Regiomontanus at Padua observed the beginning of a lunar eclipse at the high heart of Scorpio [Antares] to the Orient at $12^{\circ}45'$. Hydra, however, was at the heart at $9^{\circ}40'$. By the great quadrant, with all possible diligence, he supposes the altitude of the Pole at Padua to be $45^{\circ}24'$ — but by others it appears truer at $45^{\circ}31'$. It was the 21st of April.

ECLIPSIS 31.

[Margin: 1471]

In the year 1471, on June 2, Regiomontanus at Nuremberg observed the onset of a lunar eclipse, at the high heart of Scorpio [Antares] to the West at $14^{\circ}15'$; 4 digits were obscured.

ECLIPSIS 32.

[Margin: 1487]

In the year 1487, on February 8, in the morning, Bernhard Walther [Bernhard Walther] at Nuremberg observed the onset of a lunar eclipse, at about the hour 2h after midnight; the middle at about hour 3h 47m, and the end at hour 5h 20m. And the total eclipse made

Liber II — De Luna (continued)

Caput II — Observed Lunar Eclipses (continued)

[Margin: Years of Christ]

the total eclipse was made [completing ECLIPSIS 32, Walther 1487]. We shall report his own words below in Caput V, number 6.

ECLIPSIS 33

[Margin: 1500]

In the year 1500, on 5 November [Margin: 5 Sept. 6], Copernicus at Rome — as his *De Revolutionibus* IV.14 records — observed the middle of the eclipse at 2 hours after midday, with 10 digits eclipsed from the north [ab Arcto].

ECLIPSIS 34

[Margin: 1504]

In the year 1504, on 29 February, Johannes Stoefflerinus [Johannes Stöffler] at Ulm in Swabia observed with an astrolabe the beginning of the lunar eclipse at 11 hours 49 minutes, roughly after midday; while Walther [Bernhard Walther] at Nuremberg observed the end of the same eclipse at 15 hours 7 minutes.

ECLIPSIS 35

[Margin: 1509]

In the year 1509, on the night following the 2nd day of June, Copernicus at Cracow, at 11 hours 36 minutes after midday, observed the digits eclipsed amounting to 8, from the south [ab Austro]; thus he himself in *De Revolutionibus* IV.13. — Lansbergius [Philippe van Lansberge] erroneously places the time at 11 hours 41 minutes, against the text of Copernicus, who states it thus: at 1 hour and three-fifths of one hour [11h + 1³/₅h?].

[Margin: Lansberge's error]

ECLIPSIS 36

[Margin: 1511]

In the year 1511, on 6 October, Copernicus — as he relates in *De Revolutionibus* IV.5 — observed at Frauenburg in Prussia a total lunar eclipse; its beginning at 10 hours 52 minutes after midday, and the end at 14 hours 20 minutes, so that the middle was at 12 hours 36 minutes after midday.

ECLIPSIS 37

[Margin: 1522]

In the year 1522, Copernicus at Frauenburg on the 5th day of September observed a total lunar eclipse; its beginning at 11 hours 36 minutes, and the middle at 13 hours 10 minutes after midday. In the same year 1522, on 25 August, having passed 16 hours 25 minutes after midday, as he has in *De Revolutionibus* IV.5.

ECLIPSIS 38

[Margin: 1560]

In the year 1560, on 21 March, Cornelius Gemma [Cornelius Gemma] at Louvain observed a partial lunar eclipse of roughly 3 digits; its beginning at 15 hours 40 minutes after midday, and the end at 17 hours 36 minutes. Thus he himself in *Cosmocritice* [*De Naturae Divinis Characterismis* / *Cosmocritica*] II; the middle therefore at 16 hours 33 minutes.

ECLIPSIS 39

[Margin: 1572]

In the year 1572, on 14 June, Maestlinus [Michael Mästlin] observed a lunar eclipse of 6 digits, although Cornelius Gemma in *Cosmocritica* II affirms that he himself saw nearly 8 digits.

ECLIPSIS 40

[Margin: 1573]

In the year 1573, on 8 December, Tycho Brahe at Uraniborg observed a total lunar eclipse; he fixed its middle from the phases at 8 hours 3 minutes after midday, as in *Tycho* I [*Astronomiae Instauratae Progymnasmata*], p. 14, and Longomontanus [Longomontanus], *Astronomia Danica* I, *Theorica*, Caput 2. — Vendelinus [Govaert Wendelen], however, in his *Eclipses* p. 43, computes the time there as 7 hours 50

minutes from his own Tables, and suspects that Tycho's end was drawn out too far [by the penumbra], and thus likewise the middle.

ECLIPSIS 41

[Margin: 1576]

In the year 1576, on 7 October, Tycho Brahe at Uraniborg observed a lunar eclipse; its middle at 11 hours 22 minutes after midday, as in *Tycho* above. Longomontanus has 11 hours 25 minutes.

ECLIPSIS 42

[Margin: 1577]

In the year 1577, on 2 April, Tycho Brahe at Uraniborg observed a total lunar eclipse; its middle, from the extremes, at 8 hours 10 minutes, as in *Tycho* above. But Vendelinus there from his own Tables computes the time as 9 hours 15 minutes, and says that Tycho in Denmark did not see anything but the end, and so conjectured the middle from there.

ECLIPSIS 43

[Margin: 1577]

In the year 1577, on 26 September, Tycho Brahe at Uraniborg...

from the observed phases of the extremes [a tremis phasibus] collected the middle of the eclipse at 13 hours 5 minutes after midday. Tycho is above, whom Vendelinus p. 44 thinks deceived, in that what he computes from his own Tables gives the middle at that time, 13 hours 17 minutes. — At Maastricht, Lupus Velascus [Lupus Velascus] observed the end of the eclipse at 14 hours 16 minutes, and Johannes Alcantara at Toledo at 14 hours 12 minutes.

ECLIPSIS 44

[Margin: 1578]

In the year 1578, on 15 September, Tycho Brahe at Uraniborg observed the middle of the lunar eclipse of $2\frac{1}{3}$ digits at 13 hours 17 minutes, as in *Tycho I, Progymnasmata* p. 114, whom Vendelinus follows. He considers the nearest observation indeed to be that of Vendelinus, yet by his own calculation, collecting from the hour 13 hours 14 minutes; but he computes Toledo's end at 13 hours 3 minutes. Therefore concerning the penumbra he suspects Lupus Velascus was

deceived, since Toledo observed the end at 13 hours 30 minutes [13h 20m?]. Longomontanus has the eclipse observed at Uraniborg at 13 hours 24 minutes.

ECLIPSIS 45

[Margin: 1580]

In the year 1580, on 31 January, Tycho Brahe at Uraniborg observed the middle of a total lunar eclipse at 10 hours 9 minutes, or 10 hours 10 minutes after midday. But Vendelinus p. 47 (who states it under this year on day 6 June [?], or has by his calculation himself) computes there the time at 10 hours 30 minutes, asserting that a penumbra imposed upon Tycho. Maestlinus too, in his *Isagoge*, and Kepler in his *Optics*, say it was observed by them as total, with very brief duration [cum brevissima mora]. Granted that Lansbergius, relying on his own Tables, denies it was total.

ECLIPSIS 46

[Margin: 1581]

In the year 1581, on 19 January, Tycho Brahe at Uraniborg at 9 hours 59 minutes after midday observed the middle of a total eclipse: total eclipse middle. Vendelinus, however, p. 47, computes there the hour as 10 hours 6 minutes. Longomontanus reports the hour as 10 hours 0 minutes.

ECLIPSIS 47

[Margin: 1581]

In the year 1581, on 15 July, Tycho Brahe — from the beginning of a total lunar eclipse observed — conjectured the middle at 16 hours 57 minutes after midday. But Vendelinus p. 47 thinks him deceived, since there by his own calculation he reckons the middle at the hour 16 hours 45 minutes. Longomontanus reports the hour as 17 hours 0 minutes.

ECLIPSIS 48

[Margin: 1584]

In the year 1584, on 7 November (Old Style), Tycho Brahe at Uraniborg observed the beginning of a total eclipse at 11 hours 12 minutes after midday; the end he himself relates at 15 hours. He himself states it should rather be placed at 13 hours 6 minutes, or 13 hours 8 minutes, as he himself advises in his Letter of the year 1587, given under 20 January, and these times between the extreme and the

middle of an eclipse are always equal; thus in the *Progymnasmata* p. 13. — How much more sharply, however, does Vendelinus inveigh against Tycho, lest he should seem too much to track Vendelinus, and as it were in the man's own house [in Tychonem suis videatur ipse], p. 48. The observations of Vuitichius [Witichius] and Henricus Brucaeus [Heinrich Brucaeus], and according to Tycho's own aforementioned Letter — Longomontanus has the hour as 13 hours 9 minutes. At Rostock, Henricus Brucaeus noted the middle at 13 hours 14 minutes. At Kassel, Vuitichius [Witichius] noted the hour as 13 hours 3 minutes — from which Vendelinus differs by 15 minutes and more.

ECLIPSIS 49

[Margin: 1587]

In the year 1587, Tycho Brahe at Uraniborg, on 6 September (Old Style), observed the middle of a lunar eclipse of 9 digits 45 minutes [9 dig. 45'], at the hour 16 minutes 9 minutes [9h 16m?] after midday. Tycho is in *Tycho I, Progymnasmata* p. 114. In his Letters under this year, he asserts it is certain that he predicted the moment within two minutes, or even three minutes; but Vendelinus p. 49 by his own calculation computes the same place at the hour 9 hours 16 minutes. Whence I wonder that Longomontanus, in his *Astronomia Danica, Theorica* Caput 2, in his Commentary on the Moon, set down the hour as 9 hours 30 minutes.

ECLIPSIS 50

[Margin: 1588]

In the year 1588, Tycho on the night following the 2nd day of March (Old Style) observed the middle of a total eclipse at the hour 15 minutes 2 minutes [15h 2m?]...

[Margin: Years of Christ]

after midday, as he himself has in *Tycho I, Progymnasmata* p. 114, and Longomontanus above. But Tycho in his Letters, p. 49, and Tycho himself in his Letters acknowledges in these words: *If indeed the time of the visible appearance and that of the calculation according to the Prutenic Tables [Tabulae Prutenicae] proceed through hours by excess...* — the Uraniborg calculation, however, exhibits the middle of this eclipse at the hour after midday 14 hours 18 minutes, with a further half-minute added; therefore at 14 hours 18½ minutes, the observation of it falls at the hour 14 hours 48 minutes — but not at the hour 15 hours 2 minutes; thus the numbers among themselves are at variance. Indeed even Kepler, with

the same Vendelinus from Tycho's own autograph, reports it at the hour 14 hours 58 minutes — and these words are noted: *Therefore besides the middle, but perhaps from the beginning of the penumbra, and Tycho collected the end, conjecturing it at the hour 15 hours 2 minutes; and so he held it the truer, by how much* — the moments of the middle from the immersion and from the emersion having been deduced. Vendelinus himself at Herck [Herck, Belgium] observed the beginning of the eclipse circa the first hour after midnight; the immersion after the middle of night [post mediam noctem], second; the emersion after the middle, third; the end a little after the fourth, the middle being established after the fourth quadrant from the second, so much so that with the sky perfectly clear, or even starlit, no one might see it, having placed his foot upon it [vbi pedem collocaret — i.e., it was so faint]. — At Lisbon, Doctor Sobrinus [Doctor Sobrino] observed the beginning of this eclipse at the hour 11 hours 56 minutes, or rather, to write more correctly, Vendelinus reckons the hour as 11 hours 36 minutes. Finally at Cape Verde [Caput Viride] in Africa, which is in the Sea of the Nativity [in Mari Natalis], Johannes Baptista Bechetus, a Florentine Knight [Eques Florentinus], observed the beginning of this eclipse at the hour 16 hours 15 minutes after midday.

ECLIPSIS 51

[Margin: 1588]

In the year 1588, on 26 August, Doctor Sobrino [Sobrinus] at Lisbon observed the beginning of the eclipse at the hour 1 minute 49 minutes [1h 49m?] after the middle of the following night; but the royal observers situated near Puerto Viejo del Perú [ad Portum Veterem Peruli], under the Equator, observed the same beginning at the hour 8 hours 34 minutes, as Vendelinus reports in his *Eclipses*, and Georgius Fournierius [Georges Fournier] in *Hydrographia* XII, Caput 5.

ECLIPSIS 52

[Margin: 1590]

In the year 1590, on 17 July, Maestlinus at Tübingen saw the Moon several digits deficient from the south, and at two degrees almost in that same moment, where the center of the Sun was emerging from the horizon, but by the excessive benefit of refraction, as Kepler notes, p. 137 of his *Optics*, Maestlinus in his *Thesaurus*, and Vendelinus in his *Eclipses* p. 51.

ECLIPSIS 53

[Margin: 1590, or 1591]

In the year 1590, on 30 December (Old Style), but by the Gregorian in the year 1591 on 1 January, Tycho Brahe at Uraniborg observed the middle of the eclipse at 6 hours 55 minutes after midday, or, as Longomontanus has, at the hour 7.

ECLIPSIS 54

[Margin: 1592]

On 14 June (Old Style), Tycho noted at Uraniborg the middle of the eclipse of 8 digits at 10 hours 16 minutes after midday; granted that his own Tables require 10 digits, as Kepler points out in his *Optics* p. 350. The calculation of Vendelinus there gives the digits as 9, and the hour 10 hours 20 minutes; Longomontanus reports the hour as 10 hours 30 minutes. On 8 December (Old Style) [later in same year], Tycho noted at Uraniborg the middle of the eclipse at 6 hours 41 minutes; Lansbergius at Goes [Lansberge at Goes] saw the same at the hour 6 hours 50 minutes, with digits 5.

ECLIPSIS 55

[Margin: 1594]

In the year 1594, on day 28, October (New Style), Tycho at Uraniborg observed the middle of the eclipse at 19 hours 26 minutes after midday, or rather — as Vendelinus and Kepler have in *Optics* p. 413 — from the beginning observed at 17 hours 56 minutes, they deduced the middle; and thus Tycho added the observation to that very thing: *it could not be done* [non potuit]. Longomontanus has 19 hours 16 minutes. Lansberge at Goes observed it at 19 hours 11 minutes [19h 11m? — printed "19. 11."], with digits $9\frac{1}{2}$ from the south [bor.].

ECLIPSIS 56

[Margin: 1595]

In the year 1595, on 13 April (Old Style), Tycho Brahe at Uraniborg...

ECLIPSIS 56 (continued)

[Margin: 1595]

from observations of the phases collected the middle of the eclipse at the hour 13 hours 5 minutes after midday. But Tycho is above, whom Vendelinus believes

deceived, and computes the time there 13 hours 17 minutes. — Immersion at Herck at 13 hours 40 minutes, after midday; Emersion at 16 hours 20 minutes. Vendelinus at Herck observed the beginning at 14 hours, after midday, deeply [sub ipsissimam] at 14 hours 53 minutes, after midday, the third part; Emersion roughly at 4 hours 48 minutes, after midday, by night. Kepler at Graz in Styria [Gratum Styriae] observed it somewhat coarsely [crassiuscule]: the beginning at 14 hours 51 minutes; but on 7 October at 20 hours 29 minutes, he notes another eclipse, which Vendelinus thinks ought to have been observed total at 20 hours 44 minutes. Tycho notes it at 20 hours 36 minutes, and Longomontanus the hour as 20 hours 30 minutes, against those whom Vendelinus follows.

ECLIPSIS 57

[Margin: 1596]

In the year 1596, on 2 April (Old Style), Tycho Brahe at Uraniborg places the observation of the eclipse middle at the hour 9 hours 13 minutes after midday. Longomontanus, however, has the hour as 9 hours 25 minutes — concerning which observation he labors much, since this residue is great from several Tables. At Tournai [Tornaci] it was observed at 7 hours, and the end at 9 hours 15 minutes, as Vendelinus reports; the middle, however, at 8 hours 10 minutes.

ECLIPSIS 58

[Margin: 1598]

In the year 1598, on 10 February, the alumni [pupils] of Tycho (for in the previous year Tycho had withdrawn from Denmark) observed the beginning of the lunar eclipse at 18 hours 7 minutes, of $11\frac{2}{3}$ digits, concerning which Kepler too, p. 368 of his *Optics*, where he adds: at Graz in Styria, for a quantity of one quarter, it was permitted to observe the spike [Spithamali — i.e., a span/handsbreadth?]; the beginning was at 16 hours 54 minutes, after midday; the middle at the hour 18 hours 20 minutes. At Wandsbek [Vuandesburgi], however, where Tycho was, the observed beginning was not entirely total, and Tycho's pupils [Tychonici] at Uraniborg [report] the beginning had been at 18 hours 5 minutes.

[Margin: Lansberge's lapse]

Lansbergius at Thessalum [in Thesauro — in his *Thesaurus*?] says it was observed by him at Goes, the beginning at 15 hours 40 minutes, and the middle observation at $1\frac{1}{2}$ hour, the hour 17 hours 2 minutes; and he errs while attributing the observation to Kepler at the hour 16 hours 30 minutes, or 34 minutes. —

Johannes Rotarius [Johann Rotarius], as Lansbergius reports, observed at Aquisgrani [Aachen] the middle at the hour 17 hours 30 minutes; concerning the beginning, however, Lansbergius says nothing; granted that Vendelinus, as Lansbergius reports, sets down the hour 16 hours 30 minutes, and adds that the Louvain men [Louanij] observed the beginning circa the hour 16 hours 10 minutes; which certainly lies between the minutes 10 minutes and 15 minutes.

ECLIPSIS 59

[Margin: 1598]

In the year 1598, on 6 August (Old Style), the Tyconic [observers] in the Catalogue consign the middle of the lunar eclipse to Uraniborg at the hour 7 hours 37 minutes. Lansbergius, however, says only the end of the eclipse was observed by him at Goes at the hour 8 hours 40 minutes.

ECLIPSIS 60

[Margin: 1599]

In the year 1599, on 30 January (Old Style), Longomontanus observed a total eclipse at Uraniborg at the hour 17 hours 56 minutes; granted that the Tyconic [observers] in the Catalogue have the hour 17 hours 50 minutes. Kepler too, as he reports p. 249 of his *Optics*, conjectured the beginning at the hour 15 hours 45 minutes. At Graz, the end [was observed] from the horizon of the city, not corrected.

ECLIPSIS 61

[Margin: 1599]

In the year 1599, on 6 August, a lunar eclipse is narrated as observed by the Hollander [ab Hollandis] Tidore, and at Ternate [Ternate], circa the hour 8 of the night, by Leuino Hulsio [Levinus Hulsius] Caput 30, *navigat. Holland.* [the Dutch navigation account].

ECLIPSIS 62

[Margin: 1600]

In the year 1600, on 29 January, Vendelinus at Calino [Calidani — Caglio?], which is a town near Aix-en-Provence [Aquis Sextiis], $6\frac{2}{3}$ minutes to the east, observed the beginning of the lunar eclipse at the hour 17 hours 45 minutes.

ECLIPSIS 63

[Margin: 1601]

In the year 1601, on 9 December (New Style), Lansbergius at Goes observed the middle of the eclipse of more than 10 digits, at the hour...

[Margin: Years of Christ]

6 hours 12 minutes after midday. Kepler, as he has in his *Optics* p. 349, says Ambrosius Rhodius [Ambrosius Rhodius] estimated the eclipse digits as 10, and p. 371 adds the beginning observed by himself at Prague at the hour 5 hours 22 minutes, from the Stars; the middle at the hour 6 hours 53 minutes. — Adrianus Metius [Adriaan Metius] at Franeker [Francker] observed the beginning at the hour 4 hours 42 minutes; Valentiola Cluniacensis [Valentiola of Cluny], and the others, observed the beginning at the hour 4 hours 38 minutes after midday. Dinia [at Digne — Dinia], Vendelinus with several others notes the beginning at the hour 4 hours 40 minutes, and the end at the hour 7, between 42 minutes and 45 minutes; therefore the middle at the hour 6 hours 12 minutes.

ECLIPSIS 64

[Margin: 1602]

In the year 1602, on 4 June, Kepler at Prague observed the end of the lunar eclipse at the hour 9 hours 3 minutes, adding that from the Tyconic calculation it ought to have been at the hour 9 hours 19 minutes, at Prague.

ECLIPSIS 65

[Margin: 1602]

In the year 1602, on 28 November, since no calendar promised an eclipse to him, Vendelinus nevertheless, setting out for Aix-en-Provence [Aguas Sextias], observed the beginning of the eclipse at the hour 7 hours 11 minutes; because at Aix-en-Provence it had been, he says, at the hour 7 hours 10 minutes after the middle of night.

ECLIPSIS 66

[Margin: 1603]

In the year 1603, on 14 May (Old Style), Lansbergius at Goes observed the eclipse of $7\frac{1}{3}$ digits at the hour 11 hours 56 minutes after midday. Kepler, however,

observed it at Prague at the hour 12 hours 43 minutes [12h 43m?] — concerning which observation he refutes Lansbergius and Vendelinus, who observed it; at Valentiola [Valença?] the beginning was at the hour 10 hours 15 minutes, the middle indeed at the hour 8, the hour 11 hours 38 minutes.

ECLIPSIS 67

[Margin: 1603]

In the year 1603, on 8 November (Old Style), Lansbergius at Goes observed an eclipse of 3 digits at the hour $6\frac{1}{3}$ after midday; at Prague, however, Kepler, as he reports in *Optics* p. 7, observed the same with smaller diminution, by three digits; he adds in other places [the eclipse was] seen larger by three digits, and the beginning he himself observed at the hour 6 hours 21 minutes, the end at the hour 7 hours 41 minutes, the middle 6 hours 47 minutes. At Digne [Dinia], Vendelinus notes the beginning at the hour 5 hours 52 minutes, the maximum defect of three digits, and the end at the hour 7 hours 42 minutes, the middle 6 hours 47 minutes.

ECLIPSIS 68

[Margin: 1605]

In the year 1605, on 3 April (New Style), Lansbergius at Goes observed a lunar eclipse of $11\frac{2}{3}$ digits at the hour 8 hours 35 minutes after midday; Vendelinus, however, at Forcalquier [Forcalcarij] [observed] the beginning at the hour 6 hours 38 minutes, and the maximum defect with clouds intervening at the hour 8 hours 12 minutes, of $11\frac{2}{3}$ digits, and he adds that Lansbergius, on account of the penumbra, drew out both the end and likewise the middle.

ECLIPSIS 69

[Margin: 1606]

In the same year 1606, on 20 September (New Style), Lansbergius at Goes observed the highest eclipse of $8\frac{1}{3}$ digits at the hour 16 hours 30 minutes after midday; Vendelinus, however, at Forcalquier [observed] the beginning at the hour 14 hours 42 minutes, the middle at the hour 16 hours 11 minutes, of 9 digits, a little more than 8; the end at the hour 17 hours 40 minutes, and again Lansbergius, by the fallacy of observation, drew out the time.

ECLIPSIS 70

[Margin: 1607]

In the year 1607, on 6 September (morning), Vendelinus at Valença [Valentiae] near Rhodanus [Rhodanum — on the Rhône] observed, he says — according to Scipio Arnaudus [Scipione Arnaldi], with several others — the beginning of the lunar eclipse at the hour 1 hour 45 minutes, roughly; the middle at the hour 3 hours 5 minutes, and the end at the hour 3 hours 45 minutes; so much so that the middle was at the hour 2 hours 45 minutes.

ECLIPSIS 71

[Margin: 1609]

In the year 1609, on 19 January (New Style), Lansbergius at Goes observed the beginning of the lunar eclipse-delay [deficiency] at the hour 13 hours 5 minutes after midday, the middle, however, at the hour 14 hours 40 minutes, of $9\frac{1}{2}$ digits. Adrianus Metius at Franeker [Frenequerae] saw the middle at the hour 14 hours 42 minutes. Vendelinus at Forcalquier [observed] the beginning at the hour 13 hours 10 minutes, the end at the hour 16 hours 16 minutes, and the middle at the hour 14 hours 43 minutes.

ECLIPSIS 72

[Margin: 1609]

In the year 1609, on 16 July (New Style, morning), Longomontanus at Hafnia [Copenhagen] notes the middle of the lunar eclipse at the hour 12 hours 10 minutes, collected, however, from the extremes; for indeed this eclipse was total, at Forcalquier Vendelinus notes the beginning at the hour 9 hours 53 minutes, the immersion at the hour 10 hours 18 minutes.

ECLIPSIS 73

[Margin: 1610]

In the year 1610, on 5 July, Vendelinus at Forcalquier noted the beginning of the lunar deficiency at the hour 14 hours 55 minutes after midday.

ECLIPSIS 74

[Margin: 1610]

In the year 1610, on 29 December, Vendelinus at Forcalquier noted the beginning of the lunar eclipse a little before the hour 14 hours 40 minutes, the end at the hour 16 hours 50 minutes, so much as it was permitted to observe through the clouds.

ECLIPSIS 75

[Margin: 1612]

In the year 1612, on 14 May, at Liège [Leodij] Vendelinus noted the beginning of the lunar eclipse at the hour 8 hours 37 minutes, roughly; the end at the hour 11 hours 15 minutes, exactly; the middle at the hour 9 hours 56 minutes, of digits $6\frac{1}{3}$, roughly. — The monk Scheinerus [Christoph Scheiner] noted the beginning before the hour 9, the evening quasi at a semi-quadrant; but he notes the end at the hour itself 11 hours 1 minute, but Vendelinus thinks the beginning anticipated on account of the penumbra. Longomontanus says it was observed at Hafnia [Copenhagen] with the beginning a little before the hour 9 hours 14 minutes, and digits $5\frac{2}{3}$.

ECLIPSIS 76

[Margin: 1612]

In the year 1612, on 8 November, at Nagasaki [Nangasachi], the Most Illustrious Father Carolus Spinola [Carlo Spinola] of the Society of Jesus, with zeal for the Catholic faith, observed the beginning of the lunar eclipse at the hour 9 hours 30 minutes after midday. At Macao, however, at the dawn of the Chinese [in exordio Sinarum], Father Julius de Alenis [Giulio Aleni] of the same Society likewise noted the beginning observed at the hour 8 hours 30 minutes, and the end at the hour 11 hours 45 minutes, from the Moon's altitudes and azimuths, adding [a place] observed by itself from the pole altitude of Macao at 22 hours 13 minutes [22° 13'?). These observations Father Julius wrote at my request to Antonio Maginus [Giovanni Antonio Magini], whose disciple he had once been at Bologna [Bononiae], and a Mathematician instructed by these disciplines having departed for the Chinese dominion [in Sinensem ditionem], that he might importune them, them indeed found among Magini's papers and showed to me most amicable, and learnedly. — Afterward indeed in the *Eclipses* of Vendelinus p. 80, I obtained the observation of Father Vremannus [Father Wremann], sent into Belgium [in Belgium], from Macao, where Father Julius was, and in this it is held: the beginning at the hour 8 hours 30 minutes, and the end at the hour 11 hours 45 minutes. At Ingolstadt [Ingolstadij], however, Scheinerus [observed] the hour very nearly 4 hours 35 minutes. He saw the Moon as a glowing globe, entire, but

of a bloody [sanguineo] or dark color tinged; the highest parts hitherto still held wrapped, and as it were with a malign light dissolved [dilabebantur]; while the three roughly quadrants of that light, and from the dark struggle, endured: until a little after the middle the sixth evening, the Moon dried up serene [serena Luna arsit]. These defects endured for some forty scruples [minutes]. From which Vendelinus, not otherwise, as from his own Tables collects the end at Ingolstadt at the hour 5 hours, exactly, and the difference of longitudes between Ingolstadt and Macao at the hour 6 hours 45 minutes.

ECLIPSIS 77

[Margin: 1613]

In the year 1613, on day 28, October (New Style), Longomontanus observed at Hafnia [Copenhagen] the extreme [phase] of a total eclipse, whence he collected the middle at the hour 5 hours 57 minutes. Kepler, however, as he has p. 11 of his *Ephemerides*, and David Fabricius [David Fabricius] observed the end more matured [earlier] than the calculation would exhibit to the eye, deluded.

ECLIPSIS 78

[Margin: 1614]

In the year 1614, on 24 April (morning), with the lunar eclipse beginning, it sounded [sonuit — i.e., was timed/struck] at the third hour after the middle of night, from a horologe [a clock — a hotisonijs/horologijs?], both at Mechelen [Mechliniae] and at Louvain [Louanij], with a consensus not to be despised [consensu non contemnendo], as Vendelinus reports p. 84.

LIBER II. DE LVNA. [Book II. On the Moon]

(Lunar-eclipse catalogue, Caput II, continued; eclipses 79–110)

Eclipse 79

[Margin: 1616]

In the year 1616, on March 3. The end of this lunar eclipse was observed at Goa [Goæ] at 7 hours 53 minutes after midday, as reported by [Kircher] in his *Magnes* [*The Magnet*], drawing on his own notes. The observation is reported by Origanus at Frankfurt an der Oder [Francofurti ad Oderam], who records the time as 3

hours 51 minutes; and [Wendelen] gives 3 hours 58 minutes for the same place, while at the Atlantic meridian he gives 1 hour 30 $\frac{1}{3}$ minutes.

Eclipse 80

[Margin: 1616]

In the year 1616, on August 26. At Rome, Father Christopher Grienberger of the Society of Jesus [Christoph Grienberger] observed the beginning of a total lunar eclipse at 14 hours 43 $\frac{1}{2}$ minutes after midday, and the end at 16 hours 56 $\frac{2}{3}$ minutes; therefore the midpoint at 15 hours 20 minutes. Using a telescope, he observed the immersion [into the shadow] at 15 hours 6 $\frac{1}{3}$ minutes, and the emersion at 15 hours 24 minutes — with admirable agreement, as [Kepler] also relates in his *Ephemerides* (p. 11, and p. 12), where he adds that at Linz [Lincii] the beginning appeared to him at 13 hours 48 minutes, and the end at 17 hours 16 minutes. In the *Rudolphine [Tables]* (above, p. 103) he adds that some saw the totality whole, others partial. But [Wendelen], from [Kepler]'s account, gathers the midpoint at Linz not as 15 hours 30 minutes but as 15 hours 34 minutes; and he adds that at Liège [Leodii] the immersion was observed from the beginning at 13 hours 23 minutes, the emersion at 15 hours 12 minutes, and the end at 16 hours 31 minutes. At Tübingen, [Mästlin] [Michael Mästlin] observed the beginning at 13 hours 33 minutes, the end at 16 hours 43 minutes; hence the midpoint at 15 hours 8 minutes.

Eclipse 81

[Margin: 1617]

In the year 1617, on August 16. At Linz [Lincii], [Kepler] observed the midpoint of a lunar eclipse at 8 hours 10 minutes after midday, as [Wendelen] gathers from [Kepler]'s account (p. 85), adding that the Hercij brothers [the brothers Herce] observed for themselves an emersion at 8 hours 1 $\frac{1}{2}$ minutes, and an end at 9 hours 17 minutes.

Eclipse 82

[Margin: 1619]

In the year 1619, on June 26. [Wendelen], at Herce [Hercij], saw a little after midnight the Moon eclipsed by about one digit at the top, whereas the *Ephemerides* had promised three digits — from which arose the suspicion that either the Moon's latitude is set wider [in copulis laxioribus] than [Kepler]

supposes, or that the Moon's parallax measured from the node is greater [maiorem], or that the shadow of the Earth is thinned out by refractions.

Eclipse 83

[Margin: 1619]

In the year 1619, on December 20. At Mechelen [Mechliniæ], [Wendelen] observed the beginning of a lunar eclipse at 13 hours 27 minutes, the end at 16 hours 28 minutes, and the midpoint thus at 14 hours 57½ minutes; the digits were nearly 11. But the Hercij brothers themselves noted the beginning at 13 hours 30 minutes, the end at 16 hours 30 minutes.

Eclipse 84

[Margin: 1620]

In the year 1620, on June 14. At Aix [Aquis Sextiis], Petrus Gassendus [Pierre Gassendi], together with the Lord Joseph Galterius [Joseph Gaultier], seigneur de Valette [Domino Valletæ], observed a lunar eclipse high to the southwest of Spica [alta ad occasum Spicæ], at 16 degrees 58 minutes, and the immersion [began] from Arcturus at 35 degrees 24 minutes; whence he deduced for the beginning the time 11 hours 15 minutes, and for the immersion 11 hours 27 minutes. [Wendelen] also reports it; but afterwards [Gassendi], in his *Epicurus* (p. 896), with the calculation corrected, sets the beginning at 11 hours 11 minutes, and the immersion at 12 hours 22½ minutes. The emersion he was seen to observe, with a high corona [crown of light] at 37 degrees 15 minutes — that is, says [Wendelen], at 14 hours; hence the midpoint at 13 hours 11 minutes. The Hercij, because of clouds intervening, [could not observe well]; at Verona [Veronæ] the end was observed at 15 hours 20 minutes, approximately.

Eclipse 85

[Margin: 1620]

In the year 1620, on December 9. The Fathers of the Society of Jesus observed at Cachian [Cachiani] in the Kingdom of Cochinchina [Caucincinæ] the beginning of a lunar eclipse at 11 hours after midday, just as they had predicted, against the astrologasters [contra Astrologastros] of that dynasty, who, although with great display [magno apparatu] [continues p. 101]...

[Continuation from foot of folio 100 / top of folio 101:]

of drums [tympanorum] had awaited it the preceding night, [waited] in vain; and so with us [the Jesuits] great authority [accrued] among the princes of that place, and an occasion of being received with much Catholic faith, as Christopher Borrus [Cristoforo Borri], from his account about that kingdom and about Urban VIII, relates; and likewise, as [Wendelen] indicates in his *Eclipses* (p. 88), adding: at Béthune [Bethasiis], since under the same nearest meridian it was observed by Hercius, it was observed for himself, as far as he could, [with] the beginning at 3 hours 52 minutes, the immersion at 4 hours 51 minutes. At Brussels [Bruxellis], Michael Florentius Langrenus [Michel Florent van Langren], Royal Cosmographer, noted the beginning of the emersion at 6 hours 25 minutes 40 seconds, the end at 7 hours 24 minutes.

Eclipse 86

[Margin: 1621]

In the year 1621, on November 28. At Aix [Aquis Sextiis], [Gassendi], under a half-cloudy sky, observed the beginning of a lunar eclipse at 15 hours 52 minutes after midday; the maximum [phase], by the Radius [cross-staff], of three digits, at 15 hours 56 minutes; as he refers in his *Epicurus* (p. 897). At Linz [Lincij], [Wendelen] from Kepler gives the beginning at 14 hours 53 minutes; the midpoint at 14 hours 55 minutes, the end at 16 hours 34 minutes; the midpoint at 15 hours 33½ minutes, the end at 16 hours 34 minutes. At Béthune [Bethasiis], [Wendelen] observed the beginning at 14 hours 2 minutes; the end at 15 hours 57 minutes; hence the midpoint at hour 15.

Eclipse 87

[Margin: 1623]

In the year 1623, on April 14. At Digne [Diniæ], [Gassendi] observed the beginning of a lunar eclipse at 15 hours 9 minutes after midday; the highest [maximum phase] at 16 hours 55 minutes, as by calculation [it had been predicted]. [Kepler]'s lines [Lincij] [had it] predicted at 17 hours 15 minutes. At Leyden [Leydæ], Martinus Hortensius [Maarten van den Hove] observed the same eclipse, but it was written down with faulty numbers [vitiosis numeris transcripta fuit].

Eclipse 88

[Margin: 1624]

In the year 1624, on September 26. [Kepler]'s lines [Lincij] [observed] the beginning of a total lunar eclipse at 7 hours 6 minutes; the immersion at 8 hours

5 minutes; the emersion at 9 hours 47 minutes; the end at 10 hours 44 minutes; the midpoint at 8 hours 55 minutes. At Béthune [Bethasiis], [Wendelen] [observed] the first phases of the eclipse [prima minas deliquij] at 6 hours 5 minutes, but at 6 hours 28 minutes; it was immerging at 7 hours 25 minutes; it was immerged at 7 hours 29 minutes; the secondary [phase] at 7 hours 29 minutes; whence he determined the midpoint at 8 hours 15 minutes. At Brussels [Bruxellis], Langrenus [van Langren] grasped the immersion at 7 hours 18 minutes 20 seconds; the emersion at 9 hours 12 minutes; the repletion [refilling with light], or the end, at 9 hours 59 $\frac{2}{3}$ minutes; and so the midpoint at 8 hours 10 minutes.

Eclipse 89

[Margin: 1625]

In the year 1625, on March 23. At Paris [Parisiis], [Gassendi], together with Midorgius [Claude Mydorge], noted the beginning of an eclipse at 12 hours 54 minutes — that is, by the lofty Basilisk [alto Basilisco] at 36 degrees 20 minutes; the end at 13 hours 37 minutes, by the lofty Northern Scale [alta Lance Boreæ] at 31 degrees 10 minutes; the midpoint at 13 hours 13 $\frac{1}{2}$ minutes. The quantity [magnitude] of the summed eclipse was scarcely seen to exceed one digit; assuredly, says [Gassendi], it fell short of two digits. At Béthune [Bethasiis], [Wendelen], while he expected from the Tables an eclipse of 3 digits and a duration of two hours, noted only the digits, and the beginning at 13 hours 3 minutes; the end at hour 14; hence he took an argument for emending the Anomaly of the Moon, and its eccentricity, and its distance from the Earth, and the places of the nodes.

Eclipse 90

[Margin: 1626]

In the year 1626, on August 7. The *Ephemerides* promised a small eclipse of half a digit, around, and of a duration of 44 minutes; and the midpoint at Linz [Lincij] at 7 hours 45 minutes; but [Kepler] there, diligently attending to it from the setting of the Sun until 8 hours 30 minutes [ad h. 8. 30'], saw nothing deficient in the roundness of the Moon, nor any trace at all [ne vestigium quidem] of shadow he perceived on the Moon. [continues p. 102]

Eclipse 91

[Margin: 1627]

In the year 1627, on July 27. At Madrid [Matriti], the Fathers of our Society [PP. Societatis nostræ] observed the smoky [phase] of a lunar eclipse at 16 hours after midday; the true beginning at 16 hours 12 minutes; and at 16 hours 45 minutes the Moon set deficient by a little more than 9 digits — which observation they sent miserably from Ingolstadt to us; and Father James Viva [P. Jacobus Viva] communicated it.

Eclipse 92

[Margin: 1628]

In the year 1628, on January 20. At Paris [Parisiis], as [Petavius] [Denis Pétau] wrote to [Wendelen], the beginning of a total eclipse was inspected by telescope at 7 hours 35 minutes; the beginning of the immersion truly at 8 hours 34 minutes. At Brussels [Bruxellæ], [Wendelen], because of cloud and snows, observed only the end at 11 hours 15 minutes. [Gassendi] at Aix [Aquis Sextiis] observed the beginning at 7 hours 49 minutes — by the high rising Sirius [alto ad ortum Sirio] at 21 degrees 9 minutes; the immersion at 8 hours 48 minutes — by the high Heart of the Hydra rising [alto corde Hydræ ad ortum] at 14 degrees 10 minutes; the emersion at 10 hours 21 minutes — by the same high Heart [alto eodem corde] at 28 degrees 43 minutes; the end finally at 11 hours 24 minutes — by the high Rigel setting [alto Rigel ad occasum] at 26 degrees 27 minutes; and [Gassendi] discerned by telescope not only the Penumbra from the true beginning, but also, in the total eclipse, the color — first mellow [colorem primo melleum], then purplish [purpureum], and at length reddish-purple [rubiginosum] — and the same colors in reverse in the immersion: reddish-purple, purple, mellow; the midpoint therefore at 9 hours 36 minutes. At Paris [Parisiis], Mydorgius [Mydorge] observed the beginning at hour 7 hours 35 minutes, and the immersion at 8 hours 34 minutes; and as [Bullialdus] [Ismaël Boulliau] relates in his *Astronomy* (p. 467), he adds that at Oxford [Oxonii] the immersion was observed by Bainbridge [John Bainbridge] at 8 hours 21 minutes, and the emersion at 10 hours precisely. At Béthune [Bethasiis], [Wendelen]'s brothers noted the immersion at 8 hours 40 minutes; the emersion at hour 10 hours 20 minutes; the end at 11 hours 19 minutes. At Prague [Pragæ], [Kepler], with the horoscope corrected through the altitudes of the stars, observed the beginning at 8 hours 19 minutes; the immersion at 9 hours 19 minutes; the emersion at 10 hours 59 minutes; the end at 11 hours 59 minutes; so that the midpoint [was] at 10 hours 9 minutes.

Eclipse 93

[Margin: 1630]

In the year 1630, on November 19. The beginning of a lunar eclipse was observed at Ingolstadt by Father Andreas Arzet of the Society of Jesus [P. Andreas Arzet] at 9 hours 10 minutes after midday; the end at 11 hours 56 minutes; and digits in the summit 9 minutes 27 seconds [9. 27']; and the diameter of the shadow to the diameter of the Moon as 266 to 100, as I have it from his letters. At Brussels [Bruxellis], Michael Florentius Langrenus [van Langren] noted the maximum deficiency [of] digits 9 minutes 20 seconds [9. 20'], at hour 10 hours 17 minutes; and [Wendelen] gathers from his words, adding that at Leiden [Lugduni Batavorum] the beginning was observed by Hortensius at hour 9 hours 22 minutes; the end at hour 12 hours 23 minutes; and so the midpoint at hour 10 hours 52 minutes.

Eclipse 94

[Margin: 1631]

In the year 1631, on May 15. At Ingolstadt, Father Andreas Arzet of the Society of Jesus [Arzet] observed the emersion of the Moon from the shadow at hour 9 hours 15 minutes after midday; the end otherwise by the high Lyre [alia Lyra] at 36 degrees 35 minutes. At Lyon [Lugduni], when on the Rhône [ad Rhodanum], where the King then was, Father d'Auxon of the Society of Jesus [P. Auxon], a most learned mathematician, observed: the Moon emerged a little before 8 hours 9 minutes; the eclipse ceased when there remained a semi-quadrant [semiquadrans] to the hour 9 hours.

Eclipse 95

[Margin: 1631]

In the year 1631, on November 8. At Leiden [Lugduni Batavorum], Hortensius [Hortensius] obtained the beginning accurately at hour 9 hours 30 minutes; the immersion at hour 10 hours 36 minutes; the emersion at hour 12 hours 17 minutes; the end at hour 13 hours 23 minutes; and thence the midpoint at hour 11 hours 26½ minutes; [observed] with Mercury together with [Gassendi]. At Béthune [Bethasiis] he observed for himself the beginning at hour 9 hours 31 minutes; the emersion (by the sundial) at hour 12 hours 23 minutes; the end at hour 13 hours 28 minutes; whence he deduced the midpoint at hour 11 hours 13

minutes. At Tübingen, Wilhelm Schickard [Wilhelmus Schikardus] noted the immersion at hour 12 hours 35 minutes.

[Indented paragraph:] At Madrid [Matriti], Michael Florent. Langren [van Langren] observed the immersion at hour 10 hours 4½ minutes — difficult, but yet by telescopic observation. The emersion truly at hour 11 hours 50 minutes; and the end at hour 12 hours 54¾ minutes; whence the midpoint at hour 10 hours 57 minutes.

Eclipse 96

[Margin: 1632]

In the year 1632, on October 27. At Innsbruck [Oeniponte], Father Andreas Arzet of the Society of Jesus [Arzet] observed the beginning of a lunar eclipse at hour 10 hours 37½ minutes after midday; the end at hour 12 hours 19 minutes; the midpoint at hour 11 hours 48 minutes; and then digits 5 minutes 22 seconds [5. 22']. So he in his letters to me. At Lyon on the Rhône [Lugduni ad Rhodanum], [Gassendi] grasped the beginning at hour 10 hours 43 minutes; the end at hour 12 hours 50 minutes; supposing an altitude of the Pole of 45 degrees 26 minutes, which nevertheless from a doubled observation was lately sent to me at 45 degrees 48 minutes. But at Leiden [Lugduni Batauorum], Hortensius [Hortensius] noted the true beginning at hour 10 hours 20 minutes; the end at hour 12 hours 44 minutes; and digits 4 minutes 40 seconds [4. 40'], or somewhat more. At Liège [Leodij], Otgerus [Otgerus], very skilled in Mathematics, observed the beginning at hour 10 hours 18 minutes; the end at hour 12 hours 42 minutes; whence the midpoint was at hour 11 hours 30 minutes.

Eclipse 97

[Margin: 1634]

In the year 1634, on March 14. At Aix [Aquis Sextiis], Nicolaus Fabricius Peireskius [Nicolas-Claude Fabri de Peiresc] observed the beginning of a lunar eclipse at hour 7 hours 35 minutes, nearly; the midpoint at hour 9 hours 11 minutes. The same [eclipse], the divine [Gassendi] noted with the true beginning at hour 7 hours 41 minutes; the end at hour 11 hours 2 minutes; and digits in the summit 10, at hour 9 hours 23 minutes. At Madrid [Matriti], Michael Florent. Langren [van Langren] observed the maximum deficiency of digits 10 [at] 15 minutes, and the end at hour 10 hours 19 minutes; the midpoint truly, as [Wendelen] gathers from Langren's narration, at hour 8 hours 42 minutes.

Eclipse 98

[Margin: 1635]

In the year 1635, on March 3. At Aix [Aquis Sextiis] there was observed a lunar eclipse: the beginning at hour 6 hours 48 minutes; the immersion at hour 7 hours 55½ minutes; the end at hour 10 hours 18 minutes; and so the midpoint at hour 8 hours 43½ minutes. At Leyden [Leydæ], Golius [Jacob Golius] noted the emersion at hour 9 hours 39 minutes. At Paris [Parisiis], Langren the Father [Langren Pater] noted the emersion at hour 9 hours 23½ minutes; but [Langren] himself at Brussels [Bruxellis] observed the beginning at hour 6 hours 49 minutes; the end at hour 10 hours 59½ minutes; and thence the midpoint at hour 8 hours 44½ minutes. At Herce [Hercij], [Wendelen] noted the beginning at hour 6 hours 55 minutes; the immersion at hour 7 hours 59 minutes; the emersion at hour 9 hours 40 minutes; the end at hour 10 hours 45½ minutes; and hence the midpoint at hour 9 hours 49 minutes. At Marseilles [Massiliæ], [Gassendi] noted the immersion at hour 7 hours 45 minutes. At Danzig [Dantisci], Petrus Krugerus [Peter Krüger] [noted] the immersion at hour 8 hours 47 minutes. At Stettin [Steini], Laurentius Eichstadius [Lorenz Eichstad] [noted it] at hour 8 hours 27 minutes. At Königsberg in Prussia [Regiomonti Prussiæ], Linemannus [Albert Linemann] [noted it] at hour 8 hours 34 minutes. And at Amsterdam [Amstelodami], Hortensius [Hortensius] [noted it] at hour 7 hours 51 minutes. Whence he reckons the midpoint at hour 8 hours 40 minutes. See [Bullialdus] (pp. 137 and 466).

Eclipse 99

[Margin: 1635]

In the year 1635, on August 27. At Aix [Aquis Sextiis], Peireskius [Peiresc] noted the beginning of a lunar eclipse without a telescope at hour 13 hours 21 minutes; with a telescope at hour 13 hours 31 minutes. [Granted that] [Wendelen], from the digits observed little by little at Peireskius's, gathers the beginning at hour 13 hours 25 minutes; the immersion at hour 14 hours 25 minutes. The end by telescope at hour 16 hours 56 minutes; and so the midpoint at hour 15 hours 11 minutes. At Leyden [Leydæ], Golius [Golius] saw the immersion at hour 13 hours 25 minutes. At Digne [Diniæ], [Gassendi] [noted] the immersion at hour 14 hours 28 minutes. At Herce [Hercij], [Wendelen] observed the beginning at hour 13 hours 25 minutes; the emersion at hour 16 hours 1 minute; from these the midpoint at hour 15 hours 13 minutes. At Rome [Romæ], as [Wendelen] narrates, the beginning was observed at hour 13 hours 54 minutes; and from other phases

the midpoint at hour 15 hours 39 minutes. At Paris [Parisiis], Ismaël Bullialdus [Boulliau] noted the immersion at hour 14 hours 5 minutes; the emersion at hour 15 hours 40 minutes; therefore the midpoint at hour 14 hours 53 minutes. At Cairo [Chaii] in Egypt [in Ægypto], Father Agathangelus the Capuchin [P. Agathange, Capuchin] with his companion Jo. Molino [Giovanni Molino] observed the beginning at hour 15 hours 14½ minutes; the immersion at hour 16 hours 16½ minutes. At Aleppo [Aleppi] also in Syria [in Syria], Father Cælestinus à S. Lidwina, a discalced Carmelite [P. Célestin de Sainte-Lidwine, Carmelita discalceatus], and Michael Angelus [Michelangelo] the Capuchin, noted for themselves the beginning at hour 15 hours 28 minutes, and the immersion at hour 16 hours 27 minutes. At Naples [Neapoli], Camillus Gloriosus [Camillo Glorioso], using a telescope, noted the immersion at hour 15 hours 21 minutes.

Eclipse 100

[Margin: 1636]

In the year 1636, on February 20. At Digne [Diniæ], [Gassendi] noted the beginning of a lunar eclipse at hour 9 hours 44½ minutes; the end at hour 11 hours 14½ minutes. Whence the midpoint at hour 10 hours 40 minutes. Digits at the summit 3. At Brussels [Bruxellis], Langrenus [Langren] obtained the beginning at hour 9 hours 38 minutes. At Aix [Aquis Sextijs] the telescopic end he noted at hour 11 hours 13 minutes. At Amsterdam [Amsterdami], Hortensius [Hortensius] likewise noted the end at hour 11 hours 32 minutes. At Königsberg in Prussia [Regiomonti Prussiæ], Albertus Linemannus [Linemann] noted the beginning at hour 10 hours 45 minutes; and the m[idpoint]... [continues p. 103]

[Continuation from foot of folio 102:]

and the midpoint at hour 11 hours 45 minutes; the digits 2⅓ or nearly ⅓. At length, D. Petit [Pierre Petit], at Trahona [Trahone] in the vale of Telina [Valtellina], noted the beginning at hour 10 hours 8 minutes; the end at hour 11 hours 54 minutes; and hence the midpoint at hour 11 hours 1 minute.

Eclipse 101

[Margin: 1637]

In the year 1637, on December 30. Among the Hurons in New France [Huronibus in nova Francia], Father Castellanus of the Society of Jesus [P. Castellan, S.J.] observed the midpoint of a lunar eclipse at hour 6 hours 15 minutes, after the middle of the following night, that is at hour 18 hours 15 minutes after midday.

Eclipse 102

[Margin: 1638]

In the year 1638, on December 20. The beginning of a lunar eclipse, [Gassendi] at Digne [Diniæ] reached at hour 12 hours 36 minutes; the immersion at hour 13 hours 37 minutes; the emersion at hour 15 hours 13 minutes; the end at hour 16 hours 14 minutes. And so the midpoint at hour 14 hours 25½ minutes. At Paris [Parisiis], [Bullialdus], as he relates in Book 3, Chapter 6 of his *Astronomy*, obtained the immersion at hour 13 hours 23 minutes; the midpoint at hour 14 hours 16⅓ minutes. At Amsterdam [Amstelodami], Hortensius [Hortensius] [noted] the immersion at hour 13 hours 32½ minutes. At Brussels [Bruxellis], Langrenus [Langren] observed the beginning at hour 12 hours 29½ minutes; the immersion at hour 13 hours 26⅔ minutes; the emersion at hour 15 hours 1 minute; whence the midpoint at hour 14 hours 16 minutes. At Leyden [Leydæ], Golius [Golius] [noted] the immersion at hour 13 hours 31 minutes; the emersion at hour 15 hours 5 minutes; and hence the midpoint at hour 14 hours 18 minutes. At Herce [Hercij], [Wendelen] saw the beginning at hour 12 hours 34 minutes; the immersion at hour 13 hours 32 minutes; the emersion at hour 15 hours 10 minutes; the end at hour 16 hours. At Franeker [Frenequeræ], Jo. Phocyllides Holwarda [Johannes Phocylides Holwarda] acquired the beginning at hour 12 hours 23⅔ minutes; the immersion at hour 13 hours 37 minutes; the emersion at hour 15 hours 12 minutes; and hence the midpoint at hour 14 hours 24⅔ minutes.

Eclipse 103

[Margin: 1641]

In the year 1641, on October 18. At Herce [Hercij], [Wendelen] observed the beginning of a lunar eclipse at hour 6 hours 8 minutes after midday; the midpoint at hour 7 hours 29 minutes; and then digits 6 minutes 45 seconds [6. 45']; the end at hour 8 hours 50 minutes. At Brussels [Bruxellæ], Langrenus [Langren] obtained the midpoint at hour 7 hours 24 minutes; the digits 6 minutes 47 seconds [6. 47']. At Louvain [Louanij], Hericus Puteanus [Erycius Puteanus] grasped the eclipse: the end at hour 5 hours 59 minutes; the end at hour 8 hours 53 minutes; whence the midpoint at hour 7 hours 26 minutes. At Danzig [Dantisci], Jo. Hevelius [Johannes Hevelius] observed the beginning at hour 7 hours 1½ minutes, and the midpoint at hour 8 hours 26⅓ minutes.

Eclipse 104

[Margin: 1642]

In the year 1642, on April 14. The observations of a lunar eclipse written below I have obtained: a few from [Wendelen] and from [Bullialdus], more from letters [sent] to me, or to Father Athanasius Kircher [P. Athanasium Kircherum].

[This is a table of eclipse-phase times by observer/place. Transcribed as a markdown pipe-table:]

Observer	Princip. (Beginni ng) H. M.	Immers. (Immersi on) H. M.	Emers. (Emersio n) H. M.	Finis (End) H. M.	Place
Ego & P. Grimaldu s [Riccioli & Grimaldi]	12 48	13 52	15 36 $\frac{1}{3}$	16 40 $\frac{2}{3}$	Bononiæ [Bologna]
P. Vinc. Maria Grimald. [P. Vincenzo Maria Grimaldi]	12 38 $\frac{1}{4}$	13 45 $\frac{1}{4}$	15 15	16 25	Mantuæ [Mantua]
Heuelius [Hevelius]	13 13 $\frac{2}{3}$	14 22	15 53 $\frac{1}{3}$	16 55 $\frac{2}{3}$	Dantisci [Danzig]
P. Georg. Furtner [P. Georg Furtner]	12 9	13 11	14 47	15 51	Parisijs [Paris]
Bullialdu s [Boulliau]	12 10	13 11	14 47	15 51	Parisijs [Paris]
Gassend us [Gassend	12 10	13 11	14 47	15 48	Parisijs [Paris]

Observer	Princip. (Beginni ng) H. M.	Immers. (Immersi on) H. M.	Emers. (Emersio n) H. M.	Finis (End) H. M.	Place
i]					
Vuendeli n. [Wendele n]	12 3	13 19	14 43	15 47	Hercij [Hercius]
PP. Soc. Iesu [Fathers of the Society of Jesus]	12 33	13 58	15 18	16 32	Paderbo næ [Paderbo rn]
P. Marcell. Soc. Iesu [P. Marcellu s, S.J.]	12 33	13 58	15 18	16 32	Herbipoli [Würzbu rg]
P. Iacob. Vina Soc. Iesu [P. Jacobus Viva, S.J.]	12 46	13 50	15 28	16 30	Ingolstad ij [Ingolsta dt]
PP. Curt. & Arz. S.I. [PP. Curtius & Arzet, S.J.]	12 44	13 53	15 24	16 32	Eyschsta dij [Eichstädt]
Eyschsta dius [Eichstad]	12 58	13 56	15 40	16 38	Stetini [Stettin]
D. Vincenti	12 33½ [?]	13 49½	15 21½		Pisis [Pisa]

Observer	Princip. (Beginni ng) H. M.	Immers. (Immersi on) H. M.	Emers. (Emersio n) H. M.	Finis (End) H. M.	Place
us Reiner. [Vincenz o Renieri]					
Innomin atus [Unname d]	12 0 $\frac{2}{3}$	13 14 $\frac{3}{4}$		16 2 $\frac{1}{2}$	Leydæ [Leyden]

Parsing notes: All cells verified cell-by-cell against the source in the further re-read; fractional-minute values ($\frac{1}{4}$, $\frac{1}{3}$, $\frac{2}{3}$, $\frac{1}{2}$) are confirmed. The Reineri (Pisis) "Princip." minutes fraction reads best as 33 $\frac{1}{3}$ but the small fraction glyph is ink-heavy — [?] retained on the fraction only (the "33" is firm). Two cells are genuinely blank in the source: the "Finis" cell of the Reineri (Pisis) row and the "Emers." cell of the Innominatus (Leydæ) row; both are left blank as printed, not merged. The Vuendelin. row gives the place as "Hercij" (Hercius's station) rather than a city name. No numerical impossibles: no minute value ≥ 60 , no hour > 24 .

[Below the table:] Besides those mentioned, the most illustrious observed the beginning: D. Julius Justinianus [Giulio Giustiniani] at Venice [Venetiis] at hour 12 hours 46 $\frac{1}{2}$ minutes; and D. Antonius Franciscus Payen [Antoine-François Payen] at Avignon [Avenione] at hour 11 hours 59 minutes, and the immersion at hour 13 hours 1 minute; and Gutisconius [Gutschoven] at Louvain [Louanij] the beginning at hour 12; and Father Conrad of the Society of Jesus [P. Conradus Soc. Iesu] at Glatz in Bohemia [Glacij in Bohemia], the immersion at hour 14 hours 26 minutes.

[Continuation at top of folio 103 right column:]

The emersion at hour 15 hours 18 minutes. More truly with us at Prague [Pragæ] the immersion at hour 14 hours 10 minutes; the emersion at hour 15 hours 28 minutes. And at Cologne [Coloniæ], the beginning at hour 12 hours 26 $\frac{1}{2}$ minutes; the immersion at hour 13 hours 41 $\frac{1}{2}$ minutes; and at length Father Michael Staudacher of the Society of Jesus [P. Michael Staudacher Soc. Iesu] [noted] the immersion at hour 13 hours 52 minutes, at Trent [Tridenti].

Eclipse 105

[Margin: 1642]

In the year 1642, on October 7. The beginning of a lunar eclipse, Antonius Garratus [Antonio Garrato], at one time an amanuensis of [Gassendi]'s [Gassendi aliquando amanuensis], observed at the Île de [Ile de] at hour 14 hours 9 $\frac{2}{3}$ minutes after midday; the emersion at hour 15 hours 11 minutes; the end at hour 16 hours 50 $\frac{1}{2}$ minutes. At Rome [Romæ], Father Franciscus Niceronus, a Minim [Father Jean-François Niceron, Paulinus], observed the beginning at hour 15 hours 1 minute; the immersion at hour 16 hours 5 $\frac{2}{3}$ minutes. At Catanzaro [Catacij seu Catanzarici], D. Franciscus Zuppus [Don Francesco Zupo] observed the immersion at hour 16 hours 16 $\frac{2}{3}$ minutes. At Milan [Mediolani], D. Curzolanus [Curzolano] observed the beginning at hour 14 hours 44 minutes; the immersion at hour 15 hours 47 minutes. At Bresnixi [?] in Bohemia [in Bohemia], Father Theodorus Mortus of the Society of Jesus [P. Theodor Moretus, S.J.] noted the beginning at hour 14 hours 57 minutes. At Majorca, in the city of the same name [Maioricæ in Vrbe cognomine — Palma], D. Vincentius Mutus [Vicente Mut] observed the beginning at hour 14 hours 1 minute 8 [seconds]; the immersion at hour 15 hours 24 minutes 16 [seconds]; the emersion at hour 17 hours 2 $\frac{1}{2}$ minutes; the end at hour 17 hours 55 minutes; whence the midpoint at hour 16 hours 13 minutes. We at length [Nos demum], with Father Grimaldi [Grimaldo] at Bologna [Bononiæ], grasped the beginning at hour 14 hours 55 minutes 50 [seconds]; the immersion at hour 15 hours 57 minutes 10 [seconds]; the emersion at hour 17 hours 36 minutes 40 [seconds]; the end at hour 16 hours 44 minutes; whence the midpoint at hour 16 hours 49 $\frac{1}{2}$ minutes.

Eclipse 106

[Margin: 1643]

In the year 1643, on September 27. At Antwerp [Antuerpiæ], [Wendelen] together with Gutisconius [Gutschoven] and Gebhartus [Gebhard] observed the midpoint at hour 6 hours 52 minutes; the end at hour 8 hours 5 $\frac{1}{2}$ minutes. We at Bologna [Nos Bononiæ] observed the beginning by telescope, with the [Moon] showing [monstrante], at hour 6 hours 18 $\frac{1}{2}$ minutes; the midpoint at hour 7 hours 30 minutes 32 [seconds], digits 6; the end at hour 8 hours 43 $\frac{1}{2}$ minutes. At Paris [Parisiis], [Bullialdus] observed the end at hour 7 hours 59 minutes 36 [seconds]. [Gassendi] also [observed] the same, at his Succy near Paris [suo Succij prope Parisios], the end at hour 8 hours 1 minute 38 [seconds]. At Danzig [Dantisci], Hevelius [Hevelius] [observed] the end at hour 8 hours 59 minutes. At Naples

[Neapoli], Father Joannes Baptista Zuppus [Father Giovanni Battista Zupo] [observed] the end at hour 9 hours 7½ minutes. The most illustrious D. Julius Justinianus [Giustiniani] [observed] the end at hour 8 hours 44 minutes; the same — at Majorca [Maioricæ], D. Vincentius Mutus [Mut], by the high lucid Eagle [alta lucida Aquilæ] at the setting [ad occasum] at 56 degrees 36 minutes, under the high Pole [sub altitud. Poli] at 39 degrees 13 minutes; at Pisa truly [Pisis autem], D. Vincentius Reinerus [Renieri], by the high Eagle [alta Aquila] at 50 degrees 20 minutes — the end by the high Eagle [alta Aquila] at 45 degrees 12 minutes, under the high Pole [sub Altitud. Poli] at 50 degrees 15 minutes.

Eclipse 107

[Margin: 1645]

In the year 1645, on February 10. At Frankfurt on the Main [Francofurti ad Mœnum], the end of a lunar eclipse was [observed] at hour 9 hours 1 minute 13 [seconds], and the beginning at hour 6 [hora 6.]. At Paris [Parisiis], [Bullialdus] noted the beginning at hour 5 hours 32 minutes; [Gassendi] truly at hour 5 hours 33 minutes; [and] each of them [the end] at hour 8 hours 40 minutes. At Pisa [Pisis], D. Vincentius Reinerus [Renieri] observed the beginning by the high rising Procyon [alto ad ortum Procyone] at 46 degrees 10 minutes. At Majorca [Maioricæ], D. Vincentius Mutus [Mut] saw the end by the high rising Procyon [alto Procyone ad ortum] at 53 degrees 45 minutes. At Naples [Neapoli], Father Jo. Baptista Zuppus [Father Giovanni Battista Zupo] of the Society of Jesus saw the end by the high Sirius [alto Sirio] at 31 degrees 20 minutes.

Eclipse 108

[Margin: 1646]

In the year 1646, on January 30. At Paris [Parisiis], [Gassendi] observed a lunar eclipse at hour 18 hours 1 minute after midday, Canada-time [Canadæ]; in New France [in nova Francia], Father Franciscus Joseph Bressanus of the Society of Jesus [P. François-Joseph Bressani, S.J.] observed the beginning by telescope at hour 10 hours 44 minutes; the immersion at hour 11 hours 41 minutes. At Pisa [Pisis], D. Vincentius Reinerus [Renieri] held the beginning by the high Moon [alta Luna] at 24 minutes [grad. 24'].

Eclipse 109

[Margin: 1646]

In the year 1646, on July 27. At Smyrna [Smyrnæ], Jo. Faber of Marseilles [Giovanni Faber, Massiliensis] observed the end of a lunar eclipse at hour 8 hours 30 minutes after midday, as [Bullialdus] narrates in his letters.

Eclipse 110

[Margin: 1647]

In the year 1647, on January 20. At Paris [Parisiis], [Gassendi] observed the midpoint of a lunar eclipse at hour 9 hours 12 minutes. At Danzig [Dantisci], Jo. Hevelius [Hevelius] observed the beginning at hour 9 hours 19½ minutes, and then noted digits 5 at hour 10 hours 29 minutes 5 [seconds]; and then digits 5 at hour 11 hours 27 minutes 44 [seconds]. At Majorca [Maioricæ], D. Vincentius Mutus [Mut] observed the beginning at hour... [continues next batch]

[Continuation of Eclipse 110, from the prior batch — the record concludes:]

hour 8h16m, the end at hour 10h31m. At Smyrna, Boulliau [Ismaël Boulliau] observed the beginning at hour 10h37m, the end at hour 11h15m.

ECLIPSE 111

[Margin: 1649]

In the year 1649, May 2. The beginning of the total eclipse: Vincenzo Mut [Vincenzo Mut] at Mallorca observed it at hour 13h16m. At Trois-Rivières in New France, Father Francesco Giuseppe Bressani [Bressani] of the Society of Jesus noted the beginning of the eclipse at hour 7h48m, the end at hour 10h45m.

ECLIPSE 112

[Margin: 1649]

In the year 1649, November 18. We observed the total immersion of the Moon at Bologna at hour 18h45m30s; for us the middle came precisely at hour 19h15m. Father Francesco Giuseppe Bressani at Kebec [Quebec] observed the beginning at hour 12h12m, the immersion at hour 13h30m, the end at hour 16h25m.

ECLIPSE 113

[Margin: 1650]

In the year 1650, May 15. Vincenzo Mut at Mallorca observed the end of the lunar eclipse at hour 9h32m24s.

ECLIPSE 114

[Margin: 1650]

In the year 1650, November 7. Father Nicolás Mascardi [Nicolás Mascardi] of the Society of Jesus observed at Panama the beginning of the lunar eclipse at hour 12h15m, after midday.

ECLIPSE 115

[Margin: 1652]

In the year 1652, September 17. We at Bologna, together with Father Grimaldi [Grimaldi], obtained the end of the lunar eclipse at hour 8h42m36s, after midday; and the same end, observed by Father Domenico Cassini [Cassini] at Panzano near Modena, came three minutes later. At Paris the end of the eclipse was observed by the gentlemen [DD.] Petit and Auzout [Auzout] at hour 8h3m measured from Arcturus, but at hour 8h14m measured from the head of Andromeda. At Avignon Father Théophraste [Théophraste, i.e. D. Theophilus(?)] [?] had the end at hour 8h19m. Gassendi [Gassendi] gave the end at hour 8h19m. At Leiden someone with Boulliau gave the end at hour 8h11m45s. At Tournai, Vuendelin [Govaert Wendelen] gave it at hour 8h12m. At Brussels, Langren [Langren] likewise at hour 8h12m. Finally, the Most Illustrious Lord Johannes Nuwerus [Nuwerus], Secretary of the Most Serene Queen of Poland, of Vautoue [?], gave the end at hour 9h19m54s; and Boulliau at Paris at hour 8h3m16s.

ECLIPSE 116

[Margin: 1653]

In the year 1653, March 13. The beginning of the lunar eclipse at Bologna I myself observed, together with Father Grimaldi, at hour 14h40m27s, after midday, and the immersion at hour 15h46m30s. At Paris in the Collège de Clermont the Fathers of our Society observed the beginning at hour 14h6m34s, the immersion at hour 15h15m15s. Let the end be defined by the computation of Boulliau at hour 13h7m, the immersion at hour 6h15m. Father Nicolás Mascardi, in the Valley of Bucalemo [Bucalemu], who is in another western place, in the Occidental island of San Iago [Santiago] of Chile, observed the beginning at hour 9h15m, after midday, and the immersion at hour 10h30m, the emersion at hour 12h0m, the end at hour 13h15m.

ECLIPSE 117

[Margin: 1654]

In the year 1654, August 27. The beginning of the lunar eclipse: Hevelius [Hevelius] at Danzig observed it at hour 11h16m³/₄, the end at hour 12h40m³/₄. The middle at hour 11h58m³/₄, the digits 2¹/₂, nearly. At Paris, Gassendi gave the beginning at hour 10h5m, the end at hour 11h35m, the middle at hour 10h50m. At Avignon the gentleman [D.] Anton. Franc. Payen [Payen] gave the beginning at hour 10h20m, the middle at hour 11h6m, and then 2¹/₃ digits. The end at hour 11h50m.

ECLIPSE 118

[Margin: 1657]

In the year 1657, June 25. At Bologna, Father Grimaldi and I myself noted the total obscuration of the lunar eclipse at hour 9h1m34s; the emersion at hour 9h30m¹/₃; the end at hour 10h54m¹/₂. At Rome the gentleman [D.] Platus [Plati] gave the end at hour 11h8m, but Father Paulus Casaeus [Paolo Casati(?)] of the Society of Jesus at hour 11h6m. At Modena Father Francesco Giuseppe Bressani gave the end at hour 10h51m. At Turin Father Julius Turrinus [Giulio Turrini] gave the immersion at hour 8h41m¹/₃. At Lyon, Father Francesco Caizza [Caizza] of the Society of Jesus gave the immersion at hour 8h37m, the emersion at hour 9h11m. The end at hour 10h46m; but on account of the nearness of the horizon and the encountered penumbra, all these were uncertain in observation, as also for us.

ECLIPSE 119

[Margin: 1657]

In the year 1657, December 20. Father Grimaldi and I observed at Bologna the beginning of the lunar eclipse at hour 6h48m, after midday; the end at hour 8h40m. Digits 3 to the naked eye, but with the telescope 3h30m [recte: 3 digits 30 — i.e. 3¹/₂ digits].

ECLIPSE 120

[Margin: 1659]

In the year 1659, May 6. With the remaining phases impeded by clouds, Father Francesco Maria Grimaldi [Francesco Maria Grimaldi] with his companion Alessandro Fuccio [Fuccio] and others observed at Bologna the end of the lunar

eclipse, from a sighting-rule [ex Fidicula], altitude at hour 10h14m49s. Yet it was confirmed to me that I had chosen that moment as truly similar; for the rest, the doubt remained that those three minutes of time had not been exceeded, since beforehand too the other Moon [at] hour 6h, was seen at 3 digits already; digits obscured 3. At the end of the eclipse at Mallorca, as observed by the gentleman Vincenzo Muto [Vincenzo Mut], it was at high Regulus toward the western [Occasum] degree 46h42m [recte: 46°42'], that is, if it is rightly computed, at hour 9h33m, after midday. If you correct the observations, and take away from the Bolognese 3m, add to the Modenese 1m: the difference of meridians is easily found, which elsewhere is found to be 37m in time.

ECLIPSE 121

[Margin: 1661]

In the year 1661, October 7. The beginning of the spurious eclipse was observed at Bologna by Father Francesco Maria Grimaldi and his companions at hour 14h8m36s, after midday; but the true beginning, toward the middle of the ecliptic shore [littoris Ecliptici] in the Selenography of the same author [Grimaldi], at hour 14h23m16s. It was then carried near the spot Messala [Messalae, i.e. Mare(?)] toward Geminus [the spot called Geminus] at hour 16h55m42s, after midday; thus its duration was at hour 2h30m16s. Digits obscured 3. At Aquae Sextiae [Aix-en-Provence], Father Henricus Ignatius [Henri Ignace], Regius [Royal Professor] of the Society of Jesus, gave the beginning at hour 2h24m, after midnight, and the middle at hour 3h35m, the end at hour 5h11m. Digits 7.

CAPVT III.

An epitome of the observations of lunar eclipses, so far as we have them handed down by the authorities, and the moment of the summation, or of the middle of the eclipse, which has been reduced by us to a single common meridian, that of Bologna, from the last Table of Cap. I.

[The following is a multi-page summary table of lunar eclipses, ordered chronologically. It spans the right column of folio 105 and both columns of folio 106. The columns are:]

- **Ordo Eclipsis ex Cap. 2** — order-number of the eclipse, from Cap. 2 (and the column continues with a parallel pre-Christian-era numbering on the left side of folio 105)

- **Anni Christi, & Mens. dies labentes** (or, for the early entries, **An. labentes ante Christ., cum Mensibus, ac Diebus incompletis** — Years before Christ, with the months and incomplete days) — year, month, day
- **Observatores, & loca observationis** — observers and places of observation
- **Tempus post Merid. loco obs.** — apparent time after midday at the place of observation (columns H. / I [minutes] / II [seconds])
- **Tempus apparens p. m. in Bononia** — apparent time after midday, reduced to Bologna (columns H. / I / II)
- **Quantitas defectus / Quantitas** — magnitude of the eclipse (Digiti — digits)

[Note: in the time columns the heading "H. / I / II" denotes hours / minutes / seconds. Many cells in the seconds column are blank (printed as 0 or left empty). Pre-Christian dates use Egyptian month-names (Thoth, Phamenoth, Athyr, Epiphi, Tybi, Pachon, Payni, Choeac, Mechir, Messori, Messori, etc.). The fractional day-figures attached to some Christian dates (e.g. "1/2", "2/3") are printed as small fractions in the source and transcribed as best read.]

Caput III summary table — Part 1 (folio 105, right column: pre-Christian and early eclipses, Ordo 1–23)

Ordo (Cap. 2)	Year before Christ, month & day (incompl ete)	Observer s & place	Time after midday at place (H / m / s)	Apparent time p.m. at Bologna (H / m / s)	Digits

15	141 Tybi 1 / January	Hipparch us / Rhodes	14 30	8 37 20 [?]	3 Austr.

Ordo (Cap. 2)	Year before Christ, month & day (incompl ete)	Observer s & place	Time after midday at place (H / m / s)	Apparent time p.m. at Bologna (H / m / s)	Digits
------------------	---	-----------------------	--	---	--------

27

[Sub-heading row repeated within the table: **Anni Christi, Dies; labentes | Observatores, & loca | P. M. — H. / M. | Bononiae — H. / I / II | Digi**ti]

Ordo (Cap. 2)	Year of Christ, day	Observer s & place	P.M. at place (H / m)	Apparent at Bologna (H / m / s)	Digits
16	125 Pachon 17 / April 5	Ptolemy / Alexandr ia	8 24	6 51 20	2 Austr.
17	133 Payni 20 / May 6	Ptolemy / Alexandr ia, Sol. loc. \circ gr.	11 15 / 13 14	9 42 20	Total
18	134 Choeac 2 / October 20	Ptolemy / Alexandr ia, Sol. loc. \circ gr.	15 14 [?]	9 27 20	10 Bor.
19	136 Phamen. 19 / March 6	Ptolemy / Alexandr ia, Sol. loc. \times gr.	14 12	14 27 20 [?]	6 Bor.
22	882 Kemir 23 / July 23	al- Battānī [Albateg nius] / Aractha	8 aut plus (8 or more)	5 5 0	10 plus

Ordo (Cap. 2)	Year of Christ, day	Observer s & place	P.M. at place (H / m)	Apparent at Bologna (H / m / s)	Digits
		[Raqqa]			
23	900 Hab 11 / August 5	al- Battānī / Antioch, Syria	15 30	13 20 0	12 ferè (nearly)

Parsing notes: The pre-Christian section uses an independent order-numbering (the leftmost narrow column "Ordo Eclips. ex cap. 2"); entries 20–21 are not printed in this column (the sequence jumps from 19 to 22), which appears to be a feature of the source — likely tied to which eclipses are carried over from Cap. 2. Egyptian month-names and the second Julian date are both given per row. The astronomical sign glyphs in the "Sol. loc." (solar place) sub-notes are transcribed as \circ (opposition) and \times (likely "quartile"/aspect) as best read; both flagged. Several seconds-column values are blank in the source.

Parsing notes: Several order-numbers are skipped in this column too (25, 28, 30, 31, 34, 39, 45, 51, 52 absent), consistent with the pre-Christian pattern — a source feature, not a transcription gap. The duplicate "44" (years 1578 and 1580) is printed as such in the source and flagged below. Place-name "Hramburg" for Tycho is the source's rendering (Tycho's observatory was at Uraniborg on Hven); transcribed verbatim. The small superscript fractions on several dates (" $\frac{7}{8}$ ", " $\frac{3}{4}$ ", " $\frac{2}{3}$ ") are printed as fractions of the day and read as best as the scan allows. Multi-observer rows stack several time-values in one cell, separated here by "/".

93	1630 Noueb. 7 [¼?]	P. Arzet S.I. [Arzet] / Ingolstad . [Ingolsta dt]; Langreni us / Bruxell.; Martin. Hortensi us [Maarten Hortensi us] / Leyda [Leiden]	11 24 0 / 10 57 0 / 10 52 0	11 24 30 / 11 22 0 / 11 11 0	9 27 / 9 30

Parsing notes (Parts 3–4): Skipped order-numbers persist (61, 62, 64, 65, 73, 78, 79, 90, 91 absent) — source feature. Multi-observer rows again stack several values per cell, transcribed "/"-separated in source row order. Several "Quantitas" entries combine a digit-figure with a fractional-minute residue (e.g. "10 36", "9·30 B.") as printed; these read as "digits + arc-minutes of additional obscuration" or scribal shorthand and are transcribed verbatim. The "B." after some digit-values likely abbreviates "Borealis" (northern). Day-fractions are printed as small superscript fractions and read as best the scan allows; flagged where ambiguous.

Liber II — De Luna (continued)

Caput III (continued) — Epitome of lunar-eclipse observations reduced to the Bologna meridian

The epitome table continues. Columns: **Ordo Eclis.** (running index of the eclipse) | **Anni Christi, & Mens. diesq; labentes** (year of Christ, with the running month and day, the day-fraction printed as a superscript) | **Observatores, & loca** (observers and places) | **Tempus apparens p. m. in loco observ.** (apparent time, afternoon, at the place of observation) — sub-columns H. (hours) / I (minutes) / II (seconds) | **Bononiæ** (the same reduced to Bologna) — sub-columns H. / I / II | **Quantitas** (magnitude, in **Digiti**, digits).

The table is laid out in two side-by-side panels on this folio (left panel and right panel). I transcribe each as printed; within a multi-observer cell the rows stack against the same Ordo/date.

Left panel (folio 107)

		with Father Grimaldi [Nos cum P. Grimaldo]— Bologna [Bononia]			

Parsing notes: Magnitudes in the "Digiti" column are printed as digits and (where present) minutes of a digit, separated here by "/"; e.g. "5 / 22" = 5 digits 22 minutes. Day-fractions in the date column are printed as superscript fractions (e.g. 4/24, 4), here rendered ·n/24. The Ordo numbers skip (no 102, 109, 111–116) as a source feature of the epitome (only eclipses carried over from the catalogue with a reduced Bologna midpoint appear). The place "Aeniponte" usually = Innsbruck, but Arzet observed at Salzburg; printed form retained. van Langren's name is printed "Langren." at Ordo 97/98/101 but "Langten." at Ordo 103 — compositor variant, transcribed as printed and marked. At Ordo 97 the apparent-minute "27(?)" for van Langren is faint. At Ordo 100 the magnitudes "3" and "3 fere" and the place "Regiomont." (Königsberg) belong to Linnemann/Regiomontanus rows.

Caput IV

CAPVT IV.

On the uncertainty of ancient observations — and of certain recent ones; on the disagreement of observers regarding the same eclipse, and its causes. Nineteen disagreements [Dissidia 19].

[Margin: De Observationibus Priscorum — On the observations of the ancients.]

First, from what has been said about Eclipses 40 through 119, and from the disagreement among the more recent observations, one may sufficiently judge — notwithstanding how far astronomy has advanced — how great the discrepancy must once have been among the ancient observers of eclipses, especially when

they were destitute of the telescope and of the other instruments and refinements with which this art is now equipped. One must note, moreover, that Ptolemy, in the very rudiments of eclipse-reckoning that he handed down, determined the midpoint of those ancient eclipses by assuming the total eclipses to last very nearly four hours, and so fixed the moments of the plenilunium [full moon] on the ecliptic by adding two hours to the beginning — as he did in our Eclipses 1 and 10, in chapter 2. But when the eclipse was of six digits, he reckoned it to last three hours, and so at the start added an hour and a half, doing this according to the order of the same chapter 2 in Eclipses 3 and 7. Yet it is established that in this matter one may, owing to the differing anomalies of the luminaries, incur an error of as much as a quarter of an hour. Nothing further did the ancients of old suspect concerning refractions, nor did they distinguish the [penumbra] of the shadow as something spurious. Eclipses spurious in their first appearance they sometimes noted — yet here too an error of 10 minutes, and occasionally more, may lie hidden. Hence, excepting Eclipse 8, which on account of its brevity could be noted with some certainty, even Eclipses 9, 11, 13, and 14 — which we have on the observations of the ancients themselves — manifestly are not free of an error of 20 minutes, not to say 30. Even before Ptolemy I should grant the same of Ptolemy himself, since it is agreed that in this matter some eclipses were most accurately observed; we are nevertheless compelled to use those ancient observations, since perhaps, over the very longest interval of time, a compensation is made for the errors that they incur.

[Margin: 2 (?) — keyed to the next paragraph.]

As for the **disagreement [Dissidium]**, and thus the uncertainty, of many recent observations: we recall it to those very chapters. The **first head** is that of the differing moments of the full moon on the ecliptic, even with respect to the same meridian. That this may appear the more clearly, I have prefixed the foregoing Chapter III, in which we reduced all the moments to the meridian of our own Bologna. Run through, therefore, those Eclipses, beginning at 49, and you will recognize enormous discrepancies in some of them. For Eclipse 49 is reported by Longomontanus 14 minutes later than by Tycho [Brahe]; and 50 just as many minutes is at variance with Tycho himself, as with Wendelen in chapter 2 — noted, indeed, but foulest of all are those at Lansberg [the observations made at Lansberg, Lansbergius] compared with one another, which when collated with Tycho's, or with Wendelen's, appear as follows:

In Eclipsibus [In Eclipses]	Minutorum dissidium [Disagreement, in minutes]
54	15
66	20
68	29
69	25

Whether Lansberg was deceived by the [penumbra] — as I suspect of Wendelen, as I said, in chapter 2 — or whether the observations were dragged to fit his own Tables, and on that account are fallacious in these cases: for this whole matter cannot arise from the meridian-distance assumed by us; otherwise in the other Eclipses, say 58 and 63, Lansberg would not so nearly agree with the others. Notable too is that disagreement which, in Eclipses 104 through 22 [i.e. 122], runs up to 22 minutes, because indeed it had very many observers in different horizons.

spectators, and in the differing temper of the terrestrial vapors, whence is confirmed what I said under the first number, namely how great a discrepancy among the ancient eclipses there must have been if very many of those same eclipses had been observed by ancient observers, especially in regions far and wide apart, and in the diverse constitutions of the air. As for Eclipse 106 — the discrepancy between Us and Wendelen, in that Wendelen makes it reach as far as 14 minutes (if I consider its end on November 2 [recte: the relevant date], and that observed at Paris, and observed by others) — this discrepancy I can refer to nothing but a large part of the observation of Wendelen. But truly, that the matters which pertain to this first head may be inspected at a single view, and that the eclipses observed with less disagreement, and the more eligible ones, may be discerned before all: behold for you, drawn from Chapter 3, the sum of the minutes by which the observers of each chiefly disagree.

Minuta dissidii [Minutes of disagreement]	Ordo Eclipsium ex cap. 3. [Index numbers of the eclipses, from chapter 3]
1 / ½	88
2	63
2 / ¾	55
4	57 / 103 / 105
5	53 / 84 / 96 / 100

Minuta dissidii [Minutes of disagreement]	Ordo Eclipsium ex cap. 3. [Index numbers of the eclipses, from chapter 3]
6	86
7	88 / 90
8	67 / 98 / 110
8 / ½	117
9	75 / 80 / 92 / 102
10	58 / 71 / 97
14	101
15	54
20	60
22	114
25	65
29	56 / 68

[Margin: 3 — keyed to the next paragraph (second head).]

The **second head of the Disagreements**, which can least be ascribed to false distances of meridians, concerns the **duration [Duratio]** of one and the same eclipse, or the **stay [Mora]** in the total shadow. This same point will appear in the following Table, in which the letter **D** indicates the duration of the eclipse, and **M** the stay in the darkness.

Ordo Eclipsis. [Eclipse index]	Observator es. [Observers]	S. [D or M]	H. [hours]	M. [minutes]
56	Lansberg [Lansbergius]	M	1	40
	Wendelen [Vuendelinus]	M	1	30
67	Kepler [Keplerus]	D	1	56

Ordo Eclipsis. [Eclipse index]	Observator es. [Observers]	S. [D or M]	H. [hours]	M. [minutes]
	Wendelen [Vuendelin us]	D	1	52
75	Wendelen [Vuendelin us]	D	2	38
	Scheiner [Scheinerus]	D	3	7
80	Kepler [Keplerus]	D	3	28
	Grienberge r [Griemberg erus]	D	3	13
	Wendelen [Vuendelin us]	D	3	8
	Maestlin [Mæstlinus]	D	3	10
	Ours, at Rome [Nostr Romæ]	M	27	30
	Wendelen [Vuendelin us]	M	31	0
86	Kepler [Keplerus]	D	2	1
	Wendelen [Vuendelin us]	D	1	55

Ordo Eclipsis. [Eclipse index]	Observator es. [Observers]	S. [D or M]	H. [hours]	M. [minutes]
	Gassendi [Gassendus]	D	1	54
88	Kepler [Keplerus]	M	2	44
	Wendelen [Vuendelin us]	M	2	44
	van Langren [Langrenus]	M	2	3
89	Wendelen [Vuendelin us]	D	0	57
	Gassendi [Gassendus]	D	0	43
93	P. Arzet [Father Arzet]	D	3	6
	Hortensius	D	3	1

Parsing notes: At Ordo 80 the rows marked "M" give a stay-in-darkness reckoned in minutes (27'30, 31'0) rather than hours+minutes; the "H." figure 27/31 is to be read as minutes (the column is shared). The "S." column header abbreviates the species (D = Duratio, M = Mora) per the text.

[Margin: 4 — keyed to the foot-of-column paragraph.]

[Foot of left column, folio 109:] The causes, moreover, of the foregoing Disagreements in stay, and in magnitude, and the conditions to be observed in observing, are set out by Us in *Almagestum Novum*, Book 5; the scholia of the same; and are now to be briefly indicated.

[Margin: 1. Causa — First cause.]

The **first** is the [penumbra] of the Moon entering the shadow of the Earth, and thence emerging. For the eastern part of the limb, which first enters the shadow, is often more obscure than that western part of the limb which last emerges from the shadow. The greater part, indeed, of the eastern limb, hollowed out inward, exhibits that great spot toward the north [Boreas], or toward the Arctic [pole], which in *Almagestum Novum*, Book 4, we named the *Mare Philippicum*. When, therefore, this part is to enter the shadow, if upon its approach to the shadow it is still illuminated by some rays of the Sun — even though it be still somewhat lit by some [rays] — it can already...

appear to someone to have entered the shadow, when in truth it is still a little distance from it. And for the same cause, in the egress from the shadow, the Moon will appear not yet to have emerged when in fact it really has emerged. Hence in either case the duration of the eclipse will appear longer than the true one. Yet sometimes one may sin in the estimation of the end, when that part is to be illuminated by all the rays of the Sun. Aliquando tamen [sometimes, however] one sins in the eclipse, in the part brighter toward the [Notapelion?] — about the [southern?] Earth [Terram Sterilitatem(?)]; and on the contrary it ends in that western part of the limb which is obscured near the *Mare Langrenum*. And then, if there be no sin at the start, there can still be a sin in the estimation of the end, in expecting it until that part be illuminated by all the rays of the Sun. This first cause, indeed, the libration [libratio] itself of the lunar body magnifies, exhibiting to us now some, now other margins.

[Margin: 2. Causa — Second cause.]

The **second cause** is the privation of some of the Sun's rays, which the Moon suffers on both sides — whether the shadow be near, even before it has entered the shadow, or be near after it has emerged. For when compared to the other parts which are illuminated by all the rays of the Sun, those which are deprived of many rays appear more obscure; whence arises a certain smoke and shadowy image, which we call the *Umbrago* [penumbral shading]. Straightway a great image of the disc of the shadow infuscates [darkens] a part before the legitimate eclipse by about one quarter of an hour, more or less; and likewise, after the egress from the shadow, the Moon for a little while remains darkened. This discrepancy did not come into Tycho's mind, but it was afterwards noted by others; hence in the more recent observations it is often remarked, [as] the time of the spurious eclipse, distinct from the legitimate eclipse.

[Margin: Legitima Eclipsis quæ — What the legitimate eclipse is.]

I call the **legitimate eclipse** that one when the Moon enters the true shadow [conum Umbrosum, the shadow-cone], which is comprehended by the rays of the Sun touching the globe of the Earth, the remaining [rays] being impeded lest they penetrate directly, but some being refracted only. And the legitimate eclipse is to be awaited when the Moon is illuminated by no refracted rays whatever; otherwise many eclipses would even be total, which are none, and as we shall soon say while we treat of the [penumbra] meanwhile for this second cause — see the diagram, Book 5, chapter 5 [vide Typum lib. 5. cap. 5. expositum].

[Margin: 3. Causa — Third cause.]

The **third cause**, for which even the keenest-sighted spectators — whether with the naked eye or instructed by the telescope — are wont to err around the very limits of the eclipse, is the immersion and emersion of the [penumbra] from the shadow, so called because it is not simply a privation of rays of any kind whatever of the Sun, but a *penumbra*, that is, a privation indeed of all the direct rays of the Sun, but with a participation of the Refracted Rays — which, illuminating the Moon with a weak and malign light, instead of blackness exhibit to us other and various colors on the disc of the Moon, such as those said before at the entrance into the shadow: bluish, ferruginous [rust-red], honey-colored, cinder-colored, ruddy, sallow, and so forth — these from the diverse density and opacity of the watery vapors, which gird the terrestrial globe round about, and in which the refraction of the Sun's rays is twofold, one at ingress, the other at egress. As to the figure to be consulted, see the figure of *Almagestum Novum*, Book 5, chapter 5, set forth in the problem — to the end where you will see many admirable things about the variety of phases that arise hence, and why sometimes in the very midst of a total eclipse the Moon, passing through the axis of the predicted Cone, still appears somewhat illumined; and as Pliny says (Book 2, chapter 9), it is in deficiency, and yet conspicuous in its defect. Indeed, in the same eclipse some are total, and others, [though] not affected even by refracted rays, [show] the very darkness of the shadow set against the eyes; others, by reason of vapors of diverse density spread over the horizons, appear sub-lucent and shot through with refracted rays — as it happened in Eclipse 104, in the year 1642, and elsewhere, as we narrated in the same book, chapter 5, number 14. So that meanwhile we may say nothing of Mars and Jupiter, which sometimes when opposed to the eclipsed Moon are able to communicate some little light to it, even though it be steeped in the shadow. From this cause it comes about that the [penumbra] is mingled with the eclipse, so that the eclipses which are really total scarcely appear total, when too scanty a stay [in the shadow] has been made — as in Eclipses 23, 68, 80, 83, and 87 — of which, indeed, we put together the history

in many places of this chapter, when the observations were made by various men with differing estimations; in part also because many sat near the Horizon, and either it was serene, or elsewhere vaporous, or elsewhere a humid and airy tempest [prevailed]; but now we touch upon the fourth cause.

[Margin: 4. Causa — Fourth cause.]

The **fourth cause** is that already indicated on occasion of the third, namely...

[Caput IV, continued — the causes of observers' disagreement]

The fourth cause is the manifold variety of the horizontal vapors and of the refractions they produce. According to the differing density of these vapors, the rays passing through them suffer a greater or lesser refraction, and a greater or lesser coloration. From this arise differences of color, of quantity, and of quality. These vapors produce the penumbra, and besides this they affect the vision of the Moon by the rays carried to our eyes from the Moon by reflection, and again refracted at their entry into the terrestrial atmosphere before they reach our eyes. For that reason the extreme moments of the eclipse are estimated only with difficulty: when the Moon is near the horizon, the eclipse seems to begin, and likewise it seems to end. And so this fourth cause overlaps the difference of solar refraction noted above [in the third cause]. Both depend on the nearness of the Moon to the horizon and on the differing density of the vapors. They depend, moreover, on whether the place is at a greater or lesser height above the equator, and whether it lies within the Torrid Zone; for under the equator and within the Torrid Zone the vapors are believed to swell up to a lower and humbler level.

But if these same vapors should arise as a kind of mist or thin cloud at the Moon's margins in our direction, that variety of mist [hovering] at the Moon's limb deceives [the observer], so that what occurs in the eclipse is attributed to the Moon's eclipse, when it does not really happen. Wendelen [Wendelen] attests to this in the preface mentioned above.

[Margin: 5th cause.]

The fifth cause is the variety of the lunar globe's *Umbræ* [shadow-shades], which appear differently on different horizons — as Wendelen too has observed in the same preface. For the Moon, when first touched by the plane cutting the shadow itself, is divided into two hemispheres, even though at the place of the Moon's transit the astronomical tables suppose [the shadow to fall] on a lesser part [of the disk] than the hemisphere. And so the shadow is received over a part smaller than a hemisphere; and yet the shadow, more crowded toward the cone, is more

visible there than at the center of the Moon, where it is divided quadrangularly into semicircles. Hence — to enlarge upon the hypothesis of the tables given above — the conspicuous margins of the Moon are obscured at about the sixth part of a digit. From this it follows that the conspicuous margins of the Moon do not appear the same to all dwellers on Earth: those who have the Moon near their zenith see one set of shadows, and others, who are toward the north or toward the south, see the Moon obliquely. Thus it may happen that to southern observers the same eclipse appears $5\frac{3}{4}$ digits, and to northern observers $6\frac{1}{2}$ digits. Indeed it may even happen, by a kind of paradox, that the same eclipse is total to some, while to others — in other really-total eclipses — it appears as if it were extra-total, so that a tiny angle of contact of the shadow projects only so far over the Moon's body toward one Pole, which is not conspicuous to dwellers toward the other [Pole]. The discrepancy, however, is very small.

[Margin: 6th cause.]

The sixth cause is uncertain, yet to be noted in part: the air around the Moon, of its own that surrounds it, and of a differing quantity — whence the Moon may seem to touch the shadow earlier, or to be touched, than the shadow truly arrives, with [the moment] running ahead or lagging; or again the shadow may have departed [while] the Moon's light is still withdrawn into the darkness, or in the manner the Bolognese stone, which to our eyes when the Sun is transferred from sunlight into darkness is wont to be carried over into the darkness — which Wendelen judges not improbable in the same place.

[Margin: 7th cause, manifold.]

The seventh cause comes from those astronomical elements which combine to determine the moment of the eclipse phases — namely, the Moon's motion and its parallaxes, if the lunar altitude be employed; or the declination, and the right ascension of the fixed star, and the right ascension of the Sun, by which the time ought to be drawn out; the azimuths of the star, and the altitude of the Pole, with the situation of these in the meridian — in all of which, if there lurk any error of falsity, it is necessary that the conclusion of the time engendered from the trigonometric calculation be false. Now before Tycho [Tycho Brahe], inasmuch as men labored under the vice of the fixed stars, the exploration is as false as the correction to be applied is true: by Tycho's own [tables] of the declinations and right ascensions of the fixed stars, the [errors] of the observers will be reckoned, as is to be shown at Chapter 10, from our [tables]. [Margin: *Geographia Reformata*.] How false the altitudes of the Pole are, observed in various places by astronomers, will be apparent from our *Geographia Reformata*. He himself

[Wendelen] observed at Lyon in Gaul this eclipse, in the year 1700. At Lyon the observer reckons that whole eclipse to have begun at hour 10, 3 minutes, and to have ended at hour 12, 30 minutes, with the altitude of the Pole being gr. 45, 36 minutes — which he took from an observation of two of our Society's most outstanding mathematicians, recently sent to me, of gr. 45, 8 minutes [Margin: *the latitude of Lyon*]. And so, while from terrestrial charts the altitudes of places are rather derived from the heavens, great errors are committed in the time of eclipses. But if that moment, which is the very midpoint between the beginning and the end, is the most precise moment of the full moon.

[Margin: 8th cause.]

The eighth cause is the variety of the observers themselves, arising from natural causes; and the use [they make of their eyes]: while some are endowed with sharper sight, with greater attention, and with greater circumspection than others; especially when they have acquired greater experience beforehand in astronomical matters. Because of this, when many sharper-sighted witnesses determine the moment of an eclipse more certainly, while others miss it, and they do not agree among themselves on the same [moment], the one nearer the truth is to be preferred over this [other], the more ambiguous and fallacious to be set aside.

[Margin: 9th cause.]

The ninth cause is likewise the variety of the observers themselves, arising from the imperfections of the instruments with which the eclipse is observed — to wit, the telescopes by which the eclipse is greater [magnified] than with the naked eye, the quadrants, the astronomical rays [radii astronomici, cross-staves], the horologes [clocks], and so forth; or [arising] from their use, or their handling. For it can happen in many [cases] that the error is not lightly to be ascribed to the observers, and the diligent observers of the others' observations are to be derogated, and the better instruments to come [into use]; or because there is no agreement with the rest, as nothing has [been done] by skill of trigonometric calculation, which nevertheless can readily be repeated and corrected.

[Margin: 10th cause.]

The tenth cause is the false difference of longitude, or the distance of meridians assumed, when observations made under different meridians are referred to one [meridian], and it appears whether they agree on the same moment or not, as we did above at Chapter 3. Especially since that difference of longitude is established not from itineraries [land-journey distances] but from the lunar eclipses

themselves. Therefore it is permissible for us to expect a more certain difference of longitude from observations of more numerous [eclipses]; and so we have set the difference of meridians between Bologna and Paris at 40 minutes of time. We confess that this is by no means evident, but the false difference of one or another minute of time engenders a greater or lesser [error]; and so in the rest, the more remote regions, the discrepancy [is greater], for of near [places], or those lying under nearly the same meridian, we have from elsewhere a greater certainty than from eclipses.

CAPVT V.

On the Agreement or Disagreement of the Astronomical Tables with the Observations of the Lunar Eclipses; and first concerning the Ancient Eclipses down to Ptolemy [Ptolemy] inclusive; and concerning the enormous Disagreement, as far as it touches these [eclipses], that appears between the Astronomical Tables and the Chronological [Tables] — but in truth [arising] from Ptolemy's error in the motion of the Sun.

[Margin: 1.]

We know that this comparison [of tables with observations] is something both we ourselves have long desired, and that the more eager students of astronomy expect of us — that it may be settled how far the famous Astronomical Tables, the rest being equal, may yet be excogitated as better. And so, to this end, [as I said] at Chapter 3, I selected those eclipses of which the middle [moment], or some moment of the partial obscuration, or of the extreme phases — whether the partial, or the total — of eclipses handed down to us has been [recorded] by observers: namely, because at the moment of the ecliptic full moon, at the diametrical opposition of the Moon with the Sun, the place of the Moon in the Zodiac is foreknown from the tables computed beforehand, and the place of the Sun [is foreknown] from the moment. Then to that [foreknown] astronomical moment, reduced nevertheless to equal time, we have computed — as [will be shown] below under the naming of the place of the Sun from the tables — and from there we straightway note

— the opposite place of the Moon, [drawn] from the same tables; and indeed at the same moment we have computed the place of the Moon, with the place [of the Sun] adjoined; and the difference of the place computed from the observed [place], or [the difference] of time, [we have noted]. Inasmuch as the Astronomical Tables are for the most part constructed and affixed to a meridian

differing from that under which the observations were made, the difference of the place computed from the observed [place], or the time of the observations, [must be reduced] to the meridian [of computation] according to the distances of meridians, which the tables themselves prescribe in their catalogs of places, or at least are deficient — as is established under our *Geographia Reformata*.

[Margin: 2.]

Because the foresaid eclipses [recorded] before us, by us or by others, are recalled to calculation from their tables, we have made use of their labor; but where they have failed us, we have supplied the supplement from our own [calculation]. Accordingly, from the *Rudolphine* [Tables] we have computed altogether 91 eclipses; from the *Philolaic*, the supplement; that is, from the *Tychonic* [Tables], 24 eclipses; from others' calculation, [the rest]. So indeed we have made use of others' calculation, that — together with the difference of meridians, and from the moment of time handed down from here under the meridian of the observation by the observers — it might be established under the meridian of the tables, [and] how many minutes of an hour the tables represent the eclipse [as earlier], than the earlier observation would require; and thence too the difference in the place in the Zodiac is elicited.

[Margin: 3.]

Furthermore, because many of the foresaid eclipses began at a different moment for different observers, or are assigned a different moment, we choose one [moment], or take it from many observations; and its time, handed down under the meridian of the observation — accordingly, from the very moment, and from the table — will be established, [showing] of which observer we have chosen the observation. For example, in eclipse 110 we assigned the hour 9, 12 minutes; before which, returning to Chapter 3, eclipse 110 is established to have been made at Paris by us, namely at hour 9, 19 minutes after noon — but this admonition [warning] is to be regarded specially [as touching] the eclipses of the following chapter. And here truly this [whole] head [of the matter] looks toward the peculiar mention of the eclipse.

[Margin: 4.]

Although in Chapters 2 and 3 we reckoned the ancient eclipses to the meridional time [post-meridian reckoning] of those very days on which they fell, but [reckoned] from the true computation of our *Reformed Chronology* and the *Chronological Apparatus*, [the time] answers in the form of the Julian Year and the Months of the Egyptian day cited in Ptolemy. In what follows, nevertheless,

we have been compelled to note the day for that one of two [tables for each eclipse]: [namely] one [table] to note where the eclipses came from, [we] ought [to place] at the Ptolemaic place of the Sun — that is, of such-a-kind from the tables, the astronomical [day]; nor [should the table] exhibit the Moon opposed to the Sun, but at gr. 11 or 12 distant from the opposition with the Sun; and yet [it should] exhibit the Moon's place [as] nearer than from Ptolemy at the observed [opposition with the] Sun — the other day, namely the later, we adjoin, by which the Astronomical Tables exhibit the Moon opposed to the Sun. Let it be not the place but the place of the Sun substituted, of which kind at least the Ptolemaic [place] is from his tables handed down, but nearly at the earlier degree. Concerning the disagreement, the difference will be apparent [from what is set out] below, after the following Catalog of Eclipses.

[Margin: 5.]

For although in Chapter 2 and 3 the ancient eclipses, beginning from eclipse 40, are observed by various observers, or assigned at a different moment, [we] configure one [of them]; recurring to Chapter 3, eclipse 110 is established to have been made by us at Paris [Margin: at hour 9, 19 minutes after noon]; the rest as admonished above [touching] the eclipses of the following chapter. To this [head] looks especially the following mention concerning the day of the eclipse.

[Margin: 6.]

Meanwhile [we declare], for our sincerity's sake, [that] those [things] are to be re-examined with faith: the names of those from whose eclipses we have made use, [as set out] according to the order of the monition at Chapters 3 and 4 — they are, moreover, in alphabetical order written below.

Andreas Argolus [Andrea Argoli], who [computed] the eclipses from the *Danish* Tables of Longomontanus [Longomontanus], yet [reduced them] to the meridian of Rome; in his Ephemerides he computed the eclipses from the Year of Christ the Lord 1620 down to 1700.

Claudius Ptolemaeus [Ptolemy], who handed down not only ancient eclipses but also the foresaid [recent ones] down to his own time of observations; and he adjoined [them] to his own tables, or [to those of] Hipparchus, for the place of the Sun and of the Moon.

Christianus Severinus Longomontanus [Longomontanus], who [in] Book 1 of the *Theoricae* of the *Astronomia Danica*, Chapter 2, in the Commentary

de Luna, conferred the place of the Moon computed from his own Tables. *Danica*, with 9 eclipses anciently observed, and with Chapter 13 of Tycho [Tycho Brahe], or so far as he observes, with which observation he adjoins the tempora [moments] from the horary motion of the Moon and from the Sun, [and] responds to the difference of the observed place, computed [...].

David Origanus [David Origanus], who [computed] his [eclipses] in his Ephemerides from the *Prutenic* and the *Tychonic* Tables, but [reduced them] to the meridian of Frankfurt-on-Oder; he reduced [and] supplied [eclipses] from the Year of Christ 1595 down to 1654.

Dionysius Petavius, of the Society of Jesus [Denis Pétau], who in Book 8 of his *Doctrina temporum*, Chapter 13, [computed] all the ancient [eclipses] down to al-Battānī inclusive, and many of the more recent ones down to the Year 1600. He computed the eclipses observed by Christ[’s era] from his *Parisian* Tables — that is, the meridian affixed to Paris, and Lansberg’s [Tables], and the *Prutenic* Hypothesis very nearly; and adjoining [them], he calculated something from the *Alphonsine*, the *Prutenic*, and the *Danish* [Tables]; and besides, he predicted some eclipses of our own century.

Gotefridus Vuendelinus [Govaert Wendelen], who, after the *Tabulae Atlanticae* of the Idea, edited [tables] of many of the more recent ones; he reduced the time of the eclipses from the same tables, and [to] some quantity, from the Year 1573 down to 1643.

Io. Antonius Maginus [Giovanni Antonio Magini], who [computed] his [eclipses] in his Ephemerides from the *Prutenic* Tables, [reduced] to the meridian of Venice; he supplied the eclipses from the Year 1581 down to 1630.

Franciscus Montebrunus [Francesco Montebruno], who, from the Lansbergian Tables [reduced] to our Bolognese meridian, completed the calculation of the eclipse from the Year 1641 down to 1660.

Ioam. Keplerus [Kepler], who, from the *Rudolphine* Tables, in his Ephemerides computed the eclipses from the Year 1617 down to 1620 under the meridian of Uraniborg. We, however, have recalled to calculation 91 lunar eclipses from the *Rudolphine* [Tables].

Ismaël Bullialdus [Ismaël Boulliau], who, in Book 3 of his *Astronomia Philolaica*, Chapter 7, computed the eclipses from his own *Philolaic* Tables, ancient [ones] and recent, 25 [of them] down to the Year 1573; and these [he computed] from his *Philolaic* [Tables], adjoining a calculation [down to] the Year 1643. He selected

those from the *Philolaic* [Tables] adjoining a calculation [down to] the Year 40 [reduced] to the meridian of Uraniborg, which he selected.

Michaël Maestlinus [Michael Maestlin], who, from the *Prutenic* Tables [reduced] to the meridian of Tübingen, supplied the eclipses from the Year 1577 down to 1590.

Nicolaus Copernicus [Copernicus], who computed the eclipses observed by himself, and adjoined the place of the luminaries deduced from his own tables.

Philippus Lansbergius [Philip van Lansberge], who, from the *Goesian* meridian, computed the eclipses from his own tables, and in his *Thesaurus* of Lunar Observations of the first Class — he reported the eclipses, most of the ancient ones, and the more recent [ones] observed, the most certain ones; but perhaps these tables would resist [contradict] him.

Therefore note: the Indices of the foresaid Tables, which we shall use below, are written out below.

Alphons. — the *Alphonsine* Tables, in the calculation of Petavius, Regiomontanus, or Magini.

Atl. — the *Atlanticae* of Wendelen, from his own calculation.

Dan. — the *Danica* in the supputation [calculation] of Longomontanus, or Petavius, or Argoli.

Lansf. — the *Lansbergian*, from the computation of Lansberge himself, or Montebruno.

Parif. — the *Parisian*, from the calculation of Petavius.

Phil. — the *Philolaica*, from the supputation of Boulliau, or Ours.

Prut. — the *Prutenica*, from the calculation of Petavius, or Buntingus [Buntingus?], or Maestlin, Magini, and for the most part Origanus.

Rud. — the *Rudolphina*, by the supputation of Kepler very rarely, but everywhere [used] in all our eclipses, [or] from Ours.

Tych. — the *Tychonica*, from the supputation of Origanus, or Ours.

Ptol. — the *Ptolemaica*.

The Moments of the Ancient Eclipses, and the Quantity observed, and collated with the Time, and the Quantity represented by the Tables written

below; e indicates the Excess of the computed place of the Moon, and d the Defect of the exact opposition with the Sun.

This page presents a large citation-grade discrepancy table comparing ancient eclipse observations with values computed from the various astronomical tables. It is transcribed as a native markdown pipe-table below, not as a figure. The table continues onto the following batch.

Column headers (reading across the head-band):

- **Ordo Eclips. ex cap. 2.** — Order-number of the eclipse, from Chapter 2.
- **Observatio, & Tabulae.** — The observation [source] and the Tables.
- **Tempus Apparens post Merid. in loco Observationis.** — Apparent time after noon at the place of observation, sub-columns: *Mens.* (month), *D.* (day), *H.* (hour), *M.* (minute).
- **Solis locus Verus ex Tabulis & inde ϑ loci Ω** — True place of the Sun from the Tables, and thence the [opposite] place; sub-columns: *Sig.* (sign), *Gr.* (degree), *l* (minutes), *ll* (seconds).
- **Lunae locus Verus ex Tabulis computatus.** — True place of the Moon computed from the Tables; sub-columns: *Sig.*, *Gr.*, *l*, *ll*.
- **Differentia loci e computati & observati.** — Difference of place, e [excess] computed and observed; sub-columns: *Gr.*, *l*, *ll*.
- **Tempus huius Differentiae.** — Time of this difference; sub-columns: *H.*, *l*, *ll*.
- **Quantitas in digitis.** — Quantity in digits; sub-column: *Digit.*
- **Differentia Quantitatis.** — Difference of quantity; sub-column: *Digit.*

Parsing notes: The leftmost zodiac-sign glyphs (♊ Pisces, ♈ Aries, ♎ Virgo, ♎ Libra, ♉ Taurus, ♏ Scorpio, ♋ Cancer, ♐ Capricorn, ♊ Pisces) appear only at the head of each block in the Sun and Moon columns and carry forward to the following rows of that block; I have placed each glyph in the row where it is printed. The Sun-column "ll" (seconds) sub-column is blank throughout this opening (values given only to minutes). The "Tempus" minutes/seconds and several "ll" cells are blank where the source leaves them blank; "&c." in the time-minutes column is printed verbatim by the source (abbreviating a recurring 24/25/30-minute figure). The "d"/"e" prefixes in the Difference-of-place column are the *defectus/excessus* markers explained in the table caption. Table continues onto the next batch (catchword "Phil."). The "Differentia Quantitatis" final column is largely blank in

this opening and several digit-values straddle two physical rows in the source; flagged alignments noted with best-fit placement.

Liber II — De Luna (On the Moon)

Caput V (continued)

The great ancient-eclipse discrepancy table continues. Each numbered eclipse is compared across the source-tables (Ptolemy's observation, the Lansbergian, Parisian, Philolaic, and Rudolphine tables, and in some cases Tycho/the Danish [Astronomia Danica] and Prutenic tables). The column structure is:

- **Ordo Eclipf. ex c. 2** — eclipse number (from Chapter 2's catalogue)
- **Observatio & Tabulae** — observation source / table-set
- **Tempus Apparens post Merid. in loco Observationis** — apparent time after noon at the place of observation (Month | Day | Hour | Minute)
- **Solis locus Verus ex Tab. & inde ☉ locus ☉** — true place of the Sun from the tables, and hence the Sun's opposition point (Sign, degrees ' ")
- **Lunae locus Verus ex Tabulis computatus** — true place of the Moon computed from the tables (Sign, degrees ' ")
- **Differ. loci computati & observati** — difference between computed and observed place (degrees ' '), prefixed by **d** (*defectus*, deficit) or **e** (*excessus*, excess)
- **Tempus huius Differentiae** — time-equivalent of this difference (hours ' ")
- **Quantitas in digitis** — magnitude in digits (Dig. ')
- **Differ. Quantitatis** — difference in magnitude (Digit. ')

Zodiac glyphs head each Sun/Moon block and carry forward through the rows beneath. Hours are reckoned from noon. The "&c." entries in the time-difference column abbreviate a repeated/continued value.

Parsing notes: This is an extremely dense citation-grade table spanning three folio pages. Sign-glyphs head each Sun/Moon block and carry forward over the rows beneath until the next glyph appears; where a cell is blank in the source (especially the Moon's-place columns for the lead "Observatio" row of each eclipse), it is left blank here. The *defectus* (d) / *excessus* (e) prefixes are preserved verbatim in the difference-of-place column. "&c." in the time-difference column abbreviates a value continued from the row above. Several digit-magnitude cells are split between the "Quantitas in digitis" and "Differ. Quantitatis" columns and were merged into the final two columns; a few interior rows of eclipse 11, 13, and 18 appear to be doubled (table-set repeated for the day-before vs. day-of comparison), reproduced as printed. Where ink-bleed or gutter shadow made a glyph ambiguous, the most consistent reading with the column's progression was chosen; remaining doubtful single glyphs are flagged inline.

Caput V (conclusion of the analysis) — Page 115, lower text

Exponitur iam Dissidium Apparens inter Astronomicas Tabulas LuniSolares, & Chronologicos Canones, detectis insigniorum alioquin virorum erroribus.

Now is set forth the apparent disagreement between the astronomical luni-solar tables and the chronological canons, with the errors of otherwise distinguished men exposed.

7. For a long time I was anxious over the discord that seemed to hold — partly among the passages of Censorinus [Censorinus] themselves; partly among those who, relying on his authority, followed chronology; and finally between the solar astronomical tables and the lunar ones. On the one hand, the earlier passage of Censorinus, *On the Birthday [De Die Natali]*, chapter 8, together with the authority of the Arabs, wanted us to take the Sun's place — and hence the moment of the

predicted eclipses — as following Ptolemy; so that we would calculate the predicted eclipses by the swift day rather than as astronomers commonly reckon. And so the first eclipse [in the catalogue] would have fallen on 7 March, and likewise the rest before Ptolemy — indeed, four eclipses before the observed one — by the very fact of being predicted. For example, eclipse 17 would have happened at 11h 15' after noon of the fifth day. On the second view, following the later passage of Censorinus, it is necessary to say that the predicted eclipses fell on the following day, as set down in the foregoing catalogue. For example, eclipse 19 [fell] on 8 March, and eclipse 17 at 11h 15' after noon on 6 May; whence it follows, by way of the Chronological Canons, that the beginning of the year of Nabonassar, in the form of the Julian year, began from the meridian of 26 February.

So that we may state this more clearly and resolve it, let us lay down certain points beforehand as fixed and settled.

8. First, it is certain from other authorities, but especially from Censorinus, chapter 10, that the Romans began the civil day from the preceding midnight. But the Egyptians especially — and the astronomers in particular — took the beginning of the day from the rising of the Sun, as is clear above all from Ptolemy, *Almagest* book 3, and chapter 8. Therefore, with Censorinus's passage soon to be cited, the beginning of the Egyptian year did not [fall] on some Roman Kalends, or on some day before the Kalends entire, but began before the day VI. Kal. or XII. Kal. — that is, the Egyptians reckoned the beginning of the year 12 hours before the beginning of the Roman day, as is customary.

9. Secondly, it is certain from Ptolemy in many places that the Egyptians reckoned the days from sunrise as for the observations of eclipses, and likewise the phenomena, with the customary [hours] reckoned as incomplete; and they took the difference accordingly, and for the most part, after a day already named, they added a following day not yet begun. Thus *Almagest* book 3, chapter 8, when he says that the equinox was observed by him in the 17th year of Hadrian, and on the 7th [day]: Athir [Athyr], after midnight, in the two nearest equal hours. A little later he says: *from the first hour of Nabonassar in the first year, and the midday of the month Thoth among the Egyptians, up to the autumnal equinox set forth to us, we gather 879 years and 66 days and 2 hours.* But if he had taken the seventh day [Athyr] for the exact and completed [day] beyond the named years, he would have reckoned 67 days. Further, *Almagest* book 4, chapter 8, he says: *from the first hour of the month Thoth of the first year of Nabonassar up to the midpoint (according to the ancient eclipses, the time of which we have spoken) of the second*

eclipse, of the Mardocempad [Mardokempad], in the year of Thoth 18, the following 19, equal in 50-sexagesimal hours: but the time gathered is of 27 Egyptian years, 17 days, and 11 hours and 10' nearly. But if the 18th day of Thoth had already been completed, there would be counted in this collection 18 days. Copernicus [Copernicus] therefore errs, as often as in these cases he reckons—

[Margin: Copernici error. — "Copernicus's error."]

he numbers [numerat] the day designated by Ptolemy for the completed ones [pro exactis], or for the elapsed ones [peractis], as at Book 4, chapter 5, section 6, where he says: "On the twentieth day from the transit of the month Pauni, and soon after on the second of the elapsed days of the month Choiac, and a little later, after the transit, on the 19th day of Pharmuthi." But Ptolemy numbers the days here in another way, namely at Book 4, chapter 6: he sets down the year of the first of these eclipses as the 5th of Pauni still elapsing, and likewise the second on the 2nd of Choiac, then the third on the 19th of Pharmuthi, which the twentieth day was about to follow.

[Margin: Copernicus's error]

10. There remains finally one matter, controverted among the most learned men: the first year of the vulgar Epoch of Christ. Was it the forty-sixth of the Julian years, and likewise the first bissextile [leap year]? For the eclipse of the Sun which befell — as [Dio] Cassius reports at Book 60 — at the Nativity of the Emperor Claudius, this, on the authority of Suetonius (in the Kalends of August of the year of the Julian Epoch 90), is represented from the Astronomical Tables for the Year of the Epoch of Christ 45, on the Kalends of August, and so by other eclipses. By these arguments and the like, it is confirmed in our Reformed Chronology, as it is also the common opinion of most chronologers, that the year 1 of Christ began at the Kalends of January in the year of the Julian period 46.

11. Fourthly, it is finally established that the Egyptian year, inasmuch as it consisted always of exactly 365 days, in every fourth year began one day sooner than the Julian year — namely after the 24th of February — and on the contrary began to retrocede in the descent of the years, and conversely to advance toward the beginning of the world in the ascent. With these points laid down, the occasions of the controversy now indicated are more easily explained.

[Margin: Opinion of the Arabs on the years of Nabonassar and of Christ]

12. Jacobus Christmann [Jacob Christmann], in his book *De Kalendario Romano* page 182, writes: "The Arabs," he says, "reckon exactly in commemorating the intervening years between Nabonassar and Christ, since at the beginning of the third book of his *Almagest* they are written down from Nabonassar up to Christ as 747 transit-years, and on day 131." A little after, Paul [Christmann?] subjoins: "The observing Arabs, prudent in their reckoning, do not take the era of Christ from his Conception, nor from his Circumcision, but from the last day of December, which precedes the Circumcision or the Kalends of January of the year 46 Julian. But if you reckon from the Year of Christ 747, then it is the 26th of February." But if the year before Christ were to be reckoned, it would be at the last midnight of December preceding the Circumcision of Christ, and they would be the years 747 of so many tenths; how does Christmann number 110? — when in this way he asserts that Regiomontanus erred. Therefore if they are 131, it is fitting to begin the numbering at the midnight of the 25th of February of the year 747 before Christ. Hence it follows that the beginning of the months of the Egyptians corresponds to those days which the astronomers commonly denote as preceding by midnight: and as for the example of eclipse 17, [the one which] Ptolemy reckoned to have been on the 20th of Pauni — not, as the common reckoning has it, on the 21st.

[Margin: Opinion of the Arabs on the years of Nabonassar and of Christ]

13. I reply, however, that this opinion of the Arabs does not evince what they wish. For although the Arabs, prudent in their reckoning, have accommodated themselves to the era after Dionysius Exiguus [Dionysius the Little], introduced in the Christian world for numbering the years of Christ — and thus the years 747 — yet the beginning of Nabonassar is the 26th of February. When they considered the Astronomical Tables, they nevertheless fixed the year at the last midnight of December, for the sake of commodity, lest they might omit a whole astronomical day in the reckoning. Therefore Censorinus is rather to be examined. [Margin notes alongside: Censorinus / Scaliger's lapse in chronology]

14. Censorinus, in his book *De Die Natali* [On the Birthday] chapter 8, and Varro [whose index serves as it were], note the most illustrious epochs of the years thus: "Unless I am mistaken (whose year is as it were an index, and the title is in a way of use), and from the Olympiad" — first of all is the year 1014 of the Olympiads [?] which befell in those days on which the Olympic Games are celebrated. From the founding of Rome 1191, and

indeed at the Palilia, whence the years of the Urbs are numbered. Of their own years, which bear the Julian name, 283, ever since Julius Caesar by his own constitution made the beginnings; but those years which are called from Augustus [Margin: From Petavius and from Christmann] 267, perfect, that is the 7th, that is the 13th: M. Crassus, D. F. Augustus, by the judgment of Munatius Plancus, from the Senate and the rest received this name, that is the 7th, that is M. Vipsanius Agrippa, III consul. But the Egyptians, who two years before [came] under the power of dominion, and the people, R[oman?] conquered, hold the years of the Augustans...

[Margin: From Petavius and from Christmann]

15. But it is clearly established from Censorinus himself that one must read, in the prior place, "before the 6th day of the Kalends of July" [ante diem VI. Kal. Iul.]; for this day he confirms...

he confirms from another more notable day, at once subjoining: "Since from this point a hundred [years] elapsed for Pius and for Bruttius — the present consuls — they are the same days which were [counted] before the 12th of the Kalends of August" [ante diem XII. Kal. Aug.], as Codex, Scaliger, Christmann, and Petavius have it. But for the year — beginning the 25th, that is to say, of those years which are the Egyptian beginnings — the beginning of Thoth was anticipated for so many days. Therefore the beginning of Thoth fell, with Pius and Bruttius as consuls, at the midnight preceding the twelfth before the Kalends of August, that is, in the meridian of the 20th of July. To St. Margaret, sacred, etc. After a hundred years, it falls in that meridian on the 25th of June, that is, in that meridian which was before the 6th of the Kalends of July [ante diem VI. Kal. Iul.]. I know that Scaliger and Manutius acknowledge an error, but rather in this second place of Censorinus, and it is restored for "before the 12th of the Kalends of August" [ante diem XII. Kal. Aug.]; but in dubious cases of correcting either of these places, one must rather stand by the number of years, which favors the opinion of the beginning of Nabonassar at the 26th of February both as a matter of fact, and according to the eclipses of the Sun or the Moon. By the Astronomical Tables, they can be gathered, namely on the days which Ptolemy designates: by which the eclipses noted in the preceding Catalogue are computed, in which they suppose the year of Nabonassar 986 begun [*incaepisse*] at the midnight preceding the 6th, that is, in the meridian of the 25th of June. We conclude, therefore, that Censorinus not only does nothing against us, but rather favors us. Let this be asserted, having retained that reading "before the 7th of the Kalends of July" [ante diem septimum Kal. Iul.].

[Margin: An emendation in Censorinus is not to be made]

16. A greater, indeed almost the sole, difficulty remains regarding the place of the Sun, which Ptolemy assigns to the eclipses, and which he has observed at Book 4, chapter 6. For eclipse 17, made at Pauni of the 20th, which follows at Book 11, hour 11.15' after the meridian of the 20th, has the Sun positioned in Taurus Grade 11.14' approximately; and eclipse 18 at Libra Grade 26.37'; and eclipse 19 has the Sun constituted in Pisces Gr. 14.12'. Nor is it otherwise had in the Greek text, or in the Codices [in the] M.S. Besides, on the Aequinoctial point, the same Ptolemy in the same year of Adrian 17, who observed eclipse 17 the seventeenth day, by two hours after the meridian of the 7th of Athyr [Margin: ...], follows for whatsoever Astronomical Tables one receives — apart from the Lansbergian — that the Moon was in Taurus Grade 13, and just minutely, but no fewer, after the meridian of the 20th of Pauni in Taurus Grade 13, and just about 14'; nor by more than 34'. But from our Solar Tables it follows that the Sun was in Taurus Grade 13, and minutely about 16'; whence by supposition it follows that Pauni was the 20th, since it began at the meridian of the 5th of May; but from this it follows likewise by the same Astronomical Tables that the Moon was, from the moment of the same opposition, distant from the place of the Sun by the whole 11. of Grades, or at most Grade 11.30'; or, if you wish, at the least Grade 11.30'; and if it is to be seen, by the preceding Catalogue. But if the Moon be held in the place of the opposition, as a Plenilunium [full moon] requires, it ought above all to be proceeded eclipse-wise on the 6th of May, at the hour 11.15' after its meridian: it follows by the same Tables (subtracting the Lansbergian) the place of the Sun by Grade most-of-all-further than what Ptolemy has noted to have been in Taurus Grade 14, and just minutely than 14' minus. But what we said of eclipse 17 holds in all the ancient eclipses of the twenty taken in the preceding Catalogue, and examined later by the most celebrated Astronomical Tables.

17. The other [point] is to be said of two: either Ptolemy errs, nor do the other Astronomers err in their Tables, regarding the place of the Sun; yet that nevertheless they erred in the place of the Moon in the Tables by about 12 Grades. If the prior day be retained in the aforesaid Catalogue of those reckoned according to the Julian year, we wish to retain it. On the contrary, however, if we wish to retain it with the common reckoning of Astronomers — the later day — and not to commit so enormous an error to the Astronomical Tables, what shall we say of the place of the Moon? For

Ptolemy errs by an entire Grade [*Margin: ...*], either the Astronomical Tables (and likewise the now-celebrated Tyconic ones) would have erred by one Grade, and in eclipse 17, with the 6th day retained, at hours 11.15' after the meridian: the Sun was discovered to be lacking in Taurus Grade 13.14'; it would be necessary that the Mean motion of the Sun — which commonly does not exceed signs 11. Grade 29.45'40" — to come out at signs 11. Grade 29.45'42".20".

Whence it would follow that the Aequinoctial year is of days 365. hours 5.48'.3".& 42" — absurdly indeed and notable, it is to the experts of Astronomy; or one must admit the inequality of the years, once not excluded at Book 3 [of the] *Almagest*, [as it is] now [admitted].

18. But neither can it be said that the Astronomical Tables erred, either at eclipse 12 in the motion of the Moon at the time of Ptolemy, or that Christ's [time] represented the eclipses; or [that they] were lacking in the predicted Catalogue, and as an example at eclipse 17, ought to have been at hour 11.15' after the meridian of the 1st of May, to exhibit the Sun in Taurus Grade 13.14'; thence likewise the Moon in Scorpio Grade 13.14' approximately, which the Tables themselves represent in Scorpio Grade 13. approximately. For we have other eclipses noted on more certain days in the Roman manner, at the time of which Ptolemy and Christ note the same — which the same Tables rightly represent without error of an entire Grade. For example, as for the eclipse which Dio Cassius affirms befell at the Nativity of the Emperor Claudius — M. Vinicius II [and] M. Statilius Corvinus consuls, that is, in the Year of the Epoch of Christ 45, on the Kalends of August (as Suetonius has it *De Die Natali Claudii*) [On the Birthday of Claudius] from the Astronomical Tables, and in the species of the Rudolphine [Tables] there is exhibited: the true Novilunium [new moon] of the first of August, hours 9.& minutes 55. after the middle midnight, at which point the Romans began the Kalends. And of others. Hence therefore we recognize that it cannot be that by these Tables an error of twelve grades subsists in the motion of the Moon in that eclipse. Therefore one must either represent eclipse 17 by the said Tables, [in which] it is necessary the 6th of May, after whose meridian, at hour 11.15', Alexandria, the Moon was in Scorpio Grade 14.30' approximately, & the Sun in Taurus Grade 14.30' approximately, necessary too; or rather Ptolemy erred in the place of the Sun by one grade, assigning [it], because [it is] of that Aequinoctial of that year by one grade more slowly made than they put it, [than] truly more truly; or the Tables exhibit it for some hours

before the meridian of the 1st of September, as the Chronological Canon — days of Athyr the 6th, and we said at chapter 6, section 15.

[Margin: Ptolemy's error in the Aequinoctials]

19. Lest, however, it should seem we are accusing Ptolemy of having erred by a whole day in the Aequinoctial — for that it suffices an Armilla [armillary ring] of the Aequinoctial, as he indicates at Book 3, chapter 1: he himself saw in an observation of this kind [the sun's light] declining a little from the plane truly toward the Southern part, [whereas] truly minutely. And he himself there attests both Armillas to have remained the greater part at their site, an obliquity at the time; but in emending the defect of those by their own fault, it can easily be deceived: then with the Obliquity of the Ecliptic, as we said at chapter 6: then with the false opinion of the quantity of the Aequinoctial year, with the false Hypothesis too of the immobility of the Apogee of the Sun. It could even be that the Armilla at the ancients was not so exactly placed, or had been [placed] through some error in the altitude of the Aequator.

[Margin: Ptolemy's error in the Aequinoctials]

I. CONCLVSIO [Conclusion I].

With the LuniSolar Astronomical Tables sound, and [their] Egyptian days from Ptolemy in the Observations of the Lunar Eclipses, one must assert that the year of Nabonassar 886. began at the midnight preceding the 6th [day] of July, that is, in the meridian preceding the 12th of the Kalends of August [ante diem XII. Kal. Aug.], as the vulgar codex of Censorinus has it, *De Die Natali* chapter 8. The year of Nabonassar 986. began at the midnight preceding the 25th of June, that is, in the meridian preceding the 7th of the Kalends of July [VII. Kal. Iul.], as Censorinus has it. But we have the incorrect example of Censorinus — not "before the 7th of the Kalends of July" [VII. Kal. Iul.], but "before the 6th of the Kalends of July" [VI. Kal. Iul.]; and thus the beginning of Nabonassar collocated in the meridian of the 26th of February of the Year before Christ 747; finally the eclipses 19 in the Catalogue preceding by Ptolemy related are to be assigned to the hours after the Meridian of the Julian Month posterior, and no prior [days] in the same Julian day designated.

II. CONCLVSIO [Conclusion II].

The Lansbergian Tables, which exhibit the Sun at the time of Ptolemy in no Ecliptic place, in which Ptolemy at the moment of the eclipse establishes [it], this

Parsing notes: this table is extremely dense, with five-to-six sub-rows per eclipse and many columns. Sign glyphs are small and ink-bled; I have flagged the most uncertain (eclipse 22's "Kerm." month abbreviation, eclipse 33's Scorpio glyph). The seconds and minutes cells in the rightmost Time and Quantity columns frequently

run together or are partly cropped by the gutter at the page edge. The bottom of the table (eclipse 35's Tychonic sub-rows) shows the "Sed si" annotation in the Mens. column for the Phil. row. Several Observ. rows give only the Quantity (Dig.) with the position cells left blank — this matches the source layout (the observation recorded only the magnitude, not the computed position). The d/e markers (defectus/excessus) are preserved as printed. Table continues beyond this page boundary.

Liber II — De Luna. Caput VI (continued)

Comparison of the astronomical tables with observed lunar eclipses, from the time of al-Battānī to AD 1660 (continued from eclipse 35).

The table continues from the prior batch. Its columns are:

- **Eclipse order / Observation & astronomical tables** [*Ordo Eclipsium cap. 2; Observatio & Tabulæ Astronomicæ*] — the eclipse number (keyed to Caput II) and, in each sub-row, the source: the observation (*Observ.*) followed by the several table-sets (Lansbergian *Lansb.*, Philolaic *Phil.*, Rudolphine *Rud.*, Tychonic *Tych.*, and also Atlantic/*Atl.*, Danish/*Dan.* [Longomontanus], Parisian/*Paris.*, Prutenic/*Prut.*).
- **Apparent time past the meridian at the place of observation** [*Tempus Apparens post Meridiem in loco observationis*]: Month | Day | Hour | Minute.
- **The Sun's true place from the tables, and hence the place of the Sun's opposition** [*Solis locus Verus ex Tabulis, & inde locus ☉ ☉*]: Sign · Degree | Minutes | Seconds.
- **The Moon's place computed from the tables** [*Lunæ locus ex Tabulis computatus*]: Sign · Degree | Minutes | Seconds.
- **Difference between the computed and observed place** [*Differentia loci computata & observata*], with the d (*defectus*) / e (*excessus*) marker: Degrees | Minutes | Seconds.
- **The time corresponding to this difference** [*Tempus huius Differentiæ*]: Hours | Minutes | Seconds.
- **Magnitude in digits and minutes** [*Quantitas in Digitis & minutis*]: Digits | Minutes.

Parsing notes: time values are reckoned past noon, so hour-values above 12 are expected and not flagged. The d/e markers (*defectus* / *excessus*) are preserved verbatim in the difference column. Sign glyphs head each computed-place block

(zodiac symbols transcribed by name). Empty cells in the source (where a sub-row repeats the row above, or where the figure was not supplied) are left blank.

Parsing notes (whole batch):

- The table's seven major column-groups are as described at the head of this batch. Within the "Differentia" group the d/e marker (*defectus / excessus*) is carried in its own column and transcribed verbatim; where the source prints *exacte* (exactly) in place of a d/e marker, that word is retained.
- In eclipses 56–66 the engraver frequently sets the "Difference" degrees-and-minutes pair shifted one column to the left (so a value like 11 30 reads as Gr.=11, I=30 with the seconds cell blank); I have transcribed the digits as positioned and left the seconds cell blank where the source leaves it blank. These layout shifts are characteristic of the dense lower-page setting and are not numerical anomalies in themselves.

- Several "Sun's place" / "Moon's place" sub-rows are blank in the source (the engraver supplied only the difference, magnitude, or time). Blanks are preserved.
- Zodiac sign glyphs at the head of each computed-place block are rendered by their English sign names (Aries, Taurus, ...); the Sun's sign and the Moon's sign are opposite, as expected at a lunar eclipse (opposition).
- Eclipse numbering skips 39, 51, 52, 61, 62, 64, 65 within this batch's range — the sequence printed is 36, 37, 38, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 53, 54, 55, 56, 57, 58, 59, 60, 63, 66. The gaps reflect eclipses Riccioli did not tabulate here (cf. Caput II catalog); they are a feature of the source, not omissions in transcription.
- Eclipse 38: the Tychonic sub-row is present (with repeated date) but the engraver left the place and difference cells blank.
- Page 121 ("*Phil.*" catchword) opens with the tail of eclipse 55, continued from the foot of page 120; the two halves are presented under a single "Eclipse 55 (continued)" rubric above.

This batch continues the eclipse-versus-tables comparison table of **Caput VI** without interruption — the table runs across all three pages with no intervening prose. Catchword "67" carries over from the prior batch.

Table structure (repeated across all three pages). For each eclipse (numbered in the *Ordo Eclipsium* column, keyed to Cap. 2 of this Book), the first sub-row labelled *Observ.* gives the observed data, and each following sub-row gives the values computed from one astronomical table-set (Atl. = Atlantic; Lansb. = Lansbergian [Philip Lansberge]; Phil. = Philolaic [Boulliau]; Prut. = Prutenic; Rud./Rudol. = Rudolphine [Kepler]; Tych. = Tychonic [Tycho Brahe]; Dan. = Danish [Longomontanus]). The column groups are:

- **Ordo Eclips. cap. 2** — eclipse number (cross-reference to Cap. 2).
- **Observ. & Tab. Astron.** — "Observation," or the table-set whose computation is given on that row.
- **Tempus Apparens post Merid. in loco Observationis** — apparent time after noon at the place of observation: *Mens.* (month) | *D.* (day) | *H.* (hour) | *M.* (minute).
- **Solis locus Verus ex Tab. & inde locus** ☉ ☌ — the Sun's true place from the tables, and thence the place of the [lunar] opposition: *Sig.* (zodiac sign glyph) | *Gr.* (degree) | ' | ''.
- **Lunæ locus ex Tabul. computatus** — the Moon's place computed from the tables: *Sig.* | *Gr.* | ' | ''.

- **Differ. loci computati & observata** — difference between computed and observed place, marked *d* (*defectus*, deficiency) or *e* (*excessus*, excess): *Gr.* | ' | ''.
- **Tempus huius Differentiæ** — time corresponding to that difference: *H.* | ' | ''.
- **Quātit. in Digit. & min.** — magnitude of the eclipse: *Dig.* (digits) | ' (minutes).

Where the *Observ.* row carries the sign glyph for the whole eclipse block, the sign glyph heads the block (per the book's convention). "exacte" in the difference column means the computed and observed places agree exactly. Time-values are reckoned after noon (so hour-values may exceed 12), and the doubled-prime notation is the source's own; neither is a numerical impossibility.

Parsing notes (folio 123): On this page the *Tempus huius Differentiæ* group is frequently printed with only two of its three sub-columns filled (the seconds column often blank), and on some rows the time value (e.g. "5 35", "6 10") sits in the H. and ' columns with the " column empty; I have aligned these to H./ accordingly. The eclipse numbering jumps from 89 to 92 (eclipses 90 and 91 are absent) — consistent with the work's stated feature that some eclipse numbers are skipped. Eclipse 82's *Quātit.* reads "1 vix" (scarcely 1 digit). Sign glyph for

eclipse 92's Prutenic Sun is □ (the value 29°45' places it in the prior sign, Aquarius, by the source).

Parsing notes (folio 124): For eclipse 97 Prutenic, the *Tempus huius Differentiæ* reads "60 26" in the H./' columns — the "60" in the hour column is anomalous in context (see Numerical impossibles); transcribed as printed. Eclipse 104 carries an unusually full block, with both Danish (Dan.) and Lansbergian (Lanf.) rows present alongside the Atlantic "exactè." The numbering skips 94 (93 → 95) and 101 (100 → 102) — consistent with the skipped-eclipse-number feature. Several seconds-columns in the *Tempus* group are left blank as printed; values aligned to H./'.

Liber II — De Luna (continued)

Caput VI (continued): Comparison of Lunar Eclipse Observations against the Tables

The comparison table continues from eclipse 105 onward. The column headings are:

- **Ordo Eclips. cap. 2.** — Order of the eclipse (Cap. 2)
- **Observ. & Tab. Astron.** — Observation, and astronomical tables
- **Tempus Apparens post Merid. in loco Observationis** (Mens. / D. / H. / M.) — Apparent time after noon at the place of observation (Month / Day / Hour / Minute)
- **Solis locus Verus ex Tab. & inde locus ☿ & ♀** (Sig. Gr. / ' / ") — The Sun's true place from the tables, and thence the place of the node (☿ descending, ♀ ascending) (Sign, Degree / minutes / seconds)
- **Lunæ locus ex Tabul. computatus** (Sig. Gr. / ' / ") — The Moon's place computed from the tables (Sign, Degree / minutes / seconds)
- **Differ. loci computata, & observata** (Gr. / ' / ") — The difference of place, computed versus observed (Degrees / minutes / seconds)
- **Tempus huius Differentiæ** (H. / ' / ") — The time corresponding to this difference (Hours / minutes / seconds)
- **Quantit. in Digit. & min.** (Dig. / ') — Magnitude in digits and minutes

The leftmost rows of each block are: **Observ.** (the observation itself); **Dan.** (Danish, Longomontanus); **Lansb.** (Lansbergian); **Phil.** (Philolaic, Boulliau); **Prut.** (Prutenic); **Rud.** (Rudolphine, Kepler); **Tych.** (Tyconic). The *defectus* (d) / *excessus* (e) markers are preserved as printed.

Parsing notes: This is a citation-grade comparison table. The "Tempus Apparens" columns (Month / Day / Hour / Minute) are stated once per eclipse on the Observ. row and repeated (Hour/Minute) down each table-row. Where a cell is blank in the source it is left blank below. Zodiac signs are given as printed symbols. The d/e markers belong to the "Differ. loci" block.

[At the foot of folio 125 the body text of the preceding page's discussion is partly visible in the gutter, very degraded and largely cut off — only fragments such as "Eclipsium ... vt vocat Cap. V ..." and "Tabulae ... Cap. V. ... Commentaria ..." are recoverable; this prose belongs to the bottom of the page and is too cropped to transcribe reliably. [?]]

Caput VII (folio 126, PDF p. 158)

CAPVT VII.

On the Excellence of the Astronomical Tables, and a Comparison among Them, drawn from the Observations of Lunar Eclipses. Wherein certain notable Conclusions are established.

I. Conclusion. None of the astronomical tables thus far named agree with all the observations of lunar eclipses; many of them with very few. This is plain from what I set out in Cap. V and Cap. VI. For in Cap. V, from no. 16 onward, I showed that the astronomical tables fall short — in representing the lunar eclipses of Ptolemy's age, going back to the years before Christ 747, exactly as they ought, place by place and digit by digit — by about twelve degrees in the Moon's place.

From this we may infer, as a corollary, that those tables cannot, without error, be used to project lunar eclipses more than about fourteen centuries back, that is, as many as have elapsed between the time of Ptolemy and the more recent compilers of tables.

[Margin: Corollarium. — Corollary.]

II. Conclusion. None of the tables already named are supported by all the observations of lunar eclipses; nor are there any that some observations do not contradict. This too is clear from a careful reading of the catalogue in Cap. VI, and now, as a particular advantage, from the tally of the individual tables in favor of each — which I shall set out, leading to the Conclusion that follows.

III. Conclusion. Standing on the bare comparison of eclipse observations — taking together both the time and the magnitude of the eclipse computed from the tables — the **Lansbergian** and **Atlantic** tables would seem preferable to all the rest, then the **Tychonic**, then the **Philolaic**; with the **Danish** and **Prutenic** following last, and last of all the **Alphonsine**. For if, from the catalogue set out above, we tally the eclipses, the Alphonsine tables are supported by 1; the Parisian by 3; the Danish by 6; the Prutenic by 6; the Philolaic by 12; the Atlantic by 15; the Rudolphine by 19; the Tychonic by 13; and the Lansbergian by 19. These are ordered in the table written below.

Tally table (folio 126)

Suffragantur (Tables favored)	Eclipses (from Cap. V & VI)	Summa (Total)
Alphonsinis	27.	1
Parisinis	20. 23. 48.	3
Danicis	13. 40. 42. 50. 77. 103.	6
Prutenicis	68. 72. 83. 85. 101. 103.	6
Philolaicis	10. 15. 19. 29. 46. 76. 81. 86. 95. 110. 117. 118.	12
Atlanticis	49. 60. 63. 67. 69. 70. 74. 75. 87. 93. 96. 97. 100. 104.	15
Rudolphinis	2. 4. 5. 16. 18. 26. 32. 34. 53. 17. 18. 26. 32.	19

Suffragantur (Tables favored)	Eclipses (from Cap. V & VI)	Summa (Total)
	34. 53. 81. 82. 192. 119.	
Tychonicis	35. 41. 44. 45. 57. 71. 80. 88. 89. 98. 99. 108. 116.	13
Lansbergianis	3. 14. 16. 22. 23. 24. 33. 36. 37. 38. 47. 50. 54. 55. 56. 58. 59. 101. 107.	19

Parsing notes: This decorative-framed tally is transcribed as a pipe-table per the table rule. The numbers in the middle column are eclipse-order numbers (from the catalogue in Cap. V & VI), not coordinates. The Rudolphine row visibly repeats a run of numbers (2.4.5.16.18.26.32.34.53. then 17.18.26.32.34.53. ...) — this duplication appears in the source as printed and is preserved verbatim; the printed Summa is 19. One entry reads "192." which is likely a compositor's run-together of "19." with an adjacent figure [?]. The Tychonic Summa is printed 13 but I count 13 listed values (35.41.44.45.57.71.80.88.89.98.99.108.116.) — consistent. [See anomaly (a).]

IV. Conclusion. Yet judgment of the tables' excellence over the others cannot be passed on the bare comparison of the aforesaid observations with the tables' computation with any certainty. For just as the tables' agreement with the observations is not a sure indication of their agreement with the heavens and with the truth, so neither is the tables' disagreement from the observations a sure argument of their disagreement from the heavens and the truth. Indeed it can happen that the tables' agreement with the observations arises — in not a few cases — not from truth but from an error in transferring the time of the meridians of the observation to the meridian of the tables: a false agreement, whether because the very observation was faulty, or one out of many, or because false figures were entered (as I have noted for ourselves, and for others), or from several of the causes enumerated in Cap. IV; or at least because, among many observations of the same eclipse, that one chanced to be consonant with the heavens which least agreed with them. Hence it can still be doubted whether the discord of the tables from the observations arises from an intrinsic defect in the astronomical tables — namely from a false mean motion of the luminaries and of the anomaly, or from the eccentricity and prosthaphaeresis founded upon it, or

from the form of geometric hypotheses (circular or elliptical) assumed in it. Or indeed from an extrinsic defect in the construction of the equations. Or, on the other hand, from an extrinsic defect — from the geographical distance of meridians wrongly assumed. Or, finally, from a defect in the observation itself.

[Margin: 3 (i.e., third margin-note marker on the page); the marginal Arabic figures 1, 2, 3, 4 run down the right column keying the numbered points of the discussion.]

It is worth the effort, then, to discuss the three above-named sources of disagreement between the tables and the eclipse observations — to treat each one a little, and to apply them to certain tables, by establishing the **distance of meridians** as my starting point.

The distance of the meridians, that is, the difference of longitude, which I have used in the Tyconic, Rudolphine, and Philolaic calculation, is the very same I reviewed in Cap. I; and I took it from my *Geographia Reformata*, relying on certain eclipses and on the intervals of journeys, so that I scarcely suspect it of even the smallest error. But the distance which Lansberge and Wendelinus [Govaert Wendelen] used in their computations I judge not so certain, and in some places perceptibly false. Therefore, for the eclipses computed by the aforesaid authors from the Philolaic tables, I judge a greater disagreement and the incurring of a larger error — and, conversely, somewhat less — than would otherwise be the case.

Let the example be, first, from Lansberge, who supposes Aracta [Arak] to be more easterly than Goesa [Goa?] by 5 hours; whereas in our ordering, which Lansberge has in his *Thesaurus* at 14, the difference is greater [?]. From his own tables computing, he finds Goesa at hour 4. 27', with the Sun apparently at the 3rd degree 53'. 43" of Leo, and the Moon at the 3rd degree 53'. 43" of Aquarius; and thus he most exactly determines the moment of opposition of the luminaries, nothing further. He pushes his own tables to that observation, that they may differ thus far: namely Aracta the more easterly than Bologna by 2 hours 12', and Aracta to Goesa by 31'; and so much from Goesa, by 5 hours; so that the whole comes to only 1 hour 43' — but minutes of hours rather, the nearer Aracta and Goesa are to each other, than Lansberge assumes. Wherefore, if from our distance of meridians we should repeat the Lansbergian calculation, we should repeat the Sun at the 3rd degree 15'. 31" of Leo, the Moon truly at the 1st degree 17'. 52" of Aquarius — this being a transgression of the moment of opposition by 24'. 9" of zodiacal minutes; and therefore the Lansbergian tables would exhibit

this eclipse earlier by 24' of time than the observation of Albategnius [al-Battānī] proves.

[Margin: the marginal Arabic numeral "4" keys the next point.]

Similarly Wendelinus supposes Hercam [?], his native land, to be more westerly than Huenna [Hven], and Vraniburgum [Uraniborg] by 1 hour, when as to me it is more westerly than Uraniborg by 31'. Wherefore, if his calculations in the eclipses observed at Uraniborg I repeat, I shall find a difference of six minutes in time. And if there be anyone who would not deign to recognize how much the more celebrated tables differ from the observations in time, the distance of meridians being supposed from our *Geographia Reformata*, neither would I begrudge undertaking this labor again — though it differs from the prior 19 eclipses, ancient ones in which a single table contains nearly the whole error of the day, as I showed in Cap. V. The rest I will examine by the same method, and from the other part of the computation it will be established which of the more recent tables more nearly represent the time of the observation. Contemplate, therefore, the.

Caput VII (continued): Difference-of-Time Table (folio 127, PDF p. 159)

[Continuation of the prose from the foot of folio 126:] ...the following little table, in which the Atlantic, Danish, Lansbergian, Philolaic, Rudolphine, and Tyconic tables are indicated (At. = *Atlanticas*; D. = *Danicas*; L. = *Lansbergianas*; Ph. = *Philolaicas*; R. = *Rudolphinas*; T. = *Tychonicas*), and the order of eclipses is held running leftward, while the minutes truly run rightward, and the second [column] of time, by which the tables here predicated discrepate from the time of observation, chosen according to the prior table — but the meridian-distance being supposed from our *Geographia Reformata*.

Difference-of-time table by eclipse order (folio 127)

Column headings (repeated across four sub-columns of two-column pairs): **Ordo** (eclipse order) · **Tabula** (table abbreviation: A./At. = Atlantic, D. = Danish, L. = Lansbergian, Ph. = Philolaic, R. = Rudolphine, T. = Tyconic) · ' · '' (minutes and seconds of time-difference). The table is printed in four vertical blocks; I transcribe them in reading order (left pair, then right pair).

Parsing notes: The "Tabula" cells use the abbreviations A. (At.), D., L., Ph., R., T. Each eclipse-order number spans the set of table-rows beneath it. The two numeric columns are minutes (') and seconds ('') of the time-discrepancy. Several

second-column zeros and small values are faint; flagged where uncertain. The leftmost two blocks are on the left half of the page, the rightmost two on the right half.

Liber II — De Luna

Caput VII (continued)

Difference-of-time table (continued, Ordo 99 onward)

The table continues from the prior batch (catchword "99."). It lists, for each eclipse (by *Ordo*), the residual time-discrepancy (columns I and II, in minutes ' and seconds ") for each set of tables: D. = Danish [*Astronomia Danica*, Longomontanus], Ph. = Philolaic [Boulliau], R. = Rudolphine [Kepler], T. = Tychonic [Tycho Brahe], At. = Atlantic [Riccioli's own], A. = Alphonsine, L. = Lansbergian [Lansberge]. The page is laid out in two columns of table-blocks.

Left column (Ordo 99–106):

Ordo	Tabula	I (')	II (")
99	Ph.	7	41
99	R.	2	49

Ordo	Tabula	I (')	II (")
99	T.	11	0

119	Ph.	1	21
119	R.	1	11
119	T.	3	20

Parsing notes: The body of the table prints only single-letter/abbreviated tables and two numeric columns (minutes, seconds) per Ordo block. Skipped Ordo numbers (102, 109, 111–116) are a source feature, consistent with the skipped-eclipse-number pattern. Ordo 100's first row (A. = Alphonsine) is partly ink-faded

in the gutter region and both numeric cells are unreadable — flagged [?]. Ordo 100 prints two consecutive "R." rows as shown; whether the first should read a different abbreviation could not be confirmed from the scan.

It is therefore clear from this comparison that the Tychonic tables deserve first place; next the Philolaic; after these the Atlantic; then the Rudolphine succeed; and the Danish; and finally the Lansbergian, which held first place in the earlier comparison — could not in this one keep that position. For the said tables are corroborated by the eclipses noted below.

[Margin: 5]

Another source and cause of the discrepancy could be, as we have said, the very fallaciousness of the observations, owing to the four causes noted above in Chapter Four. For sometimes the discrepancy is so great that its whole cause cannot be assigned to a false reckoning of the meridian-distance. Take as an example Eclipse 32, observed at Nuremberg by Bernhard Walther [Walther] in the year 1487 on the 7th of February, at hour 5' 47" past noon by the clock — that is, at Wraniburg [Uraniborg], by the Rudolphine and Philolaic tables, at hour 13' 51"; yet by the Philolaic tables it appears at hour 16' 3". At that moment the Philolaic tables show the Moon already past the place of opposition by minutes 19' 53"; the Rudolphine, by 13' 4". The Opposition of the Moon with the Sun would therefore have occurred more swiftly by 39' 45" by Philolaic reckoning than by Rudolphine — I say "more swiftly" than Walther noted. This great a discrepancy cannot be ascribed by any expert astronomer to geography — that is, the whole of it cannot be thrown back upon the distance of the meridians, which in the Rudolphine and Philolaic tables is 4' of time; for if 4' is the very least minimum of all that others have assumed, who set Nuremberg west of Uraniborg by 5' — the Danish and Parisian tables by minutes 5', Nor[th] by 8'; the Atlantic by 9'; the Lansbergian by 12'; and Tycho (Tom. 1, Progymn. p. 51) by nearly a quadrant of an hour, that is, 15'.

Therefore, if the time is referred from the meridian of Nuremberg to Uraniborg, following the opinion of others, the start of the reckoning would have been later, and again the Moon would have been farther advanced and grown larger; and the discrepancy of time — to me at least it would have been 43' Philolaic minutes against 30' Rudolphine — is so far from being removed, that, in order to reconcile the meridian-distance of these places with the said tables, prudent judgment rejects a great part of the discrepancy. Indeed, the observation itself appears very doubtful from Walther's own narrative, where he says: "In the year 1487, on the 8th of February, I observed the eclipse of the Moon at about the second hour past

midnight, beginning in the early morning; and while the Moon was eclipsing, the Sun's Nadir was at an altitude of 29 degrees, at the middle of the eclipse; but at that time the clock indicated three hours and 47'. And at the end of the whole observation I obtained the Sun's altitude at 24 degrees, the clock at 4 hours and 18'. The end of the eclipse was after midnight by 5' 20', past the middle hour, and so forth." Examining the time from the altitudes, and comparing them: at the middle time of the eclipse, between the Lion's Heart [Cor Leonis, Regulus] and the Sun's Nadir, there were 35 degrees; thus the Moon's latitude had been southern. Likewise the true place of the Sun's Nadir at the middle time of the eclipse ought, by calculation, to have had sign Aquarius 28°, 39' 44" — but the arc between the Lion's Heart and the Sun's Nadir was gr. 5° 24'; and within this very place of the heart it would have been at sign 4° gr. 23° 15' 44", but only so much, not so much. Thus that excellent old man, who freely admits he was not so confident in his own foresight, and dares to doubt it, brings the matter into question. He could then, by reason of the shadow's vapors, have been deceived at the beginning, and at the end, since the eclipse's beginning was perhaps not noted to the second; but at the end indeed, and at the beginning, it yields the middle at hour 3' 40" past midnight, by 3' 47", and by the clock we noted. Therefore, when everything is reckoned, the middle of this eclipse would probably have been 20' and more swifter than Walther computed at the outset, and so on. As for the rest of the discrepancy, let it be referred back to the tables themselves, meanwhile, if the following conclusion holds:

V. Conclusio. The whole discrepancy between the astronomical tables and the observations of the foregoing eclipses cannot always be ascribed to a false meridian-distance assumed in computing the eclipse; rather, it must be ascribed either in part to a fault of the observation, or of the tables, or of both at once.

Eclipses not faithfully or not concordantly reported.

[Eclipses non fideliter, vel non concorditer relatæ.]

[Margin: 7]

This has already been proved by a single example in the foregoing — that is, from number 1, and we will show it in many more; but what pertains to the faults of the observations — whether faults of execution, or faults disfigured by the writers — provides no slight indications, which it is not without value to point out.

Eclipse 29. Lansberge, in his *Thesaurus Observationum Lunarium*, Classis 1, Eclipse 17, having followed Regiomontanus, notes that the eclipse occurred at

Viterbo at hour 14' 48" past noon. But from the truer place of the fixed stars, as we narrated in Chapter 2, we find the hour to have been 14' 37"; and so, by this account, the difference of Right Ascension and Declination of the Eagle [Aquila], which Regiomontanus used, makes the time of the observation labor under an error of eleven minutes.

[Margin: Regiomontani hallucinatio. — Regiomontanus's error.]

[Margin: Lansbergii hallucinatio. — Lansberge's error.]

Eclipse 35. Copernicus, *De Revolutionibus* lib. 4, cap. 13, says that the eclipse he observed was seen at Cracow after midday at the equinoctial hours 11, and three-fifths of one hour — that is, at minutes 36'; at Lansberge in the *Thesaurus Observationum Lunarium*, Classis 1, Eclipse 19. From the same book of Copernicus, and from the very chapter, he asserts the observation was made at Cracow after midday at hour 11' 45" — namely at three-quarters of one hour — and lest you think it a typographical error, he adds further that it was at the time apparent at Goss[au] [Frombork], hour 10' 23"; this agrees with the difference of longitude which Lansberge sets, in his *Catalogus Urbium*, between Goss[au] and Cracow — namely, hour 1' 22". Therefore, either by a slip of the imagination, or by an error of memory, he used the three-quarters for three-fifths of an hour, and exceeded it by 9' in noting the moment of the observation.

Longomontanus likewise reckoned many eclipses otherwise than Tycho, as is evident from his *Catalogus*, Chapter 2 and 3, of which this is the synopsis:

Ordo Eclips.	Tycho H.	Tycho '	Longomont anus H.	Longomont anus '
41	11	32	11	25
44	13	17	13	24
46	9	58	10	0
47	16	57	17	0
48	13	8	13	9
49	9	16	9	30
50	14	48	15	2
53	6	55	7	0
55	19	26	19	16
56	16	36	16	30
57	9	29	9	25

Ordo Eclips.	Tycho H.	Tycho '	Longomont anus H.	Longomont anus '
59	7	26	7	37
60	13	56	13	56

Parsing notes: The table has four numeric columns under two named astronomers (Tycho: H. = hours, ' = minutes; Longomontanus: H., '). All cells read cleanly.

But not even Tycho himself is consistent with himself in reporting the moments of eclipses, as in Eclipse 48.

Eclipses determined by mere conjecture.

[Eclipses ex mera coniectura determinatæ.]

[Margin: 8]

Sometimes, too, the moment of an eclipse is found noted as a maximum, or as a middle, not by the phases of mere observation, but from a single phase — whether from the beginning alone, or the end — from which the middle has been deduced by mere conjecture, or by some hypothesis not sufficiently certain. Thus Ptolemy, in the first eclipse observed at Chaldea [Babylon], adds two whole hours, reckoning the total eclipse to have lasted hour 11' 45" past midday — namely three-quarters of one hour — and lest the total eclipse be reckoned to have lasted to the third initial observation at Babylon, that it might obtain the middle, since he supposed it to be by mere conjecture. 1. The eclipse lasted 6 digits, the total lasting hour 3', nearly. He reckons the eclipse's quarter to have begun by being observed at Babylon, adding hour 1'. He determined the middle. He reckoned the eclipse of three digits to have lasted hour 2'. Moreover, Eclipse 8. He determined the middle moment partly from the beginning, partly from the end, hour 1' 30"; and what he reckoned the small eclipse to have lasted was no more than hour 1' 30", nearly — and so Petavius [Petau], lib. 8, *De Doctrina Temporum*, thought worthy of particular examination. Again, Eclipse 10. He deduced the middle from mere observation handed down at the beginning, and from his own opinion thereupon, by which he supposed the total eclipses to last hour 4', nearly; thence adding hour 2' to the beginning, he set the middle, hour 4'. But Petavius, lib. 8, *De Doctrina Temporum*, p. 812, denies that this eclipse could have lasted beyond hour 5' 48"; and so he taxes Ptolemy's annotation as a [Greek: ἀλόγηρον (alogēron?, "without reckoning" — unreasoned) [?]], as we noted in the earlier *Catalogus*, Chapter 1. See the passages of Ptolemy there indicated.

Tycho too seems to have affirmed the middle from sole conjecture, as in Eclipse 42, whose end Wendelin [Vendelinus, Govaert Wendelen] disputed; and likewise, concerning Eclipse 47 and 57, with the initial middle defined by Tycho, he speaks thus: "That middle of Tycho's, indeed not seen by his own observation, but obtruded by his conjecture and calculation: for he was able to see only its beginning; the Immersion, the Emersion, he was not able [to see]; the End he was not able [to see], because all these things happened after the setting of the Moon; and so on." And elsewhere he writes thus: "(This eclipse was at least so observed, that the Moon, half-eclipsed, had entered the shadows before she set.) Nothing certain, therefore, is to be had from these assertions of Tycho." Thus far Wendelin, who, as also concerning Eclipse 17, follows the middle of the eclipse as defined by Tycho to Tycho's [conclusion]; and at the end of the eclipse he asserts, with Tycho mediating, hour 8' 16", the Moon's middle determined boldly, since he had been able to perceive nothing beyond the beginning at Uraniborg [Huenna]. With the Sun rising there, the Moon set; he says these tables had that middle at hour 8' 44" at Wraniburg [Uraniborg]. And of Eclipse 69, he says that produced from Lansberge by calculation rather than by observation, while from the observation, I say, he speaks; the end of which is not seen by himself, he could not have so established it. But Lansberge perhaps noted the immediate middle from the maximum of the eclipse, 8 digits.

The remaining indications of eclipses not accurately observed.

[Eclipsium non accurate observatarum reliqua indicia.]

[Margin: 9]

As often as the observers themselves confess that they used poor instruments — as we have not seldom indicated in the history of Chapter 2 — or that their observation differs greatly from the observation of others of no less faith and diligence among the Authors, then it is in some measure probable that there is a fault in the observation. Thus in Eclipse 43: Tycho's middle is asserted to be fallacious, as we noted concerning the Tyconic eclipse, from the observation of others. Likewise in Eclipses 16 and 56, which is the Tyconic — Eclipse 16 from the Hercanian [?] observation is refuted on account of a discrepancy of 23'. Tycho exposes a great discrepancy of observation in Eclipse 80, of which Wendelin treats on page 83 of his *Eclipses*; and in Eclipse 98, of which on the same page 101; and in Eclipse 106, of which I have spoken — concerning which, in Chapter 4 at the end, he gives the reason on account of our observation, which we preferred to the Wendelinian.

Eclipses whose discrepancy between observations and tables must be ascribed in part to a fault of the tables.

[Eclipses quarum dissidium inter Observationes, ac Tabulas necesse est ex parte adscribere vitio Tabularum.]

[Margin: 10]

There are four indications of some latent fault in the astronomical tables, when they differ greatly from observation. The first is, that the eclipse was very long, and therefore of very brief duration; as were Eclipses 8 and 82 and 89: in these the middle could not have erred by mere conjecture, with few intervening. Hence, when the Prutenic tables differ from the observation of Eclipse 89 by minutes 48', it is plain they are in error in this.

The second indication is the enormous discrepancy of the tables from the observation of a single observer — though it be reliable — if the middle, or the immediate maximum or the partial beginning, was deduced from a clearly noted observation; for then beyond half a tenth-part [?] it is improbable, as in Eclipse 9, 11, 13, and 14, which Ptolemy did not establish from conjecture, but at once both from the beginning and from the middle, with this annotation handed down: that in these (I say, in the others) similar [discrepancies], the tables being absent from observation beyond half a tenth of an hour [?] — let no one with little doubt convene that they are vicious, the meridian-distance being excluded, if they were not brought together into a part of the discrepancy.

The third indication is the closer consensus of several observations of the same eclipse, recalled to the same meridian, of which kind is Eclipse 48 in particular, which Wendelin's tables resist, and so the consensus of the other observers favors the Tyconic rather; and Eclipses 63, 71, 86, 88, 89, 92, 93, 95, 96, 102, 103, 104.

The fourth indication is, unless the meridian-distance manifests a fault in the tables, if they could in no way have observed the eclipse in the horizon, when nevertheless these eclipses are worthy of being observed: such is Eclipse 8, which Petavius, weighing it in lib. 8 of *De Doctrina Temporum* p. 799, shows could very least have been seen at Babylon, if the calculation drawn from the Alphonsine, Ptolemaic, Prutenic, or Danish tables be attended to.

Caput VII (Conclusions VI–VIII)

VI. Conclusio. From the inspected goodness of the astronomical tables within certain limits, if some eclipse-observations differ too much from the tables, a probable judgment can be made of some fault of the observation. For when in many observations of the observers, by a close consensus, the tables agree within a few scruples, the tables are nevertheless not the best for every age — and so certain limits are established within which the whole error of the observations is contained as possible. Therefore, these things being established, if some eclipse-observations differ from the tables beyond those limits, it is probable that that excess proceeds from some fault of the observations, or from a less accurate, or less faithfully recorded one.

[Margin: 11]

Now, gathering up the earlier *Catalogus* of Chapter VI and beginning from the eclipses of our own age — that is, from Eclipse 63 — the discrepancy of the tables, which differs from the observation within 5', results in minutes; or at least within 10' in the eclipses subscribed below. And so, in the eclipses 31, the Tyconic tables agree with the observation within 10'.

The following is a tally-table (printed within a ruled frame, with the heading *Eclipsium Numerus pro Tabularum, & Observationum consensu* — "The number of eclipses for the consensus of tables and observations"). It is transcribed as a pipe-table below:

Tab.	Intra 10'. temp.	Intra 5'. temp.
Atlantica	12	[blank]
Danica	8	6
Lansberg.	12	6
Philol.	28	17
Rudolph.	29	17
Tychonica	31	17

Parsing notes: The "Intra 5'. temp." cell for *Atlantica* is blank in the source (no value printed). Heading translated: "The number of eclipses for the consensus of the tables and the observations" / column heads: "Within 10' of time" and "Within 5' of time."

[Margin: 12]

But if the *Catalogus* of this Chapter VII be examined, after number 4 placed there — in which, from our reformed and corrected geography, the meridian-distances having been put down — we have set the difference of the tables from the observations in time, for the consensus of the eclipses; the number of the eclipses is found, for the consensus of the tables and observations, within 10', or at least within 5' of time; namely, as in the following table:

Tab.	Intra 10'.	Intra 5'.
Atlantica	13	[blank]
Danica	7	5
Lansberg.	6	1
Philol.	17	10
Rudolph.	27	14
Tychon.	28	15

Parsing notes: The "Intra 5'." cell for *Atlantica* is again blank in the source.
 Column heads: "Within 10'" and "Within 5'."

[Margin: 13]

From this new comparison it appears that Wendelin, in the *Idea* of his Atlantic tables, had had some foundation for approving the eclipse-observations, when they more nearly agreed with his own tables, which he chiefly effected in the eclipses that pertain to our order: 44, 46, 49, 53, 54, 55, 58, 59, 60, 72, 76. But he reproved them when they differed enormously from his own tables — as appears in Eclipses 40, 41, 43, 44, 45, 47, 50, 57, 69, 75: not only in the amount by which the followers of the Philolaic, Rudolphine, and Tyconic tables had those eclipses within 10', but in much more — these very same Tyconic [tables] within 5' — they favored, more than the Atlantic tables. Whence arises for us the following, and worthy of being known:

Continued conclusions of Caput VII

[Conclusion, continued from the preceding Conclusion.] But meanwhile, on behalf of the preceding Conclusion, let me warn that the suspected observations are deservedly thought to be of some falsity — the observations of the eclipses of our own age 68, 76, 84, 87, 96, 97, and 105 — since they are too greatly at variance with the tables. These either differ from the tables, the Tyconic in particular, or from many eclipses of our own age accurately [observed], or from the near consensus of the observers who observed them, within 10'; and even within 5'.

VII. Conclusio. In the lunar eclipses of our own age — and probably also in those that preceded, and that will follow, by representing them — the Tyconic tables obtain first place; the Rudolphine and Philolaic obtain second place at nearly equal [merit]; and the Atlantic third.

[Margin: 14]

For by my indication, indeed — which I hope to have proved by a few of these tables — those tables that are pure [accurate] within 10', or at least within 5' for the most part, or which satisfy better observations than the tables, which satisfy more observations indiscriminately, or which lie satisfying [merely], but refute many select observations.

Accordingly, although both the first comparison — and from what has been said for *Conclusion III* — the Lansbergian tables obtained first place, the Rudolphine 2, the Atlantic and Tyconic 3; yet from the second comparison, as has been said, by number 5: the Tyconic first; the Philolaic and Atlantic 3; the Rudolphine 4 — they have come out. Yet in this third comparison, and against this table, it is established that the Tyconic tables, by the consensus of the select eclipses of our age, agree with the observations within 31', or within 28' within minute 10'. But the eclipses within 17', or within 15', within minute 5'; and so the rest excel by the other tables, after these the Rudolphine and Philolaic at nearly equal number; and then the Atlantic.

VIII. Conclusio. On account of the discrepancy of the astronomical tables from the observations of our eclipses, or for the neighboring ages, the astronomical *Equation of Apparent Time* is not to be despised, [nor] commuted into the equal [time]; nor is another form of this equation to be introduced.

[Margin: 15]

For the astronomical equation, by which the time of days — civil, or natural, that is, apparent — is converted into the equal, for the examination of observations, arises and is double, and certain among astronomers is a necessary cause. The first is that which arises from the obliquity of the ecliptic, and is the difference between the true place of the Sun in the ecliptic and the right ascension answering to it, converted into time. The second is the difference between the mean motion of the Sun and the middle [motion], arising solely from the eccentricity in the circular hypothesis; but in the elliptical hypothesis it arises partly from the apparent equation, and partly from the optical equation of the Sun's acceleration on account of the eccentricity of the centers of the ellipse, distant from the center of the Earth by a hundredth part nearly; and is really

physical — namely the acceleration of the Sun about the center of the ellipse, in that the other focus, or umbilicus of the ellipse, is the point about which the Sun is moved with a middle, or equal, motion. When, therefore, by these causes it necessarily follows that this effect [arises], and sometimes — but rarely — the apparent time is made equal to the middle, or equal; sometimes, and more often, greater, or less than the equal time, the said equation is necessary, and beforehand.

[Margin: 16]

Moreover, by using the astronomical equation of time, not for fewer — indeed for several — eclipse-observations selected to represent the astronomical tables, lest the equation beforehand be passed over, or lest another form of equation not demonstrated be used; as is plain from the table of number 5, 11, and 12. For we, in the Philolaic, Rudolphine, and Tyconic calculation, have used such an equation; and the reformed first table of the first cause of equations, according to a truer obliquity of the ecliptic — but we have followed the other cause, the Bullialdine [Boulliau's], who of all explained it best, and most scientifically, concerning the astronomical equation, lib. 2 *Astronom. Phil.* cap. 5, 6, and 7.

[Margin: Bullialdi laus. — Praise of Boulliau.]

[Margin: 16]

First, therefore, by saying this, we shall remove the false opinion of those who think every form of the astronomical equation of natural days — of which kind were Christmann [Kristmannus], Vrstisius [Wursteisen], and Wendelin [Vuendelinus] — against whom see Boulliau, lib. 3, *Astronom. Novi* cap. 32; even Wendelin introduces, in *De Luna Oscillatoria*, certain prosthaphaereses.

[Margin: Error Kristmanni, Vrstisii, & Vuendelini. — The error of Christmann, Wursteisen, and Wendelin.]

Second, by Tycho's and Longomontanus's equation, with the Bullialdine [equation], we do not approve, inasmuch as it is diminished: for although the greater part of the astronomical equation arises from the first of the said causes — namely from the Difference of Right Ascension —

Liber II — De Luna (continued)

Caput VII (conclusion) — Conclusion VIII continued

[Margin: *The defects of Tycho and Longomontanus.*]

the Difference of Right Ascension and of the true place of the Sun in the ecliptic — and this alone Tycho and Longomontanus retain. They do so because it has been seen to satisfy most eclipses, and on that account they call it the *Keplerian Empirical* equation. The other cause, however, ought not to have been omitted, even though it cannot be sufficiently demonstrated from eclipses. And yet Longomontanus admits in his *Commentary on the Sun* that it is nearly always abandoned without good reason; for this reason astronomers have found fault with Kepler — that he laid down this equation as a foundation of the *Ephemerides* (see number 30).

[Margin: *Kepler's fiction.*]

Thirdly, the new form which Kepler calls *Physical* we judge to be by no means necessary; nor does Kepler himself introduce it in the *Rudolphine [Tables]* as though he thought it necessary, but only sets it forth as an experiment, so that astronomers may examine which of these three forms gives a better account of the observed eclipses, and whether it has been demonstrated truly from the two aforesaid causes, or whether it arose empirically — Tycho's from prior data, or whether it took its origin physically from the aforesaid causes — and, beyond this, [whether it can be derived] from the supernumerary days of the year, namely 5, and the 6 hours, by which the solar year exceeds 360, that is, the number of degrees of the equator. For this fiction has no other foundation than a certain ideal phantasm in Kepler's mind.

Fourthly, in agreement with Boulliau (*Astronomia Philolaica* II, ch. 7) we reject the form of the Equation of Time devised by Giovanni Battista Morin [Jean-Baptiste Morin], which is founded on the difference of the mean place of the Sun alone, or on the difference of the Right Ascension of the true place of the Sun, while nevertheless admitting the two causes of the equation of days, namely the obliquity of the ecliptic and the eccentricity of the Sun — against whom Boulliau argues much in the same place.

Fifthly and finally, we least of all approve the daring of Lansberge [Philip van Lansberge], who, as often as he saw his own Tables differing notably from the observations of eclipses, introduced an Equation of Time as great as was

necessary to make the Tables themselves agree wholly with the observations, but without any reasoning *a priori* — indeed without sufficient experiment *a posteriori*; for neither one nor the other eclipse suffices to establish so great an Equation. And he used to say that another occa-

sion would [require it], with Kepler bearing witness — and this is a *Great Affirmation, a great foundation of the work*. And yet Lansberge, at his precept 8, says: "*But let us truly warn that, if either Luminary should fail at the very beginning of Aries, 30 minutes of an hour are to be added to the time of the Mean [conjunction].*" But in the *Treasury of Lunar Observations*, Class 1, where he records lunar eclipses, in one case only — namely the eclipse of the Moon of 23 [March], which is well known to us, observed at 38 minutes past [the hour] by Cornelius Gemma [Cornelius Gemma] at Louvain, of which the beginning he observed at the hour 15.40 — there the Tables of Lansberge gave the beginning of that [eclipse] at Louvain at the hour 15.6'. On this account Lansberge there adds: "*On account of the Equation of Time in the Moon, there are to be added to the time of the apparent [conjunction] 30 minutes of an hour. Therefore the Moon at Louvain ought to fail at 15.36' past noon, as Cornelius Gemma observed most nearly.*" But it would have been more exact had he added 36 minutes; for then the agreement would have been complete — if indeed this Equation depended on his own arbitrary judgment rather than on mere [reasoning]. He used to promise [as much]. And in truth, proceeding sincerely, I acknowledge that some defect is to be admitted, partly in the observation, partly in the Tables. Certainly the *Rudolphine* and the *Tychonic* Tables — though without the Lansbergian Equation — represent the middle of that eclipse within 5 minutes of time, whence an argument can be drawn from the beginning.

Again, however, Lansberge, in Class 1, having examined the solar eclipse of the 18th [of the month] celebrated in the 6th degree of Aries, adds 30 minutes, so that the observation may agree with his own Tables; and yet in the lunar eclipse of the 37th [in his series], which is the 69th to us, although it was determined in the 4th degree of Aries, he adds nothing, because this little device of his Tables does not need it.

[Margin: *IX. Conclusion.*]

IX. Conclusion. But neither does the change of eccentricity — on which the *prosthaphaereses* of the first inequality of the Moon depend — suffice to reconcile the Astronomical Tables with the observations of eclipses.

Parsing notes: Page 164 (p. 132) carries eclipse orders 43–119, grouped in ruled blocks. A spanning rubric between Orders 47 and 48 reads *Deinceps Dies stylo Gregoriano* ("Hereafter, the days in the Gregorian style"), marking the calendar switch. The block boundaries fall at orders 47/48, 54/55, 59/60, 68/69, 74/75, 81/82, 86/87, 93/95, 99/100, 105/106. All minute/second cells were re-transcribed cell-by-cell in a focused further reprocess and now read with confidence (no residual [?]); no minute or second value exceeds 59 and all degree values fall within 0–29 of their sign. Order 106's *Tempus differ.* pair (I = 2, II = 15) is anomalous — the time-difference is smaller than the longitude-difference (diff 9'2"), against the usual $\square 2\times$ relation — and is kept exactly as printed as a suspected source (compositor) error, to be footnoted later. Catchword at foot: "In"; the foot also shows faint gathering-tick marks at the gutter.

Caput VIII (continued) — Notes on the foregoing Catalogue

[Margin: *Explanation of the foregoing Catalogue.*]

1. In the preceding Catalogue — drawn from the history of eclipses of Chapter 2 and of the Epitome of Chapter 3, when the same eclipse was observed in several

places — I chose the time intermediate between the extremes, accommodated to the Meridian of Bologna, which is our Reformed Geography Meridian — excepting one [eclipse], or one selected Eclipse whose single time of observation I chose, having carefully examined the [observer's] diligence in the one case, and Gassendi's [Pierre Gassendi] in the other. The Apparent Time, moreover, I converted into Equated [Time] for both, by means of the Astronomical cause — namely the eccentricity of the Sun, and the obliquity of the ecliptic, 23°30'20".

2. The place of the Sun, by our Tables of Book I, I computed and constituted at the moment of the equated full Moon of the eclipse. It is established, moreover, that we have in that Book I a place of the Sun more exact than is represented by the Tyconic or Philolaic Tables, and one resting on the Rudolphine or Philolaic [Tables]; both on account of the manifest error in the Tyconic parallax of the Sun, which is too great, and likewise on account of the obliquity of the eclipse; and likewise, on account of the much more certain — because more refined — observations of the Sun made in the great Gnomon which we have in the Temple of San Petronio at Bologna. Therefore, if the Tyconic, Rudolphine, or Philolaic Tables represent the bounds of certain eclipses within a briefer span of time, it is permissible to suspect that some fallacy lurks on account of the place of the Sun being less accurately exhibited by them; and that therefore the Moon appears in a position closer to the opposition of the Sun than it really was the more remote.

3. The mean motions of the Moon and its Anomaly I have investigated rather *a posteriori* and empirically than *a priori* and by geometric demonstrations; and I have chosen them from the more certain eclipses, with the calculation repeated in turn through several [eclipses], so that they might satisfy more observations of eclipses. For which cause likewise I chose the Radices of the mean motion of the Moon and of the Anomaly written below, fixed to the Meridian of Bologna and to the last [day] of December.

Epoch of the Year of Christ 1600 completed, in the Gregorian style

	Sig.	Gr.	I	II
Mean motion of the Moon from the equinox	□	7	25	19
Motion of the simple	□	0	7	27

	Sig.	Gr.	I	II
Anomaly ☉				

Parsing notes: the radix table has two data rows; the leading "Sig." column carries ♈ (Aries) for both, then degree/minute/second values. The Moon row reads 7 25 19 20; the Anomaly row reads 0 7 27 9.

For my mean motion of the Moon, simple, is meanwhile [taken] from the equinox, an Annual [motion] of 129° 23' 2" & 30" [?] approximately, as I shall show afterward from another source. The Annual motion of the Anomaly likewise I establish at 88° 43' 7" 34" 21" — as much as Boulliau also establishes, who in Book 3 of his *Astronomia* was most diligent in this inquiry into the Anomaly; and his felicity in it was great, and in the mean motion Kepler came nearer to the truth in this our age.

4. The *prosthaphaeresis* of the first inequality of the Moon I recognize as much better derived from the circular hypothesis, which Epicyclic [reasoning] very often calls [it], and which is most nearly Tychonic, than [the one] derived from the elliptical form of Kepler or Boulliau — though this latter is not rarely very near to the celestial phenomena.

5. Resting upon these foundations, after innumerable labors of computation undertaken by myself, exercised in this practice by many friends, I constructed the New **Luni-Solar Tables**, which we give separately among the Astronomical [Tables]; and these, [tested] against the eclipses set forth in the preceding catalogue, represent [them] within 10 minutes of time, [or] within 12 minutes; while the minute of the eclipse [is represented] within 44 — but within 5 minutes of time of the 19 eclipses. From al-Battānī down to here, no Tables — that is, the Tychonic indeed, the Rudolphine, or the Philolaic (if anyone deduces it from what has been said in Chapter VII, number 12, and from the Catalogue of this chapter) — have provided this; the comparison is as follows below.

Eclipses

represented

within minutes

of Time	10'	5'	12
Tab. Tyconica	28	15	
Rudolphina	27	14	
Philolaica	27	10	
Nostra (Ours)	35	19	44

Parsing notes: the header row lists the time-band thresholds 10', 5', and 12 (the third header reads "12" as printed — i.e. 12 minutes, confirmed by §5's prose "intra 12. minuta"; only the *Nostra* row reaches that bin). The four named tables (Tyconic, Rudolphine, Philolaic, Ours) each give counts of eclipses represented within those bands; "Ours" shows 35 / 19 / 44. The final "44" appears in the third (12) column for the "Nostra" row.

6. Therefore let the estimators of these difficulties measure our Tables with fairer [judgment] than others, if in some cases they do not represent the eclipses so closely in the observations themselves, and let them not undeservedly assign part of the blame to the observations themselves, and to the configurations of the eclipses which the Meridians, still uncertain, [keep] apart from one another.

7. For — to indicate a few things by way of example: the eclipse observed at 22 [degrees] of Aria [Arabia?] will be exhibited [as] under a place more nearly our own than 23 [degrees]; observed at Antioch — perhaps therefore that Antioch is not in Syria but elsewhere, and more easterly than we supposed; nor was the observer so diligent in it, either in measuring the time, or in distinguishing the beginning of the legitimate eclipse from the penumbra [*Vmbragine*], or [from] the [full] shadow [*fumo*]. In this matter, indeed, and in all others, [we have] the use of the Telescope, and the skill acquired in our age, especially preceding [generations]; from which two fallacies a suspicion of fallacy arises from ocular estimation of the moment — namely, when the eclipse begins, or finishes, or [when there are] no instruments by which the time is measured, or [no] Horologes [clocks], or instruments [*Organa*] suitable for taking the altitudes of the stars, or [for finding] the place of the stars themselves [as] not certainly enough known in the heavens; concerning which [see] several other things [at] chapter 4.

8. Eclipses 26, 27, 32, 80. Others likewise — the Tables represent [them] nothing better; and some represent [them] a little worse. Because the sign [that there is] vice or some defect lies hidden in the Observation, or in the Meridians. In others likewise, observations, whether Tyconic, [show that those] of others, [are off by] a smaller or greater [amount] of time as the case may be, which fall within a quadrant, or even nearly the half of the better [ones], it suffices to represent [them]; see what was said above [at] this chapter, number 8 and 9.

Concerning the Ancient Eclipses, moreover, it must be discussed separately.

CAPVT IX

Concerning the Ancient Eclipses of the Moon exhibited through the Author's New Tables.

[Margin: (cropped marginal note, illegible)]

1. Now in Chapter 5 I concluded that 19 eclipses of the Moon related by Ptolemy [Ptolemy] are to be represented on those Julian days of the year which suppose the Beginning of [the era of] Nabonassar to have been on the Meridian of day 26 February of the Year of Christ — Epoch 747; and in Chapter 7, number 8, I indicated that the latitude is to be inquired into somewhat more carefully, lest anyone, by our [Tables] or [those] of other Astronomers, should impose upon the Tables a greater necessity than is just of representing the moments of those eclipses. For I do not now deny that there is a disagreement between those Observations and the Tables, [arising] in part from the [observers] themselves, [and] in part from the imperfectly examined distance of the Meridians of the [places of the] solar or lunar Tables, or both at once; and, from a Meridian-distance not altogether exactly noted, a greater [discrepancy] arises, [than] is to be noted in the Observations themselves, or it is configured more accurately in the moments, or [is noted] less accurately, [made] partly on account of the imperfect discrimination of the [observers], even as to the end, [or] because *per se* it carries an error of about 20', and more — partly on account of the crude manner of denoting the time by Clepsydras [water-clocks], or by stars; for which reason the [places] in the heaven were not perceived certainly enough. Whence it is now held as explored by the more recent Astronomers that it is sufficiently established that those eclipses are represented within about a half-hour. But some — unless one admits ampler latitudes of time — [are off more]. For it is repeated that, in the same order of eclipses as at Chapter 1 and at the places of Ptolemy, the eclipses are to be weighed individually with brief notes [*adductis*].

2. The first of the said Eclipses began at hour 1 past the rising of the Moon [*post Lunæ ortum*], and was total; and from the beginning alone, on account of the nearness of the horizontal vapors, Ptolemy observed [it]. He supposes the total eclipses to be of a duration of about 4 hours (which is not universally true), [and] he reckons the middle of the eclipse [accordingly]. The second Eclipse [was] observed lest it [be reckoned] from the beginning, or from the end, or from the true...

... [the digits] in full, when there appeared three obscured digits, was uncertain in the middle of the night. The **third** eclipse Ptolemy reports as observed only from

its beginning; he says the moon rose a little past obscured, and from the duration of the eclipse — which he determined as half [the total] — he reckoned the middle. But the difficulty of an observation made near the horizon is plain, and likewise the uncertainty as to whether the **fourth** is to be reckoned from the middle, since its beginning is noted as falling after obscured digits remain at 3. The **fifth** was observed at the very middle of the night, when the greatest degree of obscuration was seen to be 6 digits; it appears to admit a smaller error, if it is established from the moment itself, and not rather from the end, or estimated from the beginning. The same must be said of the **sixth**, observed at 3 digits a little before midnight, and of the **seventh** at 2½ digits, observed near the middle of the night.

For the **eighth**, whose beginning Ptolemy places at half an hour before sunrise, adding that the moon set still eclipsed before [the eclipse was] free of obscuration on rising — the diligence of [Petavius] is to be relied upon here [in his work] *De Doctrina Temporum*, [Liber] I [Cap.] 8, who by his own calculations affirms that the time of this observation is exceeded by the Alfonsine Tables [Tabulae Alphonsinae] by 1^h 56', by the Danish [Tables] by 41', and by the Parisian [Tables] by 33'. But Ptolemy supposes this eclipse to have lasted 1^h 30'. The smallness of the eclipse does not admit so great a latitude of error in time as do other eclipses. Our own calculation does not represent that [eclipse] within that exact phase, yet within this error, since the duration of this [eclipse] was unique, as Ptolemy himself attests (*Almagest* [Liber] 4, [Cap.] 11). Hipparchus reckoned from the eighth eclipse to the ninth 177 [years] and 13^h 45' of equal hours; Ptolemy reckoned there the same 177 years and 13^h 36'. Our Tables represent this eclipse later than the Ptolemaic by 11' 15", but later than Hipparchus by only 1' 0"; later [than the Ptolemaic] by 9" posterior to it from the observation.

[4] The **tenth** eclipse is related as having begun from sunrise; from the beginning therefore Ptolemy reckons it, and supposes the duration of totality to be 4 hours. Ptolemy assigns 1^h 12' for the meridian of Babylon, at 1^h after midnight, numbered; Ptolemy [reckons] from the ninth [eclipse] to the day 177^h; he confesses, nevertheless, that Hipparchus reckoned the hour as only 1^h 40' above 177 [days]; but Boulliau [Bullialdus], (*Astronomia Philolaica* [Liber] 3, [Cap.] 6), from the manuscripts of the Royal Library, shows that 10^h 15' should be read.

The **eleventh** eclipse — its beginning being unobservable — is supposed; while it is said to have begun to fail half an hour before its own midpoint, but because it was full in the middle of the third hour of night, Ptolemy reckons its maximum to be 7^h after midnight.

[5] The **twelfth** eclipse Ptolemy relates as observed only from its beginning (*Almagest* [Liber] 4, [Cap.] 11), and [says] that from the duration totality lasted through the middle of the night for 13^h 20', after the meridian numbered, as the preceding [eclipse] from this day [reckons] 178^h 6^h 50'. But he confesses that Hipparchus reckoned only 178 [days] and 6^h; therefore Hipparchus was 50' earlier than Ptolemy. We have therefore followed Hipparchus, lest otherwise the Tables would represent it too much, and most accurately represent the observation of Hipparchus. But in the **thirteenth** eclipse it seems we must stand rather by Ptolemy, who (*Almagest* [Liber] 4, [Cap.] 11) puts it as observed with its beginning falling after the sixth hour of night had passed.

and 40', and then [there were] other phases, since the whole moon failed, Hipparchus defined the middle at 2^h 10' after midnight. Ptolemy numbered this same time 2^h 24'. Hipparchus, however, [reckoning] from the preceding day [as] 176 [days] 1^h 20'; but if [from] the preceding [eclipse] one were to add 176 [days] of these hours, that this interval of 176^h 0^h 30' would be a little greater than the Ptolemaic. We, however, postulate this 8' earlier than the Ptolemaic time.

[6] The **fourteenth** eclipse is set down with its beginning at 2^h 20' after midnight, and its end at 5^h 10' observed, together with 7 digits obscured. The **fifteenth** eclipse the narrative reports only at its beginning, observed at 2^h ½ after moonrise, and thereafter indicates the middle when 2 digits were [obscured].

[7] Among the eclipses, however, the four that are in order 16, 17, 18, and 19: the first, that is, the **sixteenth**, is not represented by Ptolemy as observed, nor does he add that which (*Almagest* [Liber] 4, [Cap.] 6) Lansberge [Lansbergius] added concerning observations as if [drawn] from himself; this [eclipse] also Lansberge, in his *Thesaurus*, contends to have been at Alexandria at hour 8, 51' after midday, not however at 8^h 24', as Ptolemy has [it]. We likewise [place it] 22' later than Ptolemy. The **seventeenth** eclipse we likewise exhibit, [and] the **eighteenth**, which Ptolemy (*Almagest* [Liber] 4, [Cap.] 6) affirms to have been observed by himself most accurately, [we exhibit] not within 6 or 7 [minutes] — and the **nineteenth**, which he places after midnight, with all its minutes, except those which Lansberge attributes to it from himself, [is] discordant from the others in the motion of the Sun; the remaining Tables [place it] about one hour earlier than the Ptolemaic eclipse.

[8] It is permitted, however, that the Lansbergian Tables at first glance seem to be preferable to the others as regards the ancient eclipses, as can be seen in the Catalogue of [Cap.] 5. Yet because Lansberge made eclipses 8, 9, 10, 11, 12, and 13 in the other [more recent] centuries much inferior to the Tyconic [reckonings],

using the true distance from the Meridian — as is established from what was said in [Cap.] 7, num. 6 — therefore we have preferred the Tychonic [reckonings] to those, as more absolute, namely the Danish, the Rudolphine, and the Philolaic. But that a comparison may be made between them, in the following table we have set down the number of eclipses which the under-written Tables represent within hours of 5, or 10, or 15, or 20 minutes.

Within
Minutes of
an Hour.

Tables	5	10	15	20
Danish	2	3	6	6
Parisian	1	3	5	7
Philolaic	3	4	7	8
Rudolphine	2	3	6	7
Ours	3	8	8	9

[9] There now follows the Catalogue of the Ancient Eclipses with the place of the Sun and Moon, with the moment observed, with the [position] computed from our more recent Tables, [and] with the difference of the computed place of the moon added, with respect to the observed [place], and the time corresponding to this difference.

The following is a large two-part computational table (the catalogue announced at the foot of the previous page), transcribed below as a native markdown table. Its heading reads: *Eclipses of the Moon Observed in Antiquity, and Computed from the Author's New Tables. d [indicates] Defect; c indicates excess.* The upper block lists eclipses 1–15, dated "An[no] ante Ch[ristum]" (Year before Christ); the lower block lists eclipses 16–19, dated "Christi" (Year of Christ). Columns give: the eclipse order number; the apparent Bologna time after midday (Year, Month, Days, Hours, minutes — *Tempus Bonon[iense] Apparens ex cap. 3. post Meridiem*); the equated time (*Tempus Æquatam* — Hours, minutes, seconds); the true place of the Sun and thence the Moon's [opposition] (*Solis locus Verus, & inde Lunæ* \circ — Sign, Degrees, minutes, seconds); the computed place of the Moon (*Lunæ locus computatus* — Sign, Degrees, minutes, seconds); the computed difference (*Differentia comput.* — minutes, seconds, with **d/c** for defect/excess); and the time difference (*Tempus differ.* — minutes, seconds).

Parsing notes: Column groups follow the printed sub-headers (Ordo Ecl. | Tempus Bonon. Apparens post Meridiem | Tempus Æquatum | Solis locus Verus & inde Lunæ ♁ | Lunæ locus computatus | Differentia comput. | Tempus differ.). The Sun's true place and the Moon's opposition share a sign-column (opposition is the Sun's place ±6 signs; the Moon-sign shown is the opposite of the Sun-sign). The "Differentia" column carries **c** (excess) / **d** (defect) markers per the heading legend. Several zodiac glyphs in the cramped table are read by context against the opposition rule; where a glyph was ambiguous it is flagged below. Half-minute values (e.g., 27½, 58½, 42½, 47½, 37½, 51½, 27½) are printed with the fraction. Eclipse 6 Sun-place seconds and eclipse 11/12 hour-fractions confirmed against neighboring rows.

CAPVT X.

On the Motion of the Moon in Longitude, as hitherto established by the more eminent Astronomers, and by what method it is best investigated: where they have erred, or what may be found wanting.

[1] Long ago, in *Almagest* [Almagestum Novum] [Liber] 4, num. 19 and 24, I set forth a threefold device by which Astronomers investigate the lunar motions; and I showed that it is vainly attempted by Cycles of the lunar-solar [year], or by the commensuration of the Lunar year with the Solar, and consequently by the recurrence of paired Lunar eclipses, separated from one another by the longest possible interval of years, and standing in the same degree of Anomaly — or at least at the same distance from the Apogee, both Luminaries lying in the Apogee, or one in the Apogee and the other in the Perigee — which conditions, and others, Ptolemy requires (*Almagest* [Liber] 4, *Magna Constructio* [Cap.] 2), as is declared and demonstrated by Boulliau [Bullialdus] (*Astronomia Philolaica* [Liber] 3, [Cap.] 2).

[Margin: The sum of the method.]

These [conditions], however, being given, or at least the chief of them: **First**, from foreknowledge of the apparent place of the Sun in degree, and likewise [the place] observed at the time, it is to be converted into Equal time, reduced to the same Meridian. **Secondly**, that moment is to be gathered to which the motion of the Sun belongs, both Mean and True, with its own Anomaly; for thence the place of the Moon is known from the opposite place of the Moon, in which it truly was at the moment of the observed Eclipse. **Thirdly**, with the Anomaly and the lunar Prosthaphaeresis, by some best hypothesis used in the meantime, the Mean place of the Moon is to be found, adding to the Equation [aequatio] the True [place] in its place in the prior six signs of Anomaly, [and] subtracting in the others. **Fourthly**, the Difference of the Mean motions, or of the places of the Sun and Moon, is to be set in agreement by the Hourly Tables [Tabulae Horariae] from the Sun to the Syzygy, which they everywhere have; and to this time the Equal [time] of Mean Opposition observed is to be added, if the mean Motion of the Sun exceeds the Lunar [motion]; if it falls short, [it is to be subtracted], and the moment of the Mean Opposition of both will be had. **Fifthly**, it is to be reckoned diligently in the interval between both Mean Oppositions, not only in Years, but also in days, in Hours, and in Scruples [Scrupula, i.e. minutes]; having regard to

the number of days added in Bissextile Years, in the form of the Julian Year, and 10 days subtracted in the form of the Gregorian Year, in 1582 — and that time is to be reckoned, whether it be in the observed [Julian] or in the Gregorian style. **Sixthly**, the reduced interval of time in Days is to be multiplied per Lunation 4267, and the sum is to be divided by Days 126007; for the number of complete Lunations will come forth, which by that interval is made. **Seventhly**, by the found number of Lunations, that same number of Days, Hours, and the Scruples due to one Mean Lunation are to be divided between the two Eclipses of the Moon, and there will come forth the Days, Hours, and Scruples due to one Mean Lunation, or to the Mean Synodic Month, [from] the middle. But these precepts will be made clearer by the following Example, [in] [Cap.] 9, [and] the rest of the precepts, [namely] how to collect from the Synodic Month, the rest of the [lunar] motions.

[2] By this method, which Ptolemy indicated somewhat obscurely (*Almagest* [Liber] 4, [Cap.] 2 and 7), Hipparchus found, from Eclipses observed by the ancient Babylonians and from the more recent ones observed by himself, Days 126007 and an equal hour, that he completed 4267 Lunations, as I have said. But the Anomalistic Months, that is, the whole restitutions of the inequalities, [number] 4573. The Periodic Months, or Zodiacs, [number] 4612, less by degrees $7\frac{1}{2}$, [as] Hipparchus dividing therefore Days 126007 per 4267, found the Mean Month in Scruples of Days, and in...

[Margin: Hipparchus's opinion.]

D.	I	II	III	IV	V
29	31	50	8	9	20

This is in Horary Scruples [minutes]:

D. 29. Hor. 12. 44. 3". 15'''. 44^{iv}.

So Ptolemy relates (*Almagest* [Liber] 4, [Cap.] 1), adding [that] the Mean motion in Longitude from Hipparchus is to be repeated, both in Longitude, [so that] it differs sensibly in nothing from the truth; the Anomaly, however, and the Latitude, [differ] somewhat from the truth. Yet Ptolemy uses ([Cap.] 3) the Mean Lunar Month written below in scruples of days, but converted by us into Horary scruples [minutes]:

D.	I	II	III
29	30	8	20

That is, 29 Hor[ae] 12. 44'. 3". 20'''.

Therefore from Hipparchus the number of Lunations to the Anomalistic Months is, as 4267 to 4573, or in brief, as 1.21 to 269. Whence the Diurnal mean motion of Anomaly follows:

	Gr.	I	II	III	IV	V	VI
Hipparchus	13	3	53	56	17	51	59

But Ptolemy (*Almagest* [Liber] 4, [Cap.] 7) affirmed it should be corrected thus, as it would be:

	Gr.	I	II	III	IV	V	VI
Ptolemy	13	3	53	56	17	51	59

[3] But the most learned Gottfried Wendelin [Wendelinus], whose Letters to me I acknowledge as showing how profoundly he has immersed himself in the Lunar Theory, in his *Idea* of the Atlantic Tables, p. 29, says that in precisely 797326 days are completed 27000 Lunations; and that thence is born one Luration:

[Margin: Wendelin's opinion.]

D.	H.	I	II	III
29	12	44	3	12

But the Apocatastasis, that is, the Restitution of the Lunar Anomalies, [he] holds it thus to be, as the Luration [of] 16831 absolutely [completes] the Anomalistic Months [of] 18028. Finally the Months [of] 6890 complete the Draconic Orbits, or the Latitudinal Revolutions [of] 7477. Wendelin himself [makes] the proportion not quite as Hipparchus [makes it]. As the Lunations [of] 27000 [are] to the Days 797326, so are the Hipparchian Lunations 4267 to the Days of the Hipparchians 797326 ¹²⁶⁰⁰⁷. Not, however, does he set forth any pair of binary Eclipses, by which it might be established that he used this same mean motion, as did Tycho, neither Longomontanus, nor Kepler, nor Lansberge. It is permitted that Longomontanus, in the *Astronomia Danica*, in the commentary on the Moon, which is had in [Liber] 2, [in the] Theory of the Theorics, adduces three pairs of Astronomical Lunar Eclipses, three of the Hipparchians, and three of the Ptolemaics, and 23 [pairs], partly observed by Tycho, partly by himself; and these, when he confers them with his own Tables, do not show that same method by

which he was used to investigate thence the motion of the Moon, [and] scarcely [agrees] with the ancient [pairs] which Hipparchus acquired in his last [pair]; the pair which is in [Liber] 2 in the Catalogue of [Cap.] 1 is in order 13; nor [is] Lansberge in his *Thesaurus* of observations after the comparison of many Eclipses with his own Tables [the same], showing by what way the Mean places of the Moon are derived. Only do we have from himself, and from the Danish, and Rudolphine Tables, the Mean Synodic Month, and the Diurnal motion in the Zodiac, as below.

	D.	H.	I	II	III	IV	V	VI
Danish	29	12	44	3	8	39	46	48
Rudolphine	29	12	44	3	10	51	0	0
Lansberge	29	12	44	3	12	0	0	0

[Margin: Synodic Month.]

	Gr.	I	II	III	IV	V	VI
Danish	13	10	35	1	1	45	52
Rudolphine	13	10	35	1	14	30	43
Lansberge	13	10	35	1	12	0	25

[Margin: Diurnal [motion].]

The opinions of the rest see in *Almagestum Novum* [Liber] 4, [Cap.] 5. To these His Reckonings remain. Two there are who survive to us, the most celebrated Astronomers, who by some example manifestly [seek] to lay open the method, or [from] the Eclipses by which they used the way in explaining the motion of the Moon, namely Copernicus, and Boulliau [Bullialdus].

[4] For Copernicus, [the value] which he reckons the Synodic Month to be is D. 29 H. 12. 44'. 3". 10'''. 48^{iv}; whence he deduced 6. nempe [namely], from three Eclipses of the Moon observed by Ptolemy, and collated with the same [number] observed by himself. For he errs in the computing days. For he says that in the Year of

Hadrian 17 the Eclipse of the Moon was made [and] observed by Ptolemy; in the Twentieth, the [day] of the [Egyptian] Month Pauni having passed, but in the Year of Christ 133, the hundred-and-thirty-third, on the sixth day of the month of May, or the day before. But Ptolemy (*Almagest* [Liber] 4, [Cap.] 6) by no means has it that it was made [and] transacted on the 20th of Pauni, for thus it would not have followed that it was begun, but rather completed, on the 21st: but [Ptolemy says] on the day of Pauni, the second [day] before [Egyptian], on day 20, which the 21st followed. Wherefore even thus far day 20 would have been wanting.

[Margin: Copernicus's chronological lapse.]

[5] Similarly Copernicus erred, but uniformly, in referring the second and third Eclipse: he says, namely, that the second Eclipse was made in the Year 19 of Hadrian, two days of the [Egyptian] Month of Choiac having passed, in the Year of Christ 134, on the 13th, the Calends of November [13 Cal. Nov.], namely on 20 October. But Ptolemy (*Almagest* [Liber] 4, [Cap.] 6) does not have that [day] passed; but [says] Choiac on the second-following [day], the third; nor yet was its beginning current before [it had] passed two [days]; the beginning was at the Meridian of the day, after midday the Eclipse was. Likewise the third [Eclipse] Copernicus says was made in the Year 20 of Hadrian transacted, on the 19th day of the Month of Pharmuthi, in the Year of Christ 135, the [day] before having passed, [Cap.] VI of May. Yet Ptolemy says (*Almagest* [Liber] 4, [Cap.] 6) the 19th [day] of Pharmuthi, which the twentieth follows; therefore even here day 20 would have been wanting, from the Meridian of the day 19, on the 18th. But Copernicus admits the Hipparchian proportion of Lunations, and of the Days of which I spoke under number 2, & [from] the Ptolemaic Eclipse the second, to the Eclipse observed by himself in the Year of Christ 1522, the 5th of September, computed [from] the Egyptians 1388, [and on] this day, 302.

[6] Ismael Boulliau [Bullialdus], the diligent and subtle searcher of Astronomical truth, (*Astronomia Philolaica* [Liber] 3, *Astronomiae Philolaicae* [Cap.] 4) adduces the Hipparchian Doctrine of Lunations 4267; made in the interval of days 126007, that is, [he] uses [Cap.] 5, also from the interval of the Egyptian Annus [Year] of years 1788, of days 65; that is, altogether days 65368 5; he completed 22102 Lunations, and so thereafter. But [the time] which Boulliau refers from this Eclipse of the Moon made in the Year 547, Messori, Hora 5, namely 39', the apparent [time], and the other observed at Uraniborg [Uraniborg] in the Year of Christ 1587, [on] September the 6th, [old style] 9^h 28'; added, [it] was at Nabonassar Annum 2336, day 16. Paophi, Hor[ae] 9. 28' after midday, whence he collects the predicted interval of Years of Egypt 1788; that is, [from] Hor. 3. 51'. &

Lunations 22102; by which dividing the predicted interval, [he] collects the Synodic Month.

D.	H.	I	II	III	IV	V
29	12	44	3	12	41	18

[7] The same [Boulliau], in the same [Cap.] 5, [Liber] 3, brings forward another Eclipse observed at Nabonassar [Annum] 548, on the 9th [of] Mechir, at Hour [of] Uraniburg 11. 59' after midday, the apparent [time]; and another likewise [noted] by Tycho [Brahe] in the Year of Christ 1588, on the 2nd of March, old style, at hour 15. 8'; which [Boulliau] collects to have been the day of Pharmuthi 14; whence [he] collects the interval of the Egyptian Years 1788, of days 65, hor. 3. 5'. & hence Lunations likewise 22102. The Month likewise Synodic:

D.	H.	I	II	III	IV	V
29	12	44	3	5	11	45

[8] At last Boulliau (*Astronomia Philolaica* [Liber] 3, [Cap.] 6) brings forth the exact determination of the Lunar motion, which at the end of the chapter he affirms to be constructed [from] Tables of the mean Lunar motions. He adduces, however, two Lunar Eclipses; one observed at Nabonassar 366, on the 26th day [of] the Month of Thoth, at the Hour [of] Uraniburg reduced [to] 16. 5', after the Meridian; the other observed at Paris, [and] by Hortensius at Amsterdam, [and] by Gassendi in the Year of Christ 1635, on the 3rd of March, [the] Hour at Uraniburg reduced [to] 9. 18'. 5"; and [he affirms] this to have been the Egyptian Year [of] Nabonassar 2383, [on] the day of Pharmuthi 16. Hor. 9. 18'. 5"; whence [he] collects the interval of the Egyptian Years 2017, of days 199. Horae 16. 20'. 5"; that is, of days [from] Nabonassar 736404. hor. 16. 20'. 5"; but the Plenilunium [Full Moon] being reduced [to] true and to the middle, [it] has only 9.1^h 29'. & hence...

Liber II — De Luna (continued)

Caput X (continued)

hence [the number of] 24,937 lunations. By dividing that interval by these, one obtains the synodic month; and by dividing the zodiac by the synodic month, one obtains the Moon's mean diurnal motion away from the Sun [motus medius Lunæ diurnus a Sole]. By adding the Sun's mean diurnal motion, one gets the Moon's mean diurnal motion in the zodiac [motus medius diurnus in Zodiaco],

reckoned from the equinox; and from the annual motion, the diurnal motion likewise — as below.

Mo nth	D.	H.	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
Syn odic	29	12	44	3	9	37	9	59	15	15
	Sign Gr.	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	
	--- ---	--- ---	--- ---	--- ---	--- ---	--- ---	--- ---	--- ---	--- ---	--- ---
	11 26 41	31 0 46	13 26	Diurnal			Annual	4		
	9 37 22	23 59	41 11	41 14	Diurnal in the zodiac	0 13	10			
	35 1 13	2 27	27 50	Annual	4 9	23 1 24	19 57	4 22	0	

Parsing notes: the two small mean-motion tables share the heading-band columns Sign/Gr./I.–VIII.; the row labels run "Motus à Sole / Diurnus / Annuus" then "Diurnus in Zodiaco / Annuus." The sign-degree alignment of the first numeric column was hard to resolve against the heading; values are transcribed left-to-right as printed.

[Margin: 9 — Boulliau's diurnal motions.]

§9. I am surprised, however, that Boulliau settled on these motions [as derived] from two pairs of eclipses, when the Moon was in widely different positions of anomaly, rather than [from] others established on equal anomaly. For in eclipse no. 6 and no. 7 [in his catalogue], the Moon's anomaly occupied very nearly the same degree — namely, for the eclipse of no. 6 the Moon's anomaly was Sign 1, gr. 0, and gr. 2 [for the other], very nearly, while the numbers themselves [of those eclipses] are 6 and 7. But in eclipse no. 8, in the first [pairing] the Moon's anomaly was Sign 7, gr. 19; in the second, Sign 11, gr. 14 — so it was by no means at the same distance from the apogee, as it ought to have been. Hence the mean month drawn out from those two earlier eclipse-pairs is seen to be vitiated by the error of this very disparity. As for Copernicus, by contrast: while Ptolemy's precept enjoins that the two eclipses [of a pair] adhere by number 5 [to equal anomaly] — he therefore chose, in each [pairing], a Moon whose anomaly was Sign 1, gr. 6, gr. 3, very nearly.

[Margin: 10]

§10. Finally, one could wish that the mean motion of the Moon had been confirmed by several eclipse-pairs rather than by one or another, [so that] the

aforesaid astronomers' [values] might have been borne out, and the matter set forth in plain numbers; or at least [that] they had adduced a reason why they preferred to rely upon a binary [pair] of eclipses — and indeed upon what prerogative this [or that] binary [rested]. This same [wish] applies in the matter of the epochs: we have desired the motion [to be such] that the radix of the motions deduced from one eclipse should come out the same as the one [deduced] from another, and so on.

CAPVT XI.

De Mense Lunari Synodico per plures Eclipses investigando.

[On determining the synodic lunar month by means of several eclipses.]

[Margin: 1]

§1. I shall illustrate by a single example the precept handed down in the preceding chapter. I therefore select the eclipses of the Moon no. 8 and no. 92 [in the catalogue], not only because they answer very well to the astronomical tables, but also because in both the Moon obtained nearly the same degree of anomaly — namely Sign 7, gr. 4. There [in §16] it will be [shown]. I reduce, then, the moments of the equated time to the meridian of Bologna: the former [eclipse falls] in the year before Christ 383, December 22, hour 16, 13' 10" after noon — equated; and these [moments] then stood thus in our tables for the luminaries:

	Sign	Gr.	I.	II.
Sun's mean motion [Solis medius motus]		8	26	4
Its anomaly [Eius Anomalia]		0	22	36
Moon's mean motion [Lunæ medius motus]		2	23	6

	Sign	Gr.	I.	II.
Its anomaly [Eius Anomalia]		7	18	52
Difference of the means [Differentia mediorum]			2	57

The Moon at that time, then, stood somewhat short of the place of the mean opposition by gr. 2, 57' 50"; from the Moon's anomaly, so situated, an interval of 5 hours 29' 17" agrees [as the correction], which if you add to the time of the true full moon, you will have the time of the mean full moon, equated, for the year before Christ 383, December 22, hour 22, 37' — equated to Bologna.

[Margin: 2]

§2. In the year 1628, January 20, Gregorian style — but the 10th of January, old style — at one hour past noon at Bologna, hour 10, 9' 20" in equated time, there was an eclipse of the Moon, and the luminaries [stood] thus:

	Sign	Gr.	I.	II.
Sun's mean motion		9	29	40
Its anomaly		6	21	33
Moon's mean motion		5	26	51
Its anomaly		7	18	4
Difference of the means			2	49

Wherefore, in this eclipse no. 92 the Moon was likewise somewhat short [of opposition], by gr. 2, 49' 15", than the exact place of the mean opposition would require; from the Moon's anomaly, an interval of 5 hours 7' 30" agrees, which if you add to the moment of the true full moon, the mean full moon for the year 1628, January 10, at the hour observed at Bologna [namely] hour 10, [yields] hour

15, 16' 50". From the moment of the mean full moon no. 92 to the moment of the mean full moon no. 8 — counting, that is, the days 562, which there ought to be for so many bissextile years [intervening]. For from the year 383 [before Christ] to the year of Christ 1609, the days [number] 73,4128; add to these 562, and besides the aforesaid 18 hours 16, 54' 13", [and] the interval [stands] thus, days 73,4805, hour 16, 54' 13".

[Margin: 3]

§3. Now, if from Hipparchus's observation, confirmed and accepted by Copernicus, Wendelen, Boulliau, and others, the astronomers prove [it], as I said in the preceding chapter — a binary [pair] containing 4267 lunations, and the interval [being] days 126,007 $\frac{3}{4}$ — it follows that 4267 lunations [span] our days 73,4805, hour 16, 54' 13"; [and that] there are contained [in that span] 24,839 lunations, by dividing which the same days 73,4805, hour 16, 54' 13" of interval [give], the synodic month comes out [as]:

D.	H.	I.	II.	III.	IV.	V.
29	12	44	3	12	10	

Nevertheless, having examined several pairs of mean ecliptic full moons, I find the synodic month — [the one] that corresponds to a far greater number of eclipses — to be [this]:

D.	H.	I.	II.	III.	IV.	V.
29	12	44	3	10	50	30

[Margin: 4]

§4. So as not to grudge the reader the aforesaid pairs and the comparisons, we shall exhibit three Tables. In the first is the time of the equated full moons — the true ecliptic ones at the meridian of Bologna, together with the Sun's and the Moon's mean motion, and the Moon's anomaly simply — with the order of the eclipses preserved, as we have always used from the chapter's beginning; see chapters 2 and 3. The equated time is the same; see chapters 8 and 9.

In the second [Table], the same [eclipses] being repeated, is set down the difference between the mean motions of the Sun and the Moon, and the time in hours by which the Moon answers to the said difference; and [whether] this is to be added to the equated time of the true full moon, or to be subtracted [from it] insofar as the mean motion was short of, or beyond, the point of the mean

opposition with the Sun — whence the time of the mean full moon results; and that is had in the same second Table.

In the third [Table], finally, are indicated the comparisons of the ancient eclipses [each] with a more recent one, in which the Moon turns in the same degree of anomaly, very nearly — as will be plain by running back up to the first form of the Tables, or at least to the same distance from the apogee.

But because, for investigating the synodic month, there is need of a fair interval of days between the ancient and the recent full moon, I have therefore noted [them] according to the form of the old Julian year, lest the subtraction of the 10 days in the Gregorian form should be obscured to anyone [for the eclipse of] the year of Christ 1582.

]	s]]	.	.	I.	.	n	r.	I.	.	n	r.	I.	.	n	r.	I.	.					

Parsing notes: this large columnar table is partly obscured by gutter shadow and show-through; the four sexagesimal blocks (D./H./I./II. of the time; then Sun's-mean, Moon's-mean, and simple-anomaly, each Sign/Gr./I./II.) are tightly set. Several minutes/seconds entries are ambiguous against the rule-lines and adjacent-leaf show-through; readings are best-effort. Eclipse-order column skips numbers (1–4, 6–8, 10–15, 17–19, 22, 35, 41, 43–44, 47, 49–50, 54–55, 60, 74–76, 88, 92, 95, 98, 100, 104, 106, 108, 110, 119). Row 106 (1643) and row 95 (1631) appear to lack a complete final anomaly block in the scan. The doubled day-figures in some rows (e.g. row 50 "2 15 1 1") reflect tightly-set H./I./II. blocks.

Parsing notes: "Adde vel Deme" column abbreviated d (deme = subtract) / a (adde = add). The first heading-band reads "Differentia Mediorum Motuum / Tempus huius Differentiæ / Adde vel Deme / Tempus Plenilunij Medij." The "Ante Chr. Anni / M. / D. / H. / I. / II." sub-columns of the last block carry the year, month, day, and clock-time of the mean full moon. Several seconds-entries ambiguous from show-through.

III. TABULA

Comparationes graduum mediorum in eodem ferè gr. Anomalix.

22	88

Parsing notes: Table III pairs each ancient eclipse (left, "Ordo &") with one or more recent eclipses (right) sharing nearly the same anomaly. The header reads "Comparationes [graduum] mediorum in eodem ferè gr. Anomaliæ." The single repeated left-hand order-number groups the recent counterparts beneath it. Right-hand column values are the order-numbers of the matching recent eclipses.

CAPVT XII.

How, from the Synodic Lunar Month, the Remaining Motions of the Moon in Longitude Are Derived. (For the motion in anomaly and in latitude we shall treat separately below; here we treat only of the motion in longitude reckoned from the Vernal Equinoctial point.)

1. Rule concerning the Lunar Year and the Epact.

Multiply the Mean Synodic Month — which for us is 29 days, 12 hours, 44 minutes [I], 3 seconds [II], 10 thirds [III], 50 fourths [IV], 30 fifths [V] — by twelve, and you obtain the Mean Lunar Year of 354 days, 8 hours, 48 minutes [I], 38 [II], 10 [III], 6 [IV]. Take the residue and complement of this against the Julian Solar Year (that is, against 365 days), and it is called the Epact of one common year. For us this comes to 10 days, 15 hours, 11 minutes [I], 21 [II], 49 [III], 54 [IV]. Moreover, in accumulating the Epact over several years for each individual leap year, the Epact is augmented by one day. Yet always, once the accumulated Epact reaches a whole lunation, that whole lunation is subtracted, as often as it can be subtracted. A specimen of all this you have in the following Table, together with the Embolismic Lunar Year of thirteen lunations.

Annus Lunaris [Lunar Year]	D.	H.	I	II	III	IV
Commu nis [Comm on]	354	8	48	38	10	6
Emboli smicus [Emboli smic]	383	21	32	41	20	57

Epacta Annoru m [Epact of Years]	D.	H.	I	II	III	IV
Commu nis [Comm on] 1	10	15	11	21	49	54
2	21	6	22	43	39	48
3	2	8	50	2	18	50
Bissexti lis [Leap year] 4	14	0	1	24	8	43

2. Rule concerning the Periodic Lunar Month.

The 360 degrees of the Zodiac resolve into 7,776,000,000 thirds [III]. Our Synodic Month, however, resolves into 153,086,191 horary thirds [III]; and when these are multiplied by the Zodiac (as resolved above) they yield 1,190,401,316,160,000 thirds [III], to be reserved for the Number-to-be-Divided. Now the Mean Motion of the Sun in the Synodic Month, by our Tables, is 29 degrees, 6 minutes [I], 24 seconds [II], 17 thirds [III]; and when this is resolved into thirds and the Zodiac (resolved above) is added, the result is 8,047,057 thirds [III]. Therefore divide the aforesaid Number-to-be-Divided by these horary thirds, and there results the Periodic Month of the Zodiac, namely 141,631,117 thirds [III] — that is, 27 days, 7 hours, 43 minutes [I], 5 seconds [II], 17 thirds [III].

3. Rule concerning the Daily Motion of the Moon in the Zodiac.

The Zodiac, combined with the Mean Motion of the Sun corresponding to the Synodic Month, is — as we said in point 1 — 8,047,057 thirds [III]. Multiplied by the horary thirds of a single day [184,000 thirds], it makes 1,480,498,488,000 thirds [II/III?]; and this divided by the thirds of the Synodic Month already given above (153,086,191) yields the Daily Mean Motion of the Moon in the Zodiac, 1,846,101 thirds [III] — that is:

Gr.	I	II	III	IV	V	VI
13	10	35	1	17	15	49

4. Rule concerning the Daily Elongation of the Moon from the Sun.

Subtract the Mean Daily Motion of the Sun in the Zodiac — which for me is 59 minutes [I], 8 seconds [II], 19 thirds [III], 48 fourths [IV], 35 fifths [V], 35 sixths [VI] — from the Mean Daily Motion of the Moon, and at once you will have the Daily Elongation of the Moon from the Sun, namely:

Gr.	I	II	III	IV	V	VI
12	11	26	47	28	40	14

5. Rule concerning the Horary and the Annual Motion of the Moon in Longitude.

The Horary motion can be obtained by dividing the Daily motion by 24; more easily, however, by aggregating the Daily motion doubled, plus a half of the Daily, but exchanging the titles of the degrees into minutes [I] and of the minutes [I] into seconds [II], and so on. Behold the Example in our Daily figure:

☽	Gr.	I	II	III	IV	V
Diurnu s [Daily]	13	10	35	1	17	16
Duplu m [Double]	26	21	10	2	34	32
Semidi urni [of the Half- daily]	6	35	17	30	38	38
Aggreg atum [Sum]	32	56	27	33	13	10
Ergo [Theref	II	III	IV	V	VI	VII

☽	Gr.	I	II	III	IV	V
ore]						
Horari	32	56	27	33	13	10

] &	II	III	IV	V	VI	VII
minuti						
vnius						
[and of						
one						
minute]						
	32	56	27	33	13	10

6. The Annual motion is more securely obtained from the Daily, once the motion of the Months has first been investigated by means of the daily reckoning over 28, or 30, or 31 days; or, more compactly, from the several Daily motions until you arrive at the day 30 or 31 of motion. In this manner:

Parsing notes: in the "60" row the Sign value reads 2 and Gr. 10; the "360" row Sign reads 2 and Gr. 3 — both partially compressed at the gutter, transcribed as printed.

CAPVT XIII.

On the Motion of the Lunar Apogee and of the Anomaly.

1. From what was said in Book 4 of the *Almagestum Novum* [Almagestum Novum], Chapter 21, it is plain by what method Ptolemy [Ptolemy] and Copernicus [Copernicus] investigated geometrically the motions of the Lunar Anomaly, by means of triads of ancient Lunar eclipses — recent ones likewise. There it is also indicated that more than three eclipses were employed by Longomontanus [Longomontanus] and Boulliau [Boulliau]. Now I repeat what I said above concerning Hipparchus's [Hipparchus] Epilogism of Lunations: that 4267 Lunations answer to 4573 Anomalistic Months. That is, in the shorter numbering, 251 Lunations correspond exactly to 269 Anomalistic Months in the

longer numbering; whereas in [the longer numbering, those which Wuendelinus took up]

[continuation] —which Vendelinus [Vendelinus] in his *Idea Tabularum Atlanticarum* takes up, the Lunations of 1683 agreeing with 18,038 Anomalistic Months.

3. But because Ptolemy in Book 4, Chapter 2 and Chapter 7 desired a more accurate determination than the proposition handed down from Hipparchus, Boulliau in Book 3 of the *Astronomia Philolaica* [Astronomia Philolaica], Chapter 6, by means of many eclipses and their intervals re-examined geometrically, concluded that over an interval of 73,6404 days, 16 hours, 20 minutes [I], 5 seconds [II], whole Anomalistic Revolutions amounting to 26,724 were completed, plus 114 degrees, 35 minutes [I], 34 seconds [II]; and from these, resolving them into sexagesimal degrees, there results:

[Margin: Boulliau on the \curvearrowright Anomaly.]

2. We, having weighed the profundity and diligence of this man in the aforesaid investigation, and his motion drawn from the observation of Lunar Eclipses as if upon a Lydian touchstone, approving as nearly as possible to the truth, do for that reason derive the remaining motions from here — namely the Horary, the Monthly, and so on.

4. Furthermore, the Daily Mean Motion of the Lunar Apogee is obtained by subtracting the motion of the Lunar Anomaly from the motion of the Moon in the Zodiac — the Daily from the Daily, the Annual from the Annual, the Horary from the Horary, as below:

) Motu s med. [Mea n Moti on]	Sig.	Gr.	I	II	III	IV	V	VI

CAPVT XIV.

On the Motion of the Lunar Latitude, or of the Nodes.

1. As was said in Book 4 of the *Almagest*, Chapter 22, we set out the Method by which the Astronomers investigated this motion. Hipparchus indeed investigated it, and Ptolemy demonstrated it, in Book 4, Chapter 1 of the *Almagest*. But Ptolemy in that same place asserts that the Lunar latitude completes 5923 whole circles in 5458 Lunations; whereas Ptolemy himself, in that same place and chapter, says it falls far short of the truth, as he admits at point 9. *In the latitudes, however, an error of motion will previously creep in — for us, using the proportion handed down by Hipparchus — because the Moon may have traversed its own little circle six hundred and fifty times, but always under the shadow* (according to the mean state in plenilunium and the like). And after a few words he adds: *In the latitudes, indeed, certain matters were not exactly perceived, since truer observations were afterwards not attained by us.* It behooves all (assuming they are moved by love of truth, not by mere obstinacy) to take up these speculations — not only to amend the Ancients with a more certain and newer method, but even to add to one's own; nor is it base to retract one's own things if a truer view present itself, and even to recall others, professing the same with great and indeed divine candor.

[Margin: A love of truth.]

Having premised these things, I choose two Eclipses, which in the Catalogue of Chapter 2 are no. 7 and 16, in each of which the Moon was eclipsed.

2. Copernicus, in Book 4, Chapter 4 and 13, since he had two Eclipses observed — one of the ancients, the other in his own time, in each of which the Moon was descending equally from the same region [plaga], and nearly about the same Node, and at the same distance from the Apogee — chose two in which the Moon was deficient in different regions, since around opposite Nodes the eclipses arrived at their full point in the second sign; for besides the whole revolutions he described a semicircle. Such were [the Eclipses], which at our point [number] 2 [are] no. 1 and 4, and 35 [?]; among these, however, he reckons the Years 1683, days 88, hours 22 minutes [I], 35 seconds [II], in which time he says the latitude-motion of the Moon had overrun beyond whole revolutions by 179 degrees, 51 minutes [I]; and from this he establishes the daily motion. The latitudes [of these] he gives 13 minutes [I], 45 seconds [II] and 35 minutes [I]; for the prior eclipse, in the first eclipse of the month Phamenoth; but Claudius Ptolemy in Book 4, Chapter 1 does not say of the month Thoth but of the month Phamenoth, on day 27, the following 28; whence it signifies that the interval of 27 days was not yet fully completed; and so in this interval of Eclipses an error of one whole day customarily slips in. Then, since the prior Eclipse occurred in the Year before Christ 174, on day 30 of April, as is plain from our Canon and Chronological Apparatus, at the hour 9 minutes [I] 45 seconds [II] of Cracow [Craconia] after noon — while in truth it had been in the Year of Christ 1509, day 2 of June, hour after noon 9 minutes [I] 45 seconds [II], at Cracow at 11 hours 46 minutes [I]: in determining the interval one finds, in Julian Years 1683, days 88, hours 21 minutes [I] and 41 seconds [II] — so that this interval is false, which is not noted in our numbers, but is expressed in these words: *The time between each one [is] reckoned, [and] there were Years one thousand six hundred and eighty-three, days eighty-eight, hour 22 minutes [I] 35 seconds [II]. We dismiss the rest with Copernicus.*

[Margin: Motion of latitude from Ptolemy.]

[Margin: Latitude from Copernicus.]

[Margin: A lapse, however, in the Chronology.]

3. Gottfried Vendelinus [Gottfried Vendelinus], in his *Idea Tabularum Atlanticarum*, asserts that in 6890 mean Lunations there are completed 7477 absolute Draconic Orbs — that is, returns of the Apocatastasis of Latitude — and thence he gathers the Daily motion of the Latitude:

Gr.	I	II	III	IV	V	VI
13	13	45	39	32	7	36

Sig. G.	I	II	III	IV	V	VI	VII	VIII	IX
ude]									
Ann	4	28	42	46	6	44	25	49	38
uus									
[Ann									
ual]									

Parsing notes: this combined "Nodi / Latitud. Diur. / Annuus" block is printed with a long row of sexagesimal columns (I–IX); values transcribed left-to-right as printed; some interior digits are compressed at the column rules.

5. But it would be proper, or expedient, to choose two Eclipses at the same distance from the Apogee, and of the same quantity. Therefore, in the Year before Christ 720 — as is had from Chapter 3 and 9 — the Chaldeans observed a Lunar Eclipse of 6 digits, Northern, or a little less; the precise quantity is noted by Kepler in the *Astronomia Optica*, most evident of all, observed on account of the equality of the obscured part there illustrated; and it was the mean Full Moon at Bologna [Plenilunium Bononiae] on September 1, the third hour after noon, but equated [reduced to mean time], 7 minutes [I] 25 seconds [II]. The Luminaries then stood thus:

	Sign.	Gr.	I	II
Verus locus Solis [True place of the Sun]	5	0	54	9
Eiusque Anomalia [And its Anomaly]	3	5	14	0
Luna Verus locus [True place of the Moon]	11	0	54	9
Eiusque Anomalia [And its Anomaly]	5	13	18	16

	Sign.	Gr.	I	II
Medius Lunae motus [Mean motion of the Moon]	11	2	7	17

6. The Semidiameter of the Earth's Shadow, corrected according to the Sun's Anomaly, and likewise the Southern Latitude of the Moon (for the center of the Lunar disc was on the very periphery of that Shadow), was 47 minutes [I]. Hence the inclination of the Lunar orbit to the Ecliptic is supposed at Gr. 4, 58 [I], or as a maximum Gr. 5; for the solution, a right-angled spherical Triangle is to be solved.

[Margin: Latitude from observation.]

Diagram. A spherical triangle bearing the vertex labels E, L, N (with an additional L at lower left), an arc curving from the upper-left point E down to the lower-right point N. It illustrates the right-angled spherical triangle used to resolve the Moon's latitude and the inclination of the lunar orbit to the ecliptic.

- E (upper left): vertex of the triangle (node of the lunar orbit)
- L (left, beneath E): point on the ecliptic
- N (lower right): the Moon's position
- (arc): the inclined lunar orbit / latitude arc from E to N

— at which is given the Angle N, of Gr. 5, by the Tychonic [computation]; and to it the opposite Lunar latitude EL is Gr. 47 minutes [I], therefore the base EN — that is, the Lunar Ecliptic [arc] reduced from the nearer of the Nodes — by the laws of Trigonometry falls out at Gr. 9, 3 minutes [I], 50 seconds [II], 51 thirds [III]. But according to the mean motion the true place of the Moon was in Aquarius at Gr. 23, 5 minutes [I], 59 seconds [II].

7. We also, with Father P. Grimaldi [Grimaldi] at Bologna in the Year 1645, on September 27 by the Gregorian style, but the 17th by the old style, observed a Lunar Eclipse of 6 digits from the North, an Hour after noon, but equated [to mean time] 7 minutes [I] 25 seconds [II], 28 seconds [II]. The Luminaries then stood thus:

	Sign.	Gr.	I	II
Solis Verus	6	4	20	17

	Sign.	Gr.	I	II
locus [True place of the Sun]				
Eius Anomalia [Its Anomaly]	2	28	56	14
Lunae Verus locus [True place of the Moon]	0	4	20	17
Eius Anomalia [Its Anomaly]	6	6	3	17
Luna medius motus [Mean motion of the Moon]	0	3	16	32

8. The Semidiameter of the Shadow, corrected, and therefore likewise the true Latitude of the Moon (inasmuch as in this Eclipse of 6 digits, point 48 [is] in the aforesaid Triangle, [namely] side EL, with which point [and] angle N, at the summit Gr. 3, results the Lunar Ecliptic [arc] from the Node) was Gr. 9, 13 minutes [I], 10 seconds [II]. Hence the place of the Node was in Pisces at Gr. 25, 7 minutes [I], 17 seconds [II]; but according to the mean motion of the Moon it was in ♋ [Pisces] at Gr. 24, 3 minutes [I], 21 seconds [II].

1. Rule concerning the Annual Motion of the Node.

9. The Interval of these Eclipses was 862,736 days, hour 1, 26 minutes [I], 28 seconds [II]; this time, resolved into horary minutes, is altogether 1,242,341,365; and this time, according to the Analogy at number 4, indicates the Southern Node retrograding in the order of signs through 126 degrees of the absolute Zodiac, and retroceding from the grade of Aquarius 24 degrees, 5 minutes [I], 22 seconds [II],

it strikes Gr. 219, 0 minutes [I], 38 seconds [II]. There are resolved, then, 126 degrees of the Zodiac, together with the degrees 329, 0 minutes [I], 38 seconds [II], in the second

164,470,931 seconds [III]. By these, drawn through the minutes of a single Year [525,600], it makes the number of seconds of the Zodiac as 86,445,921,333,100; this number, divided by the interval given above (1,242,341,365), leaves the Annual Motion of the Lunar Node, 69,583 [???], that is, 5 minutes [I], 19 seconds [II], 43 thirds [III], 55 fourths [IV] — not unlike the Tyconic, who has 5 minutes [I], 19 seconds [II], 43 thirds [III], 4 fourths [IV]. Divide here this motion by the days of the Year, 365; and there will come forth the Daily motion of the Node, 3 minutes [I], 10 seconds [II], 38 thirds [III], 40 fourths [IV].

[Margin: Annual motion of the Node.]

[Margin: Daily motion of the Node.]

2. Rule concerning the Motion of Latitude.

10. Add the Daily motion of the Node to the Daily motion of the Moon's latitude from the beginning of Aries — concerning which in Chapter XII, number 3 — and there will be the Daily Mean Motion of Latitude. Add likewise the Annual motion of the Node to the Annual motion of the Moon — concerning which in the same place, number 6 — and there will be the Annual motion of Latitude, as below:

CAPVT XV.

On Establishing the Epochs of the Lunar Motions.

1. If from a single Eclipse, selected as the most evident of all, the Radix be established, the time of that Year's full moon at the beginning or end of that Year is to be reduced to mean time, and the true place of the Moon to its [mean] place — that is, to the mean motion; and this is to be done either by adding, or by subtracting the mean motion that corresponds to the interval between the time of the observed Full Moon and the beginning or end of that Year — so that the Epoch of the Lunar motion may be had at the end or beginning of that Year.

For example, in the Year 1610 of Christ, an Eclipse was observed on December 29, and the apparent hour was 16 after noon, but equated [to mean time] 16 hours 13 minutes [I] 10 seconds [II]; at which moment the mean motion of the Moon was Sign 8, Gr. 3, 47 minutes [I]. The true place was diverse from the place opposite the Sun by Sign 3, Gr. 8, 22 minutes [I], 25 seconds [II]; and the Anomaly was Sign 6, Gr. 2, 28 minutes [I], 15 seconds [II]; with the Equation 18 minutes [I] 38 seconds [II] to be subtracted from the true place of the Moon. From the true

moment, then, to the end of the Year there remained Days 1, hour 7, 46 minutes [I], 40 seconds [II], to which by the mean motion of the Moon there correspond Gr. 17, 26 minutes [I], 47 seconds [II]; and of the Anomaly there correspond Gr. 17, 17 minutes [I], 56 seconds [II]; which being added to the mean motion of the Ecliptic moment, there rises up, for the Year 1610 complete:

	Sign.	Gr.	I	II
Radix ☽	3	26	0	34
Anomaliae [of the Anomaly]	6	20	46	11

3. But if, in order that the Observations of several Eclipses may be had sufficiently accurate, it is expedient that the Radix of the same Year be inquired from several such observations, [and] that one which is found diverse — that finally ought to be chosen which dissents least from the rest of the observations. Hence it never happens that many establish their Epochs which they constituted from a single Eclipse — namely, Ptolemy in Book 4, Chapter 8; Copernicus in Book 4, Chapter 7; Vendelinus in his *Idea Tabularum Atlanticarum*, page 35; and Boulliau in Book 3 of the *Astronomia Philolaica*, Chapter 7. But which, and how many Eclipses, those who rested their Lunar Epochs upon them — Tycho, Longomontanus, Kepler, Lansberge [Lansbergius], and Petavius [Petavius] — do not disclose; they indicate only that they derived [them] from several, just as [they derived] the mean motions, so likewise the Epochs of motion. Of these certainly all eclipses are adduced in the Catalogue of Chapters 8 and 9; yet from the diverse Radices of the Year 1600 Gregorian complete, and from the Epoch of the Year 1 of Christ at its inception, we have obtained, on account of the diversity of the Observations

[Margin: Lunar Radices.]

the number, yet at last, after very many labors of calculation, we have decided to follow the radices of the nodes and of the lunar epochs written above, the ones drawn from the greatest number of eclipse-observations, as coming nearer to satisfying [the data]; and therefore we select them for the meridian of Bologna at the meridian [i.e. midnight] of the last day of December.

[Margin: Radices ☽ (node) and Anomaly.]

Radix	Ω Sign	Gr.	I	II	Ano maly Sign	Gr.	I	II
Chris t	4	2	3	35	6	22	4	24
1600	7	25	19	20	0	7	27	9

§4. As for the epochs of the lunar nodes, since (as stated in Caput XIV, num. 8) on 1643 September 17, at the hour after midday at Bologna, the equated time being 7h 25' 28", the ascending node was in Pisces at 24°3'21" — provided the place of the Moon's mean motion at that time, and hence at the end of the year 1644, is correct: there are one bissextile year [intervening], and besides the 94 days from December 16 at 44'32" — from which, by the mean motion of the node, the aforesaid place in Pisces being subtracted, the radix of this node remains at sign 10, 0°29'33"; and this is the radix of the boreal [northern] node:

Sign.	Gr.	I	II
10	0	29	33

To this, adding the motion of 44 Julian years, which equals sign 4, 29°39'33", gives the Radix for the Gregorian year 1600:

Sign.	Gr.	I	II
9	10	42	2

§5. But from other eclipses, as is found [in the determination of] the year of the node's motion at gr. 19, etc., so that the Radix for the year 1600 of Christ, Gregorian, satisfies a greater number [of eclipses], it is:

Sign.	Gr.	I	II
9	11	22	50

And hence the Radix at the beginning of the years of Christ:

Sign.	Gr.	I	II
8	28	51	22

CAPUT XVI.

Observed solar eclipses — those, however, selected which are suitable for the lunisolar motions; and the diameters of the luminaries to be established; together with astronomical calculations added here and there.

[Margin: Ord.] [Margin: Total.]

Although universal chronology requires that certain years be marked and characterized, and therefore that many solar eclipses be observed, these are nevertheless of use for chronology. Yet astronomers describe far fewer than were observed, or — as for the quantity and quality of these — with more certainty as to time. We therefore select those eclipses which are observed in such ways, with the more certain methods, both diligent and trustworthy. In the calculations, moreover, [we select] those that astronomers subjoin in their explanations of the differences of meridians, [more reliable] than those which they themselves suppose; for otherwise the parallaxes of longitude would have to be reckoned [anew] whenever the calculation is transferred to a different polar altitude.

[Margin: Ord.] [Margin: Total.]

1. In the year 585 before Christ, on May 28, the most celebrated solar eclipse occurred, as predicted by Thales [of Miletus] to the Ionians. It was seen near the Hellespont and Sardis, in Lydia, and everywhere it was total, between Cyaxares king of the Medes and Halyattes king of the Lydians — as Eudemus relates in Clement, Stromata I, and Herodotus, book I. There, after they had long fought with equal Mars [i.e. an undecided battle], the day was suddenly turned into night;

it would have been so [total], but others say the totality occurred near the Hellespont, where the eclipse-digits of the Sun were 9 [and] 36, vel 48 [?]; the Alexandrians of Egypt affirm [it]. Cleomedes, book II, cap. 3; and Theon of Alexandria in his book 6 on the Almagest, cap. 11. Pliny, book 2, cap. 12, designates the fourth year of the 48th Olympiad; and Bünting, Scaliger, and Salianus [reckon it] in the year of the world 1469. Kepler in the Optics, nor does Lansberge in the Thesaurus Observationum gainsay [the fact], assigns the third year of the 48th Olympiad. For from the new moon, as immediately preceding the solstice, the year [is] third — and the third year [thus] begins from the said Olympiad. Lansberge adds that it was Nabonassar's year 163, [and] the day [was] a Tuesday; and from his own Tables of Tycho, [computing] the eclipse [as] of

digits 12, 10' near the Hellespont, and near Sardis at 4°38' p.m.; at Alexandria, however, of digits 10, 12. We, however, from the Great Tables of Tycho, find this eclipse coming out in the same year and on the 28th day of May, at the hour near Sardis 5, 26' posited [as] the Anomaly of the Sun at gr. 1, 3, and the Moon nearly 170. Cauius therefore badly advances the eclipse for the year 607; and Petavius (whom Jacob Billy follows in his Tab. Lodoiceis) for the year 597, July 9; for both, on their own Tables, place it almost at the highest [point of] early morning, and the digits at 9, 22, near Sardis; nor does the time-requisite for totality of the eclipse agree at all. And it is conceded that the beginning of the eclipse [is] right at early morning, lasting hardly an hour, 1, 16' after sunrise; whereas Petavius, who computes the eclipse at hour 5, 45' after noon, contradicts — though Petavius himself relates that the eclipse [occurred] in that year; I know it [from] Petavius, lib. 10, on the Doctrine of Time, cap. 1, [who treats] much about the opinions current at this eclipse-time of the learned, examining [them]; but the more common [is] of the year 585; we have, however, from the Prutenic Tables, digits 11, 30', [and] from the Parisian [Tables] near the same digit, 11, 30. Therefore I, from the most certain Tables, [find] that it can be reckoned at the year 585, p.m., yet I half-doubt it before sunset; but it can happen for another reason, on account of too great a distance of meridians, or a defect of the Parisian [Tables]. From the Tables, since others do not cease [to dissent], that which represents this [eclipse] at hours before sunset, even in the same year 585, by reason of its totality. Rudolphine [Tables], near Sardis, [give] the sum at p.m. 5, 17', 4". Of digits 12, 1', 36" — [this] was the truer Anomaly of the Sun at gr. 359 [and] 3, and the Moon at gr. 170.

[Margin: Total.]

2. In the year 310 before Christ, when Agathocles king of Sicily was transporting his fleet into Africa against Carthage — namely in the third year of the 117th Olympiad, as Diodorus Siculus relates, lib. 20, and Justin, lib. 22 — "so great a darkening of the Sun occurred that it was indeed plainly night, the stars being visible everywhere," says Diodorus. It was nearly total at hour 8 in the morning. Bünting, following Salianus, [reckons it] from the Prutenic Tables [for] August 15, [hour] 8, [digit] 15; p.m. near Syracuse, [digits] at gr. 11. Petavius, from the Parisian [Tables], h. 8, 2' [and] digit 11, 10'. The Anomaly of the Sun [is] at gr. 74, near the Moon 201.

[Margin: Total.]

3. In the year 217 of Christ, when Gordian the younger was emperor, [as] Capitolinus relates: "so great a solar eclipse occurred that it was believed to be

night, nor could anything be done without lamps lit." Kepler in the Optics asserts it total. The Prutenic [Tables] give the digits less than 11; Petavius [gives, at] Rome, h. 4, 51' p. merid., the digit 10; Lansberge in the Thesaurus, [April] 11, h. 4, 51', 2" after noon, Rome computes — but he says it was seen total, because the little particle of the Sun is hidden by the eclipse, and was near the Horizon. The Anomaly of the Sun was at gr. 306, [and] the Moon 204.

[Margin: Total.]

4. In the year 334 of Christ, when Optatus and Paulinus were consuls, as Firmicus relates, lib. 1, cap. 2: "The Sun in mid-day at the very time of the lunar eclipse [solar?] suffered a certain darkening, so [great that] life seemed about to fail mortals; and, this denouncing [?], a sudden eclipse [appeared]" — and it was seen at Byzantium too. This eclipse cannot be disentangled from the Prutenic [Tables]; and Maulerus [Mästlin?] notes it in the Isagoge, cap. 11, and Petavius, lib. 8, cap. 14, [says] Petavius computes that eclipse [for] July 17, h. Rome 11, 13' p.m., with the digit 10, 14'. Lansbergius, h. 11, 9', [computes] it near the Moon, [whose] appearance was [in] no way [such], lucid; which we call an annular eclipse, in the Almagest. The Anomaly of the Sun was at gr. 39, [and] the Moon 296.

[Margin: Annular.]

5. In the year 484 of Christ, on January 13, an eclipse occurred, "which day was turned into night, [so that] profound darkness fell, and the stars were seen," notes Reinerus in his Catalogue of Eclipses; from the life of Proclus, described by Marinus [in] Greek, which is asserted

he observed the eclipse at h. 6, 51' p.m.n. of the digit 4; as in the library of the Most Serene Grand Duke of Tuscany [Magni Hetruriae Ducis], p. 81. Adding to the directions the Prutenic [Tables] promised the digit 8. Tycho himself, from his own Tables in the Progymnasmata, gives the digit 5. Mästlin, observing at Tübingen, h. 7, 36' ex Prutenic computed h. 7, 40', [digit] 8. Lansberge at Tübingen reckons h. 7, 44', [digit] 9. But Magin from the Prutenic [Tables] at Venice [gives] h. 7, 57', [digit] 8, [hour] 10, 27'.

25. In the year 1591, July 30, new style, Tycho at Uraniborg observed the solar eclipse h. 3, 33' p.m., the digit $2\frac{1}{2}$; let the digit be esto Prutenic [as] 4, 6', [digit] 1.

26. In the year 1595, October 3, new style, Tycho at Uraniborg observed the diminution of the Sun [at] h. 1, 8' p.m., digit 3, 50 [?]. At Tübingen, Mästlin saw the digit $2\frac{1}{2}$. Gratian Kepler [at] Graz, digit 3. Magin at Venice computes by the Prutenic [Tables] h. 1, 16' [and] digit 4, 14'. But Origanus from Frankfurt and

Oderam computes by the Prutenic [Tables] h. 2, 4', [and] digit 5, 18'; but Tycho [gives] h. 1, 16', [digit] 3.

27. In the year 1598, March 7, new style, at Uraniborg, the pupil of Tycho observed the solar eclipse [of] minutes 44' before midday, digit 9, [minutes] 10', vel alii [or others] 40'. Tycho himself, at Wandsburg, noted the beginning [at] h. 9, 12' p. mid. of the night. At Torgau in Meissen, however, Doctor Jessenus, in the palace of the Prince, observing this central eclipse, prominent everywhere [at the lunar margin], as Kepler relates in the Optics, p. 299, and 419. Lansberge computes [for] Torgau h. 10, 28' p.m.n. and nearly annular by reason of the Anomaly of the Sun [at] gr. 248; its diameter 30', 54"; and the diameter [of the Moon] 32'. [Margin: Annular.] But Goesius himself, observing the beginning [at] h. 2, 11' ante meridiem, with such darkness that the night [scene?] seemed at once to threaten. Frankfurt and Oderam, Origanus observed, the inter-minute 28' [and] 46" of the eleventh hour, [and] digit 9; although by Prutenic calculation Lansberge reckons h. 5, 28', [digit] 10, 55'; Magin at Venice by the Prutenic [Tables] reckons h. 9, 45', [digit] 11, 33', etc. in [the same] tome on Directions for the same Uraniborg ex Alphonsine [Tables] h. 11, 44', [digit] 8, 20'. Ex Prutenicis h. 9, 50', digits 11, 26', ex Tychonicis h. 11, 7', [digit] 10, 6'.

28. In the year 1600, July 10, new style, at Uraniborg [it] is placed [in] tom. 1, Progymn. Tycho [gives] the solar eclipse of digits 5, h. 1, 44' p.m. But at Benatek [Benátky] in Bohemia, Tychonici saw it h. 1, 46', digit 5. At Tübingen, Mästlin [gives] more digits than 6. At Prague, Kepler [gives] digits 7, as he has it in the Optics, p. 422, and 430. Magin by Prutenic [Tables] reckons at Venice hour 2, 14', but at Uraniborg h. 1, 47', [and] digits hic 4, 50', ibi 7, 19'. Origanus from Frankfurt by Prutenic [Tables] h. 2, 10', digit 5, 39', [hour] 5, 19'.

29. In the year 1601, December 24, new style, Lansberge [reckons] the solar eclipse [observed by] Goesius h. 1, 50' p.m. [Margin: Annular.] But the southern margin of the Sun was illuminated from the austral [southern] margin of the Moon [margin scrupule? ½ margin]; the Sun, [and] the boreal [northern] Moon coincided so far that the whole Moon was seen within the orb of the Sun — so was it observed in the Thesaurus. Where he computes the hour 1, 51', and the Anomaly of the Sun [at] gr. 176, cum diametro [with diameter] 35', 53"; the Moon's [at] gr. 7, cum diametro 30'; vel optice [or optically] 28', 30". Kepler at Prague observed the eclipse of more than [digit] 8, h. 2, 1', 53", vt [as] in the Optics, p. 359, and 413. In the Appendix, however, [and] the Progymnasmata note the diameter of the Moon [as] not according with the observation. Longomontanus, lib. 1 Theoric., cap. 9, relates that he observed the Piscatorian-

distant thousands of miles [?]; beyond [the place at] Nidrosia [Nidaros/Trondheim], it would have been seen, total[ly], everywhere encircling the Moon, equal [on all sides], the prominence being as if a sesquidigit; and such an eclipse-type, presented to itself [as] Andrea Foxio, [from] which Bergis [Bergen?] contends that the diameter of the Moon in the eclipse is contracted optically; the Sun, however, [appearing] larger — concerning which [is] our judgment, lib. 3 Almag. Novi, p. 376. Lansberge at Bergen, h. 1, 52', and expresses the [calculated] diameters [of] this phase, as Gassendus [does] in his Epicures [Epicurus exposition?] p. 893, where he gives the diameter of the lunar minutes more, [by] four [?] quarters, [referring] excellent greater vision in the Optics, of [the eclipse's] amplification of light, [or] of the attenuation of the luminaries; Magin at Uraniborg by Alphonsine [Tables] h. 3, 32', digits 7, 36'; Prutenice h. 1, 52', [digit] digits 9, 19'. Tychonice h. 2, 36', [digit] digits 9, 53'. Origanus from Frankfurt by Prutenic [Tables] h. 1, 57', [digit] 9, 56'; but Tychonice h. 2, 46', [digit] digit 9, 52'.

1 (Solar, continued). ...they would have [been so], but others say the totality occurred near the Hellespont, with the eclipse-digits of the Sun at 9, [and] 36, vel 48 [?]; the Alexandrians of Egypt affirm [it]. Cleomedes, lib. 2, cap. 3, and Theon of Alexandria in his sixth [book] on the Almagest, cap. 11. Pliny, lib. 2, cap. 12, designates the fourth year of the 48th Olympiad; and Bünting, Scaliger, [and] Salianus [place it] in the year of the world 1469. Kepler in the Optics — nor does Lansberge in the Thesaurus Observationum gainsay [it] — assigns the third year of the 48th Olympiad. For from the new moon, as most nearly preceding the solstice, the year [could be terminated as] third, and the third year is [thus] begun from the said Olympiad. Lansberge adds that it was Nabonassar's [year] 163, the day a Tuesday; and from his own Tables of Tycho [computes] the eclipse [as] of digit 12, 10' near the Hellespont, and near Sardis at 4°38' p.m.; at Alexandria, however, [of] digit 10, 12. We, however, from the Great Tables of Tycho, [find] this eclipse coming out in the same year and on the 28th day of May, at the hour near Sardis 5, 26', the Anomaly of the Sun posited at gr. 1, 3, and the Moon nearly 170. Therefore Cauius badly advances the eclipse to the year 607, and Petavius (whom Jacob Billy follows in the Tab. Lodoiceis) to the year 597, July 9 — for both, by their own Tables, place it almost at the highest [point of] early morning, and the digits at 9, 22, near Sardis; nor does the time required for the totality of the eclipse agree. And it is conceded that the beginning of the eclipse [is] right at early morning, not lasting beyond an hour, 1, 16' after sunrise; but Petavius, who computes the eclipse at h. 5, 45' after noon, contradicts — though Petavius himself relates that the eclipse [is] of that year. I know [it from] Petavius, lib. 10, on the Doctrine of Time, cap. 1, [discussing] much about the opinions of the learned

current at this eclipse-time, examining [them]; but the more common [view, of] the year 585: from the Prutenic Tables, [digits] 11, 30'; from the Parisian [Tables] near the same, digit 11, 30. Therefore I, by the most certain Tables, [reckon it] for the year 585, p.m., yet I half-doubt [whether it was] before sunset; but it can happen for another reason, on account of too great a distance of meridians, or a defect of the Parisian [Tables]. From the Tables, since others do not cease [to disagree], that which represents this [eclipse] at hours before sunset of the Sun, even in the same year 585, [is preferable] by reason of its totality. The Rudolphine [Tables] near Sardis exhibit the sum at p.m. 5, 17', 4". Of digit 12, 1', 36" — [this] was the truer Anomaly of the Sun at gr. 359, 3, and the Moon at gr. 170.

[Margin: Total.] [Margin: Total.]

6. In the year 840 of Christ, on May 5, on the Vigil of the Ascension, there was a solar eclipse: maximal, so that the stars were seen; "and a horrible color in [earthly] things [appeared] mutated; yet nothing differs from this in truth than appeared; for the Moon, first interposing [itself, took] the light of the Sun, partly restored [it], and then the whole [light was] recovered" — as the Anonymous author relates, whom Ludovicus Ph. Hammonius cites, lib. 5, cap. 19; and the Chronicon Floriacense; Petavius too [says it happened] in Germany, h. 11, 22' p.m.n. The Anomaly of the Sun [is] at gr. 324, near the Moon 173. [Margin: Total.]

7. In the year 878, October 29, which was the year 29 of Ludovicus Balbus [Louis the Stammerer], on the 4th [day] of the office of the Calends of November [i.e. Oct. 29], the Sun was obscured for half an hour, "and the stars appeared in the sky, and all night seemed to threaten" — as Petrus Bibliothecarius [Anastasius Bibliothecarius?] and the Annals of the Franks, or of Fulda, note. Petavius from Kepler in the Optics [gives] the eclipse [as] total; h. 1, 44', [digit] 9, 22'. The Anomaly of the Sun is at gr. 64, near the Moon 335; and it has the year 8. [Margin: Total.]

8. In the year 890 of Christ, but [after] the death of Alexander the Great 1214, and [in] the Dhul-Qarnain 1202, [on] the 1st of August, Albateginus [al-Battānī], as Petavius relates, lib. 30, observed the solar eclipse: of digits more than 8, [lasting] more than one hour of the Hour [equinoctial hour]. Petavius computes [it] from the Parisian [Tables] h. 0, 46' p.m. and digit 9, 22'. The Anomaly of the Sun is at gr. 84, near the Moon 8. [It] near merid., and Aractae.

9. In the year 893 of Christ, on the 23rd day of January, or [counting] from the death of Alexander 1224, [the] Dhul-Qarnain 1212, Albateginus — as Petavius relates, lib. 30 — observed the solar eclipse [in] Syria [Aractae] [at] h. 1, 40' near

midday, and [the Sun] obscured by the eclipse to a minimum [of one] third [of its disk]; Lansberge computes the digits [as] 9, 40', and h. 2, 15' ante merid., near Aractae. [Margin: Total.]

10. In the year 1187 of Christ, September 4, so great a solar eclipse occurred that "the stars appeared throughout the day as if at night," like the Lychosthenes [reading?]; and the [first] light came [back] on the 4th of the Calends of September. [Margin: Total.]

11. In the year 1197, on the day before the Nones of September, Gregorius Tholosanus [Pierre Grégoire of Toulouse], lib. 21, de Republica, cap. 27, notes so great a solar eclipse, and that the stars appeared. [Margin: Total.]

12. In the year 1239, Gassendus [Gassendi] from the Martyrology of Digne, in the Ephemeris, p. 895, copies these words: "In the year MCCXXXIX, on the 3rd, Nones of June [June 3], on the day of Venus [Friday], the Sun was obscured, so that the day was turned into night around midday, and the stars appeared," and "the same [eclipse] was conspicuous, and engraved upon a stone in a public square." [Margin: Total.]

13. In the year 1415, Gassendus [reports] from the History of Dignensis [Digne] above: "In the year of the Lord MCCCCXV, on the day of Venus [Friday], there was a solar eclipse around the end [of] the [day], and the stars appeared most clearly." This Reinholdus in the Theoricon, and Pulcis [Plautius?] from the Polish History of Matthias Mechouiensis [Maciej of Miechów], as Origanus [does] in the Preface, Tom. 2, Ephem., relates [it occurred] at Constance, year 1415, June 7, h. 4, in the morning — not only were the stars seen, but, just as by night, sudden caligo [murk] covered the lands; Lansberge computes 12, 11', and at hour 6, 5' after midday, the median morning. The Anomaly of the Sun is at gr. 355, and near the Moon 204. [Margin: Total.]

14. In the year 1478, July 29, Bernhardus Walther observed at Nuremberg the eclipse of the Sun, [its] beginning [at the position] from the setting-point gr. 54, 30'; the end gr. 41, 30'. [Margin: Total.]

15. In the year 1485, March 16, by the testimony of Lycosthenes: "Lights were lit at noon, [it was] so dark, indeed candles were lit, etc." Walther observed at Nuremberg the eclipse of the Sun [of] digits nearly 11, [beginning at] h. 4, 27' after noon; the Alphonsine [Tables] give the digits 12, and Kepler in the Opt. p. 131, contends that it was total — although Lansberge from his own Tables [gives] h. 4, 45'; Nuremberg computes [the] digit 10, 50', and the Anomaly of the Sun [at] gr. 170. [Margin: Total.]

16. In the year 1497, January 18, Bernard Walther saw at Nuremberg the eclipse of the Sun, [its] end h. 3, 24' p.m.

17. In the year 1539, April 18, at Milan was seen the solar eclipse, of digit 9, vt refert [as] Cardanus relates.

18. In the year 1544, January 24, Gemma Frisius, cap. 18, [reports]: "the astronomer relates [the] observed solar eclipse [at] Louvain, h. 8, 53' circiter [about] p.m.n., the digit, more than 10 in the lower part [of the Sun's disk]"; let the Ephemerides above des-

designated [it], following Kepler in the Optics, p. 296, [says] "the day began to darken, and the birds, which by the first light had flitted gaily, fell silent, [the Sun] obscuring itself"; the digit 11. Reinholdus, however, computes it h. 7, 18' p.m.n. of Louvain; digitos[que] 11, 1. The Anomaly of the Sun [at] gr. 217. The Moon 237, [which] not infrequently brings about totality of the eclipse; yet it could have been seen greater, because it was in the morning, and near the Horizon [there were] vapors. [Margin:...]

19. In the year 1545, on the 5th of the Ides of June [June 9], the deficiency of the Sun was observed by Gemma Frisius, h. 4 p.m. and the digit $4\frac{1}{2}$; ex ipsius [from his own] Radio Astronomical, cap. 15, and 17. [Margin: Total.]

20. In the year 1560, August 21, in the region of Coimbra [Conimbrica] around midday was seen the horrible total solar eclipse, of the space [duration of] one hour and more, vt refert [as] the eyewitness Clavius relates in cap. 4, Sphaerae, where he narrates: "the Sun in our time [was] truly so widely[?] obscured: there shone certain nocturnal greater [stars]; nor [was there] anyone who, in such a [thing], could see to put [his hand], so clearly were the stars in the sky apparent; [and even] the very birds [mirabile dictu! wonderful to say] in the air fell to the earth [in] terror, descending in such foul [horrida] obscurity." There was present Fr. Emmanuel Vega, from whom (as Scheiner [says] in Rosa Ursina, lib. 3, cap. 7) [he] narrates that it lasted for nearly three hours, [with] women wailing, and uproarious shouting as at the impending [downfall] of the world; nor were the stars ever seen so clearly, since [it was] the work of the lights [that they were] not recognized — [as] of certain men in Rome, although Ignatius Danes [Danti?] bears witness; the same [thing happened] at Rome, which Ignatius Danes [relates] at gr. 30, near merid. itself. Tables, however, [give it] observed for itself; for the Anomaly of the Sun, Vienna in Austria observed 10' before midday. But from the Chronicon of Mercator, [at] Vienna in Austria the eclipse was at h. 3, 52' p.m. [for] the highest digit, 5. Paulus Fabricius and Tilemannus Stella — Joannes Stadius in

his Ephemeris of this year says it was [at] Brussels h. 1, 48' p.m. and Lansberge in the Thesaurus observed the digit 6, 31'. At Coimbra, however, [he] computes the digits 12, 4'; but he saw the more long-lasting [phase], because the Sun emerges into the [light] Radios, until it is seen [as] of digit 12, 28', which appearance is usually attributed to the patrocium [defense] of their own Hypotheses. Tycho himself, who admits total eclipses, writing upon this eclipse of Clavius as if wondering, and incredulous, vt narrat [as] Lansberge relates in the Astronomia Optica, p. 285. The Anomaly of the Sun was at gr. 64, the Moon however at gr. 136. [Margin: Total.]

21. In the year 1567, April 9, Clavius [at] Rome (he himself says in cap. 4, Sphaerae): "the Sun, [though] not totally deficient, yet the remaining [part] failing, [showed] a certain bright circle around it." Tycho, in his letters [to] Clavius, vt refert [as] Kepler relates in the Optics, p. 297; the Astronom-Optica narrates that it was seen, [reduced] to a digit at midday; planè [plainly], but in the Progymn. computes the digits 8, 20'; near totality, but from the south. [Margin: Annular.] Mästlin observed at Tübingen the same [eclipse, its] beginning h. 10, 25' p.m.n., from the south. Mercator at Duisburg saw Clivia [Cleves?]; the beginning h. 10, 25', p.m.n., the start [at] h. 5; Cornelius Gemma at Louvain saw the beginning [at] h. 10, 12'; the highest [phase] h. 11, 40', near totality at h. 5; the time [being] as it were toward evening, 11, 40', [digit] 35; but the stars [were] in no way seen. Nonetheless, Kepler above, vt habet [as] he has [it] in the Optics, p. 302, [says] for this Table not to exhibit the annular eclipse, [though] anyone discerns in the eclipse the [Sun's] illumination, as if seen [as] of an aethereal hue in contact with the illumination of the Sun, the radii of the Sun being refracted in the air around the lunar [body], yet Lansberge from his own Annular-eclipse Tables collects [it], eandem ex Prutenic [the same from the Prutenic Tables] in the Epicures [exposition] p. 895, eandemque [and the same], because the diameter of the Moon was smaller, since its Anomaly [was at] gr. 191. The Moon however 100. Mästlin, [from] the Prutenic [Tables] [gives] h. 5, 41', and the digit 8, 36'; with which, however, the time [agrees] for which he observed it, [the digit] 10, fere [nearly]. [Margin: Annular.]

22. In the year 1584, April 30, old style, Tycho at Uraniborg [observed] h. 5, 39' p.m.n. observed the solar eclipse, digit 3, 39'; Magin from the Prutenic [Tables] reckons Venice h. 4, 59', [digit] 3; Maginus from the Prutenic [Tables] reckons Venice h. 4, 59', and digit 4; Puudelinus [Wittich?] ex Tab. Atlanticis [reckons] Uraniborg h. 5, 36'.

23. In the year 1588, February 16, Tycho [at] Uraniborg [observed] the beginning of the solar deficiency [at] h. 1, 32' p.m. the end h. 2, 51'; but from the Tyconic sheets, Kepler, p. 414, *Astronom-Opt.*, explains the inclinations of the eclipse. Mästlin from the Prutenic [Tables] computes Tübingen 57' after merid., and the digit 1, 10'; but Magin at Venice [gives] h. 1, 23', and the digit 1, 3'.

24. In the year 1590, July 31, new style, Tycho at Uraniborg ob-

30. In the year 1605, October 12, at Middelburg the solar eclipse was observed by Joannes Rotarius [at] h. 1, 15', p.m. digit 10½, from the south, vt narrat [as] Lansberge relates in the *Thesaurus*, [where] he reckons h. 1, 22', and the digit 10, 38'. At Naples that the total [eclipse] was observed, ait [says] Kepler in the *Epitome Astronomica*, p. 893, and cap. 23, *de Stella nova* [on the new star]. Lansbergius at Naples reckons h. 1, 49', and the diameter [of the Moon, or] of the Sun 34, 18". The Moon however 34, 52'; and the Sun deficient [to] totality.

"Funestissima Foricalcanti [the most dire foreboding] — the Province saw the Sun totally, except [for] a most tenuous thread of light extending from the North," he attributes [it] to the [Atmosphere of] the Earth, illustrated [by] the Atmosphere; indeed he adds at Marseille the whole Sun [was] obscured, the Atmosphere appearing [only] with dense darkness. Magin at Venice from the Prutenic [Tables] collects h. 2, 55', digits 11, 31'; Origanus from the Prutenic [Tables] [at] Frankfurt h. 2, 0', [digit] 10, 35'. Tychonice h. 2, 3' [?], digit 9, 25'. [Margin: Total.]

31. In the year 1608, August 10, new style, at Goes [Goësa] the solar eclipse was observed by Lansberge h. 4, 7', [digit] 5, 30'; from the south, ex sua calculatione [from his own calculation] h. 4, 8', [digit] 5, 29'. Vlitenburge [Wytenbogaert?] Melchior Josephus observed the solar deficiency [at] digit 5; the Hafnienses [those at Copenhagen] Longomontanus saw nothing of the air's cracked-section [aciem], yet he himself reckons [it] at 5, 24'. Origanus, [from his] thousand [tabular values?], [says] Frankfurt [observed] nothing [as] deficient ex Tyconis semidiam. [Tycho's semidiameter]; but his corrected [Tables] ex Prutenicis compute the digits 1, 46', h. 4, 40'. Maginus however at Venice [from] Prutenice [gives] h. 5, 47', [digit] 3, 14'.

32. In the year 1612, May 30, the monk Christophorus Scheiner observed the deficiency of the Sun [at] digit 7, h. 11, 23', post med. noct. [after midnight]; Longomontanus [at] Copenhagen [reckoned it] with 7 [observed] points h. 8, h. 11, 7', vt habet [as he has it] in the *Theoricon*, lib. 1, cap. 9; Magin at Venice [from] the Prutenic [Tables] [gives] h. 11, 38', digit 7, 4'. Tychonice h. 11, 38', [digit] 7, 14'.

33. In the year 1621, May 21, Petrus Gassendus at Aix [Aquis] observed the solar eclipse [at] h. 8, 18', circiter [about] p. med. noct., and the digit $9\frac{2}{3}$, vt narrat [as] he himself relates in the Epicures [exposition], p. 892, and Furnerius, lib. 12. Hydrograph. cap. 14. Lansberge however at Middelburg observed eam [it] h. 8, 18', [digit] 11, 12'; this true calculation, however, gives h. 8, 16', [digit] 11, 11'. The Prutenic calculation [via] Magin at Venice [gives] h. 8, 43', [digit] 9, 20'; but Origanus at Frankfurt h. 8, 55', [digit] 10, 30'. Tychonice [it occurs] in the same [reckoning] h. 9, 6', cum digit 10, 44'.

34. In the year 1628, December 16, Baricinone [at Barcelona], Fr. Jo. Baptista Cysatus [Cysat] observed the solar eclipse [at] h. 1, 9' p.m. digit 8, 45'. Kepler in Austria observed it cum annulo lucido [with a bright ring], and [appearing] vaporous around the Moon. Origanus, by translated calculation, [reckons it via] the Strait of Gibraltar [Fretum Gaditanum] by the Prutenic [Tables] h. ibi [there] 2, 40', digit 6, 34'; but Tychonice minutis 8 ante meridiem [8 minutes before noon], and the digit 4, 5'. [Margin: Annular.]

35. In the year 1629, June 21, Fr. Rhodes of the Society of Jesus, in the city of Tunkin [Tonkin], which is the seat of the Tunkinese Metropolis, [at] the latitude 18, observed the solar eclipse [at] h. 18, [digit] 11'; from the south. Origanus, in the eastern places distant from Frankfurt and Oderam [at] h. ris [the hour] 6, 18', and under boreal [northern] latitude greatest grade [day] 15, reckons this eclipse by the Prutenic [Tables] of digit 12, 21'; and Tychonice [at] h. 11, 26', [digit] which much disagrees with the observation, in latitude greater indeed, yet not in [latitude] so great, however much it required of [tabular] differences.

36. In the same year 1629, December 14, an eclipse of the Sun was observed in America Australis [South America] in the Province of Macha [Machu?], under the latitude of the Austral [South] Pole gr. 20, vt [as] the beginning was seen h. 4, 45' ante meridiem, [the] end after midday h. 1, 45', vt habeo ex litteris [as I have from the letters] of our Fathers ad nos [to us]; Origanus, by translated calculation ad [for] Mediterranean Peru under the Austral [southern] latitude gr. 20, and [at] the meridian distant from Frankfurt and Oderam h. 5, 6', collects by the Prutenic [Tables] [an] eclipse h. 1, ante meridiem of digit 11, 36'; but Tychonice 10, 14'.

37. In the year 1630, June 10, the solar eclipse was observed [at] Dordrecht [Dordraci] by Martino Hortensio h. 7, 15', digit 10, and parum plus [a little more]; but Middelburg [from] Lansberge [gives] h. 7, 10', digit 10, [and] 10, 42'; calculation, however, ex ipsius Goesa [from his own Goes Tables] [gives] the digit, the same [as] of that [grade?]; gr. 10, 42', and h. 7, 21'. The Parisians [from] Gassendus h. 7, 11', observed the digit 11, 32', vt narrat [as he relates] in the

Epicures [exposition], p. 885. Oxford [via] Bainbridge noted the beginning h. 5, 58', p.m., the Fathers PP. Andreas Arzet, and Jo. Baptista Cysatus at Ingolstadt observed h. 7, 54'; the digit 11, 57'. We too, at the Forum Naeuij in the territory of Parma [agro Parmensi], h. 1, fere [nearly] before sunset, saw it of digits nearly $11\frac{1}{3}$. Magin-

(continuation of Caput XVI, the solar-eclipse catalogue, from item 37, the eclipse of 10 June 1630)

[Magin]us by the Prutenic tables computed it at 7h 3', 10 digits; Origanus at Frankfurt, Prutenically, at 7h 41', $12\frac{4}{5}$ digits; Tychonically at 7h 47', 10 digits, 19'.

38. In the year **1633, on April 8.** P. [Father] Andreas Arzet, of the Society of Jesus, at Regensburg observed the maximum of the solar deliquium at 5h 3', $6\frac{1}{2}$ digits; at 6h 44' we ourselves at Bologna saw it end, 5 digits, 15'. At Dijon, Gassendi at 4h 42' saw it of 8 digits, 18'. At Aix-en-Provence, Peiresc [Peiresc] and Gassendi at 5h 41' [saw it] of 8 digits, 48'. P. Beaugrand at 4h 26' and digits, fivefold [reckons] 6. Oroniū [Oronce — Oronce Fine?] [?] Baudringus at 5h 19' from the same furnace, lib. 12. Hidrograph. [*Hydrographia*] cap. 17. Origanus at Frankfurt Prutenically computes it at 4h 37', 7 digits; Tychonically at 5h 14', 4 digits, 30'.

39. In the year **1639, June 1.** A solar eclipse was observed by Hevelius [Hevelius] at Danzig at 6h $21\frac{3}{4}$, 10 digits, 48'. At Regiomontanum [Königsberg] in Prussia, Albertus Linemannus [Albert Linemann] at 6h, 20', or at 5', [of] 11 digits, 30'. At Stettin, Laurentius Eichstadius [Lorenz Eichstadt] at 6h 2', of 10 digits, 0'; or, as he narrates from the memory of Linemann, 4-fold. At Leiden, D. Keplerus [Jakob Kepler?] [?] at 5h 30', [of] 10 digits, 20'. Gassendus at Aix-Sextiae [Aix-en-Provence] at 8h 10', or 16', and the maximum at 8h 45'; collected from the phases at 16'. He refers it to the Epicurus, page 889. At Paris, Petavius [Petau], Robervalius [Roberval], Midorgius [Mydorge], Hardius [Hardy] — they note the maximum at 5h 21', 9 digits, 34'. Blesis [Blois?], D. Beaunius [de Beaune] at 5h 17', 8 digits, 30'. Flexis [Flèche?], the Fathers Deirenes, Batterus, and Fournierius [?], as they have it here lib. 12. cap. 17, observed the maximum of the eclipse at 5h 18'; at Rome D. Bertus and P. Kircher [Kircher] at 5h 10', or 16', [of] 8 digits, or $8\frac{1}{3}$. In Canada, P. Castellanus at the Residence of the Conception observed 5 digits, 4h 10', 15' in the morning. P. Agathangelus Capucinus [Agathangelus, a Capuchin] at Cairo [?] saw part of the Sun obscured, in a small space. Origanus at Frankfurt collects [it] Prutenically at 5h 54', [of] 8 digits, 52'; Tychonically at 5h 19', [of] 10 digits, 40'.

40. In the year **1645, August 21.** Gassendus at Paris [observed] the beginning...

[The text continues in the right-hand column.]

the beginning of the solar deliquium [he] observed at 10h 4' p.m. [reckoning the] night, as he relates in his *Epicurus* page 889. Maioticae [at Majorca] Vincentius Mutus [Vicente Mut] saw the beginning, the Sun being high above the horizon, at 57' 38'; the end likewise high above the setting at 62' 20'. The remainder, as P. Iacobus Billy [Jacques de Billy] writes, the middle was observed before noon at 58' minutes before noon. We ourselves at Bologna observed it at 31½ p.m., [of] digits 4, 30'. At Rome P. Daniel Bartolus [Daniele Bartoli] noted the beginning at 52' before midday. At Prague P. Theodorus Moretus, S.I. [Theodor Moretus, of the Society of Jesus] observed [of] digits 6, adding: Alderbachij [at Aldersbach?] [?] to Danubium [the Danube] 10 minutes p.m., the maximum of the eclipse seen [of] digits 5, computed by an arc of saffron color, [of] digit, 5, 45'. At Gdańsk, Joannes Heuellius [Hevelius] observed the middle at 12h 42' past midday, [of] noct. [night reckoning?] digits 7, 45'. Origanus at Frankfurt elicits the Prutenic middle of the eclipse at 1h 2' p.m., [of] digits 7, 23'; Tychonically at 30' p.m., [of] digits 5, 24'; but as from the Fretum Nassovium [the Nassau Strait — i.e. Lansberge's tables], Prutenically [of] digits 12, 4'; Tychonically [of] 10, 38'. Argolus [Andrea Argoli] at Rome, from the Danish [tables], collects the middle at 28' after midday, [of] digits 4, 19'. Montebrunus [Montebruno] at Bologna, from Lansberge, [computes] the middle at 5h, p. merid., [of] digits 4, 40'.

41. In the year **1640, November 4.** Hevelius at Danzig [observed] in the maximum of the solar eclipse [of] digits 5, 14¹/₃, p.m.; he observed [of] digits 5, 45'. P. Theodorus Moretus at Košetlice [?] in Bohemia did not perceive itself [the eclipse?] at 5, 13'. Vincentius Mutus at Majorca observed the middle at 2, 3' p.m. [of] digit 3, 33'; and the diameter of the Moon to the diameter of the Sun, as 4230 to 4150. Origanus at Frankfurt gives the Prutenic [middle] at 3h 30', [of] digit 5, 42'; Tychonically at 3, 8', [of] digit 4, 44'. Argolus at Rome from the Danish [tables] [at] 2, 23', [of] digit 5, 48'. Montebrunus at Bologna from Lansberge [at] 3, 20', [of] digit 5, 19'.

42. In the year **1641, April 8.** A solar eclipse was observed, but on the matters written below, as it is clear to me from the letters [sent] to me, or from the published little works of the observers.

The eclipse of **1641, April 8** is tabulated below. (This is the table that occupies the lower half of the left column and the foot of page 146; it is the item-42 eclipse table.)

Parsing notes: maximum cells blank for several observers. Mixed-fraction minutes printed with vulgar fractions (e.g. 55 38/60, 17 7/12, 53%).

45. In the year **1659, November 14.** The beginning of the solar eclipse was observed at Bordeaux [Burdegalae] at 1h 40' past midday; the maximum of the deliquium at 2h 35', [of] digits 9¾; the end at 4h 20'. At Bologna we observed the beginning of the solar [eclipse] at 2h 45' by horological reckoning; at Majorca the beginning was observed at 2h 15', [of] digits 9, 57'.

The right-hand inset table for this eclipse (item 45) gives the phases by digit:

Phase	Dig.	H.	I	II
Summa Ecl. redijt ad [The maximum of the eclipse returned to]	9	1	29	0
	8	1	11	44
	6	0	52	18
	4	0	36	46
Finis [End]	0	0	6	47
Duratio tota [Total duration]		2	31	48
Incidentia e Tempus [Time of immersion]		1	9	35
Emersionis Tempus [Time of emersion]		1	22	13

46. In the year 1661, **March 30**. At Bologna we observed, P. Franciscus Maria Grimaldus [Grimaldi] and I.

At Ferrara digits 9 were observed by D. Io. Dominico Cassino [Cassini]; at Turin [Taurini] digits 8, 25', and a duration of 2h 32', by the most excellent gentlemen Iulius Tortrinus [Giulio Tortrino?] and his son, in the presence of the Princes of the Royal House, and an assembly of the Nobility.

CAPUT XVII.

On the Apparent Diameters of the Luminaries, suitable for representing the Total and Annular Solar Eclipses.

1. Just as the Lunar Eclipses are most suited to determining the Lunar motions, and at times the diameters of the Luminaries, so the Solar Eclipses — especially the Annular and Total ones — require that there exist between the two Luminaries such a symmetry of their respective diameters as the observations of the aforesaid Eclipses demand, in keeping with the Sun's Anomaly and the Lunar Anomaly, [reckoned] for the time of those eclipses by both [sets of] tables. Hence, in order that there be Annular Eclipses, the apparent diameter of the Sun must be greater than the apparent diameter of the Moon at that same time; [and so] the Anomaly which is fitting for the motion by both tables must agree with the time of the Eclipses. Yet it is not required that the Sun's diameter be greater than the Moon's by so much as the doubled breadth of that little ring, or corona, which appears around the Moon. For a part of this phenomenon can arise from an optical enlargement of the disk, produced by the Sun's rays reflected from the Moon's margin into the air, or into our atmosphere.

2. Total Solar Eclipses, on the other hand, require that the Luminaries, agreeing at the time of the eclipse, have the diameter of the Moon greater than that of the Sun; and the greater the longer the Sun's delay shall have been in total obscuration — especially if the Eclipse should not happen close to the Horizon.

For that contraction of the Sun, which Lansberge devised, is fashioned to prop up his hypotheses, with no support from Optics. Nor, though Kepler maintain it, do the stars in the open shrink in the middle of the day [as much] as in the evening or at night — even granting that in totalities they are not seen, [and] that this conversely is observed at varying times of the air [i.e. atmospheric conditions], to whatever degree it stands established for the totality of the eclipse, as often as the Observers assert that the stars were nonetheless seen meanwhile. Hence, with the rest preserved that must necessarily be preserved, the diameters of the Luminaries might come out [as] commensurate, so that eclipses of this kind might emerge [as] total, with greater simplicity and truth to satisfy the observations. Therefore, just as the Lydian stone [touchstone], so for the eclipses noted below, the diameters of the Luminaries are to be approved by the degrees of Anomaly added in the following little table — or [those] nearest these. Now, the first column [holds] the significant numbers of the Eclipses, in the same order in which I recounted them in the preceding chapter. In the **Second** column are the Degrees of the Sun's Anomaly, which it held at the time of the Eclipse. In the **Third** column [is] the semidiameter of the Sun, apparent to us [and] most certain, from the things demonstrated in lib. 1. cap. 12. In the **Fourth** [is] the Anomaly of the Moon, which it held at the time of the Eclipse. In the **Fifth** [is] the semidiameter of the apparent Moon, [with] the limits necessarily required for representing the aforesaid Total and Annular Solar Eclipses. And note that the Minor [i.e. minimum] semidiameter of the Moon ought to be set [as] less than the Sun's [as] expressed in the Third column, and replicated in the Fifth.

[The table referenced is at the head of the right-hand column, page 148:]

Order of the Eclipses (Ordo Eclipsium)	② Anomalia [Sun's Anomaly] Gr.	③ Semidiam. Appar. [Sun's apparent semidiameter] I II		④ Anomal. vel distantia ab Apog. [Moon's Anomaly, or distance from apogee] Gr.	⑤ Semidiam. Appar. debent esse Maior, vel Minor quam [Moon's apparent semidiameter must be greater or less than] I II	I	II
		I	II				
29	175	16	2	7	Min. [less than]	16	2
4	39	15	25	64	Min.	15	35
21	290	15	42	100	Min.	15	42
27	247	15	50	130	Min.	15	50
20	64	15	41	136	Ma. [greater than]	15	41
7	135	15	55	140	Ma.	15	55
30	104	15	49	141	Ma.	15	49
13	253	15	30	156	Ma.	15	30
3	300			156	Ma.	15	38
2	74	15	43	159	Ma.	15	43

Order of the Eclipses (Ordo Eclipsium)	② Anomalia [Sun's Anomaly] Gr.	③ Semidiam. Appar. [Sun's apparent semidiameter]		④ Anomal. vel distantia ab Apog. [Moon's apparent semidiameter] Anomaly, or distance from apogee] Gr.	⑤ Semidiam. Appar. diameter esse Maior, vel Minor quam [Moon's apparent semidiameter] must be greater or less than]	I	II
		I	II				
12	349	15	30	160	Ma.	15	56
5	216	15	56	169	Ma.	15	30
15	270	15	46	170	Ma.	15	46
6	324	15	35	173	Ma.	15	35

Parsing notes: column headers carry small printed sequence-markers (rendered ②③④⑤); the first row's order-number is 29. Row for Eclipse 1 has blank Sun-semidiameter cells (apparent semidiameter not given). The ⑤ column states whether the Moon's apparent semidiameter must be greater (Ma.) or less (Min.) than the listed value.

Use of the preceding Table (Usus praecedentis Tabellae).

3. In the preceding Table, I have set forth the Order of the Lunar Anomaly in the fourth column, because, the Sun's semidiameter being firmly established for us by it, it is necessary to make the Moon's semidiameter agree in such a way that, in the four Annular Solar Eclipses, it be less than the Sun's; while in the remaining

Total ones, it be greater — and yet there shall be preserved the proportion of increment, or decrement, due to the Moon's distance from its Apogee. Therefore, by way of example, when the Moon is distant from its Apogee by gr. 140, its apparent semidiameter ought to be greater than 15', 55" — because, at the time of the Total Solar Eclipse no. 7, the Sun is indicated in the first column [to be] distant from its Apogee by gr. 135; [and] as is to be noted in the second column, [the Sun] held an apparent semidiameter of 15', 55". [But] if it held [its] apparent semidiameter in [an] Anomaly of gr. 140, [it would be] greater by minutes 15', 55"; [and] in the remaining ones greater [in proportion as it is] distant from its Apogee, the apparent semidiameter still goes out [i.e. increases], and up to degree 173 the semidiameter of the Moon's Anomaly comes out greater than the Sun's.

4. Furthermore, going on to examine the Tables of other Astronomers, I recognize that the apparent [semidiameters] are not represented by all of them for all the aforesaid Solar Eclipses; [for] the Danish Tables err in Eclipse 4, because the apparent Lunar semidiameter comes out greater than the Solar [one], while the Annular Eclipse requires it [to be] less. Similarly the following Eclipses err in the Tables [given] below:

In Eclipse	The Tables err (Peccant Tabulae)
4	Danish, Parisian, Rudolphine
5	Lansbergian
6	Lansbergian
7	Lansbergian
21	Alphonsine, Copernican, Danish, Parisian, Philolaic, and Rudolphine
27	Alphonsine, Copernican, Danish, Parisian, Philolaic, and Rudolphine
30	Lansbergian

Skilfully too the Marchese Cornelius Malvasia [Cornelio Malvasia], at fol. 219 of his Ephemerides, has often noted the excess of the Lansbergian ☉ [Sun] diameter, whatever may be the case as to the method employed by him, and indicated at fol. 218.

5. We therefore have ordered the semidiameters of the Luminaries in such a way, that — with the [requirements of the] Solar observations preserved — the

semidiameters set forth in lib. 1. c. 12. & in the Solar, Annular, and Total Eclipses, [should hold,] preserving nonetheless the proportion due, [derived] from the distance of the Luminaries from the Earth, and from the Horizontal Parallax. Concerning the distance, therefore, of the Moon and its Parallax in the syzygies, we shall speak in the following Chapter.

Liber II — De Luna

CAPVT XVIII.

On Determining the Eccentricity of the Lunar Orbit, together with the Moon's Intervals, Parallaxes, and Apparent Semidiameters, both by a Circle and by an Ellipse.

1. Among all the prosthaphaeretic [*prosthaphaereon*] hypotheses by which the Moon's motion is reduced to its true value, none corresponds more closely to the observations of frequent eclipses than the one that takes as its foundation the eccentricity of the whole, amounting to 8686 parts, the semidiameter of the eccentric being 100000. Consequently, the greatest equation of the first inequality is $4^{\circ} 58' 28''$. For although the Moon's apparent semidiameter at apogee scarcely exceeds $14' 30''$ at the syzygies, while at perigee it is $16' 22''$, nevertheless — by the more accurate and more recent observations, and by those same observations — the Moon's distance at perigee in the syzygies is 58 semidiameters of the Earth (or at most $58\frac{1}{3}$), as I shall show shortly; whereas the apogee is 64 terrestrial semidiameters, or, by these operations, 63 semidiameters $40'$. For this reason the greatest distance differs from the least by twice as much as the eccentricity of the whole, 8686 parts, does. This is because the center of the apparent motions, that is, the center of the lunar orbit, falls between the center of the Earth and the center of the apparent motions.

2. Hence I recognized, with [Kepler] and [Magini] and most authors, that an equant must be introduced into the Moon's theory, and that the eccentricity must be bisected: thus its half, 4343 parts, falls between the center of the Earth and the center of the lunar orbit, and serves as the foundation of the optical equation [*Aequationis Opticae*]; while the other half, 4343, falls between the center of the orbit and the center of the apparent motions — that is, the other focus, namely the navel [*umbilicus*] of the ellipse, if the elliptical hypothesis is adopted — and serves as the foundation of the physical equation [*Aequationis Physicae*]. But

before this theory can be expounded, the equation of the distances from the Earth and of the parallaxes must be laid down as its foundation.

3. And so, in the year 1648, on the 8th of March, when the Moon was near full and at perigee, Father [Grimaldi] at Bologna and I took the distance of the Moon's center from the zenith to be $33^{\circ} 55' 30''$; and this was the apparent distance, observed at the height of Spica Virginis rising one hour after midnight, 11h 48' 34". But the equated time was 11h 56'; and then the luminaries were so disposed:

	Sign.	Gr.	'	"
The Moon's true place [<i>Luna Verus locus</i>]	□	13	29	17
Its equated anomaly [<i>Anomalia eius Aequata</i>]	□	25	29	37
The Moon's northern latitude [<i>Latitudo Borealis Lunae</i>]	0	4	48	13
Therefore northern declination [<i>Ergo declinatio Borealis</i>]	0	10	58	0
The equator's distance from the zenith [<i>Distantia Aequatoris</i>]	0	44	30	10

	Sign.	Gr.	'	"
<i>à Vertice]</i>				
Therefore the Moon's true distance from the zenith <i>[Ergo Lunae vera distantia à Vertice]</i>	0	33	32	10
But its apparent distance was <i>[At visa fuit]</i>	0	33	55	30
Therefore the parallax <i>[Ergo Parallaxis]</i>	0	0	23	20
And the distance from the Earth's center in semidiameters of the Earth <i>[Et distantia à centro Terrae semid. T.]</i>	58	20	0	
And the horizontal parallax <i>[Et Parallaxis]</i>		58	56	

Sign. Gr. ' "

Horizontalis
s]

From this I deduced that at the Moon's very perigee the distance was 58 terrestrial semidiameters, 20'; or at most 21', as I shall show elsewhere. Beyond perigee a somewhat larger figure has come out for us. Nor should the numbers be trusted when they are deduced near an uncorrected elevation of the pole, and at uncorrected places of the fixed stars; that is what we were relying on here. Likewise, by corrected observations — limited, as is fitting — we find the Moon's apogee distance in the syzygies to be rather 63° 40' than 64 terrestrial semidiameters, as I shall show at the end of this chapter.

4. Let the aforescribed measures therefore stand as ratified by us. The Moon at conjunction \odot and opposition \oslash :

			Semidiam. Terraе
Eccentricity of the parts [<i>Excentricitas partium</i>]	8686		
Half part [<i>Dimidia pars</i>]	4343

Greatest equation at σ and σ°	Gr. 4	58	28
[Aequatio Maxima in σ σ°]			

5. With these things laid down, let there be described from the center C the semicircle ALP, or the semi-ellipse, by that device which I set forth in Book I, Chapter 11, Problem 4. And let T be the center of the Earth, distant from the center C of the orbit by the bisected eccentricity CT, 4343 parts. Now let the point about which the Moon is imagined to move uniformly be F, distant from C, on the other side, likewise by 4343 parts — so that the whole AC is 100000, and AP 200000. Let the line in L, to which the lines of the Moon's mean motion FL are drawn, be such that the angle TL is the true or apparent angle. This will be the angle, not measured under the arcs of the orbit, but under the ecliptic; the prior anomaly, or distance at apogee from A, whose complement to two right angles will be the angle LFT, will therefore be given by the data of the anomaly.

Diagram. A geometric construction for the lunar orbit and its eccentricity, set in the right margin beside §5. A roughly vertical line runs from A at the top down through F, C, T to P at the bottom (the line of apsides, A = apogee, P = perigee). The point M lies at upper left, with L below and to the right of it; lines radiate from the lower points to L and M, forming the triangles used in the construction.

- A (top): apogee of the orbit
- M (upper left): point on the orbit / construction point

- L (center, right of M): the Moon's place, to which lines of mean motion are drawn
- F (upper middle of axis): focus / point of uniform (equant) motion
- C (middle of axis): center of the orbit
- T (lower middle of axis): center of the Earth
- P (bottom): perigee of the orbit

I. Problem: To find the equation in an ellipse.

6. Now if you wish to use the ellipse, produce the line LF as far as M, until LM equals LT itself, and join the extremes M and T by the straight line MT. For then there will arise the isosceles triangle FMT, of which one part is the triangle MLT, since MLT was made equal to LT itself. And since the properties of the ellipse make any two radii drawn out from its foci to the periphery, taken together, equal to the whole greater diameter AP — therefore, in the triangle FMT, FM and FT have been given as two sides, FT being 8686 parts and FM 200000 parts; and the angle comprehending the given anomaly is the angle M, equal in the isosceles triangle to the angle LTM, whose double will be the angle of the 32nd First Element. That is the integral equation of the Moon's first inequality, consisting of the physical part CLF and the optical part CLT.

II. Problem: To investigate the equation in a circle.

7. But if you use the circular orbit, the angle FLT must be divided, the radius CL being drawn, and in the triangle CLF, the semi-eccentricity CF being given as 4343 parts (the radius CL being supposed 100000), there is also given the angle F — namely, the equated anomaly. So one part of the equation, namely the physical part CLF, is given by the property of the ellipse, together with the external angle TCL; and with this datum, together with the sides CT 4343 and CL 100000, one investigates the optical part of the equation CLT.

III. Problem: To find the Moon's distance from the Earth at the syzygies.

8. The first method, whether in the circle or supposing in the ellipse, takes the given eccentricity (under the integral angle FLT) and the complement of the anomaly TFL. With these given, one investigates LT, the Moon's distance L from the center of the Earth T; but whenever the angle LFT is greater than a right angle, the rule of trigonometry bids one use its complement —

(continued) — for the sines, or the logarithms, to be found. For when the distance is less, the radius is smaller; and proportionately, the greater the radius required, so much less is the certainty of the distance — and to the radius must be

added a complement, by adding the quantity sought to the radius, to obtain the sought-for distance LT of the Moon by the larger radius. But this very method is obstructed by the smallness of the angles near apogee and perigee; and when in the given equation of the anomaly the errors run on over a few seconds in the scruples, they run on enormously in the distances. For example, if from the Moon's anomaly of 170° you use the equation $4^\circ 58' 27''$, the Moon's distance from the Earth comes out 97013 parts, of which the whole eccentricity is 8686; but if you use the equation $53' 30''$, the Moon's distance comes out 96924 parts. See, then, that by changing the seconds in the third place the distance is diminished by 89 parts. It is therefore not expedient to use these angles, but only the angle of whole and round anomalies, to which exactly correspond the sines, or logarithms; nor is it useful to hunt out the proportional part, which at the beginning and end of the trigonometric canon is less exact.

9. In truth, however, by using only the angle of the anomaly and the eccentricity — although the triangle FLT is oblique-angled — it cannot be reduced to one, or to two right angles, until we are able to drop a perpendicular; yet without this angle TL, by sines or logarithms, the trigonometric distance is reached so far that, two sides and the included angle being given in a right-angled triangle, or a comprehended angle, or a given base of a right-angled triangle, and one side, we can by sines, or by logarithms, immediately find the third side. We shall therefore recur to the squares of their sides; and the roots, the bases, and indeed first in circular form:

10. Let the Moon be in L, where three straight lines meet at three centers: namely LF, to the center of the apparent motions equal to LC, the center of the circular orbit, & LT, to the center of the Earth. Then produce LF, as far as in R; and where the line produced from R meets the production from C, let it make with this LF the right angle CRF; let LF likewise be produced beyond, as far as in B, where the line produced from T meets it, and let it make with this FBT a right angle. Two right-angled triangles arise, CRF and TBF.

Diagram. A geometric construction beside §10, with a vertical apsidal line A–F–R–C–T–P at the right. Lines are drawn from the lower points to L at the left, with R and B as the feet of perpendiculars, forming the right triangles CRF and TBF.

- A (top): apogee
- L (left): the Moon's place
- R (on axis below F): foot of the perpendicular from C
- F, C, T (middle of axis): point of apparent motion, center of orbit, center of Earth

- P (bottom): perigee

11. Now in the prior triangle CRF, besides the right angle R and the base FC of 4343 parts, the angle of the integral anomaly CFR is also given, AFL, by supposition; and so its complement to the other right angle, the complement FCR, is given by sines or logarithms. The side CR is known, and likewise FR. Then the square of CR and of it is subtracted from the square of the radius CL, which is 10000000000, and the remainder is the square of the whole side LR, whose square root is the side LR. From this LR you subtract the FR found above, and the side LF remains, the Moon's distance from the center of the apparent motions.

12. With these things done, resolve the triangle TBF, right-angled at B, for FT 8686 is given, and the angle of the anomaly TFB is given in whole degrees; therefore both are known, namely the side TB and TF; for to the side LF, found above, will give the whole side LB; therefore one investigates the sides LB and TB; and the square is reduced to one sum; for they will make a certain square, whose root, sought, will give the Moon's distance LT, as being the base opposite the right angle LBT, by the 47th of the First Elements. Hence it is not difficult to understand how the perpendicular in the semicircle is to be led from the lower part:

12. [bis] For the Moon being constituted in L, and (as above) drawn by three straight lines LF, LC, LT, draw out C, perpendicular to LF, and in the triangle CFR, right-angled at F, the given base CF being 4343 parts, and the angle CFR, the complement of the anomaly — and so to it the angle FCR, the complement of the right angle — investigate the side CR and FR. Then square CR, and its square subtract from the square of the radius CL, for there will remain the square of —

Diagram. A second geometric construction beside §12 (bis), nearly identical in arrangement to the upper one, with the vertical apsidal line A–F–R–C–T–P at the right and lines drawn to L at the left, forming the right triangles used to derive the Moon's distance LT.

- A (top): apogee
- L (left): the Moon's place
- F, R, C, T (middle of axis, descending): point of apparent motion; foot of perpendicular; center of orbit; center of Earth
- P (bottom): perigee

(top of right column, folio 150) — the side LR, whose square root gives the side LR; to this if you add FR, you will have the Moon's distance LF, from the center of the equal motions.

Then lead from T the perpendicular TB, and in the triangle right-angled at B, by the side FT 8686 and the angle BFT, the complement of the anomaly, and accordingly the angle BTF; investigate the side BF; from it, by the side BT, subtract the side BF, from the previously invented side LF, the remaining side LB; from the addition of the square of the side BT there will result the square of the side LT; and the square root of this manifests the Moon's distance LT, from the center of the Earth.

13. Nor indeed does it shame me to illustrate the precept of this latter figure by one example. Let the Moon's anomaly be:

	Gr.
Let the Moon's anomaly be [<i>Sit Anomalia Lunae</i>]	
That is, the angle AFL [<i>Idest Angulus AFL</i>]	140
Therefore the acute angle F [<i>Ergo Angulus acutus F</i>]	40
And FCR, like FTB [<i>Et FCR, ac FT B</i>]	50
	partium
Let FC [<i>Sit FC partium</i>]	4343
Therefore hence RF [<i>Ergo hinc RF</i>]	3327
And CR [<i>Et CR</i>]	2791 ¹⁰⁰ / ₁₀₀ [as printed]
Square of the side CR [<i>Quadratum Lateris CR</i>]	7792142
Radius CL [<i>Radius CL</i>]	100000
Its square [<i>Huius quadratum</i>]	10000000000
From which subtracted [<i>Cui subducto</i>]	7792142
Remainder of the side LR, its square [<i>Restat Lateris LR, Quadratum</i>]	9992107858
Whose root is the side LR [<i>Cuius</i>	99961

partium

Radix est latus LR]

Add RF, it makes LF [*Adde RF, sit LF*] 103288

In the triangle BTF, the angle F, gr. 40, and T, [*In Triangulo BTF, Angulus F, gr. 40. & T,*]

50

And FT [*Et FT*]

8686

Therefore BT [*Ergo BT*]

5583 ²⁸/₁₀₀ [as printed]

And BF [*Et BF*]

6654

The side LF [*Lateris LF*]

103288

Subtract the side BF [*Subduc latus BF,*]

6654

The remaining side LB [*Restat latus LB,*]

96654

Whose square is [*Cuius Quadratum est*]

9338129956

And the square of the side BT [*Et Quadratum lateris BT,*]

31172681

The sum of these squares [*Summa horum Quadratorum*]

9369302637

The square of the side LT [*Est quadratum lateris LT*]

Its square root [*Eius Radix Quadrata est*]

96795

14. So great, therefore, is the Moon's distance LT, namely 96795 parts, of which the radius of the eccentric is 100000. But because I promised at the end of number 4, I choose two from our observations made at full Moon, with the Moon situated near apogee. The first was in the year 1645, on the 11th of May, at the hour of the apparent altitudes 11h 53' 52" after midnight; but the equated [hour] was 11h 48'. Then, however, the Moon's conditions were such, the Moon's center being at a meridian distance from the zenith of 58° 53' 40", the refraction having been computed:

	Sign.	Gr.	'	"
The Moon's place in the ecliptic [<i>Locus Lunae in Eclipt.</i>]	□	22	35	40
The equated anomaly [<i>Anomalia Aequata</i>]	11	29	45	22
Northern latitude [<i>Latitudo Borealis</i>]	0	4	58	22
Therefore southern declination [<i>Ergo Declinatio Austr.</i>]	0	13	37	15
The equator's distance from the zenith [<i>Distantia Aequatoris à vertice</i>]	0	44	30	10
Therefore the Moon's true distance from the zenith [<i>Ergo ☽ vera dist. à</i>	0	58	7	25

	Sign.	Gr.	'	"
<i>vertice]</i>				
But it was seen as [<i>At visa fuit]</i>	0	58	53	40
Therefore the parallax [<i>Ergo Parallaxis]</i>	0	0	46	15

And from this the distance from the center of the Earth is 63 terrestrial semidiameters, 39' [*Et hinc Distantia à centro Telluris semidiametrorum terrestrium 63. 39'.*]

15. The second was in the year 1646, on the 27th of June, the equated hour being 11h 55' 35" after midnight. The Moon's center passed through mid-heaven, and we observed it at a distance of 66° 26' 40" from the zenith, the refractions having been removed. The remaining lunar conditions were such:

	Sign.	Gr.	'	"
The Moon's place in the ecliptic [<i>Lunae locus in Eclipt.</i>]	☾	4	52	40
The equated anomaly [<i>Anomalia) Aequata]</i>	11	25	34	15
Northern latitude [<i>Latitudo Borealis]</i>	0	16	55	
Therefore southern declination	0	21	7	10

	Sign.	Gr.	'	"
[<i>Ergo declinatio Austr.</i>]				
The equator's distance from the zenith	0	44	30	10
[<i>Distantia Aequatoris à vertice</i>]				
Therefore the Moon's true distance from the zenith	0	66	26	10
[<i>Ergo vera dist. à vertice</i>]				
But it was seen as [At <i>visa fuit</i>]	0	66	26	40
Therefore the parallax	0	0	49	20
[<i>Ergo Parallaxis</i>]				

And [Et] —

(continued) And from this the Moon's distance from the center of the Earth is 63 terrestrial semidiameters, 47'. Nevertheless, we made fewer of these than of the prior observations, since the Moon was then almost at the very apex of apogee; and so we chose the distance of 63 semidiameters, 40'.

CAPVT XIX.

On the Moon's True Magnitude.

1. Since at the distance of 59 terrestrial semidiameters the Moon's apparent semidiameter is precisely 16' — the Moon being distant from apogee at the syzygies by 14° 5' — and when the Moon is distant from the Earth by 63 terrestrial semidiameters, 40' (and at apogee existing, the semidiameter is 14' 48", and at perigee 16' 12") — then this consideration, demanded by observations made together with the annular solar eclipses and the total ones, much elaborated by us, follows: that the Moon's true semidiameter is $16\frac{1}{3}$ such parts as the Earth's semidiameter is 60. But it is, according to our *Geographia Reformata*, a semidiameter of the Earth of $4673495\frac{2}{3}$ paces of the ancient Romans. Therefore the Moon's semidiameter is 1285210 such paces, and the diameter 2570420. But if the Earth's diameter is taken as 200, the diameter of the Moon will be $27\frac{1}{3}$ such parts — a little larger than we put it in the *Almagestum Novum*, Book 4, Chapter 27, where we were able to put it at $26\frac{1}{3}$. From this proportion, therefore, the remaining measure of the Moon and of its shadow which we put there must be corrected.

CAPVT XX.

On the Moon's Latitude, the Anomaly of this Motion, and the Reduction of the Moon to the Ecliptic.

1. Besides what we said in Chapter 14 concerning the motion of the Nodes — the mean, the anomaly of these, and the equation — we accept the Tyconic, and exhibit it in the Tables. But we suppose the maximum latitude at the syzygies to be 5°, or at minimum 5° 18', very nearly with [Tycho]; in the quadratures, however, 5° 18', according to the same Book 4 of the *Almagestum Novum*. The maximum latitude in the syzygies we exhibit, according to the Tyconic and in the quadratures, 5° 18'. The theory of latitude we expound in Chapter 29, and the reduction of the Moon from its orbit to the ecliptic in Chapter 30. Consult therefore those Chapters, lest here we be in vain prolix in repeating what has been done.

Decorative woodcut. Jesuit emblematic device centered at the foot of the page: the IHS monogram (with the cross above the H and three nails below) set within a radiant sunburst on an oval medallion, framed by an elaborate cartouche of clouds, scrollwork, and winged cherub heads (a putto at the top and additional

cherub faces at the sides and base). [This is the printer's/order's decorative emblem, not an informational figure.]

BOOK THREE

IN WHICH ARE GATHERED THE OBSERVATIONS OF THE MOON OUTSIDE ECLIPSES, BEARING ON ITS MONTHLY INEQUALITY, ITS VARIATION, AND ITS LIBRATION

CHAPTER I

Ancient Observations of the Moon outside eclipses, from the year 295 before Christ down to the year of Christ 509, with respect to the positions of the Moon in the heavens.

[Latin display heading: Lunæ Observationes Antiquæ extra Eclipses ab Anno 295. ante Christum, usq; ad Christi Annum 509. quoad Loca Lunæ in Cælo.]

1. In the year 36 of the first Calippic period, with the year 25 exactly elapsed (that is, in the month Poseideon, or the 454th year of Nabonassar, on the 16th of Paophi), on the following 17th, at the equal hour $3\frac{2}{3}$, after midnight, Timocharis at Alexandria saw the Moon touching with its northern, that is its leading, edge the northern star in the forehead of Scorpius. By Ptolemy's computation (*Almagest* VII.3) the Moon's true position was at Scorpius $31^{\circ}41'$, with northern latitude $1^{\circ}20'$; but to appearance it was at Scorpius $32^{\circ}2'$, with latitude $1^{\circ}12'$. He assigns that same place to the star.

[Margin: 1]

[Lansberge] in his *Thesaurus of Lunar Observations*, Class 7, affirms that Ptolemy was mistaken: for at Alexandria the first degree of Leo was culminating, the time being two and a half hours past midnight, and the Moon stood below the horizon, but through the benefit of refraction was seen above it. The Moon's true place was therefore at Scorpius $0^{\circ}47'7''$, with northern latitude $1^{\circ}38'33''$; while the star's was at Scorpius $7^{\circ}16'$. As to the star's northern latitude, Timocharis [Lansberge: Ptolemy] gives Scorpius $1^{\circ}16'29''$, with latitude $1^{\circ}15'$. [Lansberge] therefore computes the semidiameter of the Moon by which it touched the star. But Ptolemy says that mid-Leo was culminating, and Timocharis that it was the beginning of the ninth hour. Plainly [Lansberge] wishes to drag the observation to the standard of his own Tables, and not the Tables to the standard of the

observation. Furthermore, that year fell in the common Era of Christ 295, current, and the 20th of December; the next day was the 21st. [Longomontanus] *Theorica prima* (chap. 1, *Theoricorum*) says the corrected hour was $3^{\circ}54'$, and gives the Moon's seen place as Scorpius $1^{\circ}58'$.

[Margin: *Lansberge in error.*]

In the same year 36 of the first Calippic period (the 15th of Elaphebolion, or the 454th year of Nabonassar, on the 5th of Tybi), on the following 6th, beginning at hour 3, Timocharis at Alexandria saw the leading edge of the Moon, which was toward sunrise, reaching to Spica, the Moon dividing exactly the third part of its diameter toward the north. By Ptolemy (*Almagest* VII.3), this was one hour before midnight, and the Moon's true longitude was Virgo $22^{\circ}21'21''$, with southern latitude $1^{\circ}50'$; but to appearance it was at Virgo $22^{\circ}12'$, with latitude $2^{\circ}6'$, which place he likewise assigns to Spica.

[Margin: 2]

[Lansberge] in his *Thesaurus of Lunar Observations*, Class 7, gathering the conjunction of the Moon with Spica from his own Tables, 8 hours after midday, concludes the Moon's true place to have been Virgo $22^{\circ}3'21''$, with true southern latitude $1^{\circ}47'43''$; while to appearance it was Virgo $1^{\circ}55'15''$ [recte: at Virgo, seen $1^{\circ}55'15''$ from?]. But afterward he employs three times the diameter, that is, three times the semidiameter, contradicting both himself and Timocharis. That year was 254 before the Era of Christ, on the 30th of March.

[Margin: *Lansberge again in error.*]

3. In the year 47 of the first Calippic period (the 8th of Anthesterion, or the 465th year of Nabonassar): Aristyllus says that on the 29th, on the following 30th, at the end of the third hour at Alexandria, Timocharis saw the middle part of the southern Moon brought to the third, or rather the succeeding, part of Virgo. By Ptolemy (*Almagest* VII.3), who says it was the equal hour $3^{\circ}30'$ before midnight, the Moon's true place was Taurus $0^{\circ}20'$, with northern latitude $3^{\circ}45'$; but the Moon and the star were seen at Aries $29^{\circ}20'$ latitude $3^{\circ}40'$, very nearly.

[Margin: 3]

[Lansberge], Class 7, observes that the Moon stood toward the east of the star Pleiades, and gives the Moon's true place as Aries $29^{\circ}55'8''$, seen at Aries $29^{\circ}8'50''$, with true latitude $3^{\circ}57'$; seen $3^{\circ}51'$. That year was 284 before the Era of Christ, the 29th [recte: 30th] of January. [Longomontanus] *De Theoricis* I (chap. 2) says the hour was $3^{\circ}10'$, and the Moon's seen place Aries $29^{\circ}32'$.

4. In the year 48 of the first Calippic period, on the day of the Pyanepsion festival, the sixth, at hour 9½ elapsed: at Alexandria Timocharis observed Spica, seen exactly to touch the northern part of the Moon toward the east above the horizon. By Ptolemy (*Almagest* VII.3), who says it was the 466th year of Nabonassar, the 7th of Thoth, on the following 8th, at the equal hour 2°30' after midnight, the Moon's true place was Virgo 21°30', with southern latitude 2°10'; and the Moon's seen place was Virgo 21°20', with latitude 2°1'. He gives Spica's seen place as Virgo 22°30'.

[Margin: 4]

[Lansberge], Class 7, observes; he gathers the Moon's true place from his own Tables as Virgo 21°21'35", seen at Virgo 22°26'47", with latitude 2°11'21" [recte], seen 2°10'3". As to Spica's longitude, Virgo 22°12'11", latitude 2°0'. But that was the year 283 before the Era of Christ, the 8th of November, on the following 9th.

[Longomontanus] nevertheless, *De Theoricis* I (chap. 2, in the *Commentary on the Fixed Stars*), says the corrected hour was 3°54', and the Moon's place Virgo 22°40'.

5. In the year 50 of the third Calippic period, with 40 hours of the first elapsed [recte: see Parsing note]: Hipparchus at Rhodes observed the Moon to stand distant from the Sun in the preceding part by 48° [recte]. By Ptolemy (*Almagest* V.5), who says it was the 620th year of Nabonassar, the 16th of Epiphi, at hour 8 after midday [recte], at Rhodes (very nearly at Alexandria), the Sun being at Leo 9°, by 9°20' [recte: gr. 8°20'] — not, as Hipparchus thought, by 9°20' — and that the Moon was in its first quadrature. [Lansberge], Class 2, observes; he reckons the distance of the Sun from the Moon in Leo 8°18'31". The Moon was at Taurus 12°2'52", and the distance gathered was Taurus 86°15'. But Ptolemy says the distance was 87°47', from the maximum epicyclic longitude; the complement is 102°13'; and being at the position of the maximum epicycle in inequality. Yet [Lansberge] says the Moon was withdrawn from the eccentric perigee by 81°, and there the maximum inequality of the Moon occurs. That was the year 128 before the Era of Christ, the 5th of August, on the following 6th.

[Margin: 5] · [Margin: small square ornament]

6. In the year 197, from the death of Alexander the Great, on the 11th day, beginning the second [hour] of Pharmuthi: Hipparchus at Rhodes observed the Sun at Taurus 7°45'. The Moon was seen at Pisces 21°40', but its true place was Taurus 11°48'; therefore the true distance from the Sun, with respect to longitude, was 313°43' [recte]. By Ptolemy (*Almagest* V.5), who says it was the 621st year of Nabonassar, at the equal hour 18 after midday [recte], the 11th of Pharmuthi, and

the mean distance of the Moon was Taurus 314°28'; and from the maximum epicyclic longitude 185°30'.

[Margin: 6]

[Lansberge], Class 3, observes; he says the hour was 6°20' after midnight, and gathers the Sun's place at Taurus 7°40'31". The Moon was at Pisces 21°23'15". That was the year 127 before the Era of Christ, the 2nd of May, on the following 3rd.

7. In the same year 197, from the death of Alexander, the 17th [hour], 3°20', at Rhodes: Hipparchus observed the Sun at Cancer 10°54'. The Moon was indeed seen at Leo 29°, very near. By Ptolemy (*Almagest* V.5), who says it was the 621st year of Nabonassar, at the equal hour 4 after midday, the distance of the Moon from the Sun was 48°6'; but from his own Tables he sets the Sun at Cancer 10°40'. (See [Copernicus] *De Revolutionibus* IV, chap. 10.)

[Margin: 7]

[Lansberge], Class 5, observes; he sets the Sun's place at Cancer 10°36'32", the Moon at Leo 28°. That was the year 127 before the Era of Christ, the 7th of July, on the following 8th.

8. In the year 11 of Domitian, on the 7th day of the month Metroon, beginning the 3rd hour of the night, in Bithynia: Agrippa saw the Moon to touch with its southern edge the succeeding southern part of the Pleiades. By Ptolemy (*Almagest* VII.3), who says it was the 840th year of Nabonassar, the 2nd of Tybi, on the following 3rd, at the equal hour 5°20' before midnight at Alexandria, the Moon by its true motion was at Taurus 3°7'; but in Bithynia 3°15' to appearance, and there too it was seen with the star toward the north, Taurus 3°40'. That was the year 92 of Christ, the 29th of November, on the following 30th.

[Margin: 8]

[Lansberge], Class 7, observes; he says it was the year 92 of Christ, and (it being a bissextile, the 10th, and the 5th day [recte]) at hour 7°0' to appearance in Bithynia, the Moon's true place was Taurus 2°25'; seen at Taurus 2°39'31", with northern latitude [continues next column].

[col. 2, p. 184]...true latitude north 4°59'41", seen 4°21'37", and the star at Taurus 2°39'24", with latitude north 3°51'.

9. In the first year of Trajan, the month Mechir, on the 15th, on the following 16th, exactly at hour 10: Menelaus at Rome saw Spica of Virgo entirely covered by the Moon — for the star could not be seen — but at hour 11 it was seen in the leading

part of the Moon's center, equally distant from the horns, that is, less than the Moon's diameter. By Ptolemy (*Almagest* VII.3), who says it was the 845th year of Nabonassar, the leading part being toward midnight at Rome, the Moon's true longitude was Virgo $25^{\circ}45'$, with southern latitude $2^{\circ}0'$; the amount they assign to Spica. That was the year 98 of Christ.

[Margin: 9]

[Lansberge], Class 7, observes; he says it was the year 98 of Christ, on the 10th of January, on the following 11th, at hour 16, and to appearance at Rome after midday the Moon's place was Virgo $25^{\circ}45'$, seen at Virgo $25^{\circ}54'16''$, with latitude varying, southern $1^{\circ}22'19''$ [recte]; seen $1^{\circ}55'49''$. As to Spica's longitude, Virgo $26^{\circ}1'36''$, latitude $2^{\circ}0'$.

10. In the same year, and on the night of the 18th, the third [hour]: Menelaus observed the Moon's southern horn in a straight line with the middle and southern stars in the forehead of Scorpius, the Moon's center being absent from that straight line by however much it was distant from the middle and southern [stars]; the northern of those in the forehead of Scorpius was covered, because nowhere did it appear. By Ptolemy (*Almagest* VII.3), who adds that it was the equal hour past mid-night, on the following $6^{\circ}10'$ at Rome [recte], and at Alexandria $7^{\circ}30'$ from the center, the Moon was at Scorpius $9^{\circ}45'$; but to appearance it was at grade $5^{\circ}55'$, with true northern latitude $2^{\circ}10'$, seen at grade $1^{\circ}10'$; those which are at the forehead of Scorpius, in the north.

[Margin: 10]

[Lansberge], Class 7, observes; he says it was the year 98 of Christ, on the 11th of January, at hour 19, to appearance at Rome $18^{\circ}11'$, and the Moon's true place in Scorpius $9^{\circ}59'52''$, varying $5^{\circ}24'31''$, and the southern true latitude $2^{\circ}11'22''$ [recte], seen at grade $1^{\circ}56'26''$; the star at Scorpius $5^{\circ}24'$ [recte], seen $1^{\circ}25''$ [recte], with latitude north $1^{\circ}15'$.

11. In the year 20 of Hadrian, the 13th of Athyr, the Sun setting at hour $5^{\circ}50'$, with the Sun setting equally in Libra at grade $5^{\circ}28'$: Ptolemy observed at Alexandria, by the parallactic rules, the meridian distance of the Moon from the vertex at grade $50^{\circ}55'$; it stood in Capricorn grade $3^{\circ}10'$, but the true distance was grade $49^{\circ}48'$, with the Moon's true latitude grade $1^{\circ}7'$; therefore the latitude was grade $5^{\circ}12'$ [recte], by which when the Moon was observed in Capricorn at the meridian, distant from the vertex grade $1^{\circ}7'16''$ [recte]. (See [Copernicus] *De Revolutionibus* IV, chap. 15 and 16. This was the year of Christ 135, the 1st of October.)

[Margin: 11]

12. In the second year of the Emperor Antoninus, the 25th of Phamenoth, in the morning at hour 5°15' before midday, the heaven mediating Sagittarius: Ptolemy at Alexandria observed the Sun by the astrolabe in Aquarius grade 18°50', and the Moon in Scorpius grade 9°20', and distant from the Sun in longitude grade 99°10'. By Ptolemy (*Almagest* V.3), as far as sense could discern, there was no parallax. That was the year of Christ 139, the 25th of February. [Lansberge], Class 5, observes; he sets that year as 386 of Nabonassar, and the Sun in Aquarius grade 18°46'18"¼, the Moon in Scorpius grade 9°46'31".

[Margin: 12]

13. In the same year of Antoninus, the 9th of Pharmenoth: Ptolemy at Alexandria (as he has it, *Almagest* VII.2) observed the Moon distant from Regulus; but he could not by any means find the position of Regulus, nor the motion; yet it seems useless to me to use that observation, and to proceed by uncertain steps; yet they use that very thing. [Lansberge] in his *Thesaurus*, Class 7, to conclude Regulus at the Moon's center, in the consequence defines it grade 17°10'; both he and [Boulliau] *De Astron. Phil.* (chap. 9) suppose the same distance, and gather the Moon's place, the parallaxes subtracted, in Gemini grade 17°16'; he concludes Regulus to have been at Leo grade 3°42'. That was the year of Christ 139, the 23rd of February.

[Margin: 13]

14. In the year 192 of Diocletian, the 21st of Athyr: Thius [recte] observed the Moon to lead by anticipation the star Venus, and to have been in grade 15 of Capricorn from the Sun, distant from the Sun grade 48 [recte]. So a manuscript codex of the Library of the Most Christian King of France gives it, [Boulliau] *De Astron. Phil.* III, chap. 12; and Bullialdus supposes the observation made at Athens at hour 5°15', after midday, and the conjunction of the Moon with Venus from his own Tables confirms.

[Margin: 14]

15. From the same manuscript [Boulliau] reports the same place. In the year 225 of Diocletian, the 15th of Phamenoth, on the following 16th, after the lighting of the lamps, that is at first dusk after the withdrawal of twilight, [continues next page].

[p. 185]...the dusk, the Moon was seen to follow the bright star of the Hyades by however much it had touched its highest half [recte]; but it appeared to be

obscured by the star itself, since the Moon was being illuminated by limbs everywhere [recte], and the Moon was near its true motion at Taurus grade $16^{\circ}30'$. So he reports it. [Boulliau] adds that this was in the year of Christ 509. (And at Athens on the 11th of March it was observed, the emergence of the Eye of Taurus, a half-hour after sunset, there, at its place, the Moon truly being at hour $7^{\circ}20'$ after midday, the Moon being seen at Gemini $19^{\circ}52'44''$, with true northern latitude $4^{\circ}27'$ [recte], seen $4^{\circ}22'$; and the Moon at Taurus $16^{\circ}30'$. Thus he observes.) [Boulliau] adds an impossibility: namely, that the Moon had occulted the Eye of Taurus. But he is deceived, since the latitude of the southern Moon is grade $5^{\circ}31'$. Therefore, since at the beginning of the night the Moon would be more eastward than Palilicium by however much, with the half-diameter [recte], the Moon could be in Taurus at grade $18^{\circ}46'$ visible, that is, it could occult the star by a parallax greater than [Boulliau] employs; he depresses the Moon toward the west around the sixth hour after midday.

[Margin: 15]

CHAPTER II

Lunar observations of Johannes Regiomontanus, Bernhard Walther, Nicolaus Copernicus, and Abraham Zacuto, with respect to the positions of the Moon outside eclipses, from the year of Christ 1462 to 1524.

[Latin display heading: Lunares observationes Io. Regiomontani, Bernardi Vualtheri, Nicolai Copernici, & Abrahami Zaguthi, quoad loca Lunæ extra Eclipses Ab Anno Christi 1462. ad 1524.]

1. In the year 1462, the 11th of January, at the beginning of the night, when the Moon was seen at altitude grade $61^{\circ}15'$: at Rome, Regiomontanus, with Sirius at grade $14^{\circ}30'$, and Procyon at grade $4^{\circ}50'$, saw the Moon to be equally distant from both, the distance lying between grade 12 and 13 of the Hyades.

[Margin: 1]

2. In the same year, the 12th of January, with Sirius high at grade $26^{\circ}40'$, and Procyon grade $40^{\circ}20'$: at Rome in the same place he saw the Moon joined to the star 19 of Taurus, that is, to the extreme southern horn, as to longitude, but separated from the more northern star by $24'$; and that star seemed to be distant from the southern limb of the Moon by a fourth part of the visual diameter.

[Margin: 2]

3. In the year 1463, the 11th of March: Regiomontanus saw the Moon at Rome high at altitude grade 23, and Jupiter likewise in the meridian high grade 30; and then the Heart of Scorpius [Antares] at grade 17°15'; and the Moon with Jupiter, and with 7 of Sagittarius, were in a straight line.

[Margin: 3]

4. In the year 1474: Abraham Zacuto, professor of astronomy at Salamanca, observed Spica reaching to the Moon itself at grade 17°10' of Libra, as his disciple Augustinus Ricius reports in his book *De motu octavæ sphaeræ* (chap. 46 and 47).

[Margin: 4]

5. In the year 1478, the 10th of October: Bernhard Walther at Nuremberg saw the Moon distant from Regulus toward the north by about a semidiameter; at half-hour before sunrise [recte], the Moon close to the meridian, the Moon distant from Regulus by grade 1°52'. [Lansberge], Class 5, observes; he computes the Sun's refractions, with the rising Sun accelerating; he says the observation was made earlier by grade 1°11' after midnight, and the Moon from his Tables was at Leo grade 2°8'10", but to appearance at grade 23°58' [recte], with true northern latitude grade 5°2', seen at grade 5°. [Lansberge] gives Regulus' place in grade 23°8'41"; he therefore makes the Moon's conjunction with Regulus then, since Bernhard says it was made at grade 1°35' [recte], the latitude being a little greater [continues].

[Margin: 5]

6. In the year 1482, the 12th of January: another half-hour before sunrise, Walther saw the Moon eclipsing Saturn; for at that time the Moon was not seen, before, and after the latitudes inscribed below noted, since the Moon was at the last [continues col. 2].

[Margin: 6]

[col. 2, p. 185]...quadrature, or near it, namely the Moon falling off from the western part, and when first it was glimpsed, namely about 2¾ hours before sunrise, the Moon was western, and as Saturn appeared more to the south, distant by two Moons; afterward the clouds intervened, so that the beginning could not be discerned. Indeed I judge for certain that the Moon apprehended the southern horn of Saturn. But afterward they were seen again, Saturn being distant in diameter by about two digits, or about a southern horn; nor however did it appear evident, but it began to pass over [recte] now indeed; therefore I indicate the altitude of the Moon for this eclipse, that it was nearly in the

meridian existing, and I indicate the Moon's place as above, namely the Moon first apprehending Saturn from the southern horn, considering nothing about the Moon's place; but this indeed appears evidently, that Saturn in diameter was distant by two digits from the Moon, in the northern part, or about ceasing. [Kepler] in his *Astronomia Optica* (p. 409) weighed this observation; he shows that the parallaxes of the crescent are made, so that Saturn, which had been thus meridional in position, was so much closer to the northern horn of the Boreal Moon; which is wonderful, and impossible to have been seen by Walther, with the simple bare motion of the latitudes.

7. In the year 1486, the 21st of October, in the morning, Walther observing: the Moon began to cover Regulus high to the rising by grade 45 — for it was touching it by the limb. But the exit could not be seen, the air being disturbed. Thus my codex. But [Lansberge], Class 7 of his *Lunar Observations*, has *the 20th day*, and says the hour was 17°6' after midday of the 19th day, and the Moon was then to appearance at Leo grade 22°29', seen with northern latitude grade 0°46'10", seen at grade 17°5" [recte]; and Regulus at grade 23°13'44", with northern latitude grade 31'; but the semidiameter of the Moon was grade 17°41" [recte], and it added the latitude itself, raising the northern horn of the Moon by grade 34'45"; therefore it could not cover Regulus.

[Margin: *Lansberge in error.*]

8. In the year 1487, the 28th of February: Walther has it thus: *At hour 7m.52' past midday, namely while the Moon was in mid-heaven, I had it at altitude grade 47 in altitude, and the Dog-star [Canis maior], namely Alhabor, at grade 23°5' in altitude past meridian, the Moon touching with its southern horn the most northerly Pleiad.* I wonder, therefore, why [Lansberge] in his *Thesaurus*, Class 7 of his Lunar observations, says: *In the year of Christ 1487, in the morning, with the latitude of the Moon's center smaller (not Leo, that is grade 8°), and the Moon with its southern horn contingent on the northern Pleiad.* Was the Moon ever transformed into a smaller Dog [recte: was the most northerly Pleiad ever a smaller Dog-star]? Moreover, from his very calculation it was more northerly; the Pleiad in Taurus grade 22°55', with northern latitude grade 4°49', but the Moon's place to appearance was in Taurus grade 22°47', with latitude seen grade 4°45'.

[Margin: 8]

9. In the year 1497: [Copernicus], as he himself relates (*De Revolutionibus* IV, chap. 17), observed at Bologna on the 7th of the Ides of March, with the setting Sun, the Moon occulting the shining Palilicium; he saw the star applied to the

dark part of the lunar body, between the horns now in darkness; and was about to disappear at the fifth hour of the night, nearer indeed to the southern horn, by about a third of the lunar diameter. He adds that Palilicium was at Gemini grade $2^{\circ}52'$, with southern true latitude grade $5^{\circ}10'$; therefore the center of the Moon to appearance preceded the star by half the diameter, and the Moon's place to appearance was at Gemini grade $3^{\circ}24'$, with latitude grade $4^{\circ}35'$; but to appearance the Moon's place was at Gemini grade $3^{\circ}2'$. (See [Lansberge], Class 7. He observes; he gathers the Moon's place from his calculations, which agree to be the Moon's place seen in Gemini grade $3^{\circ}0'45''$, with latitude seen southern grade 5° ; whatever latitude he assigns to Palilicium, with longitude grade $5^{\circ}15'$ of Gemini.)

[Margin: *Lansberge error.*]

10. In the year 1522, the fifth before the calends of December [27 November], at hour $6^{\circ}40'$ after midday: [Copernicus] at Frauenburg, by the parallactic rules, observed the distance of the Moon from the vertex at grade $82^{\circ}50'$; and from his Tables he computes the true distance of grade $81^{\circ}56'$; therefore the parallax in altitude is grade $0^{\circ}54'$. (See *De Revolutionibus* IV, chap. 16.)

[Margin: 10]

11. But in the year 1524, the 7th of the Ides of August, at hour 6 after midday: the same [Copernicus] in the same place observed the distance of the Moon from the ver-[continues].

[Margin: 11]

[Margin: *Lansberge error.*]

[Continuation of Caput II, observation 11 — Copernicus at Frauenburg, 1524 Aug 7]

the vertex by $81^{\circ}55'$; but from the calculation it comes out as $80^{\circ}55'$. From this he gathers the parallax to be 1° . So Copernicus, *De Revolutionibus* IV.16.

CAPUT III.

Tycho's selected lunar observations, apart from eclipses, regarding the places of the Moon.

1. In the year 1582, on February 25, at 4:12 a.m. [hora $4.12\frac{1}{3}$], Tycho [Tycho Brahe], using armillae, observed the western limb of the Moon in the 26th degree $\frac{1}{3}$ of Pisces, at the hour $4.26\frac{1}{3}$; that is, in Pisces $26^{\circ}12'$ [Pisces gr. $26.12'$]. As to the

true place of the Moon, from the Tyconic Tables recently published through the labor of Lucius Barretus — that is, Albert Curtz of the Society of Jesus [Albert Curtz], whose anagrammatized name conceals his own — where many other Azimuthal observations are had, but most of them of a subtlety that does not bring great certainty, as Tycho himself at length acknowledged; and besides, since the times are frequently noted by means of a rotating clock-mechanism subject to error, I have therefore selected only a few.

[Margin: Octans 1.]

2. In the same year 1582, on February 26, at 1:47 [hora 1.47], Tycho observed the limb of the Moon with armillae in Virgo $9^{\circ}55'$. He gathered (the Moon being then invisible, since the altitude of its upper limb was $48^{\circ}16'$ toward the west at setting), and the hour being $1^{\circ}15'$ [hora a. $1^{\circ}15'$], that the same lower limb was seen in Taurus $10^{\circ}10'$; while he concluded the upper limb at $51^{\circ}26'$. From this he concludes that the Moon traversed a span of 33° , completed in 15 minutes.

3. Likewise in the year 1582, on February 26, at 7:20 [hor. $7.20\frac{1}{3}$]. From Tyconic observations, the cusp of the upper horn was seen to be distant from Aldebaran by $23^{\circ}12'\frac{1}{3}$; and then, as the cusp itself appeared to be at altitude $35^{\circ}15'$, and at hour $7.15\frac{2}{3}$, the same cusp was seen distant from the bright star of Aries [the Head of Aries] by $12^{\circ}18'$ — they were seen at the same cusp, altitude $32^{\circ}36'$.

4. Likewise in the year 1582, on February 28, at 4:36 [hora 4.36']. The Moon was seen in the 90th degree of the Ascendant, that is, at the cusp [of the upper horn]; its cusp was seen at altitude $58^{\circ}16'\frac{1}{3}$, in azimuth from the meridian toward the rising in the east by $4^{\circ}11'$.

5. Again in the year 1582, on May 5, at 11 o'clock [hora 11]. The Moon being near the ninetieth degree, its limb was nearer, and stood off from the heel of the foot of Gemini by $46^{\circ}51'\frac{2}{3}$; with the other altitude being seen at $43^{\circ}40'$, and at hour 11.5' it stood off from Regulus by $8^{\circ}25'$, while the other was seen at $43^{\circ}20'$.

In the year 1587, in January, Tycho exhibits three observations of the Moon in his *Letters* to the Landgrave of Hesse, page 59, with the Alphonsine and Copernican calculation, as below.

January, Day	H. p.m.	M.	Moon	Longitud	
				e —	Latitude
				Sign /	— Gr. /
				Gr. / M.	M.
6	9	6	58	Observed	$\square 1 / 0\frac{1}{3}$

January, Day	H. p.m.	M.	Moon	Longitude — Sign / Gr. / M.	Latitude — Gr. / M.
				Alphons.	2 / 0
				Copernic.	1 / 45
7	14	13	40	Observed	□ 10 / 39
				Alphons.	9 / 59
				Copernic.	10 / 6
8	15	15	5	Observed	□ 25 / 38½
				Alphons.	24 / 34
				Copernic.	24 / 42

Parsing notes: longitude signs given as zodiacal glyphs (Scorpio □ for obs. 6, Leo □ for obs. 7–8). "A" in the latitude column = *Austr.* (south/austral).

Because the Moon had been observed alongside the ninetieth degree from the Ascendant, and the longitude seen coincided with the true longitude, only the latitudes seen differed from the true ones — that is, the parallax of latitude is noted as below.

[Margin: Parallaxis.]

January, Day	9 — Gr. / M.	14 — Gr. / M.	15 — Gr. / M.
Latitude seen	4 / 28	5 / 5	4 / 19
True Moon	3 / 59	4 / 35	3 / 46
Parallax of latitude	0 / 29	0 / 30	0 / 33

9. In the same year 1587, on August 18, at 17:25 [H. 17.25'] a.m., Tycho observed the true place of the Moon in Gemini 26°23'; so Tycho himself in *Progymnasmata* [Tycho, *Progymnasmata*] vol. 1, ch. 6; but Longomontanus [Longomontanus] in his *Astronomia Danica* [*Astronomia Danica*] vol. 1, ch. 6, puts it at 21¾.

10. In the same year, month, and at hour 7.25' a.m., he observed the Moon in quadrature [□]; its true southern latitude was 5°13'–15'. So Tycho, in the same place.

11. In the year 1592, on February 12, at hour 8.12 [Hor. 8.12], Tycho observed the true latitude of the Moon at $16^{\circ}5'$. So *Progymnasmata* vol. 1, ch. 1. In the year 1594, Tycho at Uraniborg observed the longitudes of the Moon written below, together with the true latitudes, which Kepler [Kepler] exhibits before the Ephemerides of the year 1617, page 13, adding that it is most difficult to represent all of them by the calculation of the Tables.

December ☽ — D. / H. / M.	Longitude ☽ — Gr. / M. / S.	Latitude South or North — Gr. / M. — vel Bor.
12 10 / 4 / 0 ☐ 6 / 47 / 45 3 / 18 A		
13 11 / 5 / 6 19 / 20 / 40 2 / 18 A 14 14 / 8 / 34 29 / 5 / 10 1 / 6 B		
15 15 / 9 / 56 ☐ 13 / 13 / 50 2 / 19 B 16 20 / 3 / 50 13 / 49 / 30 ☐ 4 / 27 B		
17 21 / 6 / 0 29 / 44 / 20 ☐ 3 / 59 B 18 22 / 6 / 30 14 / 28 / 45 ☐ 3 / 28 B		
19 23 / 7 / 36 29 / 27 / 50 ☐ 2 / 44 B 20 26 / 9 / 40 12 / 3 / 20 ☐ 1 / 15 A		
21 27 / 10 / 10 25 / 26 / 0 ☐ 2 / 15 A 22 28 / 7 / 45 7 / 50 / 20 ☐ 3 / 11 A		

Parsing notes: "A" = *Austr.* (south), "B" = *Bor.* (north). Zodiacal glyphs appear scattered in the Longitude and Latitude columns; transcribed as printed. Some sign-glyphs ambiguous in the scan.

Boulliau [Boulliau], in his *Astronomia* [book 3], ch. 12, reduced [these] to the time of the meridian of Uraniborg, by direct adjustment from the Tables in his calculation, in order to display that Variation which the Tychonics ascribe to the Moon when in the octants of its conjunctions and quadratures, asserting it not to be always of the same magnitude. Whoever is worthy, let him consult [the source].

23. In the year 1595, on February 18, at hour 5.43' a.m., the Moon's true latitude was observed at $5^{\circ}20'$ south. So *Progymnasmata* vol. 1.

24. In the year 1596, on January 4, at hour 11.43' p.m., the Moon's latitude was seen north at $4^{\circ}59'$, observed by Tycho — Tycho vol. 1, *Progymnasmata*, ch. 1.

25. In the year 1600, on April 10, by the old style, at hour 7.27 $\frac{1}{3}$, Tycho at Benátky castle near Prague [Benátky nad Jizerou] observed the western limb of the Moon distant from Regulus by $18^{\circ}19'$, and at hour 7.45 $\frac{1}{3}$ past noon distant from Procyon by $21^{\circ}18\frac{3}{4}$. From this he concludes that, on that day on April 10, at hour 7.32 $\frac{1}{3}$, the Moon was in Leo $6^{\circ}20'22''$, with south latitude $3^{\circ}40'$; as Snel [Willebrord Snel] reports in his *Observations of the Bohemians* [*Observationes Bohemicae*].

CAPUT IV.

A few lunar observations of Kepler, Lansberge, and Longomontanus, apart from eclipses, from the year 1598 to 1608.

1. In the year 1598, on May 29 (old style), in the evening at hour 8, Kepler at Graz saw the Moon joined to the western stars in the quadrilateral of the Pleiades, in such a way that it receded from them by no more than a sixth of the Moon's diameter; but its margin so touched the bright star of the Pleiades that the whole extent of its body was distinct, so wide was it. The Moon was three days old, and tended toward apogee. So Kepler, *Astronomia Optica [Ad Vitellionem Paralipomena / Astronomiae Pars Optica]*, page 347. Lansberge, in his *Thesaurus*, class 7, observed the Moon: from his Tables he finds the western Pleiad in Taurus $23^{\circ}23'$, with north latitude $4^{\circ}12'$; and the bright Pleiad in Taurus $24^{\circ}22'$, with north latitude $4^{\circ}6'$; and the more northerly Pleiad in Taurus $24^{\circ}2'$, with north latitude $4^{\circ}29'$. But the place of the Moon was seen in Taurus $23^{\circ}43'16''$, with latitude seen $4^{\circ}31'57''$ north.

2. In the same year, on July 17 (old style), Kepler in the same place, in the morning, between hours 2 and 3, saw the Moon with horns turned toward the Pleiades, in such a way that, with the section drawn perpendicularly and from the lowest horn, it would graze the Pleiades higher up. The Moon had already crossed the Pleiades, and was distant from the brightest of them, Palilicium [Aldebaran], more than by Palilicium's distance from the nearest little stars turned toward Taurus, but smaller, as in the nostrils; therefore the distance of the two bright stars stood between them — in such a way that it was distant in the Pleiades, as there, *Astronomia Optica* page 347.

3. In the year 1600, on March 11 (old style), Lansberge at Goes observed the Moon on the meridian, equal by 3 o'clock, distant from the Sun in consequence by $89^{\circ}50'$; it would have been seen even in the 1st degree of Aries $1^{\circ}25'$, and the Moon in Cancer $1^{\circ}15'$, about the ninetieth, where the longitude seen does not differ from the true. About perigee, the Moon is of maximum eccentricity at $82'$; so he himself in his *Thesaurus*, class 2, where the Tables underlie [the calculation]: the place of the Sun in Aries $1^{\circ}15'10''$, the Moon in Cancer $1^{\circ}15'$, with north latitude $2^{\circ}18'47''$. But he makes no mention of any parallax, since there is no mention of solar refraction.

[Margin: Parallaxis.]

4. In the same year and on the same day — nay, at the same hour, 6 a.m. on the meridian — Lansberge in the same place observed the southern meridian altitude of the Moon's upper limb at $64^{\circ}7'1/3$; and since he sets the Moon's semidiameter at $16'2/3$, therefore he saw the Moon's center at $63^{\circ}51'$; and so it was truly $64^{\circ}17'1/3$. Therefore the parallax of altitude was $26'30'$, which he also at the same place [Margin: Parallaxis.] in his *Thesaurus*, class 2.

5. In the year 1600, on March 26 (old style), Lansberge at Goes observed the Moon on the meridian, distant from the Sun in precedence by $96^{\circ}36'$, because the Sun was seen in Aries $16^{\circ}19'$, the Moon in Capricorn $10^{\circ}3'$, when it was in degree $89^{\circ}40'$ from eccentric apogee. From this, and from other observations, he contends that the maximum [latitude] of the Moon differs between mean motion and true [motion], as actually happens, when the Moon being dichotomous is distant from eccentric apogee $98'$; and that it is in degree $7^{\circ}38'$, as Tycho wishes — but he says $7^{\circ}40'$ — *Thesaurus*, class 2.

6. In the year 1600, on August 17 (new style), Kepler at the frontier of Styria and Hungary, under Pole-altitude $47^{\circ}24'$, in the evening, saw the Moon an hour before its setting joined with the Heart of Scorpio [Antares]; for it entered in the Septentrional [northern] part, in such a way that, as it were, a third part of the section stood out above, and how small a difference the section presented from a straight line. The Sun was in the 2nd degree of Leo, yet [the Moon] was seen much wider, since the part of the trajectory's light fell upon that very Moon, and the rising section presented an amplitude greater than the smaller one near the position set down — *Kepler*, page 117. *Astronomia Optica*. Lansberge in his class 7 of lunar observations presupposes the Moon there to have occupied the hour $10.40'$ on the meridian at setting, hour $8.50'$, and at egress hour $9.40'$; and from this, from his Tables, he gathers the hour $8.50'$ to have been seen in Sagittarius $4^{\circ}29'$, seen at $4^{\circ}17'1/3$, and the true south latitude $3^{\circ}42'$, seen at $4^{\circ}26'$. But the Heart of Scorpio he set in Sagittarius $4^{\circ}30'23''$, with south latitude $4^{\circ}26'$.

7. In the year 1601, on November 29 (old style), Lansberge at Goes, at hour $11.15'$ past noon, observed the meridian altitude of the Moon at $61^{\circ}25'$; but compared with the true $64^{\circ}55'1/3$, he produced a parallax of altitude of $30^{\circ}32''$, adding that the observation is certain, because it was made by means of shadows, since the Moon at perigee illuminates very brightly with the dioptra, inasmuch as a shadow in a plane could be discerned by the lower dioptra of the upper [dioptra]. So Lansberge in his class 5 of lunar observations.

[Margin: Parallaxis.]

8. In the year 1602, on September 26 (old style), Lansberge at Goes observed the meridian altitude of the Moon at $59^{\circ}39'$; but he said it was truly $60^{\circ}12\frac{1}{3}'$; therefore the parallax of altitude was $30''$, which he also says he saw through the shadow of the Moon — Lansberge, class 5 of lunar observations.

[Margin: Parallaxis.]

9. In the year 1602, on December 21 (new style), in the evening, Kepler in *Astronomia Optica*, page 237, says: with the quadrature [□] not yet completed at the hour, the Moon was seen, although it was hollow [crescent-shaped]; at the hour of one-and-a-half, the sixth after midday. But because Kepler came to the [moment of] dichotomy [half-Moon], for the Sun was in Capricorn $29^{\circ}30'$. From this he concludes the delineation of the waxing and waning Moon, which Albategnius [al-Battānī] teaches in ch. 30.

And he was not able to determine the number well by the fingers. See him, where, by the judgment of the quadrature within a few hours, but in respect of the section the Moon was dichotomous, that I have mentioned these very things of parallaxes, and of what is said by us in the Appendix to the first volume of the *Almagestum Novum* [*Almagestum Novum*].

10. In the year 1603, on March 14 (old style), Kepler contemplating the new phases of the Moon, saw the circumferential illumination fail evidently at the semicircle. Hence he demonstrates in *Astronomia Optica*, page 345, the Moon's diameter, that for the most part the disk of the Sun is seen larger than the Moon's, and therefore the whole Sun can be covered by the Moon.

[Margin: Diameter ☉.]

11. In the year 1608, on February 12 (old style), Lansberge at Goes, a third of an hour past the seventh in the evening, saw the Moon with its dark part entering toward the southerly Palilicium [Aldebaran]; the more northerly star [was] at the Moon's center, by almost half a semidiameter. So he himself in vol. 7 of *Lansberge's lunar observations*, where from his Tables he computes the place of the Moon: namely, in Gemini $4^{\circ}15'$; seen however in Gemini $4^{\circ}15'52''$, with south latitude $5^{\circ}10'43''$; and the place of Palilicium in Gemini $4^{\circ}23'48''$, with south latitude $5^{\circ}30'$.

12. Likewise in 1608, on February 12 (old style), Longomontanus at Hafnia [Copenhagen], at the evening hour $8.43'$, observed the conjunction of the upper Horn of the Moon with Aldebaran, when the Moon, near quadrature, was already at half-course of its digression. He saw this same conjunction at hour $8.46'$;

Melchior Levitius [?] writes it, but Longomontanus in his *Astronomia Danica*, vol. 1, ch. 6, where from his Tables he computes the longitude of Aldebaran in Gemini $4^{\circ}16'20''$, south latitude $5^{\circ}31'$; but the Moon's true place in the ecliptic, Gemini $4^{\circ}16'38''$, from which he gathers the parallax of longitude greater by $30'$, when it would have appeared at $4^{\circ}16'\frac{1}{3}$ of Gemini; and conversely the south latitude having been seen at almost $5^{\circ}47'$.

Lansberge in his class 7 observed the same lunar [phenomenon]: he says it was at Hafnia $8^{\circ}36'$, not $43'$, because he supposes Hafnia more easterly than Goes by $11^{\circ}15'$; but in the place of Palilicium [Aldebaran], that is, Aldebaran, Lansberge differs from Longomontanus by $7\frac{1}{3}$. Boulliau, in vol. 3, *Astronomia Philolaica* [*Astronomia Philolaica*], retains hour $8.43'$ in the narration, because nevertheless the Sun was in Pisces $3^{\circ}42'44''$, and the Moon was in $39^{\circ}45'$; it appears the true sky in $49^{\circ}35'$; and so he gathers hour $8.36'$, and the time added to the equation $11'7''$; the medium of time at Hafnia hour $8.47'$, at which time from his Tables he gathers the Moon's true place in Gemini $4^{\circ}50'$, and the true latitude $5^{\circ}12'43''$; but seen at $5^{\circ}44'4''$ south; he adds that the Moon was not yet seen at quadrature, but more than half at $5^{\circ}47'$.

13. Afterward, subjoining an observation of the same conjunction made by a Father [member] in his college [house] at hour 7 in the evening, when the Moon began to occult Aldebaran — *of whose sight, he says, to the hour 8: but the first of us [witnessed it] when the other limb of the Moon revealed the star, at hour 9.* He adds: Boulliau, the altitude of the Pole at Goes to be $48^{\circ}1'$; and from his Tables, the occultation to have begun there at hour $6.54'$, the end truly at hour $7.54'$; and the true place of the Moon in Gemini $4^{\circ}31'$; but let this very thing be seen, if one likes, by manifold practical calculation.

CAPUT V.

Lunar observations apart from eclipses, by Boulliau, Gassendi, Hevelius, Hodierna, Hortensius, Michael Langren, and Vincenzo Mutus, from the year 1623 up to the year 1653, regarding the places of the Moon.

[Glossary note: Hevelius (*Selenographia*), Hodierna, Martinus Hortensius (Maarten van den Hove), Michael Florent van Langren, Vincenzo Mutus.]

1. In the year 1623, on July 5, Boulliau at Paris, at hour $9.30'$ past noon, [observed] Spica [Spica] occulted by the Moon, the latter at altitude $17^{\circ}20'$. Boulliau, in *Astronomia Philolaica* book 3, ch. 10, says that Spica was at altitude $18^{\circ}34'$ in

Libra, with south latitude $1^{\circ}59'$; the Moon's true place in Libra $18^{\circ}35'10''$; and the Moon's center

having had the latitude of the Moon seen at $1^{\circ}46'$; the parallax of latitude $59'50''$; and truly the latitude $46^{\circ}10'$. For he had observed the center of the northern Moon distant from Spica by $1^{\circ}5'$.

2. In the year 1624, on September 3, Michael Florent van Langren [van Langren], cosmographer to the Catholic King of Spain, at Brussels, when the Equator culminated on the meridian at $31^{\circ}10'$, saw the eye of Taurus deserted at the dark margin of the Moon; so in letters sent to me afterward, as he himself attests.

3. In the year 1626, on February 4, Michael Florent van Langren at Brussels, when the Equator culminated at $43^{\circ}12'$, saw the 14th [degree] of Taurus, which is above the nose, covered by the shadowy part of the Moon; and in the same instant a moist wind extremely excited [the eye], so that they ceased about that very hour. So in letters sent to me by himself.

4. In the year 1627, on February 22, Michael Florent van Langren at Brussels saw the eye of Taurus emerge from the dark part of the Moon, where a somewhat higher and middling spot of the Caspian [Mare Caspium], or the Crisium Sea [Mare Crisium], stood perpendicularly in our *Selenographia*; while at the perpendicular minute $10\frac{1}{3}$; Sirius crossed the meridian, from which he gathered it to have culminated at $97^{\circ}21\frac{1}{3}$ in altitude. So he himself in letters sent to me.

5. In the same year 1627, on February 18, by the old style, Martin Hortensius [Martinus Hortensius] at Leiden, at hour 5.36' past noon, saw through the telescope the Heart of the Lion [Regulus] distant from the limb of the Moon by about two lunar fingers [digits], or, then, by minutes $5\frac{1}{3}$; the center, however, of the more easterly Moon [distant] from Regulus, according to longitude, by lunar digits $10\frac{2}{3}$; and of southerly digits 6'; but a little more, namely by minutes 19'. Lansberge in his *Thesaurus*, class 7, of lunar observations.

6. In the year 1627, on July 17, Gassendi [Gassendi] at Digne [Dignæ], at hour 10.30' past noon, [observed] the high tail of the Lion at occasus [setting] at $25^{\circ}13'$; he saw through the Basilisc [Basiliscus = Regulus] telescope, that it touched the eastern limb partly with the obscure horn of the lower part, through the quadrant about the Moon, *Bullialdus* book 3, ch. 12; and Gassendi himself in *Epicuro* page 901. But Boulliau takes it thus: that the Basilisc stood off from the center of the Moon at setting up to the lowest minute, 11'; and so the place of the Moon was seen in the Lion at degree $24^{\circ}59'$; and seen truly in degree $24^{\circ}55'$; and Gassendi says that this observation was made by the telescope, in such a way

that, made by the naked eye, Iulioduni [at Digne], at hour 9.35', since by the splendor of the Moon the occultation of the Basilisc appears sooner to him than it actually happens. But Gassendi seems to understand that he covered the Moon, not from the distance of Regulus at setting, but from the position by which the Moon covered Regulus.

7. In the year 1633, on February 14, with Gassendi observing at Digne, at hour 11.30', the Moon next eviscerated dichotomy by its obscure part and the twentieth, or twenty-fifth, of the obscure limb; it underwent the preceding stars of three little stars at the lowest cusp in the tail of Aries. Gassendi in *Epicuro* page 902.

8. In the year 1634, on December 30, Boulliau at Iulioduni [Digne] near the Pictones [Poitou], in the evening at hour 5.42', [saw] the high Aldebaran at $32^{\circ}42'$; he saw the bright Pleiades occupy the obscure margin of the Moon; thus through the telescope the star would appear higher than the lower limb of the Moon by minutes 4'. *Bullialdus* book 3, *Astronomia* ch. 12, who adds the star to have been in Taurus $24^{\circ}52'$; with latitude north $4^{\circ}8'$; the place of the Moon was seen in Taurus $24^{\circ}38\frac{1}{2}'$; truly $24^{\circ}17'55''$, and latitude seen north degree $4^{\circ}8'21''$; truly degree $4^{\circ}45'48''$.

9. In the year 1635, on January 26, Michael Florent van Langren at Brussels [observed] the Moon occulting Taygeta of the Pleiades, the Equator culminating at degree $122^{\circ}55\frac{1}{3}'$; and the Sterope of the Pleiades culminating at degree $138^{\circ}11\frac{2}{3}'$; so in letters of himself to me. But Taygeta is that star 33, in southerly Taurus, near Bayer [Bayerum].

10. In the year 1635, on August 26, at hour 9.49', Gassendi at Digne saw the Moon, at full Moon, approach a preceding star of two in the tail of Capricorn; the part of the lower margin of the inferior eastern limbs, or, from the region of the spot which we noted in the *Almagestum Novum* book 4; Hevelius gathers it thus from things said by Gassendi in *Epicuro* page 902.

11. In the year 1636, on November 25, in the same place, Michael Florent van Langren observing at Brussels, when the Equator culminated at degree $341^{\circ}8'$, saw the knee of Gemini emerge from the limb of the Moon, in a line drawn through the mountain Guthschovius [Mons Guthschovii] and Moretus [Mons Moretus], distant from the Moretus mountain by as much as Moretus is distant from Eugenia [Mons Eugenia]:

In the *Selenographia* itself in our [Appendix], book 4, the *Almagestum Novum* sets out: Guthschovius is Ariadnæus, and Moretus, Proclus, and Eugenia, Vitruvius.

12. In the year 1637, on March 29, Boulliau at Paris, in the evening at hour 8.19', observing — Boulliau; but truly *in Epicuro* Gassendi — saw Aldebaran at degree 20.55', that is, hour 8.43'36". The Moon grazed it, since it had occulted the angle of the southern quadrilateral of the Pleiades, which entered the bright Pleiades in the preceding [position]; if the bright stars are in the middle and the Moon is equally distant from the Cornu [horns] of both bright stars, [Margin: ?] then the southern limb [was occulted] from the southern cusp, when at hour 9.26' the Moon occulted the star at the angle of the austral quadrilateral of the Pleiades, [the star] of that same limb almost the seventh from the southern cusp; and at hour 9.40'. The star at the angle [was] seen at last to emerge, and to escape from the Moon near the middle, tending toward the boreal, nor at such a distance from the lower limb did it shorten much. He occulted at hour 9.54'; in such a way, by 8", he occulted the bright Pleiad in three sevenths of the obscure limb, at a cusp of southern latitude at hour 9.54'; the angle boreal emerged from the bright Pleiad, with one minute conjoined and added [from] obscure distance, [and] the limb, which was in the middle near the southern cusp toward the boreal, and the spot Mare Crisium, by us Mare Crisium [Margin: Gassendi *in Epicuro* page 902]. Boulliau adds, book 3, ch. 12. At Paris, the highest [point] impending over the boreal angle of the Pleiades, higher, was that 8'; and in the same azimuth it had been with the center of the bright Pleiades, [which was] Tyconically there in Taurus then, in degree 24°55'28"; and the western quadrilateral occulted at degree 161°56'18"; he numbers the intervals of the times by the oscillations perpendicularly, *or he himself wrote it to me.*

13. But Michael Florent van Langren, in the same year, on the day 29 of March, at Brussels saw Maia, or the Boreal Angle of the Pleiades, occulted by the Moon, the Equator culminating at degree 140°29'⅔; and the most boreal Asterope of the Pleiades culminating at degree 152°9'18", that is, the western angle culminating at degree 161°56'18"; he numbers the intervals of the times by oscillations perpendicularly, *or he himself wrote it to me.*

14. In the year 1638, on January 14, Gassendi at Digne in the evening saw an hour 2.15'; the bright cusp of the Boreal [horn] transited near the western angle of the quadrilateral of the Pleiades, nor at so great a distance more than a tenth part of the lunar diameter. But truly at hour 7.31' it touched the southern angle with the obscure limb, by about four minutes in the boreal parts from the boreal cusp. At hour 8.21'. The southern angle emerged, and stood off from the bright limb by one and twelve-fourteenths of the lunar diameter, and by three [of the same] of its own limb, almost the seventh from the boreal cusp distant, meanwhile it touched the easterly Pleiad. At hour 9.19' the bright Pleiad emerged, and stood off

from the boreal limb by two diameters of the Moon, and a third of the limb toward the boreal; the most boreal Pleiad emerged from the bright limb, and stood off, and from the other part 48 diameters of the lunar [Margin: Gassendi *in Epicuro* page 902 & Bullialdus book 3, ch. 12], concerning which see in the end of the following observations.

15. Likewise in 1638, on December 11, Gassendi observing at hour 4.37' past midnight, saw the Moon to occult the eastern oriental [limb], about the middle of the obscure limb, a star which is in the foot of the eastern part of Castor, preceding another, which is in the foot of the preceding Gemini. Gassendi *in Epicuro* page 902. Bullialdus likewise book 3, ch. 12, refers it [to] Gassendi, observing in the year 1638, January 12, at hour 8.5'; with reckoning made in the year 1648, January 14, at hour 8.5'·48"; the center of the Moon at the fifth from the boreal cusp. From this he gathers the center of the Moon at minute 5' distant from the star, in the longitude in Taurus 24°56'·18"; and so the place of the Moon was seen to be in Taurus 24°51'·18", and latitude truly boreal at degree 4°55'; seen at degree 5°44'·48".

16. In the year 1639, on February 12, Gassendi at Aix observed the transit of the Moon over a preceding star of two in the foot of the preceding Gemini at degree 31°45'; for it was at hour 10·17', noting that it lay in the same line conjoined, nevertheless at the same longitude, distant by minutes 1', from the southern horn; and so *Bullialdus* book 3, *Astronomia* ch. 12, attesting that the star was in Gemini at degree 28°48'·48", and the Moon's true place in Gemini at degree 28°48'·48"; and the parallax of longitude having been seen at 23°48' latitude at 23°50'. **17.** In the year 1639, on April 7, Boulliau at Paris, [with] high Procyon at degree 33°52', that is, hour 9.8', saw the Moon with obscure limb...

Liber III — De Luna (Caput V, continued)

[The observation series continues from the prior batch. The opening lines of p. 190 complete observation 17 — Boulliau's Paris observation of 1639 April 7 — begun at the foot of the previous batch.]

the upper limb being occulted by the apex of the Moon's horn, the star of fifth magnitude that lies in the origin of the northern horn of Gemini — which is to say, by the Tyconic reckoning, in the 7th degree, 34 minutes [grad. 7. 34'] of Gemini, with northern latitude 40 minutes [40']. The center of the Moon was therefore distant from there by 14 minutes [14'] in the preceding part. Accordingly the Moon's place was seen to be in the 6th degree, 53 minutes [6. 53'] of Gemini, and its latitude seen to be smaller by 5 minutes [5'] than the star's.

Hence its place is not gathered from this. He concludes the matter in Book III, Chapter 12 [lib. 3. c. 12], in these words: "*Why this place is suspect to me.*"

18. In the year 1641, on April 14 [Anno 1641. Aprilis 14], Boulliau observed at Paris that, at the very moment of the Moon's setting, by the hour 24, minutes 8 [hor. 24. min. 8], the more northern of the two stars of fifth magnitude that are obscurely seen at the lower horn of Taurus, and that are distant from the lower horn itself, was occulted — Boulliau places it in the 23rd degree, 27 minutes [gr. 23. 27'] of Gemini, its latitude being southern 2 degrees, 37 minutes [gr. 2. 37'] in Gemini. From this it follows that the Moon's place was southern by 2 degrees, 37 minutes [gr. 2. 37']. Hence Boulliau, in Book III, Chapter 12 [lib. 3. c. 12], places the Moon in the 23rd degree, 27 minutes [gr. 23. 27'] of Gemini, and (its latitude having been seen) in the 2nd degree, 32 minutes, 11 seconds [gr. 2. 32'. 11"], and the parallax, in longitude, 32 minutes [32'].

19. In the same year 1641, and in the month of April, on day 13 [Anno eodem 1641. & Mense Aprili die 13], Michael Florent van Langren observed the eye of the Bull [oculum Borealem Tauri] occulted at the obscure limb of the Moon, the Moon culminating, in the 9th degree, 26 minutes [grad. Æquatoris 149. 26'] of the equator. (*Va habeo in litteris ad me scriptis*) — Thus I have it in the letters written to me.

20. In the year 1641, on June 24 [Anno 1641. Iunii 24], Boulliau at Paris, before the setting of Arcturus, in the 41st degree, 47 minutes [gr. 41. 47'], that is to say at the hour 11, minute 5, second 20 [hor. 11. 5'. 20"], saw the star of third magnitude that is the lower of those in the horns of Capricorn, nearest to it on the preceding edge. Boulliau, in Book III, Chapter 12 [lib. 3. c. 12], holds that this star was in the 19th degree, 5 minutes [gr. 19. 5'] of Capricorn, with northern latitude. From this the Moon's place was seen to be in the 19th degree, 40 minutes, 54 seconds [gr. 19. 40'. 54"] of Capricorn, and its latitude seen to be 4 degrees, 8 minutes [gr. 4. 8'] northern. Hence the Moon's place by longitude was 9 degrees, 13 minutes [9. 13'] of Capricorn, its latitude 5 degrees, 17 minutes [5. 17'].

21. In the year 1642, on October 2 [Anno 1642. Octobris 2], Markab being on the meridian of Brussels, Michael Florent van Langren observed the eye of the Bull [oculum Tauri] in a straight line with that streak, which he himself, in his *Selenographia*, calls Promontorium Clauui [Promontorium Clauij — Cape Clavius], and Mount Bias [Montem Biæi], so that the eye of the Bull was placed a little further than Mount Bias, by however much Cape Clavius is distant from Mount Bias itself. In our *Selenographia* this Mount Bias is called Mount Hercules [Mons Biæi vocatur Hercules], being distant — as is plain from the letters — by the third

part of that spot, by which Cape Clavius is distant from the most western edge, and the same spot is distant from the Moon's western diameter, as the spot itself appears, by 1/200. And this eye of the Bull was now more western, and was setting from the Moon.

22. In the year 1642, on November 10 [Anno 1642. Nouembr. 10], at the hour 7, at midnight [hora 7. à media nocte], Hevelius at Danzig saw the last phase of the waning Moon, on the last day before conjunction, in the 2nd degree [in 2. gr.] of Scorpio. (Hevelius, Chapter 44, *Selenographia* [Heuelius cap. 44. Selenographiæ].)

23. In the year 1642, on November 26 [Anno 1642. Nouembr. 26], at the hour 11 past midday [hora 11. post merid.], Hevelius at Danzig saw that the Moon, from the moment of opposition, decreased more than was usual. And this decrease, by a sensible amount, the telescope had detected. Hevelius, Chapter 27, *Selenographia* [Heuelius cap. 27. Selenographiæ], where he refutes Blancanus and Aguilonius, who suppose that this decrease, not after some two days, but barely three days after opposition, can be discerned. And he learnedly shows that this decrease of the Moon does not always appear at the obscure limb of the Moon. (Hevelius, Chapter 27, *Selenographia*.)

24. In the year 1644, on April 13 [Anno 1644. Aprilis 13], at the hour 9 past midday [hora 9. post merid.], Hevelius at Danzig observed the Moon in the first quadrature, in the 25th degree [in Cancri gr. 25] of Cancer, around its maximum libration; and yet the lines of section separating the obscure part from the luminous part were noticeably distant by a tenth part of the Moon's diameter [decima parte diametri Lunarum]. This he himself attributes to the libration. (Chapter 18, *Selenographia* [Cap. 18. Selenographiæ].) But to this he does not concur in establishing the parallax.

25. In the year 1644, on October 8 [Anno 1644. Octobr. 8], at the hour 7 past midday [hora 7. post merid.], Hevelius at Danzig observed the Moon before the true quadrature, of which the lines of section seemed to exceed beyond the center of the Moon's disk, so that there appeared so many spots not yet covered by the line of section of the Moon. (Hevelius, Chapter 18, *Selenographia* [Heuelius cap. 18. Selenographiæ].)

26. In the year 1644, on November 13 [Anno 1644. Nouembr. 13], Hevelius at Danzig observed the eclipse of Palilicium [= Aldebaran], beginning to be occulted by the Moon, at the hour 3, minutes 5 [hora 3. minuto 5], at the middle of the eastern limb; it emerged at the hour 4, minute 5 [hora 4. 5'], above the middle of the western limb; and at the hour 4, minutes 10 [& hora 4. 10'], Palilicium was

distant from the obscure part by a twelfth of the Moon's diameter [duodecima Lunaris diametri]. (Hevelius, page 472, *Selenographia* [Hevelius pag. 472. Selenographiæ].)

27. In the year 1645, on April 27, day 5, hour 8 of the Danzig evening [Anno 1645. Aprilis 27. feria 5. hora 8. vespertina Gedani], Hevelius saw the first phase of the Moon; from another after [the New Moon, the Moon being in Taurus, of the sign of long descensions], and in its perigee, and in its greatest southern austral latitude, having departed from its conjunction with the Sun, the hours being 41. (Hevelius, page 278, *Selenographia* [Hevelius pag. 278. Selenographiæ].)

28. In the year 1645, on October 8 [Anno 1645. Octob. 8], Hevelius at Danzig observed the eclipse of Palilicium made by the gibbous Moon, beginning to cover it at the eastern limb, at the height above the horizon of 38 degrees, 48 minutes [gr. 38. 48'], that is at the hour 1, minutes 47 [hora 1. 47']; but at night, it emerged at the middle of the western limb, near the bright shoulder of Orion, in the 38th degree, 45 minutes [gr. 38. 45'], namely at the hour 2, minutes 57 [hor. 2. 57']; and the line of Palilicium did not yet reach the lower center of the Moon, so much was the duration of the eclipse — namely, the duration of the eclipse was 1 hour, 10 minutes [hor. 1. 10']; the hour was 3, minutes 30 [hora 3. 30']. The Moon reached the 90th degree of the ecliptic [nonagesimum Eclipticæ]. (Hevelius, Chapter 43, *Selenographia* [Hevelius cap. 43. Selenographiæ pag. 473].)

29. In the year 1645, on November 17 [Anno 1645. Nouemb. 17], Hevelius at Danzig saw the very old phase of the Moon before conjunction, for the Moon was situated in the 13th degree [in gradu 13] of Scorpio, and in its greatest northern boreal latitude. (Hevelius, Chapter 43, *Selenographia* [Hevelius cap. 43. Selenographiæ].)

30. In the year 1645, on December 2 [Anno 1645. Decembr. 2], the Moon being at perigee and at opposition to the Sun, he observed the eye of the Bull [oculum Tauri] to rise; the Moon's altitude being higher than 49 degrees, 28 minutes [alt. gr. 49. 28'], at the southern limb, so that it then emerged from the middle of the western limb in the 49th degree [gr. 49]. (D. Vincenzo Mut [D. Vincentio Muto] of Majorca observed this, and accomplished it.)

31. In the year 1647, on April 8 [Anno 1647. Aprilis 8], D. Vincenzo Mut of Majorca, with the right ankle of high Auriga setting, in the 35th degree, 14 minutes [grad. 35. 14'], that is at the hour 8, minutes 19 [hora 8. 19'], saw with an optical tube the application of the Moon to the Hyades [Lunæ ad Hyadas] — that is, to that star of Taurus, which is at the eye of the Bull, the star itself having

entered toward the northern part almost a third [quasi tertiam], at the dark northern limb. (*Sic ille in Epistola ad me* — Thus he writes in a letter to me.)

32. In the same year 1647, on April 12 [Anno pariter 1647. Aprilis 12], D. Vincenzo Mut of Majorca saw Jupiter [Iouem] entering the northern part of the Moon [Borealem Lunæ], at the high western edge, in the 57th degree, 18 minutes [Regulo gr. 57. 18'], that is at the hour 9, minutes 56 [hora 9. 56']; thereafter, Jupiter having emerged, at the high western straight line [Iupiter à limbo occiduo Lunæ], in the 49th degree, 12 minutes [Regulo gr. 49. 12'], namely at the hour 10, minutes 48 [hora 10. 48'], so that it lurked for 52 minutes [52']. (*Ita idem in suis ad me litteris* — Thus the same in his letters to me.)

33. In the year 1647, on June 6 [Anno 1647. Iunij 6], Hevelius observed another star of Lyra [aliam Lyræ], in the 53rd degree, 36 minutes [gr. 53. 36'], that is at the hour 10, minutes 10 [hora 10. 10']; Gedani [at Danzig], in the rectilinear part toward the apexes of the horns, the Moon being drawn, at the apex of the lower edge distant by a fifth part of the Moon's diameter [quinta parte diametri Lunaris]. So he writes, and inscribed the diagram. (Hevelius, among other things, communicated this to me most liberally — *Hevelius inter alia ad me liberalissime transmisso.*)

34. In the year 1650, on August 4 [Anno 1650. Augusti die 4], when the Moon was at the very 90th degree, around quadrature, and almost without latitude, D. Vincenzo Mut of Majorca, with the naked eyes [nudis oculis], saw the Moon still hollow [Lunam adhuc cauam], but through the optical tube not so hollow [Tubo optico non adeo cauam], the hour being 9, minutes 30 [hora vero 9. 30']; that the lines of section were in the exact dichotomy [in ipsa exacta dichotomia]; but the parts remaining, except at the horns, was hollow somewhere, somewhere protruding toward the line of section dichotomy, both to the naked eye, and to the hour 10, minutes 15 [hora 10. 15']; to the naked eyes the Moon would seem hollow somewhere, as in Kepler's *Astronomia Optica*, page 217 [Kepleri *Astronom. Optica* pag. 217], yet not for the whole hour [non per horam] would the Moon's quadrature be seen hollow. So he wrote in the same year, and to me, D. Vincenzo Mut [D. Vincentius Mutus], whose many letters, full of astronomical learning, I keep. (*cuius Epistolas multas Astronomica eruditione plenas conseruo.*)

35. In the year 1653, on the 19th day of May [Anno 1653. die 19. Maij], D. Io. Baptista Hodierna [= Giovanni Battista Odierna], a Sicilian, a most skilled astronomer, after he (as the *Almagestum Novum* has noted in the *Selenographia*, and on the Dichotomy of the Moon) had calculated, deferred the dichotomy of the Moon under the southern hour 15, minutes 46 [sub horam post meridiem 15. 46'],

at the meridian of Palma [in Meridiano Palmæ], which is between Gela [Gelum] more eastern and Agrigentum [Agrigentum] more western; for then the line of section dichotomy passed through the western edge Marginem Anaxagoræ [the edge of Anaxagoras], and bifariously cut Archimedes [Archimedem], and Alpetragium [Alpetragium], in a luminous place where Plato and Tycho were still whole [totus Plato, & Tycho], and Cavi [Cauij] the western edge, and whole Blancanus [integer Blancanus]. See in Book IV of the *Almagestum Novum* [lib. 4. Almagesti] the location of the lunar spots noted. And indeed the *Almagestum Novum* indeed reached the 90th degree, minutes 14 [grad. 394. hora & hor. 15. 46'], by which the Moon perfectly arrived at the dichotomy at the protruding horns; yet he confesses it is difficult to avoid the deception of the half-hour [horæ dimidiæ]. So it is in his letters to me, most humane, and most learned. (*Ita ille in suis ad me humanissimis, & doctissimis Epistolis, quas custodio* — whose epistles I keep.)

36. In the year 1654, on May 1 [Anno 1654. Maij 1], with D. Vincenzo Mut of Majorca observing, the Moon began to cover Regulus [Regulum] high and at the western Rigel, in the 34th degree, 16 minutes [gr. 34. 16'], that is at the hour 8, minutes 6 [hor. 8. 6']. Regulus emerged from the Moon, high and at the western shoulder of reddish Orion [Occid. humero rubescenti Orionis], that is at the hour 9, minutes 7 [hora 9. 7'].

[Top-of-page text completing observation 36 from the prior page, with marginalia at the page head:]

the angle of the ecliptic, and of the Moon's path, was 12 degrees, 8 minutes [grad. 12. 8']; and therefore the Moon was seen in the 24th degree, 48 minutes [Leonis gradu 24. 48'] of Leo, with northern boreal latitude 29 $\frac{1}{3}$ minutes [29' $\frac{1}{3}$]. Let it be by Lansberg [Lansbergio] that it would have been in the 25th degree, 24 minutes [gr. 25. 24'] of [Leo] with latitude 34 minutes, 15 seconds [latit. 34. 15"]. For the Danes [Danicis], indeed, and for Argol [Argolo], it was in the 24th degree, 57 minutes [gr. 24. 57']; and for Boulliau in the 25th degree, 2 minutes [gr. 25. 2'], with the latitude seen 35 degrees, 45 minutes [35. 45']. Thus D. Vincenzo Mut [Mutus], in his learned letter to me at present [in sua eruditissima ad me Epistola].

Caput VI

****Table (Caput VI) — Source: **** A large folio-width tabulation occupying nearly the entire page, framed with rule-lines, presenting the calculated places of 24 lunar observations. The header text along the right margin reads, in full:

CAPUT VI. — *"In which is exhibited a Table of 24 Lunar Observations together with the calculation, that is, the workings of Boulliau, which he himself in Book 3 of the Astronomia Philolaica, Chapter 12, promised, but having set it aside, deferred to page 175 of his Tables."*

A second marginal-header line reads: *"The calculation of the observed places of 24 motions of the Moon, of which the prior 14 were observed by Tycho; the remaining 10 were reduced to mean time at the Meridian of Uraniborg by D. P. Gassendi and Io. Boulliau."*

The header marginalia at the top of the page (above the table) reads: [Margin (page-head, completing obs. 36): see the prose above — the ecliptic-angle and the comparative lunar places by Lansberg, the Danes, Argol, and Boulliau, per Mut's letter.]

The table is read in **columns running down** the page (each labeled at the top by a column-head), with the **24 observations as rows**. The column-heads (reading right to left across the framed head, as printed) are:

Column head (Latin)	English
Numerus (1...24)	Observation number (1 through 24)
Anni	Year
Menses	Month
Temp. Med. — D. H. '	Mean time — days, hours, minutes
Locus Solis verus — Sig. Gr. '	True place of the Sun — sign, degrees, minutes
Locus ☾ visus ad Argum. — Sig. Gr. '	Place of the Moon seen, for the argument — sign, degrees, minutes
Locus ☾ observ. & reductus — Sig. Gr. '	Place of the Moon observed and reduced — sign, degrees, minutes
Differ. seu æquationis dispens. — ' "	Difference, or dispensation of the equation — minutes, seconds
Anomalia simplex — Sig. Gr. '	Simple anomaly — sign, degrees, minutes

Column head (Latin)	English
Distantia Lunæ à Sole — Sig. Gr. '	Distance of the Moon from the Sun — sign, degrees, minutes
Motus lat. æquatus — Sig. Gr. '	Equated motion of latitude — sign, degrees, minutes
Refractio maxima in limite syzigiae — ' " (Subtr./Add.)	Maximum refraction at the limit of syzygy — minutes, seconds (Subtract / Add)
Differ. observ. seu à Tychone — ' "	Difference of the observation, or [the difference] from Tycho — minutes, seconds

Observation rows (year / month, with the leading entries as I can read them):

No.	Year	Month
1	1586	September [Septembri]
2	1587	January [Ianuarij]
3	1587	January [Ianuarij]
4	1594	December 1 [Decemb. 1]
5	—	—
6	—	—
7	—	—
8	—	—
9	—	—
10	—	—
11	1594	December 11 [Decemb. 11] (these 14 places observed in the year 1594 December, by old style — <i>Hæc XIV. loca observata sunt Anno 1594. Decembri diebus stylo veteri</i>)

No.	Year	Month
12	—	—
13	—	—
14	—	—
15	1617	June [Iunij]
16	1617	June [Iunij]
17	1619	February [Februarij]
18	1619	January [Ianuarij]
19	1628	January [Ianuarij]
20	1634	June [Iunij]
21	1634	June [Iunij]
22	1641	March [Martij]
23	1641	April [April.]
24	1641	April [April.]

Parsing notes: This is a very dense, framed folio table read in columns down the page, with the numbered observation-rows entered transversely. At the available resolution the year/month spine (left edge) and the column-head labels (right edge) are legible, but the great majority of the interior numerical cells — the sexagesimal entries for Sun's place, Moon's place observed and reduced, equation-difference, simple anomaly, Moon–Sun distance, equated latitude-motion, syzygy refraction, and the Tycho-difference — cannot be transcribed reliably at this resolution; the digits within the framed grid are too fine and ink-bled to resolve cell-by-cell without misreading. **This whole table for full cell-by-cell transcription at higher resolution.** The structural skeleton (column heads, 24-row spine, the two header captions, the "first 14 from Tycho / last 10 reduced by Gassendi & Boulliau" provenance note, and the "old style 1594 December" sub-note) is recorded here. The bracketed note "Add./Subtr." marks the refraction column's sign convention per row, and "m." within several columns marks the minute-sign on those sexagesimal entries.

Caput VII

Lunares Observationes selectæ ex multis Bononiæ factis à PP. Io. Baptista Ricciolio, & Franc. Maria Grimaldo Societatis Iesu, pro Lunæ locis extra Eclipses.

Caput VII. — Select Lunar Observations, out of many made at Bologna by Fathers Giovanni Battista Riccioli and Francesco Maria Grimaldi of the Society of Jesus, for the places of the Moon outside eclipses.

1. In the year 1642, on April 14, in the following night [Anno 1642. April. 14. nocte seq.], an eclipse was observed (concerning which, see the eclipse observations); part of that night the meridian altitude of the Moon's center was seen to be 35 degrees, 31 minutes [gr. 35. 31']; thence, to the transit of Arcturus by the meridian-circle [M. C.], the parts were numbered perpendicular, 28 degrees, 16 minutes [28. 16'].

2. In the year 1642, on June 18, in the following night, minutes 34 1/2 [Anno 1642. Iunij 18. nocte seq. minutis 34 1/2], after the transit of Aquila by the middle of the heavens [Coeli], the meridian altitude of the Moon's center was seen to be 24 degrees, 15 minutes [gr. 24. 15']; [the heavens being] clear, the same center was seen distant from Fomalhaut by 23 degrees, 18 minutes [gr. 23. 18'], apparent; and after three minutes of time, the altitude of Fomalhaut was seen to be 20 degrees, 4 minutes [gr. 20. 4'].

3. In the year 1642, on July 7, in the following night [Anno 1642. Iulij 7. nocte seq.], the meridian altitude of the Moon's upper limb was seen to be 30 degrees, 28 minutes [gr. 30. 28']; thence, to the transit by the meridian-circle [M. C.] of the middle star in the forehead of Scorpio, we numbered 44 degrees, 5 minutes [44. 5']. On day 8, in the following night, the altitude of the Moon's center was seen to be 27 degrees, 18 minutes [gr. 27. 18']; thence, to the transit of the heart of Scorpio [cordis Scorpij] by the meridian-circle, we numbered 11 degrees, 40 minutes [11. 40'].

4. In the year 1642, on July 15, in the following night [Anno 1642. Iulij 15. nocte seq.], from the transit of Fomalhaut by the meridian-circle [M. C.], and to the transit of the eastern margin of the Moon [marginis Orientalis Lunæ], 42 degrees, 16 minutes flowed [fluxere 42. 16']; and then the altitude of the Moon's lower limb [limbi inferioris Lunæ] was 47 degrees, 14 minutes [gr. 47. 14']; and thence, at the physical rising of the Sun, the parts numbered were 42 degrees [42'].

5. In the year 1642, on July 18, in the morning, the Sun having risen [Anno 1642. Iulij 18. manè orto Sole], the meridian altitude of the lunar center was seen to be 51 degrees, 59 minutes [gr. 51. 59']; and after 2 minutes of time, the altitude of the center seen was 7 degrees, 3 minutes [gr. 7. 3'].

6. In the year 1642, on August 6, in the evening [Anno 1642. Augusti 6. vespere], from the transit of Ophiuchus [Ophiuchi] by the meridian-circle, the minutes numbered were 8 minutes [8'], and from the transit of the lunar [center], whose meridian altitude was seen to be 25 degrees, 55 minutes [gr. 25. 55'].

7. In the year 1642, on August 16, in the morning [Anno 1642. Augusti 16. manè], the altitude of the upper lunar margin was 56 degrees, 24 minutes [gr. 56. 24']; and a little after, [the altitude] of the lower margin was 55 degrees, 56 minutes [gr. 55. 56']; the hour, after 2, the bright [star] of Aries [lucida Arietis] transits by the meridian-circle [M. C.].

8. In the year 1642, on August 20, in the morning, minutes 24 1/2 [Anno 1642. Aug. 20. manè 24 1/2], before the rising of the Sun, the northern and eastern horn of the Moon was seen to be distant from Capella [à Capella orientali], in the 30th degree, 27 minutes [gr. 30. 27']; the western lucid [star], in the 30th degree, 29 minutes [gr. 30. 29'].

9. But on the same day, in the morning, minutes 21, 18 seconds [Die autem seq. manè min. 21. 18"], after the transit of the bright [star] of Aries [lucidæ Arietis] by the meridian-circle, the Moon's center was seen to be distant from the bright shoulder of Orion [Orionis humero lucido] by 10 degrees, 12 minutes 1/2 [gr. 10. 12' 1/2]; and after 2 minutes of time, it was distant from Rigel by 47 degrees, 57 minutes [gr. 47. 57']; and the refractions are to be noted within the foregoing times, and the altitudes seen.

10. In the year 1642, on August 23, in the morning, minutes 48, before the true rising of the Sun [Anno 1642. Aug. 23. manè 48'. ante verum Solis ortum], the Moon's center was seen to be distant from the bright shoulder of Orion [ab Orionis humero lucido] by 42 degrees, 16 minutes [grad. 42. 16']; and after 4 minutes, [it was] distant from Rigel by 16 degrees, 21 minutes 1/2 [grad. 16. 21' 1/2].

11. In the year 1642, on October 15, in the morning [Anno 1642. Octob. 15. manè], from the transit of Sirius by the meridian-circle [M. C.], namely from the hour 7, minutes 12 past midday [ab hora 7. post merid. 17. 12'], the minutes numbered were 18 minutes, 52 seconds [min. 18'. 52"], at whose end the Moon's center was seen to be distant...

12. In the year 1642, on October 19, in the morning, minutes 5, 10 seconds [Anno 1642. Octob. 19. manè minut. 5. 10"], after the transit of Sirius by the meridian-circle, the Moon's center was distant from the heart of Hydra [à corde Hydræ] by 20 degrees, 38 minutes [gr. 20. 38']; thence, after the hour, by minutes 7, 12 seconds [post min. 7. 12"], [it was] seen to be distant from the tail of Leo [à cauda Leonis] by 20 degrees, 19 minutes [gr. 20. 19'].

13. In the year 1642, on October 30, in the evening, at the same moment [Anno 1642. Octob. 30. vespere eodem momento] at which the western lucid [star] of Aquila's altitude [occidua lucida Aquilæ] was 51 degrees, 21 minutes [gr. 51. 21'], the Moon's center transited by the meridian-circle [M. C.]; its meridian altitude

was seen to be 30 degrees, 49 minutes [grad. 30. 49']; the hour was 7, minutes 56, seconds 16 past midday [hora 7. 56. 16". erat hora post merid.].

14. In the year 1642, on November 2, in the following night [Anno 1642. Nouemb. 2. nocte seq.], the meridian altitude of the Moon's center was seen to be 43 degrees, 14 minutes [gr. 43. 14']; from which transit the minutes numbered were 5 minutes, 37 seconds [min. 5. 37']; Aldebara [Aldebarae] was reached at its meridian altitude of 24 degrees, 9 minutes [grad. 24. 9'].

15. In the year 1642, on November 10, in the morning, under the civic hour 11 1/4 [Anno 1642. Nouemb. 10. manè sub horam ciuilem 11 1/4], when the Moon was at the beginning of Cancer, and around the southern limit, the altitude of the western lucid [star] [altitudine occidua lucida] was taken at 38 degrees, 37 minutes [grad. 38. 37']; thence, after the transit of Procyon by the meridian-circle [M. C.], they were 4 degrees, 16 minutes [gr. 4. 16']; and then the meridian altitude of Procyon was 51 degrees, 36 minutes [grad. 51. 36'].

16. In the year 1642, on December 5, in the following night [Anno 1642. Decembr. 5. nocte seq.], the meridian altitude of the Moon's center near full Moon [prope Plenilunium] was seen to be 62 degrees, 41 minutes [gr. 62. 41']; thence, to the transit of Rigel by the meridian-circle [M. C.], the meridian altitude was seen to be 23 degrees, 45 minutes [gr. 23. 45'].

17. In the year 1642, on December 7, the Moon's transit by the meridian-circle [M. C.], the minutes numbered were 27 minutes, 41 seconds [min. 27. 41']; the center of the Moon transited by the meridian-circle, and was seen distant; its altitude, the meridian by two observations, was 61 degrees, 12 minutes [gr. 61. 12']; thence the numbered minutes were 27 minutes, 52 seconds [min. 27. 52"]. The Moon was near the 90th degree [prope Nonagesimum], it would seem, in the 60th degree, 36 minutes [alta grad. 60. 36']; and at its setting, around the beginning of Cancer, and not far from apogee [prope initium Cancri, nec longè ab Apogeo].

18. In the year 1643, on January 31, in the following night [Anno 1643. Ian. 31. nocte seq.], from the transit of the Moon by the meridian-circle [M. C.], the meridian altitude of itself was 63 degrees, 8 minutes [grad. 63. 8']; the numbered minutes were 6 minutes, 17 seconds [min. 6. 17"]; and the meridian altitude of Procyon was [taken] in degrees, 10 minutes, 17 seconds [gradum 10. 17"], when the Moon was in the 12th degree, almost, of Cancer [esset Luna in gradu ferè 9. Cancri], and in that very 90th degree [in ipso ferè Nonagesimo]; the parallax can hence be drawn [poterit hinc elici parallaxis].

19. In the year 1643, on February 3, in the evening, two minutes before the transit of the heart of Hydra by the meridian-circle [M. C.] [Anno 1643. Febr. 3. vespere minutis duobus ante transitum cordis Hydræ per M. C.], that is, at the very [moment of the] hour 12, the meridian altitude of the Moon's center [altitudo meridiana centri Lunæ] was seen to be 57 degrees, 10 minutes [gr. 57. 10']; since it was in apogee [cum esset in Apogeo], and at the hours [the Moon was] near full Moon by about two days [circiter duabus post Plenilunium].

20. In the year 1643, on February 12, in the morning, a little after quadrature [Anno 1643. Febr. 12. manè paulo post Quadraturam], the meridian altitude of the Moon's center was seen to be 29 degrees, 14 minutes [gr. 29. 14']; thence the numbered minutes were 5 minutes, 3 seconds [min. 5. 3']; the rising altitude of the heart of Scorpio [altitudo ortiua cordis Scorpj] was seen to be 19 degrees, 50 minutes [gr. 19. 50']; the Moon would appear now hollow [apparebat autem Luna iam caua], the hour being almost 1 [hora ferme 1].

21. In the year 1643, on March 5, the meridian distance of the Moon's center from the vertex [Anno 1643. Martij 5. distantia meridiana centri Lunæ à vertice] was 47 degrees, 57 minutes 1/2 [gr. 47. 57' 1/2], at the hour past midday 12 degrees, 21 minutes 1/4, seconds 34 [hora post meridiem 12. 21' 1/4. 34"]; and it constitutes [the place] toward Regulus [vt ex Regulo constitat].

22. In the year 1643, on March 13, the Moon's center was seen in the meridian to be 26 degrees, 40 minutes [Anno 1643. Martij 13. manè visa Lunaris centri in Meridiano fuit gr. 26. 40']; at the same moment, the lucid [star] of Aquila rose [lucida Aquilæ ortum versus alta], the altitude being 42 degrees, 41 minutes [erat gr. 42. 41'].

23. In the year 1643, on March 23, in the evening [Anno 1643. Martij 23. vespere], the altitude of the Moon's center by the meridian-circle was seen to be 63 degrees, 15 minutes [gr. 63. 15']; thence, after the transit of Procyon by the meridian-circle, the Moon flowed by 80 minutes [fluxere 80']; at which end the meridian altitude of Cancer [Cancuræ] was 51 degrees, 37 minutes [gr. 51. 37']. But on the following day, the meridian altitude of the Moon was seen to be 62 degrees, 40 minutes [gr. 62. 40']; thence the numbered minutes were 11 minutes [min. 11']; the altitude of Procyon was toward its rising 51 degrees, 24 minutes [gr. 51. 24']. On the same night, at my request, P. Theodorus Moretus of Breslau [P. Theodorus Moretus Bresnici] — where the altitude of the pole is 49 degrees, 24 minutes [Poli gr. 49. 24'] — observed the meridian altitude of the Moon to be 57 degrees, 17 minutes, 25 seconds [Meridianam Lunæ altitudinem gr. 57. 17. 25"]. At length, on day 28, the meridian altitude of the Moon's center was seen by us to be 58 degrees, 59

minutes, 15 seconds [gr. 58. 59'. 15"]; at the same moment the altitude of the eastern lucid Regulus [orientalis Reguli] was 35 degrees, 18 minutes [gr. 35. 18']; and then it transited by the meridian-circle, the southern arm of Cancer [brachium australe Cancrici] being high, the altitude being 52 degrees, 45 minutes [gr. 52. 45'].

24. In the year 1643, on April 3, in the following night [Anno 1643. Aprilis 3. nocte seq.], the meridian altitude of the Moon's center was seen to be 41 degrees, 30 minutes 1/2 [gr. 41. 30' 1/2]; thence the numbered minutes were 9 minutes, 41 seconds [min. 9. 41"]; the rising altitude of the ear of Spica [orientalis Spicæ] was 14 degrees, 35 minutes 1/2 [gr. 14. 35' 1/2]; thence we computed the meridian-circle hour to be 11 degrees, 52 minutes, 44 seconds [11. 52'. 44"]; and therefore the Moon's transit was at the hour 11, minutes 42 [hora 11. 42'].

- against obs. 20–24: □ and § (section-mark) symbols against several

[The numerous small □ (square) and §-mark side-glyphs are Riccioli's running tally-symbols flagging which observations bear on occultations (*Occultant.*), refraction (*Refract.*), parallax (*Parallax.*), perigee (*Perig.*) and apogee (*Apog.*). They are transcribed by type above; precise per-row alignment of the bare square-glyphs is approximate at this resolution.]

The Bologna lunar observations of Riccioli and Grimaldi continue (Caput VII), numbered as in the original.

25. In the year 1643, on July 7, in the morning, with the Moon near perigee, its center was seen on the meridian at an altitude of 32°38'. From there to the observed altitude of the Sun, 8°4', 60 minutes 10 seconds [of time] elapsed; and from this the Moon's center at setting appeared to be at an altitude of 31°29'.

[Margin: *Perig.*]

26. In the year 1643, on July 7, the observed altitude of the Moon's center on the meridian was 41°, precisely; and from it I counted 4°8'. The Moon's altitude was

16°52', that is, at the time of the meridian transit at 6h55'. The apparent moment of quadrature had not yet arrived, since I made certain that the Moon's transit had occurred at 18h0'52" past the meridian of the eighth day.

27. In the year 1643, on July 21, in the night following, the Moon's center was seen to be distant from Arcturus 34°33'. Then after 4 minutes [of time] it was distant from Spica 15°13', and after 2 minutes from the haunches [clunibus] of Leo 30°45', and after 6 minutes Arcturus' altitude at setting was 51°18'; and after 2 minutes the Moon's center was seen to be distant from the tail of Leo 75°25'; and at the vertex 73°25'.

28. In the year 1643, on August 3, in the morning before the Trigon of the Moon with the Sun, the rising altitude of the bright [star] in Aries was 60°48'; and after 5 minutes [the Moon] stood distant 41°35'. From the center of the Moon there appeared, higher and toward setting, the bright [star] 40°54', and afterward, in another 3 minutes, the Moon's center was seen distant from the bright [star] of the jaw of the Whale [lucida Mandibulæ Ceti] 48°15'.

[Margin: Trigon symbol]

29. In the year 1643, on August 7, in the morning, while the Sun was visible, [the Moon stood at] 12°52'. The Moon's center was on the meridian, [I observed] it; the altitude was 58°56'.

30. In the year 1643, on August 11, in the morning, the rising altitude of Aldebaran was 47°5'. From there I count 17 minutes. The Moon's center was seen distant from Aldebaran 36°31'. From there, after 5 minutes, the Moon's altitude at the vertex was 17°2', and distant from the bright shoulder of Orion 28°26'.

31. In the year 1643, on August 11, the Moon, a little past its 18th degree, was distant from the following conjunction with the Sun; yet it appeared at an altitude of 2°10', and distant toward the east, at the margin, from Rigel [Regel] 57°35'. From there, after 1 minute, it was seen at an altitude of 4°30'; and then distant, toward the eastern limb, from the foot of Orion 43°27'.

[Margin: Phasis ultima] [phase: last (waning)]

32. In the year 1643, on August 22, in the evening, while the Sun's center was still appearing, the Moon transited the meridian [M.C.] at an altitude of 10°40'. The Moon stood at a meridian distance from the vertex of 60°56'; it was 5h44' past meridian.

33. In the year 1643, on August 25, the Moon's center on the meridian was seen distant from the vertex $63^{\circ}14\frac{3}{4}'$, and after 5 minutes the rising distance of [Altair, the] Eagle [Aquilæ] from the vertex was $37^{\circ}14\frac{1}{4}'$.

[Margin: Octant.]

34. In the year 1643, on August 27, in the night following, when the bright [star] of the Eagle [Altair] was distant from the vertex $40^{\circ}9\frac{1}{3}'$, the meridian distance of the Moon from the vertex was seen to be $58^{\circ}56'$.

[Margin: 8 symbol]

35. In the year 1643, on August 30, in the evening, the bright [star] of the Eagle [Altair] at setting was distant from the vertex $36^{\circ}48'$, and after 2 minutes the Moon was seen distant from the vertex $20^{\circ}15'$; and from there it was distant from the foot of Andromeda $49^{\circ}11'$. Then, after 4 minutes, [the Moon] was seen distant from the vertex $20^{\circ}34'$, and distant from the head of Andromeda 29.

36. In the year 1643, on September 5, in the morning, half an hour before the Sun's physical rising, the Moon appeared somewhat smaller than dichotomized; but when, half-dichotomized, it shone to us, that was at 16h31'. After the meridian of the preceding day, scarcely an hour before, all the tables of quadrature were upset — whence Aristarchus' problem of finding the Sun's distance from the Earth is much weakened, as Tycho [held].

[Margin: Dichot.]

37. In the year 1644, on October 3, the Moon was seen distant from the vertex by 2 quadrantal measures $16^{\circ}50'$, and then, from the altitude of the rising bright shoulder of Orion, we concluded the apparent time to be 17h48 $\frac{2}{3}'$ past meridian.

38. In the year 1643, on October 20, in the evening, an hour before the Sun set, the Moon, inspected through the telescope, manifestly appeared a very little larger than dichotomized; but afterward, when the bright [star] of the Eagle [Altair] was distant at setting from the vertex $36^{\circ}53'$, at the same moment the Moon's center was seen distant from the vertex $61^{\circ}19\frac{2}{3}'$.

[Margin: Dichot.]

39. In the year 1643, on October 31, the meridian distance of the Moon's center from the vertex was $27^{\circ}5'$. From there I counted $27^{\circ}35'$. Procyon was at meridian transit [M.C.].

40. In the year 1643, on November 3, the meridian distance of the Moon's center from the vertex was seen, by a double quadrant, to be $30^{\circ}30'$; and then Sirius at setting was seen distant from the vertex $67^{\circ}42'$.

[col. 2]

41. In the year 1644, on May 22, in the night following, the Moon's center was seen distant from the vertex $43^{\circ}20\frac{1}{3}'$, and then distant from Spica toward the vertex $56^{\circ}26'$; toward setting.

[Margin: Apog.] [Margin: 8 symbol]

42. In the year 1644, on April 13, the Moon's center on the meridian, by a double quadrant, was seen distant from the vertex $62^{\circ}43\frac{1}{3}'$; and from there I count $5^{\circ}2'$. The Sun's altitude was seen toward setting $6^{\circ}36'$; therefore the hour was 6h36' past meridian.

[Margin: □]

43. In the year 1644, on July 11, in the evening, the Moon's center on the meridian was seen distant from the vertex $49^{\circ}42'$, one quarter [of an hour]; in another quarter, then $42^{\circ}48'$; and then the Sun's altitude was seen $11^{\circ}26'$.

44. In the year 1644, on June 28, in the morning, with the Moon at the very perigee, [and] at the apparent rising of the Sun, the Moon was distant, toward rising, from the vertex $52^{\circ}38'$. Then at the rising of the Sun the altitude was seen $23^{\circ}14'$. The Moon transited M.C., and then was distant from the vertex $23^{\circ}14'$.

[Margin: Octant. 3.] [Margin: Perig.]

45. In the year 1644, on November 13, in the night following, at the moment when the Moon's center on the meridian reached the vertex, it was seen distant from the vertex $32^{\circ}11'$; and afterward, at quadrature, $33^{\circ}12'$.

[Margin: Perig.]

46. In the year 1644, on November 21, in the morning, the Moon was distant from the vertex, toward rising, $31'$. The half-dichotomized Moon was seen to shine, or by the witness of the telescope to be a little less than dichotomized. But when Regulus was distant from the vertex $31^{\circ}11'$, the Moon's center was on the meridian, in minutes 4 before, with the distance seen from the vertex $33^{\circ}50'$. The Moon transited M.C. at 11h53'45".

[Margin: Dichotom.]

47. In the year 1644, on November 26, in the morning, Arcturus' rising distance from the vertex was $45^{\circ}32'$; and after two minutes the Moon's center on the meridian was distant from the vertex $31^{\circ}42'$, precisely; and from there Arcturus distant $29^{\circ}24\frac{1}{3}'$. From there, after 1 minute, the Moon's center was seen at an altitude of $22^{\circ}36'$, and distant from Spica $13^{\circ}11\frac{1}{3}'$.

[Margin: Octant.] [Margin: Apog.]

48. In the year 1645, on May 11, in the morning, the Moon stood at the vertex $41^{\circ}32'$. The Moon's center transited the meridian; it appeared distant from the vertex $38^{\circ}11'$.

49. In the year 1645, on May 20, in the morning, the Moon, a very little larger than dichotomized, appeared; but its meridian distance from the vertex was seen to be $64^{\circ}9\frac{1}{3}'$. From there to the rising of the upper limb the counted minutes were $12^{\circ}16'$; and from this point Solis [the Sun] the altitude was $3^{\circ}18'$; the measured time was 4h15'.

[Margin: Dichot.]

50. In the year 1645, on April 2, in the evening, at the moment when the Sun's center was seen at an altitude of $9^{\circ}28'$, the Moon's center was on the meridian, and was seen distant from the vertex $25^{\circ}35\frac{1}{3}'$; most exactly.

51. In the year 1645, on April 10, in the night following, the Moon's center on the meridian was seen distant from the vertex $45^{\circ}9'$; and then Arcturus rising stood distant from the vertex $24^{\circ}47'$.

[Margin: 8 symbol]

52. In the year 1645, on April 19, in the morning, before the rising [of the Sun], the Moon was seen scarcely dichotomized; [it] transited the meridian afterward, and [was] distant from the vertex $63^{\circ}23'$; at the apparent altitude of the Sun $12^{\circ}10'$.

[Margin: □]

53. In the year 1645, on May 10, in the night following, when Spica at setting stood at an altitude of $27^{\circ}50'$, the Moon's center on the meridian was seen distant from the vertex $58^{\circ}53'$.

[Margin: Apog.] [Margin: 8 symbol]

54. In the year 1645, on October 4, in the night following, the Moon's center [transiting] M.C. was seen distant from the vertex $46^{\circ}44\frac{1}{3}'$; and from there, in

time, Aldebaran stood distant from the vertex $56^{\circ}15'$. But the day before, in the night following, the meridian distance of the Moon's center from the vertex was $41^{\circ}34'$; and then Aldebaran stood distant from the vertex $46^{\circ}48'$.

[Margin: 8 symbol]

55. In the year 1645, on October 8, in the night following, the Moon's center [transiting] M.C. was seen distant from the vertex $63^{\circ}41\frac{1}{3}'$; and after 1 minute $46''$ [the Moon was] distant from the bright [star] of the Eagle [Altair] at setting $37^{\circ}55'$.

56. In the year 1646, on November 1, in the night following, the Moon [transiting] M.C. was seen distant from the vertex $34^{\circ}8'$; and after 5 minutes $46''$ Aldebaran rising stood distant from the vertex $33^{\circ}46'$.

[Margin: 8 symbol]

57. In the year 1646, on March 1, in the night following, the meridian distance of the Moon's center from the vertex was $36^{\circ}13\frac{2}{3}'$. From there I count $25\frac{2}{3}'$. The bright [star] of the tail of Leo transited M.C. But on day 13, hour 5, 10', $26''$, p.m., its meridian distance from the vertex was $25^{\circ}5'$, near perigee, in time [tempus]. [In the margin the figure reads: gr. 156. 30'. prope Perig. in time.]

[Margin: Perig.]

58. In the year 1646, on March 30, in the night following, from the transit of the tail of Leo [transiting] M.C. the counted [minutes] were $18^{\circ}26'$, also; and from the transit of the Moon's center across the meridian, in which it was seen distant from the vertex $43^{\circ}44'$.

59. In the year 1646, on May 8, in the morning, the Moon's center [transiting] M.C. was seen distant from the vertex $61^{\circ}20'$. From there I counted $6^{\circ}10'$. The Moon's center was seen distant from the vertex $74^{\circ}33\frac{1}{3}'$.

[Margin: □]

60. In the year 1646, on May 28, in the night following, the Moon's center on the meridian was seen distant from the vertex $61^{\circ}32'$. From there I count $4^{\circ}54'$. Antares transited M.C.

[Margin: 8 symbol]

61. In the year 1646, on June 19, the Moon's center was seen distant from the vertex $28^{\circ}19\frac{1}{3}'$. From there, after 5 minutes $41''$, the Sun's center at setting on the horizon was seen distant $72^{\circ}32'$.

[Margin: □]

62. In the year 1646, on June 27, the meridian distance of the Moon's center from the vertex was $66^{\circ}24'$; and from there, after 7 minutes 12", the bright [star] of the Eagle [Altair] rising stood distant from the vertex $35^{\circ}20\frac{1}{3}'$.

[Margin: Apog.]

63. In the year 1646, on July 3, in the morning, with the Sun risen, the Moon manifestly appeared to us less than dichotomized — but in truth the moment of dichotomy is to be reckoned from the ratio of parallax.

[Margin: Dichot.]

64. In the year 1646, on July 9, in the morning, the Moon's center was seen distant from the vertex $32^{\circ}10'58''$, and distant from the bright [star] of the side of Perseus $35^{\circ}37'$; and at the same moment Capella stood distant from the vertex 61° , precisely; when afterward the Moon stood distant from the vertex $60^{\circ}36'$, precisely. The Moon's center was seen at an altitude of $21^{\circ}2\frac{1}{3}'$, and distant from Capella $34^{\circ}45'$.

[Margin: Octant.]

65. In the year 1646, on July 27, in the night, on which night there was an eclipse of the Moon, its center on the meridian was seen distant from the vertex $64^{\circ}18'$. From there, after 6 minutes 7", the bright [star] of the Eagle [Altair] at setting was distant from the vertex $39^{\circ}46'$.

[Margin: 8 symbol]

66. In the year 1646, on August 4, the meridian distance of the Moon's center from the vertex was seen $35^{\circ}39\frac{1}{3}'$; and from there, after 10 minutes 30", the Sun's altitude was $9^{\circ}30\frac{2}{3}'$. The cause of this is to be doubted on account of parallax — yet in truth it was not so.

[Margin: Dichot.]

67. In the year 1646, on September 16, the Moon's center [transiting] M.C. was seen distant from the vertex $64^{\circ}24\frac{2}{3}'$. From there, after 6 minutes, the Sun's center at setting was seen distant from the vertex $86^{\circ}46\frac{1}{3}'$.

[Margin: □]

68. In the year 1646, on October 16, in the evening, the Moon's center on the meridian was seen distant from the vertex $66^{\circ}26'$. From there, after 11 minutes

16", the bright [star] of the Eagle [Altair] at setting stood distant $35^{\circ}44'$. But at a high altitude it appeared distant $3^{\circ}40'$; and although it was seen with the naked eye as dichotomized, and was scarcely seen as semi-dichotomized; yet for that hour it appeared more manifestly than dichotomized; for it had been in apogee the preceding day. The hour of the Moon's transit was $8h34'0''$, past meridian.

[Margin: Dichot.] [Margin: Apog.]

69. In the year 1646, on November 15, the Moon's center [transiting] M.C. was seen distant from the vertex $60^{\circ}56'$. From there, after 4 minutes $51''$, the bright [star] of Aries stood distant from the vertex $51^{\circ}56'$; and the Moon did not yet appear dichotomized.

70. In the year 1646, on November 21, the Moon's center was seen distant from the vertex $28^{\circ}36'$; from there, after 6 minutes, the bright shoulder of Orion rising stood distant from the vertex $42^{\circ}10\frac{1}{3}'$.

[Margin: 8 symbol]

71. In the year 1647, on March 28, in the morning, the meridian distance of the Moon's center from the vertex was $67^{\circ}47'$; and from there, after 9 minutes $10''$, the Sun's center was seen distant from the vertex $9^{\circ}10'$. But, in truth, on the quadrant it was somewhat larger before the rising of the Sun: the Moon appeared less than dichotomized, and that more manifestly with the Sun rising.

[Margin: Dichot.]

72. In the year 1647, on March 18, the Moon's center on the meridian was seen distant from the vertex $62^{\circ}33\frac{2}{3}'$. But the meridian distance was corrected for declination at rising, by the noted [observation] $62^{\circ}34'$; from there, after 4 minutes $48''$, Lyra rising stood high $26^{\circ}42'$.

[Margin: Meridiana corrected (corrected meridian)]

73. In the year 1647, on May 26, in the morning, the Moon's center [transiting] M.C. was seen distant from the vertex $9^{\circ}60'12''$; and after 6 minutes $30''$, the Moon's center stood distant from the vertex $16^{\circ}21'$.

[Margin: □]

74. In the year 1647, on June 1, in the evening, [the Moon] appeared distant from the vertex $54^{\circ}44'$; the Moon's center was then seen distant from the vertex $46^{\circ}16'$.

[Margin: Neomenia (new moon)]

75. In the year 1647, on June 16, the Moon's center on the meridian was seen distant from the vertex $66^{\circ}54'$; and from there, after $30''$, the bright [star] of the Eagle [Altair] rising stood distant from the vertex $44^{\circ}42'$.

[Margin: Merid. dist. (meridian distance)]

76. In the year 1647, on July 16, in the night following, the meridian distance of the Moon's center from the vertex was seen $67^{\circ}24\frac{1}{3}'$; and after 8 minutes $53''$, [the Moon] took up Andromeda toward the rising vertex $49^{\circ}44'$.

[Margin: 8 symbol]

77. In the year 1648, on March 25, in the evening, with the Sun set, the first phase of the Moon was seen, of about two minutes, in diameter — that is, scarcely $35'$ past the preceding new moon. And in full moon also, in the preceding of this month, see the observations adduced in lib. 2, cap. ult., num. 3.

[col. 2]

[Margin: Prima phasis (first phase)]

78. In the year 1648, on June 13, in the morning, from the altitudes of the Sun, reckoning the extreme of a doubtful time, the Moon's dichotomy was seen to be made at hour 5, $19'$, $52''$, before noon; and beforehand, in truth, at h. 5, $43'$, $52''$, the Moon had transited M.C., and then was seen distant from the vertex $52^{\circ}50'$.

[Margin: Dichot.]

79. In the year 1649, on September 8, in the evening, the first phase of the Moon appeared; [it] completed the conjunction with the Sun in two days, just as in the year 1650 on day 4, March, it was seen by us [in] the first phase of the Moon, two days past the conjunction with the Sun.

80. In the year 1650, on May 8, in the evening following, the Moon appeared to us falcate [crescent], even to the setting of Procyon at an altitude of $21^{\circ}40'$. After this, by the calculation [tunc] of the hour at $7\text{h}54'11''$ past meridian; then, indeed, the first dubious [moment] arose: it was falcate, an undifferentiated [moment] appeared; in the counted minutes $107'$, we began to doubt whether [it was] dichotomized, or rather a gibbous appearance; therefore in the second doubtful moment, in truth, the hour was at $9\text{h}41'$ past meridian. The middle time for dichotomy was $8\text{h}47'36''$.

81. In the year 1650, on October 24, in the morning, the last phase of the Moon was seen through the telescope, even to the rising of the Sun itself — namely, at hour 22h3', nearest to the conjunction with the Sun.

[Margin: Vltima phasis (last phase)]

82. In the year 1650, on December 29, the Moon's center [transiting] M.C. was seen distant from the vertex 44°36'; and after 4 minutes 10" Aldebaran at rising stood distant from the vertex 54°34'; the Moon was manifestly distant from dichotomy.

83. In the year 1651, on August 5, in the morning, the last phase of the Moon was seen through the telescope, that very [phase], hour [hoc est], past it the conjunction with the Sun began at 26 [hours], past meridian.

84. In the year 1652, on July 17, in the evening, the Moon's center was seen distant from the vertex 65°18' (because I deduced from this the time at hour 8.11'; and then, when the altitude was seen distant from the vertex, from Spica 65°32'; and from Spica 15°14'; the southern arm of the Whale [Vindemiatrix] was distant from the vertex 55°15'; and then the Moon's center was seen distant from the vertex 66°26'; and from the Vindemiatrix distant from the vertex 55°13'; and then the Moon's center was seen distant from the vertex 66°26'. And from there, exactly, distant from the tail of Leo 26°15½'.

85. In the year 1652, on July 14, in the evening, [the Moon was] distant from Spica 65°18' (which I deduced, the same time, hour 8.13'; and then [it stood] distant from the vertex 65°32'. And from Spica 15°14', the Vindemiatrix distant from the vertex 55°15'; and then the Moon's center was seen distant from the vertex 65°36'. From these P. Grimaldi, by computing the refraction and parallaxes through the triangular analysis, deduced the Moon's place in Scorpio at 0°30'25"; this the Danish Tables put at 3°11'; the Lansbergian at 4'; Argolus at 12'. But the southern latitude of the Moon, from P. Grimaldi's calculation, was 2°40'33".

86. In the year 1652, on July 24, in the morning, about one hour before the rising of the Sun, the Moon was observed distant from the vertex 54°25'; and from the bright [star] of Aries 51°9'; and from there, after a little, the same center was seen distant from the vertex 54°40'; and from the tail of the Whale [Ceti] 23°14'; the distance was seen from the vertex 64°44'; and after a little the Moon's center was seen distant from the vertex 55°5'; and from the jaws of the Whale [Ceti] 16°42½'; distant from the vertex 59°4'.

[Margin: 3. Octant.]

87. In the year 1652, on August 1, in the morning, the Moon's center was seen distant from the vertex $68^{\circ}50'$; and from Aldebaran $30^{\circ}16'$; distant from the vertex $55^{\circ}42'$; and the Moon's center was seen distant from the vertex $68^{\circ}15'$; and from the preceding shoulder of Orion $27^{\circ}26'$; distant from that vertex $70^{\circ}2'$.

[Margin: 4. Octant.]

88. In the year 1653, on May 3, in the evening, with Spica toward rising, [the Moon] stood distant from the vertex $58^{\circ}18'$. The Moon's center was seen distant from the vertex $51^{\circ}22'$, and from Arcturus $34^{\circ}47'$. Soon, in time, it was seen distant from the vertex $51^{\circ}19'$; and from Spica $11^{\circ}16'$.

[Margin: 2. Octant.]

89. In the year 1653, on December 23, the Moon's center, expected at the western azimuth, by a degree of $25'$ precisely, was in it distant from the vertex $67^{\circ}1'10''$. From there I count $8^{\circ}45'$; in time the bright [star] of the Eagle [Altair] at setting stood distant from the vertex $61^{\circ}41'40''$.

[Margin: 1. Octant.]

90. In the year 1654, on January 25, in the evening — then, first seen, the Moon was dichotomized, when Aldebaran was distant from the vertex $38^{\circ}38'$. But the Moon stood at $28^{\circ}27'$. Then, the time elapsed in min. $27'$, the Moon began to appear gibbous, distantly; apparently at the vertex $42'$.

[Margin: 1. Octant.] [Margin: $38^{\circ}38'$.]

[col. 1]

$42^{\circ}55'$; then [the Moon was] expected at the western azimuth $1^{\circ}65'$; it was seen distant from the vertex $44^{\circ}9'$; and from there, in counted time, after 5 minutes $20'$, the bright [star] of Aries stood distant from the vertex $44^{\circ}31'$.

91. In the year 1654, on March 21, in the night following, the Moon grazed Regulus when Sirius at setting was distant from the vertex $62^{\circ}48'$; it took up the limb of that very part of it, [where] there was, in a direct line, the maculate Pitati [Petavius], and Krisman[us] in the eastern margin. Regulus then emerged from the limb of the Moon, on the particle of the line by which, with the center of the Vigor [region] of the Earth, at the very moment of emergence, the counted [minutes] were $9^{\circ}40'$; for then Sirius stood distant from the vertex $70^{\circ}21'$.

[Margin: Regul. & tellus] [Regulus & the Earth]

92. In the year 1655, on May 9, in the evening, with Procyon at high altitude $25^{\circ}20'$, the Moon's center was seen at an altitude of $30^{\circ}43'$; and distant from the head of Pollux $11^{\circ}2'$. Then after 2 minutes, in time, the Moon's center was seen at an altitude of $29^{\circ}40'$; and distant from Procyon $21^{\circ}45'$.

[Margin: 1. Octant.]

93. In the year 1655, from day 6 July onward, even to 16, in continuous nights, we observed the Moon's place; but we set down here, for the sake of brevity, a single observation, taken in the middle from the Earth's distance on day 10, on whose evening was taken the distance of Spica from the vertex toward setting 66° , precisely; and from there in the counted minutes $10^{\circ}18''$, the Moon's center, expected at the azimuth toward setting 45° , was seen in it distant from the vertex $70^{\circ}49\frac{1}{3}'$.

[Margin: Media distantia (mean distance)]

94. In the year 1655, on August 9, in the evening, the Moon's center, expected at the western azimuth of 75 degrees, and in it seen distant from the vertex $38^{\circ}57'40''$; and in the counted minutes $5^{\circ}40'$, Arcturus transited the azimuth; and from there [the Moon] stood distant from the vertex $45^{\circ}36'$.

[Margin: 1. Octant.]

By this method of observing we have used in the following nights; but from these I select certain notable observations, for the third Moon octant.

95. Therefore, in the year 1655, on August 21, the Moon's center, expected at the western azimuth of 15 degrees, and in it seen distant from the vertex $36^{\circ}30\frac{1}{3}'$; and in the counted minutes $10^{\circ}4''$, the bright [star] of the tail of the Whale [Ceti] arrived at the same azimuth toward rising; and was seen distant from the vertex $61^{\circ}61\frac{1}{3}'$.

[Margin: 3. Octant.]

96. In the year 1655, on September 2, in the morning, three hours before the rising of the Sun, when the tail of the Swan [Cygni] stood distant from the vertex $86^{\circ}8'$, the Moon was seen distant from the vertex $86^{\circ}8'$; thus a very little before, dichotomy appeared to have been made, when the dichotomy was reckoned by one of our [number] in the day before this; from the tail of the Swan [Cygni], hour $3^{\circ}20'$.

[Margin: Dichot.]

97. In the year 1646, on August 16, in the morning, by a quadrant one [hour] before the rising of the Sun, when the tail of the Swan [Cygni] stood distant from the vertex $47^{\circ}9'$, the Moon was seen distant from the vertex $61^{\circ}20'$. From there, when [the Moon] was seen distant from the vertex $60^{\circ}45'$, it was also distant from the preceding shoulder of Orion $22^{\circ}19'$.

98. In the year 1657, on March 18, in the evening, and further after the setting of the Sun, the meridian distance of the Moon's center from the vertex was seen $55^{\circ}11\frac{1}{3}'$. From there, after $25'$, Aldebaran stood distant from the vertex $41^{\circ}2\frac{1}{3}'$; toward setting. But for the lunar azimuth Aldebaran was expected, at the same azimuth, in which the Moon had been; and in it Aldebaran stood distant from the vertex $53^{\circ}11\frac{1}{3}'$.

[Margin: Octant 3.]

99. In the year 1657, on November 12, in the night following, the Moon was seen, in a new altitude, distant from the vertex $56^{\circ}10'40''$. And from there, in the counted time, after 6 minutes $50''$, the bright [star] of Pegasus' mouth transited the meridian.

[Margin: □]

At Bologna, on day 13 May, in the night following, in the year 1661.

The conjunction of the Moon with Saturn was thus observed.

About 2 hours after the setting of the Sun, the Moon was seen scarcely more than one diameter of the Moon distant from Saturn in apparent [terms]; and the companion [Comes] of Saturn tended toward the Moon's center, so that if it had proceeded along that line, the eclipse of Saturn would have seemed to be future, or by the middle of that covering [tectura], or it would conjoin centrally with it in respect of the eye of the observer. But because the line of the companion is parallel to the Equator, and the Moon, with northern latitude, proceeded along a path nearly parallel to the Ecliptic; and these [two lines], the Planet [Moon] beyond the middle of Scorpio, were therefore made [non-parallel]; and the Moon would visit Saturn, and that very [planet], and the rest [were carried] toward the North. For there was indeed, in the Moon, some parallax, when the Moon had not yet reached the meridian, nor had it [reached] the nonagesimal; therefore, if no obstructing parallax [were present], the Moon would have visited Saturn more nearly, even — as it proceeded after the conjunction — it would be seen, along the line of refraction [retracta], by a parallax not negligible, [the Moon] to be carried, as if depressed below Saturn, unless the progress of the Moon had been

made along an oblique path, in the aforesaid line of the companion; and so it would be proved hence that such a line is the oblique [line] of the Ecliptic. But [if] now elsewhere, and at the very moment in which it was seen, [it was] certain to be parallel to the Equator.

[col. 2]

And the Moon, with northern latitude, proceeded along a path nearly parallel to the Ecliptic; and these [lines], the Planet beyond the middle of Scorpio, were therefore made [thus], and the Moon would visit Saturn, and that very [planet], and the rest [were carried] toward the North. The matter being so, when the Moon was seen [near] Saturn, the altitude of Spica Virginis [Spica] was taken by quadrant; and it was distant from the vertex $60^{\circ}25'$. And toward the western [side] Saturn was distant, toward the south, by however much latitude Caspi [the spot] inter the maculae [spots] of the Moon [was], yet the maximum approach to Saturn was near the lake of ice [Stagnum glaciei], toward Euctemon.

Hence it will easily be established from the Ephemerides of Argoli, this conjunction [agreeing] more nearly than the rest, when constructed for the meridian of Rome, [and] this observation will more verify the correction of that, and may favor Argolus.

CAPVT VIII.

On the Distances of the Moon outside Conjunctions [De Lunæ Distantiis extra copulas]

1. Just as in lib. 3, cap. ult., we determined the distance of the Moon from the center of the Earth at new moons, both from the Horizontal Parallaxes and from the Equations of the first inequality of motion: so now, for the remaining inequalities, which we have in conjunction with the Sun, we ought to determine the distance of the Moon from the center of the Earth at the quadratures with respect to the Sun. For these purposes we select from our observations two, in which the inequalities are greater.

2. The first was in the year 1646, on November 23. The hour was reckoned 3h50'. The Moon's center transited the meridian of the Lunar Disc, and in it [eumque], the distance from the vertex taken by us was $44^{\circ}56'30''$. Now the Moon's conditions were as follows:

	Sign / Gr.	'	"
The place of	□ 26	22	10

	Sign / Gr.	'	"
the Moon in the Ecliptic [Locus Lunæ in Ecliptica]			
Its equated anomaly [Eius Anomalia Æquata]	□ [5] 27	20	0
Southern latitude [Latitudo Australis]	3	26	38
Therefore northern declination [Ergo Declinatio Boreal.]	20	1	10
Distance of the Equator from the vertex [Distantia Æquatoris à vertice]	44	30	10
Therefore the true [Moon] distance from the vertex [Ergo ⊂ vera dist. à vertice]	24	55	30
Therefore the parallax [Ergo Parallaxis]	27	50 [?]	

Hence there results, by the triangular analysis, the distance of the Moon from the center of the Earth of terrestrial semidiameters $52^{\circ}46'$. Now the Moon was near

the quadrature that was to occur 13 hours later, and near perigee, as is established from the Anomaly.

3. The second was in the same year 1646, on October 16. For when the rising altitude of the Eagle [Altair] became apparent, at hour 8h8'20" past meridian, the Moon's center transited our meridian, and was distant from the vertex 66°26'. Now the Moon was situated as below.

Liber III — De Luna (continued)

Caput VIII — De Lunæ Distantiis extra copulas (continued)

The conditions of the second worked example (1646 October 16) are tabulated as follows:

	Sign.	Gr.	'	"
Moon's place in the ecliptic [<i>Locus ☾ in Ecliptica</i>]	☐	24	3	20
Equated anomaly [<i>Anomalia Aequata</i>]	9	3	24	20
Northern latitude [<i>Latitudo Borealis</i>]			14	2
Therefore the southern declination [<i>Ergo declinatio Austr.</i>]		21	10	0
Distance from the vertex		44	30	10

	Sign.	Gr.	'	"
[<i>Distantia Aequatoris à vertice</i>]				
Therefore the true distance from the vertex		65	40	10
[<i>Ergo C vera dist. à vertice</i>]				
But it was observed		66	26	0
[<i>At visa fuit</i>]				
Therefore the parallax			27	30
[<i>Ergo Parallaxis</i>]				

Parsing notes: the first data row carries values in all four columns (Sign./Gr./"/"); subsequent rows omit the sign-column where not applicable. The "Latitudo Borealis" row shows 14' 2"; the parallax row shows 27' 30". The "Anomalia Aequata" row carries sign-number 9 (i.e. nine signs) followed by 3 24 20. The printed parallax 27'30" does not equal the difference of the two preceding rows (visa 66°26' – vera 65°40' = 0°46'); the digits 27 30 are crisp, so this is a suspected source error, transcribed as printed (see batch report).

From this the Moon's distance from Earth's center came out to be 68 terrestrial semidiameters 50'. But the Moon had moved past the point of quadrature by about 2 hours, and past apogee by 1 degree; so we may infer that at the quadrature itself, and at apogee, its distance from Earth's center was a full 69 terrestrial semidiameters.

§4. Now since we have said in Book III, Chapter 12 [lib. 3. cap. ult.] that the Moon's mean distance from Earth's center is 61 terrestrial semidiameters, its difference at the quadratures from the distance at apogee — by the methods just

shown — is 8 terrestrial semidiameters. And if from these one removes the terrestrial semidiameters by which the Moon's distance at perigee falls short of the distance from Earth's center at the quadratures, namely 53 terrestrial semidiameters, then to this nearest value we add our first repetition, 52' 46". And since it is to 61, as 100000 is to 8.8, this gives 4 [?] 13414 [as printed — REVIEW: further reads the tile proportion as "8. ad 13114", suggesting this "13414" is a likely digit-slip for 13114; §4 chain was out of scope, flagged for reconciliation, not applied]; therefore the aforesaid difference is 13115. Hence let the semidiameter of the Moon's orbit be 100000. But since, from what was said in Book III, Chapter 12, the eccentricity of the first inequality has been bisected into the parts 4343, this triple of the eccentricity in the quadratures comes to parts 13029, somewhat less than 13114. Now since 100000 is to 13029, as the semidiameter [Terræ] is to 7 53/61 [as printed], or 7' 17" — therefore, if it please, this ideal triple-the-distance of the Moon's orbit's center from Earth's center is corrected, and the Moon's distances in quadrature will be: so that the apogee will be 68 terrestrial semidiameters 57', and the perigee 13 [?] 3'. It follows then that the maximum equation of the Moon, compounded of the first and second inequalities, is 7° 29' 10" — closest of all to that which Tycho found, namely 7° 7' 28", as Tycho [Brahe] and Longomontanus, or 7° 7' 30", as Kepler and Boulliau [Bullialdus], which is our mean among these.

CAPVT IX

Proponitur Theoria Lunaribus motus in Longitudinem pro inæqualitate composita ex prima, & secunda (*The theory of the Moon's motion in longitude is set out, for the inequality compounded of the first and second.*)

§1. We here suppose, from the observations of many ages noted by astronomers, that the Moon's motion in longitude is of several kinds — namely the *periodic*, the *synodic*, the inequality-bearing [*variationis*], and the *librations*.

The *periodic* motion of the Moon in longitude is that by which the Moon completes its course around the Earth through the whole zodiac in 27 days 7 hours 43' or thereabouts. This motion is unequal and irregular, but it returns to regularity in 27 days 7 hours 13' 12" [as printed]. This inequality, moreover, is referred to the line drawn through the Earth's center and the Moon's apogee — the line on which, when the Moon's body is found, no equation is required, and the Moon's mean motion coincides with the true and with the apparent as seen from Earth. This periodic revolution is called *absolute*, since no second [synodic] motion of the Sun [?] enters into it.

§2. [margin: *Synodicus Lunæ motus*] The *synodic* motion of the Moon is that by which the Moon so traverses the zodiac as always to overtake the Sun by as much as the Sun has meanwhile measured out; and therefore it accomplishes the synodic revolution in 29 days 12 hours 44' etc., and is restored from one conjunction of the Moon and Sun to the next. Hence this revolution is not absolute, as the periodic is, but depends on the configuration of the Moon with the Sun and with the Earth; and it is restored from new moon to new moon, and is referred to the line which passes through the Earth's center and the Sun's — the line on which, when the Moon is found, the synodic inequalities are said to be nil. The motions of these two kinds are so intermixed in their inequalities that, when the synodic falls together with the apogee absolute one, the synodic inequality comes out maximal over the whole lunation; but when the synodic falls into the mean longitudes, scarcely any second inequality occurs over the whole lunation.

§4. [margin: numbered 4] Hence it comes about that, when the synodic falls at the 270th degree of revolution of the anomalistic, there is no second inequality through the whole synodic revolution. But as the synodic line advances toward the apogee of the periodic revolution, the synodic inequality grows little by little; when, however, the synodic coincides with the apogee, the first inequality ceases. The first inequality is greatest, therefore, when the synodic falls at the 90th degree from apogee, where the second is again nil; while the synodic inequalities decrease until the synodic line, running on, reaches the mean longitudes — until, that is, from the 270th degree of anomaly down to the 90th, in the first semicircle of synodic revolutions (from new moon to full moon), the second equations are subtractive [*ablatæ*], and in the second semicircle additive [*adiectivæ*].

§5. [margin: numbered 5] But when the mean longitudes have been passed, the synodic line tends toward the perigee of the eccentric; and from there the anomalies, increasing in the second [semicircle] of the inequalities again, occur until the perigee and the maximum inequality [*maxima fiant*], and decrease again until they vanish at the mean longitudes. So, while the synodic proceeds from the 90th degree, the anomalies of synodic inequality reach the 270th. The synodic equations in the prior semicircle of synodic revolutions, namely from σ and σ° , are additive [*Adiectinæ*]; and in the latter, namely from σ and σ° [as printed], subtractive [*Subtractivæ*]. Hence the second inequality begins from the 90th degree, and from the apogee of the periodic revolutions; and the first semicircle from the 90th down to the 90th [as printed]. The anomalies, therefore, since the two inequalities are of diverse nature, must necessarily concur to some degree, while one is additive, the other subtractive, and vice versa. This befalls when the

synodic line nears the 270th degree of anomaly, or the apogee of the periodic revolutions, or the perigee at the 90th degree of anomaly, or the perigee.

§6 [?]. Finally, when through lunations and synodic revolutions the second inequality grows or shrinks — but at every true new moon or full moon, when there is no second inequality, the maximum inequality appears at the quadratures.

§ [margin]. *Of the variation and the libration* I shall speak below. Meanwhile, to represent the two foregoing inequalities, astronomers have devised diverse hypotheses, by circles eccentric, epicyclic, or elliptic — which I have set out at length in Book 4 of the *Almagestum Novum*, Chapter 26 [cap. 26.] to 29, where I have also indicated my own preference and my judgment of the rest.

Now, however, considering that the Moon's proper motion cannot be reconciled — by which it appears to be carried from west to east, contrary to the diurnal motion, which they call from-the-east into-the-west, and at the same time with the fluidity of the planets and the rest of the heaven [*quiete Telluris*, the rest/quiet of the Earth], which I have demonstrated in Book 9 of the *Almagestum Novum*, Section 4 — unless by some single spiral motion in the east into the west, I do not venture to propose any theory of the Moon's motion measured out by geometry, as though it exactly answered to all the phenomena. Yet among all of them I prefer the one which uses a manifold eccentric, circle, and ellipse; because it is not perilous, as is the use of epicycles, which represent the lunar spots [*Maculae Lunares*] to us in their proper [?] alien situation [*alieno situ*]; while it represents the things themselves to us. And indeed the ellipse — *Comes Paganus* [Ismaël Boulliau, "Paganus" — i.e., Boulliau] chose it in his *Theoria Planetarum* published at Paris in the year 1657. The eccentric circle, however, we have chosen, along with [*Io. Antonio Magino*] Giovanni Antonio Magini [Magini], in Book 4 of the *Almagestum Novum*, Chapters 26 and 28. But this theory we do not now disdain to reform, if anyone for a true reason demand it.

§7. [margin: numbered 7] In the adjoined scheme, therefore, from the Earth's center A, I describe the ecliptic GXT — though this figure represents it much too small relative to the lunar orbit; and on this line of the apsides GT, given the assumed [?] portion AB, of parts 4343, such as is the radius, or semidiameter of the prior eccentric [*Excentrici*]...

DH, namely 100000; and, with center made at D, I describe the circle HIFY, and by doubling the eccentricity AD — that is, taking AB as assumed, of parts 8686 — having made the center at B, and with semidiameter BC of parts 4343, I describe

the small circle CDV, in whose periphery the center of the lunar eccentric is carried; from the apogee C of this small circle I describe another eccentric equal to the prior one, which shall be GIEY.

Diagram. A geometric construction of the lunar theory by manifold eccentric circles. A large outer circle is centered near the middle of the figure; within it are nested smaller circles and a central cluster of lettered points. The figure illustrates the eccentric-on-eccentric construction described in §8: the Earth's center, the center of the prior eccentric, the small carrying-circle, and the apsidal line.

Readable labels:

- G (top): upper apsidal point / apogee region
- R (upper-left arc), X (upper-right, near apex), k (upper-right): points on the upper circle [R, X, k — all firm]
- H (upper left): point on the eccentric
- C (center-upper): center of the small carrying-circle / apogee of small circle
- I (left mid): point on the line of mean longitudes
- B (center): center of the doubled-eccentricity circle
- V (center, near B): point on the small circle CDV
- M (lower-left): point on the outer circle
- Y (right mid): point on the eccentric / outer circle
- Z (lower-right): point on the eccentric / outer circle
- D (center-lower): center of the prior eccentric
- A (center-lower, below D): Earth's center
- E (lower-center): apsidal point
- Θ (theta, lower-center): apsidal point
- T, F (bottom): lower apsidal region / perigee

Note: figure labels resolved at native resolution; no longer a

§8. [margin: numbered 8] Now the center of the equal motions, for the first inequality, is at B, where the angle of anomaly is considered; but for the second inequality it is at the center of the eccentric carried [*delato*] in the small circle CD, and the whole eccentricity for the equations of the first inequality is AB, of parts 8686. As for the rest, the inequality varies, but the greatest is at AC, of parts 13029, such as is the radius of the eccentric of either, namely 100000. Now the absolute anomaly of the apogee, and of the eccentricity, is reckoned from the center of the eccentric carried in the periphery of the small circle CD, in consequence from D

toward V, and to the same degree of motion by which the Moon's duplicate elongation from the Sun is carried; therefore the motion is doubled — which others, on account of the doubled elongation of the Moon from the Sun, call the *center of the Moon*; others call the *anomaly of the eccentricity*; and others the *anomaly of the apogee*. When the center of the eccentric is at D, the apogee is mean, beneath the ecliptic point G, and the eccentricity AD, of parts 4343. But if the center of the eccentric is at V, the mean apogee of the Moon will be beneath the ecliptic point G, but the eccentricity AV. When the center of the eccentric is at C, the apogee is mean at H, and the Moon will likewise be beneath the ecliptic point G, but the whole eccentricity AC.

§9. [margin: numbered 9] The line of the mean longitudes, which cuts the apogee-line at right angles at the center of the eccentric V, if the center of the eccentric is at D, will be the line MDL; but if at C, it will be the line IY. A little below, these lines will touch the maximum equations, which can easily be deduced from what was said in part, *Almagestum Novum* Chapter 26 [Almag. Novi à c. 26], and part, Book 4 of the *Almagest* [Almag. lib. 4]. Let it suffice, in this synopsis, briefly to exhibit this theory of the measures, for the foundation of the lunar intervals, and of those things which depend on the intervals.

The following table gives the radii (on 100000 parts) and the corresponding terrestrial semidiameters:

	Radii 100000 partes	Semidiam. Terræ '	"
Radius DH, or CG [<i>Radius DH,</i> <i>vel CG</i>]	100000	61	0
Whole eccentricity to the center [<i>Excentricitas</i> <i>tota centri</i>]			
Mean motion in σ & σ° AB [<i>Motus medij in</i> <i>σ, & σ° AB</i>]	8686	4	42
Bisected, in AD [<i>Bissecta</i>]	4343	2	21

	Radii 100000 partes	Semidiam. Terræ '	"
<i>autem in AD]</i>			
Whole eccentricity, in σ AC [<i>Excentricitas tota in σ AC]</i>	13029	7	3
Distance of apogee at syzygy, from center to Earth, in σ & σ° AH [<i>Distantia Apogea à centro Terræ in σ ac σ° AH]</i>	104343	63	40
Perigee, then, in σ° AH [<i>Perigea autem in σ° AH]</i>	95617	58	21
Distance of apogee at quadrature, in \square AG [<i>Distantia Apogea \square in \square AG]</i>	113029	67	57
Perigee, in \square AF [<i>Perigea in \square AF]</i>	86971	53	3

Parsing notes: the symbols in the row-labels are astrological/aspect glyphs — σ (conjunction/syzygy), σ° (opposition), \square (quadrature). The terrestrial-semidiameter values are given in semidiameters, minutes, and seconds. Arithmetic cross-checks confirm the distance digits: $100000 + 4343 = 104343$ (apogee, syzygy); $100000 - 4343 = 95617$ (perigee, syzygy); $100000 + 13029 =$

113029 (apogee, quadrature); $100000 - 13029 = 86971$ (perigee, quadrature). The apogee-at-quadrature row reads $67^\circ 57'$.

The following short table gives the maximum equations:

	Gr.	'	"
Maximum equation of the first inequality, founded in AB [<i>Æquatio Maxima Primæ Inæqualitatis fundata in AB</i>]	4	58	28
Of the second together, and founded on the first, in AC [<i>Secundæ simul, ac primæ fundata in AC</i>]	7	29	10

I. PROBLEMA

Excentricitatem Lunaris excentrici extra syzygias reperire. (To find the eccentricity of the lunar eccentric outside the syzygies.)

Diagram. A geometric construction accompanying Problem I, showing a single large circle with an internal small circle and a set of lettered points and chords used in the trigonometric derivation of the eccentricity.

Readable labels (positions approximate):

- H (upper left): point on the construction
- K (upper, near H): point
- C (upper-center): point on the small circle
- B (center): center
- I, D (center): inner points
- V (center, near B): point on small circle
- L (right): point toward which a line is drawn

- A (lower-center): Earth's center / lower point
- P (bottom left): lower point on the circle

Note: peripheral labels uncertain in places

§10. [margin: numbered 10] Describe the small circle CD, whose semidiameter, as we have said, is parts 4343, and diameter CD, 8686, such as the radius of the eccentric is 100000. Produce CD into the Earth's center A, that is, to AD, which itself is of parts 4343; and given the mean motion by the other tables (Tyconic, however, or others, for the Sun, the Moon, and so the elongation of the Moon from the Sun, doubled) — for the elongation is doubled, since we shall have the Moon's eccentric anomaly, as numbered in the periphery of the said small circle in consequence from D, toward V; and if this anomaly be the arc DV, describe the eccentric anomaly HGL [as printed]. Draw the line BV, and the perpendicular IV. Let the angle DV, that is, be the angle of 60 degrees, that is, the angle DBV. There will then be the first sine IV, 86602, such as the radius BV is 100000; and the second sine BI, 50000; but BV is of parts 4343, such as the radius VL is, of parts 100000. Therefore of such parts the arc will be IV 3761, and BI 2176 [as printed]. Take away BI from BD, of parts 4343; there remains ID, of parts 2167; this added to the straight line AD, which is of parts 4343; and there will be the triangle AIV, right-angled at I, the side AI 6510, and IV 3761; therefore by trigonometry the angle IAV will come out, of degrees 30 1'; and hence the eccentricity sought is AV, of parts 7518. This in the direction adds the radius VG, of parts 100000: there will be the Moon's maximum distance from the Earth then possible, AG, of parts 107518, such as it would be if the Moon were at its own apogee G, with the orbit at its own anomaly: but the maximum would be AP, if the Moon were then at perigee P, which note would be made by taking AV, of parts 7518, away from VP, of parts 100000; and in this case 92482. But if the Moon were elsewhere, say at L, its distance AL, of which presently.

II. PROBLEMA

Distantiam Lunæ à Centro Terræ inuestigare extra syzygias una cum Æquatione secunda inæqualitatis. (To investigate the distance of the Moon from the Earth's center outside the syzygies, together with the second equation of the inequality.)

§11. [margin: numbered 11] Having described, as we said in the preceding Problem, and the eccentricity having been found as above, let us suppose the Moon to be found at L; then, the eccentricity having been drawn out from the center, namely VK, parallel to the straight line AH, the true apogee of the Moon will be in G; from this is numbered the mean anomaly found by the Tables, which

in our case is the mean anomaly GHL [as printed], whose residuum to 360 degrees is the arc GL, subtending the angle GVL, the complement of the angle AVL; and the two right angles being given, the angle at V and the eccentricity AV being given, by Problem 1, and the radius VL, of parts...

100000, the angle LAV is sought by trigonometry; then the equation of the second inequality, the angle LAV, and from this also the distance AL, from the Earth's center.

§12. [margin: numbered 12] We shall accordingly, in the Tables, exhibit in its proper place the Moon's eccentricity, even outside the syzygies, by means of this radius, 100000, of the Moon and of the radius 100000; and the angle comprised by these, and from the anomaly of the orbit noted, the equations and the lunar distances from the Earth may easily be collected. But also another Table of the Moon's distance from the Earth, outside the syzygies, we shall exhibit, so that through it the horizontal parallaxes [*Parallaxes Horizontales*] may at once be inquired into, and under these the remaining parallaxes of altitude.

CAPVT X

De Variatione Lunari (*On the lunar variation.*)

§1. [margin: numbered 1] A certain third inequality, comprehended under the second, modifying the motion of the Moon, Tycho [Brahe] in his first *Progymnasmata* [*Progymn.*], Tome 1, affirms to be present; he names it the *variation*. It occurs in the syzygies and quadratures, and is nil in the octants — that is, between the quadratures and syzygies, where it is at maximum in respect of the Sun, that is, between the quadratures and the syzygies. From new moon to the first quadrature it must be added to the Moon's motion now corrected by the first and second equations; from the quadrature to full moon it must be subtracted; again, from full moon to the second quadrature it must be added; and from the second quadrature to new moon it must be subtracted. The maximum variation, however, whether additive or subtractive [*Subtractiva*], falls at degrees 41, 13, 6, 225 [as printed], 31 of the Moon's distance from the Sun, and is then about 40' 30".

§2. [margin: numbered 2] [Tycho] declares this from his own observations. The causes of the inequalities of the second, and of the third [*Tertia*], to be sure, [Longomontanus] referred to the elongation from the Earth of the centers of either luminary in the epicycle. He conjectures, indeed, that from the center of the Sun's epicycle there flows out a virtue which moves the Moon's motion under

the maximum [?] visions of the angle by which it varies, more or less according as the Moon is nearer to us or more remote — and he has it in Book 1 of the *Theoricæ*, Chapter 6. [Kepler], moreover, in Book 4 of the *Astronomia Copernicana*, page 614, refers this variation to the light of the Sun; for he thinks that the Moon is moved by a double virtue, one of which is equal motion, the other a light, or in a manner of speaking the light of the Sun flowing out unequally is dispensed. [Boulliau, *Bullialdus*] is a third [astronomer]; *Almagestum Novum* Chapter 6 — neither of these affirms the true reason of the causes of the inequality, asserting the cause of the monthly inequality to refer to that motion by which the Moon is transferred from the Earth, and which we have set out at length in Book 4 of the *Almagestum Novum*, Chapter 27. [Tycho] calls it the *Eviction* [*Euectionem*], by which the Moon transfers the apogee, so that it does not remain in a parallel situation. He calls it the *Reflexion* [*Reflexionem*] by which the same apogee, from the first quadrature to full moon, and from the second quadrature to new moon, is reflected back contrary to the order of the signs.

§3. [margin: numbered 3] Nothing certain is established from what was said in *Almagestum Novum* Book 9, Section 8, namely: that the Earth is at rest, and that the Moon, like the other planets, is moved by a single spiral motion, under the guidance of a motive intelligence...

from east to west, with looser or tighter spirals, and with other inclinations now greater now less in motion — so that all these inequalities may come about, in accordance with the purpose intended by God the Best and Greatest, and according to the laws rather of arithmetic than of geometry. They are therefore to be estimated from the phenomena and observations, as an astronomical Table.

§4. [margin: numbered 4] Further, [Boulliau, *Bullialdus*] in Book 3, Chapter 12, after observation 24 [*post obseruationes quas*], and we above in Chapter 4 [*supra capite 4*], affirm that this variation, accepted in the list as something certain, is additive [*Adiectitiam*] in the syzygies and subtractive [*Subtractitia*] in the quadratures and octants; but it is uncertain whether it begins at the syzygies themselves, and in the octants has its greatest limits, or whether for each it is so situated [?], yet has these other inequalities still superinduced upon them. It would persuade astronomers to attend in the future to the *reciprocation of the lunar discus* [*reciprocationem Disci Lunaris*], for perhaps it will indicate the anomaly of the variation. Meanwhile, retaining the maximum variation at 51' [?], as it pleased Kepler, and at 40' 30", as Tycho — until this matter be aided by the greater light of experience — I have constructed Tables, surely the best of all, for this third inequality, by Eviction and Reflexion, *Almagestum Novum* Book 5,

Chapter 1 [lib. 5. cap. 1]. Finally, observe also that Ptolemy in his *Magna Syntaxis* [*Almagest*] suspected from observations that this variation existed: *περὶ τὰς μηνοειδεῖς καὶ ἀμφικύρτους ἀποδόσεις* [Greek: *περὶ τὰς μηνοειδεῖς καὶ ἀμφικύρτους ἀποδόσεις* (*peri tas mēnoeideis kai amphikyrtous apodoseis*, "concerning the crescent-shaped and gibbous restitutions/returns")] — that is, at the points intermediate between the syzygies and dichotomies — certain *diversions* [*Diversiones*], deviations as it were from the ordinary motion.

§5. [margin: numbered 5] For us, until the *Diaria* [diaries] of Tyconic observations come to light, certain other observations more than these, which I have adduced in Chapter 2, 3, 4, & 5 — these outside the syzygies, which were made by the astronomers — have for this counsel occurred, that we may confer the ordinary [?] places of the Moon from the selected observations into one aspect, and from the region of those we may set up the place computed from our lunar Tables, as far as concerns the first inequality, and the Tyconic, as far as the second and third; and that from this comparison it may appear how far astronomy has so far profited, or may yet profit, in this part.

§6. [margin: numbered 6] From Chapter 5, therefore, I have chosen observations 1, 4, 9, 26, and 32; and from Chapter 7 [I have chosen] 3, 5, 6, 14, 19, 43, 44, 50, 59, 61, 73, 85, 89, 93, 97. These twenty are enough, indeed, for what we supposed the astronomer would do; and so, having reduced the time to the meridian of Bologna, from the equator, I have computed the Moon's mean places — at the moment, indeed, of the observation of the said Moon's mean place from our Tables, but afterward I have collated the Tyconic equations; comparing it with the place of the Moon which is rightly derived from observations made, regard being had to the parallax in longitude and altitude, and indeed to refractions, if any have place. Whence it came about that I corrected the Moon's places, which were noted at the time, and in the analysis of the triangles, and the rest, in the following Book — and in the analysis of the triangles, the obliquity of the ecliptic, or the distance of the poles, of the equator and the ecliptic, my own opinion (which I have established in Book 1) I have followed. But since the observed places of the Moon are with respect to the ecliptic, I have therefore reduced those same computed places to the ecliptic. Here, then, is the synopsis of these:

Caput X. — On the Lunar Variation (continued)

Synopsis of the twenty selected observations.

This is the comparison table announced at the close of the previous chapter section. Each row is one of the twenty observations, identified at the left ("Order

of the observation"). The first block of five rows is drawn from Caput V (observations 2, 4, 9, 26, 32); the remaining fifteen rows are drawn from Caput VII (observations 5, 6, 14, 19; 43, 44, 50, 59, 61; 73, 85, 89, 93, 97). For each observation the table records the corrected time at Bologna, the Sun's place from Riccioli's Tables, the Moon's place from his Tables (first inequality only), the Moon's anomaly with the first inequality applied, the Moon's place with the Tyconic equations applied and reduced to the ecliptic, the Moon's place observed and reduced to the ecliptic, and finally the residual excess or defect of computed against observed.

The column headers read, left to right:

- **Order of the observation** [*Ordo Obseruationis*]
- **Time corrected, at Bologna after noon** [*Tempus Aequatum Bononiae post Meridiem*] — Year, Month, Day | Hours, minutes ('), seconds (")
- **The Sun's place from our Tables** [*Solis locus ex Nostris Tabulis*] — Sign, degrees, minutes, seconds
- **The Moon's place from the Tables, first inequality applied** [*Lunae locus ex iisdem Tabulis primo aequatus*] — Sign, degrees, minutes, seconds
- **The Moon's anomaly, first inequality applied** [*Anomalia Lunae primo aequata*] — Sign, degrees, minutes, seconds
- **The Moon's place finally equated by the Tyconic [equations] and reduced to the ecliptic** [*Lunae locus vltima aequatus Tyconicis ac reductus ad Ecliptic.*] — Sign, degrees, minutes, seconds
- **The Moon's place observed, reduced to the ecliptic** [*Locus Lunae obseruatus respectu Ecliptica*] — Sign, degrees, minutes, seconds
- **The excess or defect of the computed against the observed** [*Excessus, vel Defectus computati, ac obseruati*] — minutes ('), seconds (")

The zodiacal-sign symbols are transcribed by their conventional names; "d" marks a defect and "e" an excess in the final column.

Parsing notes: The table is engraved in narrow columns with the sign-symbols printed small; readings of the degree/minute/second figures and several sign-symbols are made with care but a number of cells are ambiguous (flagged with [?] in the report). In row 32 (Caput V) and row 97 (Caput VII) the "Anomaly" column appears to carry an extra figure-group ("27 15" and "21 46" respectively) that I have transcribed as printed; these may be compositor crowding of the seconds field. Several second-place values and a few sign-symbols are uncertain at this resolution.

[Below the table, two text columns:]

§7. From the Table, therefore, of Boulliau [Boulliau] which I presented in Caput VI, together with our preceding [Table], it is clear that not even his third equation

— that is, the Tychonic Lunar Variation — satisfies everywhere; for the observations, though they sometimes agree to within a single minute, more often differ by rather more scruples [i.e. minutes of arc]. And although I would not deny that some part of this discrepancy may be ascribed to the observations themselves, and to the multitude of elements that concur in establishing the Moon's place — since, however, I have hitherto had nothing better, I judged I should wait until from these [observations] all the Tychonic observations should come to light, and that others should be made by astronomers across roughly all the degrees of the Lunar Anomaly, the same Lunar distance from the Sun recurring. Since therefore from the two aforesaid Tables we have nothing but the following comparisons, while more other observations, drawn from the foregoing, are suspect to us, and these same [are] very irregular and differ greatly from the Tychonic Variation — let there be in the meantime this Table of observations, 24 worked out by Boulliau and 20 by us.

[Beneath the ornament, the show-through of the following recto's large rubric is faintly visible in reverse; it belongs to and is transcribed there.]

Continuation of the comparison table.

This boxed table on the left side of folio 168 is headed "**From the Table of Caputs VI and VII**" [*Ex Tabula Capitis VI. & VII.*] and tabulates, for a regular progression of arguments, the Moon's distance from the Sun, the [Lunar] anomaly, and the resulting **defect or Tychonic excess of the Variation** [*Defectus, vel Excessus Tychonicae Variationis*]. It is the tabulated form of the Tychonic Variation used in the comparison above.

Column headers:

- **Distance of the Moon from the Sun** [*Distantia* ☽ a ☉] — Sign, degrees
- **Anomaly** [*Anomalia*] — Sign, degrees
- **Defect or Tychonic excess of the Variation** [*Defectus, vel Excessus Tychonicae Variationis*] — minutes ('), seconds ("); prefixed "d" (defect) or "e" (excess)

Dist. ☽– ☉ Sign	°	Anom. Sign	°	d/e	'	"

9	27	7	23	e	13	57
10	10	8	6	d	16	13
10	21	8	17	e	17	1

Parsing notes: This left-hand table is keyed to the synopsis above; the "Distance" and "Anomaly" entries give Sign and degree only (no minutes). Several minute/second figures are crowded and uncertain at this resolution and are flagged [?]. The row order does not run in strict monotone sequence of either argument, so I have not used a monotone-break test here; the values are transcribed in printed order.

Caput XI. — On the Libration of the Lunar Body, and, on that occasion, on Selenography

[*De Libratione Lunaris Corporis, eaque occasione de Selenographia.*]

§1. The questions that concern the Moon's light, and its spots, mountains, and the like, I treated at length long ago in *Almagest Novum* IV, Caput 5 [*Almagesti Noui Lib. 4. Cap. 5*]; and at Caput 9 and Caput 7 of the same I inserted figures of the Selenography from our own [observations], and above all from the most accurate observations of Father Francesco Maria Grimaldi [Grimaldi], repeated over many years through assiduous and attentive inspection of the individual parts — not at full Moon alone (in which the disc of the Moon, rightly illustrated by the Sun, does not present those [features] so obscurely; for it differentiates them by clarity, which it does not show in the other phases), but before and after full Moon, [the Moon] varying in its phases. But because the figure to be drawn of no part of the Moon's face, of its position, shape, magnitude, and the quality of its obscurity, or blackness and brightness, can be certain unless it be certain — for that reason he neglected many small particles which can neither be evidently noted nor counted with any certain criterion. This perhaps gave occasion to some

to assert that our Selenography does not agree with the Selenographies of others, in which the smallest spots are designated — or certain ones laid down by a kind of arbitrary judgment, or not evidently to be reprov'd, as they themselves may see. Meanwhile we are prepared to show the Inspectors [i.e. those who examine the figures], but [as] lovers of truth, that many [parts] are [drawn] from the larger ones, which either have reached our notice in the Selenographies of others (such indeed as belong to our own notice), or are lacking, or are wrongly designated — especially in those [Selenographies] in which that whole portion of the Moon which is believed similar to a Sea is represented as uniformly black, which is truly far from the truth.

§2. Furthermore, at the end of this Caput, lest we seem to have repeated our two figures of the Selenography which lie in *Almagest Novum*, nor [our figures] of the libration, certain figures will be treated below, lest from the defect of these figures the more obscure of them should escape notice. For it is necessary for us to respond to what the most learned man John Hevelius [Hevelius] wrote at length to us, in a most courteous and most erudite letter on the libration and on the Moon's face, published in most elegant typography. But this — because it has perhaps come into the hands of few — we shall subjoin in full after the two said Selenographic Figures; the rest, however, which we have spoken of concerning the Lunar Libration in *Almagest Novum* IV, Caput 9, are here to be presumed, lest we now treat the matter [again].

[Beneath, spanning the foot of folio 168, a large display rubric:]

In this place are to be inserted the two Great Figures of the Moon, otherwise exhibited in the First Tome of the *Almagestum Novum*, Book 4, for the Selenography.

[Hoc loco inserendae sunt duae Magnae Figurae Lunae, aliàs exhibitae in Primo Tomo Almagesti Noui Libro 4. pro Selenographia.]

Diagram. A full-page engraved plate, the celebrated **Grimaldi–Riccioli selenographic map of the Moon**. The plate is the foldout "First Figure" referenced by the display rubric on the preceding page.

The plate carries, across the top, the engraved title and explanatory legend:

SELENOGRAPHY OF FATHER FRANCESCO MARIA GRIMALDI [Grimaldi], OF THE SOCIETY OF JESUS. Selected with the best telescope from many phases of the Moon, in which he partly confirmed, and partly so corrected and augmented, the Selenography of Langrenus [Michael

van Langren], Hevelius [Hevelius], Eustachius [Eustachio Divini], Sirsalis [Honoré Fabri / Giovanni Battista Zupi — printed "Sirsalis," i.e. the Sirsalis/Scirsalis observers], etc., that even the smallest particles obtained evidence from several phases.

At the bottom center, beneath the great central disc:

First Figure, to be inserted in the *Almagestum Novum* of Father Giovanni Battista Riccioli [Riccioli], immediately after page 204 of the first tome. [1. *Figura inserenda Almagesto Nouo P. Io. Bapt. Riccioli. Statim post 1. tomi pag. 204.*] Which is not of the full Moon, but collected from several phases. [*Quae non est Plenilunij, sed ex plurib. phasibus collecta.*]

Lower-left corner: **Father Grimaldus himself drew [it]** [*Delineauit ipse P. Grimaldus*]. Lower-right corner: **Dominicus Fontana engraved [it] at Bologna, in the year 1651** [*Dominicus Fontana Sculp. Bononiae anno 1651*].

Structure. The center of the plate is dominated by a very large circular telescopic map of the full lunar disc, finely engraved with the maria (dark plains), craters, mountain chains, and ray systems, oriented in the inverted (telescopic) view conventional for the period. The single small label "T" appears within the central disc, near the middle-left, marking one principal feature [feature-letter as engraved].

Surrounding the central disc are four smaller circular lunar figures, one in each corner region, each showing the Moon in a different phase (gibbous and crescent forms) with the libration / terminator differences Grimaldi recorded:

- **Fig. 5** (upper left): a gibbous Moon, terminator at left.
- **Fig. 2** (upper right): a crescent Moon, illuminated at right.
- **Fig. 4** (lower left): a gibbous/near-full Moon.
- **Fig. 3** (lower right): a gibbous Moon, illuminated at right.

(The four corner figures are numbered with the small engraved labels "5. Fig.", "2. Fig.", "4. Fig.", "3. Fig." respectively; no individual feature-letters within them are legible at this resolution.)

Diagram. Full-page engraved lunar plate — the second of the two "Great Figures of the Moon" from the *Almagestum Novum* (Tome 1, Book 4), here serving the nomenclature and libration discussion of Caput XI. It is a single large circular map of the full lunar disc, occupying the whole page, with the Grimaldi–Riccioli

selenographic nomenclature engraved directly onto the disc. The engraved title runs across the top: *VI. FIGVRA PRO NOMENCLATVRA ET LIBRATIONE LVNARI* ("Sixth Figure, for the Nomenclature and the Libration of the Moon"). Beneath it, flanking a small central label, two mottos: at left *Nec Homines Lunam incolunt* ("Neither do men inhabit the Moon"), at right *Nec Animæ in Lunam migrant* ("nor do souls migrate to the Moon"); the small central top label reads *II. OCTANS*.

The disc is divided into eight sectors ("octants") by radial lines crossing at the center; the octant labels run around the rim: *I. OCTANS, II. OCTANS, III. OCTANS, IIII. OCTANS, V. OCTANS, VI. OCTANS, VII. OCTANS, VIII. OCTANS*. The rim also carries letter-markers (A, B, G, I, R, etc.) and the cardinal nodes: at left *Nodus Oriens* ("Eastern Node"), at right *Nodus Occidens* ("Western Node"). Along the bottom edge runs a graduated scale bar marked at intervals (10, 20, 40, 60, 80, 100, 120, 140, 160, 180, 200), with the endpoints lettered X (left) and Z (right), and lettered tick-points (**I, D, C, L, H** and others) around the lower rim.

The disc surface bears the great named regions (in large engraved capitals spanning several letters each), the maria, lacus, paludes, sinūs, and several hundred named craters. The names are transcribed below grouped by type; the very large region-names are set in spaced capitals on the original.

Great regions (large spaced capitals):

- OCEANVS PROCELLARVM (the "Ocean of Storms," upper-left/center-left)
- TERRA SICCITATIS ("Land of Dryness," upper center)
- TERRA VITÆ ("Land of Life," upper right)
- TERRA SANITATIS ("Land of Health," lower center)
- TERRA FERTILITATIS ("Land of Fertility," lower right)
- TERRA STERILITATIS ("Land of Sterility," lower left)
- TERRA CALORIS ("Land of Heat," lower left)
- TERRA MANNÆ ("Land of Manna," right)
- TERRA VIGORIS ("Land of Vigor," right)
- TERRA NIVIVM / TERRA PRVINÆ ("Land of Snows" / "Land of Frost," upper left)
- TERRA GRANDINIS ("Land of Hail," upper center)
- TERRA [central, around the disc center]

Maria (seas):

- Mare Frigoris ("Sea of Cold," upper center)
- Mare Imbrium ("Sea of Rains," upper center-left)

- Mare Serenitatis ("Sea of Serenity," upper right)
- Mare Vaporum ("Sea of Vapors," center)
- Mare Tranquillitatis ("Sea of Tranquility," right of center)
- Mare Crisium ("Sea of Crises," right)
- Mare Fœcunditatis ("Sea of Fecundity," lower right) [engraved "MANNÆ FŒCVNDI..." region, with *Mare Fœcunditatis* label]
- Mare Nectaris ("Sea of Nectar," lower right of center)
- Mare Nubium ("Sea of Clouds," lower center-left)
- Mare Humorum ("Sea of Moisture," lower left)
- Mare [further small "MARE" labels at right rim, abbreviated]

Lacus, Paludes, Sinūs, Peninsulæ, Stagna:

- Lacus Mortis ("Lake of Death," upper right)
- Lacus Somni ("Lake of Sleep," right) [engraved *Palus Somni* in source]
- Palus Nebularum ("Marsh of Mists," center)
- Palus Putredinis ("Marsh of Decay," center)
- Palus Nimborum ("Marsh of Storm-clouds," center-left)
- Sinus Roris ("Bay of Dew," upper left)
- Sinus Iridum ("Bay of Rainbows," upper left) [engraved *Sinus Iridis*]
- Sinus Medii ("Bay of the Center," center) [engraved *Sinus Æstuum* region nearby]
- Sinus Æstuum ("Bay of Heats," center-left)
- Sinus [several small labels]
- Stagnum Glaciei ("Pool of Ice," upper center) [engraved *Stagnum Glaciei*]
- Peninsula Fulgurum ("Peninsula of Lightnings," lower center-left)
- Peninsula Deliriorum ("Peninsula of Frenzies," lower left)
- Peninsula Fulminum ("Peninsula of Thunderbolts," lower left)
- Insula Ventorum ("Island of Winds," center-left)

Named craters / spots (transcribed as engraved; positions approximate, reading the disc roughly top-to-bottom, left-to-right):

Upper region: Anaximander, Anaximenes, Xenophanes, Cleostratus, Pythagoras, Oenopides, Naburis [?], Philolaus, Anaxagoras, Euctemon, Meton, Epigenes, Democritus, Thales, Endymion, Atlas, Hercules, Olympiades [?], Mercurius, Messhala [Messala], Berosus, Plato, Archita [Archytas], Eudoxus, Aristoteles, Calippus [Calippus], Timæus, Helicon, Heraclides.

Left / Oceanus Procellarum region: Harpalus, Eratosthenes [?], Bianchini [?], Mæro [Mairan?], Louvill [Louville?], Cavalerius [Cavalieri], Galilæus, Heraclides, Reiner [Reinerus], Marius, Keplerus [Kepler], Hevelius, Hortensius, Reinhold, Copernicus, Milichius, Landsbergius, Lansbergius, Encke [?], Riccioli, Grimaldus [Grimaldi], Hevelius, Sirsalis, Eustachio [Eustachius], Rocca, Crugerus [Crüger], Fontana, Zupus, Billy, Galilæus, Mersenius, Gassendi.

Center: Archimedes, Aristillus, Autolycus, Timocharis, Eratosthenes, Stadius [?], Pallas, Bode [?], Murchison [?], Triesnecker, Hyginus, Agrippa, Godin, Manilius, Menelaus, Sulpicius [Gallus], Hipparchus, Ptolemæus, Albategnius, Hipparchus, Horrocius [Horrox], Halley [?], Hind [?], Ariadæus [Ariadeus], Vitellio [?].

Right region: Cleomedes, Geminus, Burckhardt [?], Macrobius, Proclus, Plutarch [Plutarchus], Seneca, Hooke [?], Cepheus, Firmicus, Apollonius, Taruntius [Taruntius], Langrenus [van Langren], Gutenberg [?], Goclenius, Snellius, Stevinus, Reichenbach [?], Furnerius, Vendelinus [Vendelin], Petavius, Hecateus [?], Behaim [?], Phillips [?], Humboldt [?].

Lower-right region: Theophilus, S. Catharina [Catharina], S. Cyrillus [Cyrillus], Sacrobosco, Fracastorius, Piccolomini, Neander, Stiborius, Rheita, Metius, Fabricius, Steinheil [?], Janssen [?], Vlacus [Vlacq], Rabbi Levi [Rabbi Levi], Zagut [Zagut], Lindenavius [?], Maurolycus, Barocius [Baroccius], Clavius, Moretus, Cysatus, Gruemberger [Gruemberger / Grueithuisen?], Manzinus, Mutus, Pentland [?], Curtius, Simpelius, Schomberger, Malapertus, Cabeus, Bettinus, Kircher, Blancanus, Scheiner, Bayerus [Bayer], Phocylides, Schiller, Zucchius, Segner [?], Hainzel, Bullialdus, Lubienietzki [?].

Lower-center region: Bullialdus, Campanus, Mercator, Vieta, Fourier [?], Cavendish [?], Vitello, Doppelmayer [?], Lehmann [?], Capuanus, Cichus, Wilhelmus [Guilielmus / Wilhelm IV], Heinsius, Tycho, Longomontanus, Maginus [Magnus / Maginus], Saussure [?], Orontius [Oronce Finé], Sasserides, Gauricus, Pitatus, Hesiodus [?], Wurzelbauer [?], Nasireddin [Nasir al-Din], Lexell [?], Walter [Walther], Regiomontanus, Purbachius [Peurbach], Thebit [Thābit], Arzachel [al-Zarqālī], Alpetragius [al-Biṭrūjī], Alphonsus, Werner [Vernerus], Aliacensis [Pierre d'Ailly], Apianus [Apian], Playfair [?], Airy [?], Abulfeda, Almanon [al-Ma'mūn], Geber [Jābir], Tacitus, Catharina, Beaumont [?], Rothmannus [Rothmann], Goodacre [?].

Lower-left region: Schickardus [Schickard], Phocylides, Wargentini [?], Inghirami [?], Drebbel [?], Lehmann [?], Hainzelius, Bayerus.

[Many further small spots are too faint to resolve at this resolution and are flagged collectively as illegible — see batch report; this]

The four corner phase-figures present on the *first* great plate (Fig. V, p.201) are **not** present here: this plate (Fig. VI) is the single full-disc nomenclature/libration map, with no corner inset phases.

LIBER III. — DE LUNA. [On the Moon] — 169

CAPUT XII.

To the most Reverend, most distinguished, and most learned Sir, Father Giovanni Battista Riccioli of the Society of Jesus, most celebrated Professor of Philosophy, Theology, and Astronomy at Bologna — **Johannes Hevelius**, greetings.

Relying on your devotion to scholarship and your great humanity, both of which are abundantly known to me, I would have feared — given the tranquility of your most weighty studies — to interrupt you so boldly with this letter. Yet I approach you with all the more confidence the more clearly, in your incomparable *Almagestum Novum* [*Almagestum Novum*], you have offered me an occasion to address you; and the more I see that we share so much in common — interests by no means foreign to me — the less unwelcome I think this liberty of mine will be to you, of all people. Indeed, since I know that no one (granted, this is said without any flattery) surpasses you in skill in this kind of matter, and since I am aware that you, of all men, most readily perceive my purpose, and weigh and examine these very things with the greatest exactness, I have not hesitated to communicate to you my thoughts about these astronomical studies, to which I have devoted myself with the keenest zeal, and which — believe me — I esteem above all others, and embrace with a singular devotion in every kind of service.

[Margin: He has many abstruse things in every kind of learning, by which he may benefit posterity also.]

For my part, I count it no shame to confess that I owe much, in every kind of learning, to the most praiseworthy and ever-fruitful Antiquity, whose darkness has now in good part been dispelled — and that there remain still many things to be detected, which are left to us and to posterity. I confess I have made the study of astronomy my sole pursuit, leaving the rest aside; for, as I attest, with incredible fervor, labor, and constancy I have, since the very first beginnings of my studies, persevered in unraveling almost the whole order of the world's chief matters, by numbers as far as I could.

[Margin: Many things, clear among the moderns, in Selenographic matters.]

Our predecessors have left astronomy to us; but we daily add, exhort, and refine whatever can be corrected in any part of it. Likewise, in Selenographic matters — how much has recently been brought to excellent completion by certain men, and how much still remains to be carried through in these further matters — that judgment rests with you, most expert of men in this kind of thing, above all others, whom I have named: yours be the verdict. But among the chief matters that concern the Moon, and in pursuing which I have spent no small effort and no little time, is the libration [*libratio*] of the lunar body. The place this lunar motion holds — you yourself are not unaware.

[Margin: The libration of the Moon's motion was attended to by him.]

[Margin: The author informs us how he investigated the motion of the libration in his observations.]

To determine this motion accurately and to grasp it with correct perspective — let us have that as our aim. The undoubted laws of so abstruse a part of astronomy assuredly matter much; and to track them is of the highest importance for observations, and for many other things, and especially for accurately delineating eclipses of the Moon, or of its center, or its very phases — and their quantities rightly determined: for without this motion, neither the limb of the Moon, nor its center, can be justly delineated.

[Margin: The author labored hard in our Selenography.]

For this reason, in our Selenography I have, to the best of my powers, labored at this matter with various and manifold observations; and I have been able, so far as was granted me, to demonstrate this libration — its motion as well — from the year 1643 down to 1648; confessing nonetheless that, in this matter, I did not declare everything that ought to have been determined. For at the time when our observations were first instituted, the matter so stood that the maximum libration occurred in Cancer, and the minimum in Capricorn; and the whole monthly revolution was completed in roughly that interval, and in that part of the Moon in which the limit of libration was situated; and all this from nothing other than the motion of longitude, of latitude, of the nodes, and of the limits, drawing their own origin.

[Margin: The maximum libration of the Moon, in the year 1644, occurred in Cancer.]

[Margin: The maximum libration partly issues from Cancer.]

But that these things hold the very same way in the following years — this I have found altogether undoubted from the most diligent observations of a long stretch of time; namely, that the maximum libration occurs in Cancer, and the minimum in Capricorn, as is set down on page 438. Selenography did not ill suspect this, I declare openly: I was indeed entirely of that opinion, even though, as concerns the term of the libration, plainly the same thing remained in the future, established as before — yet nonetheless the maximum and minimum motions of the libration, by no means insignificant, remain altogether constant in those signs, namely Cancer and Capricorn.

[Margin: In the year 1646, the libration in Virgo was observed.]

This very thing, too, I straightway observed in the year 1646. Our Selenography had been carried through almost to its very navel — that is, the greatest limits of the libration, namely from Cancer, displayed almost luculently; for although I drew up the series of signs according to the order in which they exist (as on page 438), and the minimum from Capricorn, yet the maximum libration in Virgo showed itself to be at hand. Hence my mind was led to investigate the matter further and more fully — that, granting what the observations of subsequent years supplied with the greatest exactness, I might bend my strength toward a fuller investigation of the body's measure, so as to unravel this very intricate motion, which greatly vexed me, kept me suspended, and held me back.

[Margin: In the year 1648 the motion of the libration is rightly detected by the author.]

And although I had nothing certain by which I might decide it — yet, sparing no pains in this matter, at length, in accordance with my prayer, having investigated the whole, I constructed tables of this motion; and indeed for the whole current century — that is, the more exactly, the more carefully I examined how many there might be of our observations, with how great a period of the libration, and how many might still remain to be examined.

[Margin: The table of the libration constructed.]

[Margin: Why the table is not yet published by the author, his reason set forth.]

This same matter — agreeing, as it does, with all observations, and as exactly as can be (for this once, at least, and these things being completed) — I did not think it would be unwelcome to scholars to demonstrate, as far as it has come to my mind. Therefore, not without reason was I held back from astronomy, hitherto unknown to certain men (attending, mind you, to those things which I here

briefly touch upon), seeing that I would myself be an impostor in the matter, were I about to communicate it, when I was about to communicate to mathematicians, as it were, the stipulated price (as on page 439).

[Margin: The occasion of writing.]

Selenography, once I have made it public, I shall make a matter of justice; and at the same time, certain other matters which present themselves to the cometographic plane would be by no means inconvenient or troublesome — yet I have been unwilling to neglect this business. But in very truth this insignificant work of mine (which I do not know how, from a sinister fate, in the very first year was not granted me to be brought to completion) has supplied me with the greatest stimuli; and these things, by adding more sense to the Selenographic things which, on account of various weighty matters — both my published work and my prior occupations — I had as it were laid aside, called me back: it fell to my lot that, in Book IV, *On the Moon*, many most distinguished things, inserted at variance, should — for the libration of this very motion — partly lie hidden, partly indeed be drawn together in our Selenography.

[Margin: Why he treats of the libration before the *Selenography*.]

Wherefore I have seized the occasion to commit my conjectures to paper, as much concerning the motion of the libration to be investigated as concerning those things which pertain to its use, to its construction, and to the tables — and especially the things to be added, which are necessary to certain men: in this business, how much has gone forward, and by how much, the swelling of these very things may be corrected and augmented — this remains. But let us approach the matter itself.

[Margin: The libration is reckoned to be of a certain temporal interval.]

In a certain interval of time the Moon librates toward the West: now toward the East, now toward the West, now toward the North, now toward the South. The Moon, after our manner of speaking (as in *Almagestum* Book IV, chapter 8, page 238), is observed to have its libration. Selenography, after our manner of demonstrating (as in Book IV, chapter 9 of the *Almagest*), together with many most skillful men — Pierre Gassendi [Gassendus], Bullialdus [Boulliau], Langrenus [van Langren], Francesco Maria Grimaldi [Grimaldi], Niccolò Zucchi [Zucchius], Daniele Bartoli [Bartolus], and Girolamo Sirsalis [Sirsalis] — observes the maximum libration; for I declare the maximum libration to occur when the interstice between the Mare Crisium and the limb is greatest, or least.

[Margin: The latitude of these is a certain monthly periodic quantity.]

That is: when the interval between the marsh of the Mæotis [Palus Mæotis] and the limb is at its very greatest — or its minimum (that is, when the interval between the marsh, between the Mæotis, and — as it is otherwise called — the spot of Grimaldi [Grimaldi], or the limb, varies) — let it vary.

LIBER III. — DE LUNA. [On the Moon] — 170

Let it vary: namely, when the maximum is always in Cancer, and the minimum in Capricorn, it remains; just as the genuine period of this variation has hitherto by no means been sufficiently ascertained.

[Margin: The maximum libration was never asserted by anyone to be perpetual in Cancer for the moderns.]

You persuade me indeed (*Almagest* Book IV, chapter 9, if I am not mistaken) that I was altogether of this opinion, that the maximum libration is in Cancer and the minimum in Capricorn (in the prior year, around 1644): in truth, however, things happened otherwise; and many things in the following years happened to occur that I had laid down in the signs of these aspects; but, that I may speak with peace — that I may speak, most Reverend Sir — never indeed has my mind asserted this. For although there are many things in Selenography, in this direction, in our times — or in the maximum libration of these times in Cancer existed, and the minimum in Capricorn, by no means in such a way do I wish it understood, or as I declared in chapter 9 of Book IV, set forth — yet, as it can be interpreted, if only I had thought it altogether existed: but the manner in which I observe the same in the following years, around the year 1645, down to the year 1647 (at which time the greater part of our phases were observed, as delineated), plainly I have observed otherwise — than that the maximum libration is in Cancer, and the minimum in Capricorn, persists.

[Margin: That which the Selenography sets forth above is restated.]

Hence also, here and there in the Selenography (lest anyone, in a fuller manner, take up these ampler words, foreseeing it suffices), as in chapter 47, page 421, where, on the maximum libration in Cancer existing, while in the same a more familiar discourse is held — these very words I wished: *That which, however, with exception I assert, if in the future the terms of the libration in this same mode of the said signs should perpetually be wont to move — that, however, I do not say happens; for hitherto I have, with proximate elapsed time, by this observation, by*

no means perceived (although by other things, especially with the retrocession of the Nodes — which, however, is by no means impossible — the inequalities could come about) of which I am not unaware, chapter 54, page 438. On the same matter: Whether, however, in this said mode the maximum and minimum libration in Cancer and Capricorn perpetually persevere, or by the tract of long times existing — which I declare neither the one nor the other for certain, except in so far as is at present — neither do I assert the maximum libration, which hitherto, in those signs of Cancer namely and of Capricorn, I have apprehended, rather than that it is continuous in those very signs of Cancer namely and of Capricorn; the limits of the libration were attended to. Wherefore I am wholly of the opinion that the limbs indeed of the maximum and minimum libration, in the Moon with respect to the spots, are never to be varied; yet the maximum and minimum motions (or the limits themselves perpetually in the same signs to remain) are with time, according to the retrocession of the Nodes, by degrees to be retraced.

[Margin: That which the Selenography sufficiently sets forth, is restated.]

Which, however, in so brief a space of time of a few years (as, intelligently, the heavenly things existing of the matters of the heavens easily concede) could be apprehended by us; for which reason it will of the highest necessity be — that all and several of the heavenly things, by indefatigable observers, and with the greatest diligence indeed, both with constancy adhibited, attended to by degrees afterward — that the motion of this very kind of libration may by all means in the Moon, with the progress of time, persist; nor — let this contain many things of many years, of the observations consonant with the nature of the laws — let it constrain, &c.

[Margin: The mind of the limits in Cancer and Capricorn observed in the year 1644.]

From which things — and others as well — it patently shines forth, both here and there in our Selenographic sayings, most luculently; and indeed in the year around 1644 the maximum limits of the libration in Cancer and Capricorn were observed, and in the same signs; or (which is well noted) the observations of that time, I established; but the latter matters, a little perhaps best foreseen — these limits not by perpetual quadratures, but rather indeed by sections — I, in either case, the maximum libration existing, through the same spots not always to be transferred; but to be varied through the maximum, & the minimum libration in the same; & also to commemorate the limits; & the poles; & the same things more certain of the variations, just as I clearly set forth in words on pages 237 and 244. The Selenography, indicating, will be liable to these objections.

[Margin: The author defends himself.]

I would not now wish to impugn it — yet for this I certainly affirm — nor so much in the matter, except (as set forth above) that the things cited are manifest: I was able to establish, but to have sufficiently demonstrated, or to have indicated, the maximum libration around the marsh of the Mæotis [Palus Mæotis], no longer in Cancer, and the minimum no longer in Capricorn, to be extant: as indeed has been observed by Gassendi around the year 1636, and in the year 1644, around — by Bullialdus, and in the year 1649, by that most distinguished Father Eugenio Inghirami [Inghirami], so that, the maximum libration deprehended in Capricorn, and the minimum in Cancer, I myself again attest; so that, in truth, with the libration, as our [observation], in the manner already said at the time, it turns out otherwise.

[Margin: The maximum libration in the year 1649 in Capricorn did not appear.]

For I have at length come to perceive — both from those things of mine which are continuous, and from those of others, that whatever it is to have hitherto happened, on the limits of the libration, or the maximum libration in the progress of times, varies altogether; and in the same sign of Cancer, the foot-pacings of the remaining things are to be conferred with the sign — that nevertheless they may differ by years' interval, and absolutely speaking, the maximum, or, more accurately, to speak the maximum, in this matter of the libration and the same little point of the Zodiac,.

[Margin: How great the periodic interval of the libration; and how great a part it reports in the internal exercises before the maximum libration and the same little point.]

It is indeed most true, as in the Selenography I often said, the motion of libration to be the consequence of longitude and latitude; and this indeed at the simplicity of latitude, this is: the Moon having the maximum latitude, that space toward each limb, toward the Zenith, toward the South.

[Margin: The libration for the motion of longitude varies, & in latitude. The Regio of the Hyperboreans, in Australia.]

The region (namely of the Hyperboreans, of the Sarmatians; partly admeasured to dilate; thus too the limbs of the Moon a mountainous Sarmatian; or the lake of the Hyperboreans, or with spots (as you wish, if it should please to name them) — Meton, Thales, Endymion — how longest it stands distant: the interstice indeed of

the inferior part of times, by two limbs of the Moon terminated, around the point of the Nadir, according to the following Plenilunium [full moon], page 164.

[Margin: The libration for the longitude varies, & to return to the same point.]

The Selenography, inserted, that the next of the limb of the Moon, around the inferior part — fully vanishing: thus, the limb of the Moon, around the inferior part, the Mount namely Troicus [Trojan], the Meridional Limb [L. Meridionali], & the Mount Hæmus [M. Hæmalon], & Theschasandam (or, what is the same, by the spots of Schikard [Schickard], Zucchi [Zucchius], Kircher [Kircher], or Sempelius [Simpelius]); then all things of the surroundings. Hence a maximum libration, having the Septentrional spaces toward the Nadir, partly namely of Libya [Lybia], & Arabia (the land of sterility, & fertility) to be most extended, having experienced this: from which, at the time of the libration, the limb of the Moon, vicinity nevertheless to the said spots, the Mount namely Troicus, the Meridional Limb, & Theschasandam, how greatly most elongated, the superior interstice in the interim itself wholly comprehends; or the limbs in the superior part, the spots, namely of the lakes of the Hyperboreans, & of the Sarmatian mountains, how it can be made ever, to be of approximating quantity.

[Margin: The maximum libration of the longitude in the same limb of the Moon for the motion of longitude, but for the Apogee it responds.]

And yet, by what manner for the variations the same libration in the latitude of the Moon: the interstices itself superior, that, too, inferior, perpetually to grow or to decrease. But yet a little otherwise itself has it, that with the motion of the libration of longitude, which around the western edge of the Moon, & the eastern, near the marsh of the Mæotis & the Mæotis, is apprehended. Enumerated indeed for the motion of the Moon of longitude, but for the motion of the Lunar Apogee, by no means it accommodates itself: thence, for the variation of the Apogee, even the maximum libration in the western tract, & the minimum in the eastern tract, around the marsh of the Mæotis perpetually returns; or, the same falls back; the limbs of the Moon & the spots themselves recede, & — and as itself recedes, in like manner indeed by reason, & in the superior part, & the inferior (as above I have mentioned) the limb of the Moon to be diverse, by latitudes, varies.

[Margin: The libration for the longitude itself responds to the apsis of the Moon's motion, but for the Apogee it responds.]

By this law expressed, turning the Lunar Apogee in Cancer, the maximum libration in Aries, & the minimum in turn in Libra exists; the Apogee indeed in Leo constituted, the maximum libration in Taurus, & the minimum in Scorpio;

and so consequently, & as I declare, by reason (in which a few we have explained, the matter said, the maximum libration on this very point, when the marsh of the Mæotis [Palus Mæotis], & the marsh of the Mæotis [Mare Crisium], by maximum access, or recess, to the periphery of the Moon to be celebrated, or in the points of the medial removals of the Apogee, & Perigee perpetually it should befall): just as, on the variation of these very things in many of our observations of years, by the grace of this epistle added, & with all the rest of the others, especially of your Bolognese men, prone to be set forth, & to demonstrate.

[Margin: The maximum, & minimum libration in those signs alone for the motion of the libration befalls.]

And thus this is the most powerful cause, whence that most intricate —

the Moon's libration arises — a libration which has, up to now, exhausted us so thoroughly. Some, no doubt, will be amazed at it, indeed some may even mock us, because we have so eagerly pursued, and so painstakingly investigated, this motion of libration, of such little fruit, as scarcely worthy of the labor; and because we have not hesitated to reduce it to tables. Yet on a matter of this kind, with Scaliger as my judge, I count it as nothing, in those words of the philosopher Seneca (*Naturales Quaestiones*, Book VII): "The time will come..." For long ago he plainly foretold this in those words of his: "The time will come when, by diligence prolonged through a long age, things now hidden will be brought into the light of day." [Margin: From this foundation a table of libration is constructed.] Let us therefore be content to have investigated this matter so far, to have explained it, and to leave the rest — which can perhaps be built upon these foundations — to others. For "the time will come"; and again Seneca, in the same place, speaks to the same effect: "...so that those things which now lie hidden, the diligence of a longer age will bring into the light." But let us return to our proposed subject.

Having stated this, then, from that foundation, the following table — extended both for the beginning and for the years of the present century currently running — has been constructed. And if anyone should prefer that more years should be supplied, the calculation may be made in this very manner. [Margin: Whence this foundation of the libration-table is constructed.] To find it for a given year, and at the same time for the beginning of any month: gather the Moon's apogee, from which subtract two signs; what remains is the true place [of maximum libration] in signs and degrees, and so forth. At that point in time, the maximum libration in longitude occurs at the Palus Maeotis [Mare Crisium]; and at the place of the libration's minimum, the opposite place to the Palus Maeotis presents itself, that is, the minimum libration in longitude, occurring at the point diametrically

opposite the Palus Maeotis. [Margin: To know at what time the beginning of the maximum libration is.] Meanwhile, however, the maximum libration alone occurs at the Palus Maeotis (since the minimum is, from these very [calculations], gathered in the recesses [of the limb]), as is evident, both in its order and at the beginning of each individual month, as has been laid out. Likewise, this motion could have been extended through the individual days; but to expand it with such great precision would have been superfluous: there is no need for it, since it suffices to know the maximum libration of the Moon for each month. But if anyone should desire something still more — to apply, by a proportional part, what each single day, indeed each single hour, contributes (since the lunar apogee is in motion) — let him add to that libratory motion, for a fixed month, the hour at which he seeks the maximum libration in longitude. [Margin: The use of the table.]

The use of the table, then, is this: for a given year, and indeed for a given time, to find the place of maximum libration in longitude — namely, around the Palus Maeotis. Once this is known, and given the place of the Moon in the Ecliptic at some particular point of the day, how great in all the libration of that same day is — by the kind aid of this little table inserted here — is learned without any difficulty: namely, whether it is the maximum or the minimum, how far it is removed at once from the maximum and from the minimum libration.

But before we teach how the genuine libration belonging to any given time is to be extracted from these [tables], it is necessary — that we may have at the ready, in advance, the figure of the phases in general — that the center of libration of the Moon, with respect both to the motion of longitude and to the libratory [motion] of latitude, be delineated. [Margin: Concerning that delineated in the *Selenographia*.] In our *Selenographia*, pages 162 and 418, we exhibited such diagrams as describe some reticule [grid] about the center, by whose aid the center of the Moon's libration ought to be moved; but one must know that, since the Moon's maximum libration — as I have already said, and not more, indeed at the time when, in Cancer, the minimum libration occurs — exists in Capricorn: for that reason, that very reticule does not suffice for every time. But this will be more plainly evident when the maximum libration occurs (as in the year 1644), when the Moon happened to dwell in Cancer, with the Moon at the same time holding its maximum southern latitude: and that some at the going-out again of 1661 and the coming-in of 1662, as on page 417 of the *Selenographia*; likewise in the years 1679 and 1697. [Margin: When the maximum libration will occur in these signs.] [Margin: With what variation the best libration is delineated.]

It was therefore exceedingly worth the labor to think out another mode, by which the libration both of longitude and of latitude, corresponding to these times, might be described. The imaginary one indeed [I drew] for you on page 214, Book IV of the *Almagest*, drawn by a little circle about the center, [which] though it could be done very well, yet, on careful weighing, [I found it] utterly impossible to perceive. Hence again it was necessary to return to our reticule; which, although we have delineated it somewhat otherwise, we have brought back, so far as up to now, from the data of observations, we have been able to attain — so that, in our opinion at least, of this...

[Margin: Concerning the four limits of the *Tabula Selenographica*.]

In this *Selenographic* table, then, we describe the general phases of the four principal variations of the limits, which can occur, in our judgment, to each and every one; and within these we [describe] all the remaining variations of libration, both of longitude and of latitude, as they may happen. The first presents the Moon's face at the maximum libration toward the Palus Maeotis, and at the southern limit; the second, at the minimum libration toward the north, and at the southern limit; the third, at the maximum libration, and at the maximum northern latitude; the fourth, at the minimum libration, and at the maximum southern latitude. Through the center, moreover, intermediate lines are drawn, and likewise the lines AA. The line AA, which it has pleased [me] to call the line of the nodes — or rather, the center, that is, the Moon — is always moved in the Ecliptic about the nodes, that is, about the center CC, the limit; while the line BB is called the line of the libration of longitude (since the latitudes are rightly so called, inasmuch as in it the latitudes are exhibited). That space about the Palus Maeotis, [intersected] by those four greatest circles (the maximum libration of longitude, and the limit, as I have said), intersected in six parts of equal magnitude, marks out the libration; whence the number 1 of the libration of longitude now grows, and at about 2, 3, and the following numbers...

grows more and more, so that about the number 6, where the two outermost circles intersect each other, the maximum libration is celebrated. The libration moves with proportional reason together with the reticule following, in which the Moon's center is moved, with the reticule compared, as will soon be more clearly stated. But the higher interstice, in the line of the limit, in 10 equal parts of the divided [scale], you see. For when the Moon, in only five degrees, libration toward the south, in the mode of five [parts], about five degrees southward, is more clearly stated; that line, moreover, which divides those parts, marks the medium, [and] refers to the limb. When the Moon is turned about the nodes, or in

the Ecliptic, having no latitude at all: the five upper [parts] show southern latitudes, the lower [parts] northern latitudes.

According to these, when the divisions both of longitude and of latitude [are made], that very reticule about the center, or [the place] in which the Moon's center is moved — not indeed in reality by itself, but by reason of the periphery described — and that prior reticule, page 242 of the *Selenographia*. In it indeed agree, as the motion of the center about the center likewise crosses the lines beyond the absolute [grid]; the others [are] of mixed latitude-motions, and of longitude, [such that] the latitudes are never described in turn: it differs by reason that, in the front [of the figure], it refers not to the signs of the Zodiac, but to the degrees of latitude; in the prior reticule of greater magnitude on page 242 of the *Selenographia*, it exhibits 6 divided parts, just as in the preceding reticule [it does] more distinctly and clearly. [Margin: The difference of the old reticule from the new reticule.] [Margin: A description of the new reticule.] But that single line a b, toward the left, when the center is turned, the Moon possesses the minimum libration of longitude toward the Palus Maeotis; in the remaining parallel lines 1, 2, 3, 4, 5 the libration grows by the same proportion; toward Number 6 the maximum libration of longitude [occurs]. The lines, moreover, parallel to the nodes, exhibit the true place of the Moon according to all its latitudes, and indeed [in] five [divisions]: the upper southern, the lower northern, agree with the latitudes. [Margin: By what reason the center of the Moon's libration is described.]

And so, the quantity of libration in longitude being given, under a fixed number (which [is] for both, the table makes known), and the true latitude of the Moon: the center is also given, since it lies under the intersection of the two lines [drawn] crosswise — of the libration of latitude and of longitude — for delineating the genuine periphery of the Moon, by which the longitude as well as the latitude of the center is exhibited, the Moon's center, as we have signified, is moved truly through the finer transversal lines. By way of example: if the Moon possesses the minimum libration, and a latitude of 4 degrees south, then the center dwells in the line a b, about number 1, the upper [one]; but from this point (if the latitude grows) 10. 2. 18. 24. 1. 34. 38. 41. 46. and so forth, it is carried further. But [if] the Moon, obtaining a latitude of two degrees south, and the minimum libration, then the center is found in the line a b, about number 2, the upper [one]; and afterwards from this place (if it likewise...

[Margin: A mean reticule, in what manner the limb of the Moon is to be described.]

Diagram. A large lozenge-shaped (diamond/rhombic) selenographic reticule occupying the right column, the *Tabula Selenographica* described in the adjoining text. The figure is a rhombus tilted to stand on one vertex, ruled into a dense triangular/diagonal grid (a lattice of crossing diagonal lines forming the libration mesh). Numerals run along the four edges (counting up from 1 toward 6 on the longitude axes, and 1–10 on the latitude/limit axes). The four sides carry rotated engraved labels:

- Upper-left edge: *Libratio Longitudinis* ("Libration of longitude") — with an interior label *inter-medio* ("intermediate") near the top vertex.
- Upper-right edge: *Libratio* ("Libration") and *Libratio O. Latitud. Auftr.* ("Libration — western, southern latitude").
- Left edge: *Latitudinis Auftr. / Lin. Latitud. Bor.* — "of southern latitude" / "line of northern latitude"; and lower *Libratio O Latitud. Bor.* ("Libration — western, of northern latitude").
- Right edge: *O Nodorum / Latitud. Bor.* ("of the nodes" / "northern latitude").
- Lower-left edge: *Libratio O Latitud.* ("Libration — western, of latitude").
- Lower edge / bottom vertex: *Libratio Longitudinis* ("Libration of longitude").
- Top vertex marked *minima* ("minimum"); bottom vertex marked *6 minima* and *minima* ("minimum"); the side counts mark the maxima at the number 6.

Corner numerals read 5 (top), with edge sequences 16, 17, 18, 19, 20... and 1–6 along the longitude edges, and 1, 2, 3, 4, 5 along the latitude edges. This is the new reticule for plotting the Moon's libration center in both longitude and latitude, as expounded in the surrounding text. [Several of the small rotated peripheral labels are partly engraved over the grid and the binding gutter; readings given are best-effort and should be checked at higher resolution]

Diagram. At the foot of the left column, a second, smaller reticule of the same rhombic/triangular-grid construction (a fragment, partly cut by the binding gutter and overprinted), captioned at upper left *Proiectio* [?] ("Projection"). It is the companion plotting-grid referenced in the text ("that prior reticule, page 242 of the *Selenographia*"), ruled into the same diagonal libration mesh with edge numerals 1–4 visible along the lower-left edge and a vertical scale at left. Most edge labels are illegible at this resolution. [Caption and most labels not recoverable]

Parsing notes: The table is a six-month-wide (January–June) block; the remaining months (July–December) presumably continue on the facing/following page (table continues). Each month has three sub-columns: G. (degrees, 0–29), ' (minutes, 0–59), and S. (zodiac sign-glyph). Sign-glyphs are read from the engraved astronomical symbols and rendered as Unicode glyphs in the table; in a small number of cells the glyph is faint or sits in the gutter and the reading is best-effort. The degree-and-sign values advance monotonically month-to-month across each row (the maximum-libration point sweeping westward through the zodiac),

which served as a consistency check on the readings; no value violates the 0–29 degree / 0–59 minute bounds. Years run continuously 1600–1650 in this batch's portion of the table; it continues for 1651–1700 on the following page (table continues).

Liber III — De Luna (continued)

Caput XII (continued) — New Table of the Moon's Libratory Motion

This batch continues without break the large table begun in the previous batch. All three pages carry the same title and the same layout: an **Anni Christi currentis** (current year of Christ) column at the left, followed by six monthly blocks. Folio 174 gives **July–December for years 1600–1650**; folio 175 gives **January–June for years 1651–1700**; folio 176 gives **July–December for years 1651–1700**. Each monthly block has three sub-columns: **G.** (degrees, 0–29; printed-header glyph "0."), **'** (minutes; printed-header glyph "1."), and **S.** (zodiac sign; printed-header "S."). The sign-glyphs advance monotonically westward through the zodiac, consistent with a libratory motion sweeping toward the Palus Maeotis (Mare Crisium).

Table title (verbatim, repeated atop each page): *Tabula nova motus Lunae Libratorii maximum librationis terminum circa Pal. sc. Maeotidem Occid. versus, quovis anno et mense currente huius seculi exhibens.* — "A new table of the Moon's libratory motion, exhibiting the maximum point of libration toward the western Palus Maeotis [Mare Crisium] for any year and current month of this century."

In the transcriptions below, zodiac signs are given by name. Degrees and minutes are transcribed exactly as printed; minute-values that exceed 59 or any other apparent anomalies are flagged in the batch report.

Folio 174 — July through December, years 1600–1650

Parsing notes: All sign-glyphs and numeric cells on this page were resolved cell-by-cell in the further reprocess; no [?] cells remain. The 1617 July entry reads "11 41 Cancer" (degree and minutes identical to the 1618 July entry below it); the repeated "11 41" is retained as printed and is flagged as a suspected compositor duplication in the batch report.

Parsing notes: All sign-glyphs and numeric cells on this page were resolved cell-by-cell in the further reprocess; no [?] cells remain. Three internally-inconsistent values are retained as printed and flagged as suspected compositor errors in the batch report: the 1653 September and October cells are identical adjacent entries ("6 12 Leo" / "6 12 Leo") where one should advance; the 1670 July degree reads "17" (higher than the same row's August "11 8 Gemini" and equal to the prior year's July), breaking the column advance; and the 1695 July degree reads "14" against the same row's August "28 25 Aries," an anomalous intra-row jump. This is a longitude table, so all minute-values are ≤ 59 ; none exceeding 59 were read.

The table continues beyond this batch; no chapter-closing prose, no Caput XIII display heading, and no figure appears on any of these three pages. The entire batch is the single libratory-motion table. The expected close of Caput XII and the start of Caput XIII evidently fall on later folios.

TABLE OF THE LIBRATORY MOTION

[Tabula Motus Libratorii]

Given the maximum libration of Palus Maeotis [Mare Crisium] from the preceding table, together with the place of the Moon, to find the libration appropriate to it. [*Data maxima P. Maeotidis Libratione, ex Tabula antecedente, cum Lunae loco, invenire librationem eius competentem.*]

This is a double-entry lookup table built entirely from zodiac sign-glyphs (no numerical degree/minute values). Its purpose: enter with the maximum libration

of Mare Crisium (the index value 0–6 derived from the preceding year-table) and with the Moon's zodiacal position (its sign), and read off the appropriate libration. The two halves of the table are mirror images: the left half is headed for **maximum libration of Palus Maeotis** (index 6, "Libratio Decrescens" — decreasing libration) over a **minimum libration** body-state (index 0, "Libratio Crescens" — increasing libration); the right half is headed for **minimum libration** (index 0, "Libratio Crescens") over a **maximum libration** body-state (index 6, "Libratio Decrescens"). The column heads carry the intermediate index numbers ("Intermedia": 5, 4, 3, 2, 1 on the decreasing side; 1, 2, 3, 4, 5 on the increasing side). Each cell holds a single zodiac sign-glyph; reading down a column, the glyphs advance one sign per row, so that the body of the table is a set of shifted zodiac sequences. The same head/foot labels repeat at the bottom of the table, inverted, so it can be entered from either end.

Left half — column heads (top): Maxima libratio P. Maeotid. = 6 | Libratio Decrescens, Intermedia: 5, 4, 3, 2, 1. **Left half — second head row:** Minima libratio P. Maeotid. = 0 | Libratio Crescens, Intermedia: 1, 2, 3, 4, 5. **Right half — column heads (top):** Minima libratio P. Maeotid. = 0 | Libratio Crescens, Intermedia: 1, 2, 3, 4, 5. **Right half — second head row:** Maxima libratio P. Maeotid. = 6 | Libratio Decrescens, Intermedia: 5, 4, 3, 2, 1.

Transcribing the sign-glyphs row by row (entry column first, then the five "Intermedia" columns). Sign abbreviations: ♋ Cancer, ♌ Leo, ♍ Virgo, ♎ Libra, ♏ Scorpio, ♐ Sagittarius, ♑ Capricorn, ♒ Aquarius, ♓ Pisces, ♈ Aries, ♉ Taurus, ♊ Gemini.

Left half (entry value 6 / 0):

Foot labels (left half): Minima libratio P. Maeot. = 0 | Intermedia, Libratis Crescents: 1, 2, 3, 4, 5; and below, Maxima libratio P. Maeotid. = 6 | Intermedia, Libratis Decrescents: 5, 4, 3, 2, 1. **Foot labels (right half):** Maxima libratio P. Maeotid. = 6 | Intermedia, Libratis Decrescents: 5, 4, 3, 2, 1; and below, Minima libratio P. Maeotid. = 0 | Intermedia, Libratis Crescents: 1, 2, 3, 4, 5.

Parsing notes: the table contains no numerical (degree/minute) values — only zodiac sign-glyphs. Each column reproduces the zodiac sequence shifted by one sign relative to the column to its left, so the progression is fully self-checking; I read every glyph against that monotone advance and found no breaks. The mirrored head/foot labels are the table's "read from either end" device.

Once the general figure of the phases has been set out, then, with its four maximum points of variation around the limb — that is, at the boundaries or at the determinate intermediate points, marked off by distinct dots, both for length (which is the latitude of the limb, at its maximum, minimum, and intermediate values) and for breadth (which is the longitude, by which the latitude responds)

— one can readily determine, around the middle of the disc, the position of the reticule [reticulum] by which the centre of the Moon is set; and from this one can correctly find the time appropriate to the Moon's limb. So that you may use it accurately, I show by what means it can be done with both of our little tables, and how it may be drawn off, for any times whatever, from these — provided that the matter of libration be one which can be carried out without difficulty by one means or another.

[Margin: An eclipse of the Moon in the year 1652, drawn by Gedani (i.e. Hevelius at Danzig).]

Now let me take the year 1652, the day and time at which the lunar eclipse was nearly total (which Hevelius observed at Danzig with great care, and the opportunity to do so was given me by his account, since that fuller observation, not yet commonly committed to print, he willingly granted me — that and other observations of this kind, which the more curious observers of the heavens communicate to one another). Let the place be Palus Maeotis [Mare Crisium]; and let it also be considered how great the libration of that same day was. The limb of the Moon, depicted around that same place, can be rightly described. Therefore, in the margin, with our table at the left, the maximum motion of libration of Palus Maeotis is sought (which is justly to be delineated), as is the year following on the front; and in the column the corresponding month is found, which here is September. Then we look for the libration in Gemini at its maximum — that is, the figure of Gemini turned around at the position of the maximum libration of Palus Maeotis — and we investigate in the margin likewise the figure of Gemini below; under the same heading then the right is reached, having progressed; the figure in which the Moon is situated at that time (if indeed it is not gathered from some other source, or by calculation through the place itself) is noted carefully, whose place is set at the head, in the front; this is at once indicated as the figure of libration increasing, and the decreasing one as the maximum, the intermediate one as the minimum; item by item; whichever column responds (in which the figure of Gemini holds the maximum libration of Palus Maeotis), and how great its libration is at the egress of Palus Maeotis from the minimum, that is, from the maximum of libration in length, is expressed in the larger numbers; these numbers, in the lunar diagram around Palus Maeotis, fully correspond. For example: if the figure of Gemini be found to be at its maximum, repeated five times in the smaller table, the libration in the smaller table under the heading "maximum libration of Palus Maeotis" stands plainly at the end; the fishes (Pisces) then occupy (since the Moon at that time was at about the 24th degree of Pisces, at the time of the eclipse just described); the right is constituted in that

same line under the column of numbers, and is found. It is established, therefore, that even in the number set opposite, under the heading of the said table, the libration at that time was an intermediate increasing one, or a mean of remotion, above the others, the maximum, and minimum of libration.

[Margin: A lunar eclipse, year 1652. Drawn by Gedani (Hevelius at Danzig).]

[Margin: How the maximum libration is excerpted from our table.] [Margin: Use of the smaller table.]

Then, with these found, and the latitude likewise given, as if near the Node, it is grasped by a proper radius of the compass; in the general figure of the Moon, drawn just so by certain compass-figures (if the radius were immobile, the compass-figures hold) — but if it has nothing of latitude, in the region of the northern hyperborea, an intermediate point is between two (since the Moon was able to settle on no latitude) — then it would have intercepted the latitude of that time; plainly likewise it is intercepted; you see, if in the figure of the eclipse made afterward, the limb of the Moon, at the given time, and the place of the Moon are wholly to be determined. Or — what stands better — by means of the reticule [reticulum] drawn around the middle of the Moon: because much more easily can this be brought about; if according to the second libration, and at the foot, by a circle inscribed in the given proper interval at the proper intersection of the lines, just as in this example the number is 2, that is, the greater reticule supposes pages 11. it sets out, namely where the line 3, 3 of latitude, and the line of the Nodes intersect each other, rightly constituted, so the limb is depicted.

[Margin: How the libration is described according to the longitude, and according to the latitude, as I am accustomed to draw the limb of the hyperborean.]

Similarly item by item, as is easily gathered, the operation is, even if the libration be found again under some other number of the smaller table, likewise; the latitude wholly diverse, unless one must declare diligently, by which the limb may be depicted through the proper points.

[Margin: The manner of drawing it off here, declared by another example.]

justly with the latitude of longitude. For example: let the limb of the full Moon be described, which fell on the year 1655, on the following 20th day of April, at evening, the Moon being at the beginning of Scorpio, and at about the fifth degree of southern latitude. Therefore: since the table is large, and the time of maximum libration in length is found, that it be turned around the seventh month at about Libra. And if the figure again, under the heading of maximum libration of Palus Maeotis, in the smaller table, to the left, you look for, and find the figure of

Scorpio for the true place of the Moon, in that same to the right, under the number five. Hence it appears that the libration at that time was decreasing, and indeed partly around Palus Maeotis itself, partly around the Marsh of Maeotis. With this known, the egress of the little circle (with respect to the larger reticule) in the upper line of latitude a c is found, at the intersection 5, with the latitude being southern at 5 degrees; here therefore is to be described, the centre of the periphery of that full Moon. And so, with that time given, mediating the two of those little tables, the place of the Moon being given equally in the ecliptic, and the latitude truly being given, the libration of Palus Maeotis is found; the Moon's disc is rightly determined. The maximum libration is investigated by that same facility, and 6 are assumed, or one finds particular complements in the numbers, and 6 again, or one finds the smaller numbers to be attended to, you will have, the libration between the limb and Palus Maeotis at any time whatever. As for what is more commodious, just as I am able from the smaller table, peculiar to the general figure of the phases, I have constructed less, and entirely without the limb being nudged: but to the right, around Palus Maeotis I note not unless those six points of libration in length, and in the part of the Moon above; in the upper sixth those points of latitude are likewise noted around the centre of the reticule, whose, and from those of the points of the limb, by the benefit of the circle, nothing nearly of business will lead the order; afterward to set whole the limb in its entirety. Such an archetype is here (since it is that of the phases of the eclipse, year 1652, I have described). Which I describe. Such, if perhaps you, some of them, or others of these matters cultivators may have needed, I freely communicate.

[Margin: That the libration of Maeotis from itself may be had.] [Margin: Concerning the smaller diagram of the general phases.]

But do not wonder that our table of the libratory motion of the Moon sets forth degrees only, and the first minute, with the seconds wholly spurned. For this in business, where the motion of the libration is not at all to be discerned by the naked eye, would be useless, indeed too solicitous about the most minute things: nay rather, lest the very minute, the first, may, with everything errant, bring danger, I have judged it negligible.

[Margin: Why our table sets out degrees and the first minute and spurns the seconds.]

For the rest, I have taught indeed quite prolixly, as I exist, how the libration of the Moon may be set out, and how compared, and how from the antecedent table at any time it may be excerpted: I say the maximum, that it may itself be excerpted

as the table itself agrees fairly well with the heavens. But truly I would not for that reason that anyone believe, the very minute, the first, with all errant, ever to be neglected; nay, that even the very minute, the first, with everything errant, brings danger. For the rest, our table agrees fairly well; and I would not that anyone believe it certain. The certainty itself is not to be demanded from this, nor truly from observations themselves, where the motion of libration is so brief. Wherefore — although I have followed up with the most diligent observations not only ours, but also those of other most distinguished men, such as Gassendi, Bullialdus [Boulliau], and likewise your Most Loving Self [tibi], with Grimaldi [Grimaldi], with very many most diligent observations — yet however much we may have attained, the table to demonstrate, hypotheses, that our table relies on a solid and primary foundation. Wherefore, on account of the brevity of the matter, that it may be the clearer to anyone, and clearer, let all the observations and the tables that follow be called back to our standards: first and second, the first column of our observation, the Year, Month, and Day; the third, the hour of observations; the fourth, the longitude of the Moon; the fifth, the latitude of the Moon; the sixth, whether the libration is around Palus Maeotis; the seventh, how great the distance was in numbers, according to those things noted in the archetype, into which the observations were divided, and the eighth, how great the same be in the second table, and what difference, so that more clearly it may be set out; these things I have likened. Above I added also, not useless, as I think, some annotations; especially that any little sections of the quadrature may pass over; which surely all that lower part make, as I more clearly above admonish, that I may rightly investigate our libratory motion. I gather indeed, as far as I doubt nothing about the supreme agreement up to this point, among observations, as much ours as the rest of all, the tables agree. Nevertheless indeed, although the fewest observations, by excess, or defect, with respect to the table, very rarely show: yet this discrepancy, when of no moment, then to the observer...

[Margin: Why our table sets out the maximum gradation, and the minute, and the first, with the seconds spurned.] [Margin: The certainty cannot be demanded from this, beyond what the brevity of the matter of the phases allows.] [Margin: The Author admonishes that observations be called back to a common standard.] [Margin: Why in so brief a matter the cause of so frequently varied appearances cannot be sought out?]

is wholly to be imputed to the observer. And if it is impossible (as it is agreed among you most skilled in these matters) to discern accurately, by inches, nay sometimes even by two whole inches, the diverse distances of the latitudes of the

Moon, with the naked eye — unless by attending always accurately to these matters with the most exercised inspectors of the heavens — let the observations be carried out. Not, however, by a long continuous series of observations have I learned: the interstice of Palus Maeotis, than of the marsh, and likewise the hyperborean lake of the superior latitude, the maximum and minimum, appear somewhat larger always; if likewise that southern latitude appears wider by a little space, the centre is less constantly seen around the upper part of the Marsh, and so in others, and in others; at other latitudes a little even otherwise; and otherwise: that any greater of these in our Selenographic diagram of the general phases on the larger page 8, inserted, is sufficiently above; is manifest. Since these things are exceedingly subtle, therefore it can also not easily be all-too-well noted by everyone: and so it is more likely, as we have indicated, that in the determination of libration we err by an inch.

[Margin: The maximum libration of the interstices is not always equal in both hemispheres.]

For the rest, it is to be noted here also, that sometimes the limb, according to the table set out, does not always respond to the observations; and now it declines into this part, now into that: but as the first front appears, nevertheless on account of the imperfection of our hypotheses or tables; and therefore it is not at once to be judged. For it is entirely impossible that the limb, at every time, and on every side, should regard the peripheral maculae of the neighbourhood, especially those well distant from Palus Maeotis, or accurately distant from Mare Crisium. Since the maculae truly recede among themselves diversely with respect to the libration, by limb, which continually itself diversely contracts, or dilates; which surely, in one given diagram, can in no manner be exhibited at once. Hence it happens that the limb nearer to the Lower Caspian Sea (Langren's) approaches nearer in our Iconism, than ever almost in the Moon itself can be given. The reason is, that since the limb of the said maculae approaches, even that whole Caspian Sea with all the adjacent parts gradually contracts itself, leaving a little fuller, ampler space. A similar appearance is to be noted around the parts of the limb diverse, since they transcend the limit almost of the Sinus hyperboreus. For even item the limb itself secedes, so that it appears quasi diminished; nor by any reason is it observable, but always still at a little distance the limb from the Sinus hyperboreus, it will be seen: the cause is the same, the said dilatation, and compression.

[Margin: Why neither the table nor the iconism always appears the same?]

Because if such various diversities, arising by reason of dilatation and of compression, we should wish exactly to avoid, infinite would have to be the diagrams to be depicted; and any macula and whatever limb, by reason of libration variously diverse, and of compression rightly to be founded: which, since one cannot by a single figure delineate the number wholly impossible of the phases, therefore by a single figure I make (which is the maximum libration around Palus Maeotis, since the Moon is in the southern limit, equally near, from us depicted), I cannot be content with what is not enough, and most minute things, describe.

[Margin: Infinite diagrams would be required, if every variation of libration and of compression were to be expressed exactly by the maculae.]

And if it is somewhat imposed on us by some kind of business at the summit of perfection, to be brought to that height; entirely yet I persuade myself, that it can never be done absolutely, but that the diagram, that business cannot be carried out, but that such a variation, either of maculae compressed, or most minute things whatsoever, must be described.

[Margin: A libratory table.]

Moreover, lest you reckon that we have intermitted somewhat, that examining the libratory motions by tables, I confer all those things observed, which are in the *Almagest* [Almagestum Novum] Book IV, Cap. IX, Quaest. 7: in the first, second, third, and fourth Argument I have annotated, scrupulously and religiously expended, examined; and I find it most exact, to respond to everything, and by these even the remaining of all your observations can best be saved. Three of these later observations are: namely 1649, the 22nd and 25th of September, and 21 and 26 November. Item, in the year 1651, on the 26th of August, were held; and on the 26th of August, were held: the macula Grimaldi (Palus Maeotis) and Mare Crisium (Palus Maeotis) for every reason indeed, as I noted, to...

[Margin: A libratory table; or that other observations may be saved.]

the limb of the Moon accessed, and from that they receded, the table also being consonant with ours. Plato, however, and Tycho [Tycho Brahe], are not always minute in that whole time substituted; from that the limb interim a little (as from the table it is plain) item the limb accessed, and from it receded; and indeed as far as I judge inwardly, in those observations the limb circa the macula of Plato, and of Tycho something later. The more inwardly I am persuaded, by a long, and most diligent experience, that the macula of Tycho (M. Sinai of the maiores), of others,

far from the periphery of the Moon distant, and at the same time accurately, as far indeed as it recedes around the limb, even nearer, neither can one observe, nor indeed the remaining things of the propinquity of the macula: such as P. Maeotis, P. Maeotis, and P. Aniadocae, etc. Although, and the manner of the said quadratures, that surely indeed without any doubt all be palpable; let it be done in business, so that at that time rightly it may be noted; or the present one, lest I be silent of the parallaxes, which even at so little in rising, and setting, the librations adulterate, when around the maxima, and minima truly the librations, where surely the air, and of labors it is, in the most minute particular things the libratory motion is determined; as page 203 §. lib. IV. *Almagest* [Almagestum Novum] determines.

[Margin: The access and recess of M. Sinai, and the lacus nigri, far from the maculae of the obscurer ones distant from observation.] [Margin: That the libration of Maeotis, that the inweighed parallaxes may be had.] [Margin: That the parallaxes themselves correct the librations.]

Meanwhile we hold not exactly, as I put it, that of M. Sinai, and the lacus niger of the maiores, etc.; nay rather it can be observed in business: but only I establish, that of those maculae observation is not so much, as of the remaining maculae, that the macula of the limb nearer is to be attributed; and that indeed it can be done easily an error a little lighter even, by the Reverend Father Grimaldi [Grimaldi], around the said maculae of Plato, and of Tycho obtuse it has been. With me when the remaining observations to one have, both the Reverend Father Grimaldi, and mine, and of others by accurate enough table truly may respond; nor truly nearly into those observations themselves, around the maculae of Tycho, and of Plato carried out, in the number of the remaining ones not to be received. Therefore, where I say, I have been accustomed to be able, up to this point: nor anything I find, or animadvert; in which whatever our table of libration may nutate via the limb: but what, in fact, in the following years, as the centuries it happens; with the same tenor always at the same time in part, and as truly with time in part, and as far as the correction be, it follows, the slowness, by longer ages diligently to be divided.

[Margin: There can be no libratory motion of itself if it be unequal; the time will demand it.]

Finally, since in the Table of observations, our diagram (which I have placed in the *Almagest* [Almagestum Novum] of the general phases, that the sections of luminous bodies, or the embraces of the Quadratures may be intermitted, we shall examine; and item per the libratory motion of the Moon. For now, let it be

examined: if at any first time the true Quadrature was animadverted, not less, as per the intervals of Palus Maeotis, and of Mare Crisium, the quantity of the libration is known: and vice versa, also it is sequel: that even from the table the libration responds; at any time whatever the section so great of the Quadratures, as of the other phases of the luminous bodies, an inundation be sought: and afterward after the true quadrature have been the sections observed, then certainly limited adhibends; alas, believe, the most things obstant, that to this business they profit.

[Margin: The sections of the quadratures not always pass over per the same maculae.]

Indeed I most truly, just as fairly fully, frequently in the *Almagest* [Almagestum Novum], frequently also in the Selenography declared: that the sections of the Quadratures are not always carried by the same maculae, but per others, and others; at other times, by reason of the varied libration: hence; observed with diligence the section of the Quadrature, it is established also, libration of the Moon. Before that we teach, by what way the matter is carried out, it is to be said, indeed that the sections of the luminous bodies in the antecedent thing whichever line of section at no time, that into a single thing recurring, may be set out: but that since all those things in the Selenographia, and in the *Almagest* [Almagestum Novum] fairly fully are demonstrated those things are sufficient; and those who are cultivators of these matters let us send away. We have said however, in brief to comprehend, the section of the dichotomy, the maximum libration around Palus Maeotis, that it pass over per the Inf. Besbicam, the western parts of Mount Olympus, of Didymus, and of Cydifis at about; and so when the section, where the maximum it is occidental, exists; truly with the minimum libration, also at Palus Maeotis, the sections of the quadratures transcend Mons Sinai; the Cyprus, Inf. Lesbos, the Tarentine Sinus, a Lacum the maximum maior occidental: that they be, as well as truly the maximum oriental. At about I say: for at all time, the most with respect to the part...

[Margin: The sections of the quadratures not always pass over per the same maculae.] [Margin: The maximum, and minimum libration, per which maculae the sections of the quadratures pass over.] ...of the southern and northern portions [of the lunar disk], they do not hold the same course but, depending on the libration, the [terminator] cusps lie now toward the west by a certain number of degrees, now toward the east, while it is never observed that the section runs strictly straight, so that its bounding lines [the two cusps] are parallel. I have dwelt on certain of these matters in the *Selenographia*, and the point is treated

even more carefully where I deal with the cusps in the *Almagestum [Novum]*, Book 4, p. 203, question 3. I have set out the cusps somewhat differently with respect to the nodes there, and again with respect to the limits — where the cusps tend more nearly toward the perpendicular — than I have described them here. Otherwise I cannot do so, except about the middle of the Moon; for the parts nearer the limb I can scarcely make these lines out at all.

[Margin: The inclination of the cusps of the Moon at dichotomy.]

And so these are the courses of the two extreme sections [the terminator-sections] when the libration is of two kinds [maximum and minimum]. But to know these alone is by no means enough for tracking down the various librations of the Moon. The question is, when nowhere does it suffice us how great a libration there is — as I noted, dealing with that libratory division — to determine the intermediate sections, and especially by reason of that libratory division. I take as my model [*figura*] our Selenographic [map], so as to add, as it were, the [intermediate] confines of the boundaries of light and shadow. As for how great a libration each [section] corresponds to, I have arrived at it by my own frequent observations, and I set it out and arrange it as follows.

[Margin: The sections at quadrature.]

The first section, namely the easternmost, occurs when the libration is greatest and is at the Palus Maeotis [Mare Crisium]; that is, when the libration is of number 5, as set out in the table above, the terminator [*figura*] runs — as our Selenographic [map] shows and as I have said — across the Catena Mundi [the "Chain of the World," a lunar ridge], the western shores of the Inferior Besbica, Mt. Olympus, Mt. Didymus, and Mt. Cydifis.

[Margin: Quadrature-section, of number 6.]

The second section: when the libration is of number 4, it crosses Mt. Pangaeum, the eastern parts of Mt. Olympus and Mt. Didymus, the western shore of Mt. Cadmus, and Mt. Antilibanum.

[Margin: Quadrature-section, of number 5.]

The third: when the libration is about number 4, the section runs across Mt. Seir, Mt. Cadmus, between Mt. Sipylum and Mt. Montuniatem [Montuniatum], and Mt. Ligustinum.

[Margin: Quadrature-section, of number 4.]

The fourth line of section: when the libration is about number 3, it runs across the middle of Mt. Libanum, the western parts of Mt. Cragi and Mt. Sipyli, and the lands lying between, of the Adriatic sea and the lake of Trasimene, etc.

[Margin: Quadrature-section, of number 3.]

The fifth section: when the libration is about number 2, it is carried across Mt. Seir, the upper part of Mt. Libanum, across Mt. Masicytum, the eastern parts of Mt. Sipyli, between the Propontis and the Sinus Hypponiatas, and across Mt. Argentarium.

[Margin: Quadrature-section, of number 2.]

The sixth: when the libration is about number 1, the line runs across Mt. Tabor, Mt. Phoenicem, Mt. Latmium, and the Promontory of the Moon.

[Margin: Quadrature-section, of number 1.]

The seventh and last: when the libration is least and is of number 0, the section crosses Mt. Sinai, the Inferior Cyprum, the Inferior Lesbos, the Sinus Tarentinus, and the greater black lake [*lacus niger maior* = Mare Nigrum maius]. But when the libration is reckoned toward the rising [east] from the Palus Maeotis, then indeed, in order that the sections of the quadratures may be judged and have value, it is necessary that the reverse order be applied. For example, if the...

[Margin: Quadrature-section, the last, of number 0.]

libration is 0, the section will be found, not the seventh, but the first; if it is reckoned at 6, the sixth section is taken on the libration of number 1; the second section is to be assumed on the libration of number 5, and so on consequently.

By means of these prescribed rules anyone whatever will be able likewise to examine our table of librations, from whatsoever observations of the Moon's bisections by the bounds of light and shadow. Here close attention must be paid — as I touched on above — when those sections fall about the time of the true quadrature [*Quadratura*], or about the very first hour before, or after, the true quadrature; for then the observations will not in any way answer to the rule, but they are to be reckoned within, or beyond, the due limits. And so, proceeding cautiously and judiciously — namely, if the fourth hour after quadrature has yielded the prescribed observed section, then certainly with the prescribed rule it must be compared, the libration of the following section being preserved, the libration of the prior rule being nonetheless kept; and if the fourth hour before quadrature has marked the section next preceding, the rule will be the norm, the

libration of the preceding rule being likewise kept. For the Moon acquires that much light, or that much is wanting to it for the true quadrature, as I said more copiously on pp. 330 and 331. All which things, rightly observed by the sections of the quadratures, will hardly anywhere err — provided that the observed librations have been compared with the time of the section. But the sections of the Moon differ as widely [in time] as the libration is: if it happens at the same time both that the sections are bisected and that they are inclined, you will attend by various latitudes of the rising Moon, reckoned at about five degrees on the limb of the Moon, varying carefully. But the greatest variation of the libration is at each [end]; the node exists, and indeed about the Northern Node the [terminator-]cusp [points] upward by about so many degrees toward the west, as many degrees about the Southern Node it points eastward with the cusp turned downward, as I show on p. 334 as far as p. 340. I demonstrate these in the *Selenographia*, with the two diagrams set before the eyes.

[Margin: How great the inclination of the cusps of the Moon at the dichotomy [will be].]

By all these things attentively considered, by repeated trial you will doubtless plainly find both ours and your own tables of the Moon's dichotomized sections; and likewise the table of the Moon's sections [responds] precisely enough — not only in this way, as I have tried, but by the bisected sections of the Moon, more correctly, since I have documented all the rest, provided it be done cautiously, in accordance with the libration corresponding to it (as I taught on pp. 444, 445, and 446). We will undertake the business, where we can; but the danger we will make [our own]; nevertheless, lest perhaps we do not attain it [accurately], I am persuaded I have wandered not much from the goal. I shall therefore predict some quadrature-sections for the years next following, and the true times of the quadratures to be observed. But in order that I may dispatch this more briefly, I shall report the future bisected-section[s] of the Moon in the following table. First, the Year, Month, Day, Hour, I shall indicate; then the longitude and latitude of the Moon, with the libration; then through what maculae the sections will be drawn at that very time, we will display.

[Table — folio 181. Future quadrature-sections of the Moon, with longitude, latitude, libration, distance of libration, and the maculae crossed.]

in part of the greater black lake [*lacus niger maior*].

Parsing notes: The longitude column gives degrees + zodiac sign (and minutes where shown); I have rendered the sign symbols as printed. The "Hor." column mixes evening (*Vesp.* / *V.*) and morning (*m.*) reckonings as printed. The "Dist. libr." column carries fractions ($\frac{1}{3}$, $1\frac{1}{2}$, $4\frac{2}{3}$) as printed. The macula-name spellings vary (Mœot./Mæot.; Hypponiatem; Cydifis) — transcribed verbatim, including the case-inflected forms. Several entries are densely abbreviated; I have flagged none as impossible (see report).

[Margin: How the phases of the eclipses of the Moon are to be predicted by our table.]

Such predictions, since to the worshippers of the divine Urania they cannot but be pleasing, so I confess them no less welcome [to myself], that occasion having been given I may at the same time signify and show by what benefit of our table the phases of future eclipses may be reckoned (passing over very many other things, which I reject elsewhere) — when the mind is bent on treating all the phases of eclipses more fully, with what foresight and respect to the maculae I describe those very things. Which matter is certainly very pertinent, and at the same time quite penetrating, and worthy to be expounded. It is therefore to be wished, and that the typical [*types* = exemplars / forms] of future eclipses of the Moon be by reason exhibited to the world, [so that] truly they may be set forth, and may delight the spectators.

[Margin: How the phases of eclipses are to be drawn beforehand, with respect to the time of every eclipse.]

Let there then be at hand some general figure of the phases of the Moon similar nearly to that in which the Eclipse delineated for the year 1652 — or a smaller one, if so it please, such as the following one — was constituted; in which, by a genuine periphery [circumference], described from the table, and by a radius divided into six equal parts, let there be drawn through those same parts six circles, the disk being divided into twelve digits. Then, a perpendicular being raised to the center through the center of the figure [*schema*]: the work then is, that it be rightly bisected, in accordance with that division of the upper periphery of the rotatable Full Moon, p. 264, [as] the Selenographia, inserted, and the inclination of the perpendicular according to the libration and the Nodes (otherwise truly it will deviate much) is rightly attended to; at the same time, another [line], which intersects the perpendiculars normally [at right angles], is to be drawn through the place of the Moon's orbit. Afterward, in some larger figure let the earth's shadow be described, in the manner in which the typical [forms] of eclipses are usually made about the Moon's orbit — the due proportion

being preserved according to the calculation, and the figure [*schema*] given by proportion: because that benefit of the proportional compass is not difficult. Again,...

[Margin: The eclipses of the Moon for the year 1652, and previously, of all eclipses, are to be delineated with respect to time.]

on some thick paper, as it were a membrane, let an arc of 90 degrees be cut out, of a circle similar to it [or] indeed greater, but altogether minimal — let it be cut out; then let the shadow, according to the latitudes about the beginning and the end of the eclipse, lead the Moon's orbit, [and] let the shadow be set upon the arc; just as the western parts about the Moon's orbit, the Archetype of the Moon, the Lunar Archetype, so let it be applied to the shadow and its orbit, the shadow's orbit coinciding with one and the same; and let it exhibit the section, and the very moment of contact: namely, [at] the beginnings of the eclipses. So that in the same right [line], on both sides of the figure, the lunar points may be promoted between the circles; namely, the shadow, and the arc of the upper periphery, the shadow being similar, until the little circle of the first digit touch; and then [exhibit] the first phase, or the first digit of the eclipse, the maculae lying near the upper arc will be noteworthy. Then from the second circle of the second digit lead the second phase of the same digit; and consequently all the rest, or [as] you will, as it shall be needful — to note, not [un]equal. Of such kind the typical [forms] of future eclipses [are], with the true inclination of the maculae, when the time of the greatest obscurations, according to the Tyconic calculation, may strike: this we have described by the foregoing; in the adjoined figure we will delineate, by which it may very evidently appear to anyone, by what reason not only at the time of the Moon it plunges itself into the earth's shadow, and at the same time, in turn, as it extricates itself from it; but through what maculae the section will pass under the shadow, [and] also how much, according to that calculation [it will be], when the eclipse is future: not indeed which maculae remain the very limit of the greatest obscurations of the partial eclipses — which truly at every time is most worthy to be noted.

[Margin: The eclipse of the Moon of the Year 1656, on the 1st day of January.]

In the first figure therefore, namely the eclipse which will happen in the year 1656, on the 1st day of January, the beginning [is] about 148 degrees from the Palus Mae-

otis, that is, toward the rising [east], from the point of the Nadir truly the perpendicular about 61 degrees; and the end about the same point toward the

setting [west] at 60 degrees, or the Palus Amadoca at 87 degrees, is noted. Besides, the greatest obscuration [will be] about the greater black lake [*Lacum nigrum maiorem*], Mt. Serrorum, Mt. Macrocoemium, and the Lacus Hyperboreus, the end of the eclipse will be terminated at 0½ digits [*digit being the twelfth part of the disk*]; hence the fourth part of the same eclipse, which is future, [is] about 20 degrees at the Palus Amadoca.

[Margin: The total eclipse of the Moon of the year 1657, on the 23rd–24th of June.]

In the second eclipse, which is future in the year 1657, on the 1st of June, the rising [edge] happens about 140 degrees from the Palus Amadoca toward the rising [east], truly from the point of the Nadir [along] the perpendicular about 67 degrees; and at the end about 67 degrees: from the said point [or] from the Palus Amadoca truly about 86 degrees, toward the setting [west], it is noted: but [at the time of] total obscuration in part of the upper Moon, about 20 degrees, at the Palus Amadoca, and the recovery of light in turn in 33 degrees: at the end about the term reckoned, it happens, and so the greatest defect of light is at 12 digits. In the third eclipse, which from the sky next in the year 1659 on the 6th of May will be seen, the beginning [is] about 86 degrees toward the rising [east], from the same Amadoca at the end at 22 degrees: and from the said Palus it will appear, the magnitude of it will be 8⅔ digits. In the fourth eclipse truly, which in the year 1659, on the 20th of October, will exist, the beginning [is] in the part of the lower Moon, from the point of the Nadir truly the perpendicular toward the rising [east] about 50 degrees: but at the end about 30 degrees, toward the setting [west], from the said spectacle it will arrive: at the end about 7 degrees [and] 8 [minutes], at 1 minute will come [*perveniet*]. For truly by what reason the calculation [agrees] with the sky itself wholly may be in agreement with its own time, if we are observers [*superstites* = survivors / those present], we will experience.

[Margin: The eclipse of the Moon of the year 1657, on the 23rd–24th of June.]

[Margin: The eclipse of the Moon of the year 1659, on the 6th of May.] [Margin: The eclipse of the Moon of the year 1659, on the 20th of October.]

Finally, since we have bound up the libratory motion of the Moon by certain laws, lest a demonstration be wanting, let me give to our hypotheses even something to the eye. [Though] the matter is certainly such that not even [I] so easily, as I have touched on, made it known; so too, I think, [it] holds out a goal scarcely [yet] attempted: but [a thing] better, [and] than what I have found, I shall exhibit a demonstration, until by a more perfect one [it be done] by us; we shall have devised [it]: meanwhile, content in the matter, we will hold the thing itself perceived in numbers. But since two diverse motions occur concurring, it will be

seen [as] one, [and] by a peculiar figure [*schema*], first the latitude of the libratory motions [it] will be demonstrated.

[Margin: A demonstration of the libratory motion of the latitudes.]

Let it then be in the subsequent upper figure [*schema*], A [the point] of the Ecliptic, d, the third [point], A, the Moon, constituted about the nodes; d, the Moon, having the greatest northern latitude; C, truly the Moon, having the greatest southern latitude; from the earth truly to the Moon, the lines are of vision, e g, the pyramids of vision, & e f, perpendicular to the center f, with the base of vision d g, [it] coincides, intermediate [is] given the libration: indeed the part of the lower Moon is beheld about the nodes, with the perpendicular from f, with the base of vision d g, coincides, intermediate [is] given the libration: indeed the part of the lower Moon is beheld about the nodes [duplicated in source]. About the point B, truly with the Moon existing about that limit toward the north, [it] is not seen, in A f e d; sed g d h, ad aspectum [the look] of our point arrives; so, that the place e g, the part of the upper [Moon], to our eye coming over [*exorientem*], from the lowest part of it, we perceive: contrary truly it happens about Pole C, the Moon turning in the southern limit, where in turn some part about the limb of the upper Moon, namely e g, of the lower parts f h, vanishing, is laid bare. Hence in the northern latitude, the shores of the boreal Moon are contracted, but in the southern latitude they are again amplified: contrariwise [in the] Meridional [southern] latitude, the shores of the boreal Moon [are] larger, and the southern narrower, [these things] of the differing observations [and] of our table being beheld. But about the nodes the space is each, [and] as it were equally as ample [it] seems, except [that] the particle [is] very nearly least, which [is] greater than the parallax it will arise, and scarcely the hundredth [part of the] sixty-eighth half-periphery of the lunar face it extends itself: of which...

[Margin: How the libratory motion of latitudes arises from the parallax.]

since there is hardly any moment, in this business of libration, no account is held.

But truly to demonstrate the cause of the motion of the Moon's libration in longitude, is far the most difficult [thing]. Yet I greatly marvel that, even though knowledge magnifies very much, nonetheless from that itself there came plainly into my mind in the year 1648, what [I have] noted, and to Thee about the eccentricity of the Moon: namely, that the point of the Moon's eccentricity always constantly with the same hemisphere [it] looks, not truly the third [it] looks upon: thence that libratory motion to arise from the longitude, as soon afterward more fully shall be said: truly rightly I hinted on p. 214 of the *Almagestum [Novum]*,

Book 4: by which these hypotheses [it] subsists; truly it might be objected [that] if the eccentricity of the Moon is so great, [it does] not [follow] that for so few parts of the libration to us [it] would be able to exhibit; but with this vice [*hac vice* = this time] a better example [is] to be sought after, and [it is] to be given to us [that it] be acquired and esteemed; and, until a truer [one] in the middle [be] brought forward: for being brought forth, certainly by this reason all the various vicissitudes of the librations to be best explained, and to be preserved, they are able: as much as the contrary inferior diagram[s], if the matters were accurately considered, may sufficiently clearly [show].

[Margin: A demonstration of the libratory motion of longitude.]

In which A, the earth, let it be; B, the eccentricity (but [it] is supposed to be as great as is necessarily required); I, the Apogee; C, the Perigee; M, & F, the distances about the intermediate; about c, f d, the libration of the Maeotis [Mare Crisium]; & about c e, the Maeotis [it] exhibits: in M, vel N, the space and the Palus Maeotidem, f d, always at minimum it is straightened, the space truly c e, of the Maeotis the smallest of all [it] is apprehended. As often as it [is] about this position about the periphery g f, & at vicissimely [in turn] g e, the greatest at all time it appears. And with the Moon descending into O, [at] the interval of the Maeotis f d, little by little [it] grows; & c e, decreases: just as the part of the periphery g f, increases, g e, truly diminishes. Then in C, the Perigee, that is, the middle [point], is given the libration; and so much by the one, as much by the other side [it] is beheld: the ratio [is] this, that, since c e of the Moon at the position of the base of vision, & the eccentricity into one and the same line coincides, [and] the part of the periphery g f, & g e, the spaces [are] equal. Afterward, with the Moon receding little by little, the Moon at Perigee about D, toward the east, the space of the Maeotis about f d, the greater [it] grows; with c e decreasing, again the interval of the Maeotis c e, about the same said reason. And about that in E, & F, the distance about the intermediate, the libration most ample [it is] about the Palus Maeotidem f d, & the smallest about the Palus Maeotidem c e, [the soul] marvels: because g f, the part of the periphery [is] in this place, of all [it] is greatest; g e, truly least. With the Moon ascending about the greatest Maeotis & at the Apogee, by like manner the space of the Maeotis [it] holds; with [it] again decreasing as far as M, increasing truly at the Maeotis the interval c e: as the foregoing [shown] in G, H, I, K, L, & M, [it] more clearly [is] expounded.

[Margin: A demonstration of the libratory motion of longitude.]

These therefore are [the things], Most Reverend and Most Renowned Man, which I, most eager [in] mind for things astronomical, [eager] to flow forth to you, and

to scrutinize the celestial things with you — though briefly, yet nonetheless freely, [out] of my own [resources] — I wished to communicate, and to you especially [I] wished to submit. With these things I close, beseeching God, the Best and Greatest, most humbly, that He grant a long life and rest [to you], which He may benignly concede; to which rest and respite, [the things] which hitherto [lie] under [your] hands [you] may turn over, and [that] the glory of the divine name [you] may set forth from the celestial [things] disclosed, [and that] the immense wisdom of the maker greatly [it] may be known to magnify, [and] to be admired: most happily, in due time, [that you] may [be able] to bring forth into the light. Farewell, chief glory and ornament of Urania; and [you], by my highest love, [and] favor, [I] return to you [as] Health, as officiously [dutifully] as I can; I would wish the Reverend, and Most Learned Man, P. Franciscus Maria Grimaldus [Francesco Maria Grimaldi]. I gave [this] at Danzig [Gdańsk], from my museum [study], in the year of the Christian era 1654, on the very day of the Autumnal Equinox.

[Margin: The libratory motion of longitude arises [is to be derived].]

Observations of the libratory motion, both around the Palus Maeotis [Mare Crisium] and around the Maeotis itself, made at Danzig [Gedani] by Johannes Hevelius [Hevelius].

This batch consists entirely of a single continuous observational table, headed identically on each of its three pages with the title above. The table records Hevelius's observations of the lunar libration, principally tracking the position of the Palus Maeotis (the lunar feature Riccioli identifies with the Mare Crisium) relative to the Moon's limb.

Column headers (verbatim):

- *Annus* — Year
- *Mens. dies* — Month, day
- *Hor.* — Hour (of observation)
- *Longit. Lunae* — Longitude of the Moon (sign and degrees: O. = degrees, S. = sign / minutes)
- *Latit. Lunae* — Latitude of the Moon (degrees, minutes; A = austral/south, S = septentrional/north — see parsing note)
- *Libratio* — Libration (the selenographic feature against which libration was measured: *P. Maeot.* = *Palus Maeotis*; *P. Maraetot.* = *Palus Mareotis*)
- *Dist. limbi iuxta Obse.* — Distance from the limb according to observation
- *Dist. limbi ex Tab.* — Distance from the limb from the tables

- *Animaduertenda* — Things to be noted (remarks)

In the *Libratio* column the entries alternate between "P. Maeot." (*Palus Maeotis*) and "P. Maraet." (*Palus Mareotis*) — two distinct selenographic features, both transcribed as printed. The longitude column gives a degree-of-sign value followed by a zodiacal sign symbol and then minutes. Zodiacal signs are rendered by their names in brackets.

Parsing notes:

- The *Latit. Lunae* column carries a one-letter direction flag after the minutes: **A** = *Australis* (south) and **S** = *Septentrionalis* (north). These are transcribed verbatim as printed.
- The *Longit. Lunae* sub-headers read **O.** (= *gradus*, degrees) and **S.** (= *signa*, sign) with the zodiacal sign symbol; in each cell the degree-of-sign value precedes the sign symbol, and the minutes follow it. Zodiacal sign identifications are given in brackets; after the focused re-read, nearly all

sign glyphs are resolved with confidence — only the few genuinely ambiguous or gutter-lost glyphs retain a [?].

- The *Hor.* (hour-of-observation) column is frequently blank in the source on pp. 218–219; genuinely blank hour cells are left empty rather than flagged. Hour values are reckoned from noon; values >12 (none here) would not be impossibilities.
- The remarks (*Animaduertenda*) column is set in small italic with heavily abbreviated selenographic place-names (Hevelius's *Selenographia* nomenclature: M. = Mons/Mare, Ins. = Insula, lac. = lacus, etc.) and astronomical symbols (☾ = Moon, ☽ = opposition/full Moon, ◻ = quadrature/last quarter). Abbreviations are expanded in brackets where confident and left as printed (with the abbreviation point) where the expansion is uncertain.
- Two "Dist." columns (*iuxta Obse.* = by observation; *ex Tab.* = from the tables) hold small whole numbers and fractions (½, ⅔, ⅘, 3½, etc.); these are the limb-distances Hevelius is comparing observation against computation. Several anomalous magnitude spikes (13, 13½, 14½, 15, 15½, 25) are flagged as numerical impossibles below and transcribed as printed.

Observations of the libratory motion, both around Palus Maeotis and around Maraotis [Mare Maraoticum], made at Danzig [Gedani] by Johannes Hevelius [Hevelius].

(Table continued from the previous batch. The column headings are: Year [Annus] | Month, day [Mens. dies] | Hour [Hor.] | Moon's longitude [Longit. Lunæ: O. = degrees, S. = sign + minutes] | Moon's latitude [Latit. Lunæ, with A = Australis/south, S = Septentrionalis/north] | Libration [Libratio] | Distance of the limb according to observation [Dist. limbi iuxta Obs.] | Distance of the limb from the table [Dist. limbi ex Tab.] | Remarks [Animadvertenda]. The Libration column reads "P. Mæot." = Palus Maeotis or "P. Maraot." = Palus Maraotis. The italic remarks describe selenographic place-names and the appearance of the libration interstice.)

Parsing notes: This table is dense and the figures partly faint at the gutter and along the inner edge. The Hour column (Hor.) is frequently blank where Hevelius did not record an hour; where a value follows the day in the "Mens. dies" column it is the recorded hour (e.g. "Feb. 1 11" = February 1 at hour 11). The Longitude is split: O. = whole degrees, S. = zodiac sign + minutes; many entries show 0 in one sub-column. Several year-cells in the leftmost column are blank where the year carries down from the row-group above; I have repeated the governing year at each visible group-marker. The 1642 and 1648 year-values that interrupt the otherwise 1648→1654 progression appear as printed (see anomalies). The marginalia symbols ☉ (opposition), ☾ (Moon), □ (a section/quadrant observation marker used by Hevelius), and ♂ are transcribed as printed. Latin selenonyms (Hevelius's *Selenographia* place-names: M. Sinai, Prom. Lunae, Sin. Tarantius, Mons Tabor, Lacus Niger, Mare Maris/Stagnum Miris, Palus Amadoca, Ins. Maris Caspii, etc.) are kept in their abbreviated Latin forms as printed, since they are proper names on Hevelius's lunar map.

Liber III — De Luna (continued)

Pierre Gassendi's Observations of the Librational Motion, both around Palus Maeotis and around Palus Maraotis

[Petri Gassendi Observationes motus Libratorij, tam circa Paludem Maeotidem, quam Maraotidem]

The table records, for each observation: the year; month and day; hour; the Moon's longitude (O. = degrees, S. = zodiacal sign); the Moon's latitude (in degrees and minutes, A = south, S = north); the libration point (P. Maeot. = Palus Maeotis [Mare Crisium]; P. Maraot. = Palus Maraotis); the limb-distance taken from the table [Dist. limbi ex Tab.]; and Gassendi's selenographic remarks on the libration according to his observations [Libratio secundum Observationes].

The Observations of P. Francesco Maria Grimaldi

[P. Francisci Mariae Grimaldi Observationes]

This page is laid out in two columns, each containing several short titled sub-tables. The column scheme for each sub-table is: year; month-day; Moon's longitude (O°. S = sign); Moon's latitude (O'. — A/S); the distance [Distantia]; whether the distance is at maximum or minimum [Maxim. / Minim.]; the value from observation [Ex Obse.]; and the value from the table [Ex Tab.].

Left column

Distance of Mare Crisium, or Palus Maeotis, from the western limb — both according to observation and according to our table, in parts of which the Moon's semidiameter is 100

[Distantia Maris Crisij, sive Palud. Maeotidis à limbo occidentali, tam secundum Observat. quàm nostram tabulam, in partibus qualium Semidiameter Lunae est 100]

Parsing notes: the right column's sub-tables are heavily faded with show-through from the verso; longitude signs and several Ex Obse./Ex Tab. integers are faint. Values transcribed as best read; uncertain cells flagged. The "Febr. 7, 1651" row of the Tycho sub-table shows Ex Tab. "37" against Ex Obse. "17", a large discrepancy that may be a compositor error or a faded misread — flagged.

[Margin / foot of right column, partly illegible analytical note]: *Margin:... Bullialdus, when he reported these observations... in which the macula... is contained: but in our observations and in those communicated to us, the distance is not yet brought into agreement with the Almagestum Novum... [?]*

Liber III — De Luna (continued)

CAPVT XIII.

Brief Reply to Hevelius's Remonstrance. [*Breuis Responsio ad Heuelij expositulata.*]

[Margin: 1] There are two points in all that Hevelius, in the preceding Letter, supposes I have falsely ascribed to him. The first is the permanent residence, throughout this present age, of the maximum libration in Cancer and the minimum in Capricorn — not that he expressly stated this in so many words, but because no one could interpret his remarks otherwise. See Book IV, Chapter 5 of the *Almagestum Novum* [Almagestum Novum]. The second is the perpetual immobility of the libration's limits, which I asserted he held when in fact he taught the opposite.

[Margin: 2] As to the seat of the maximum libration in Cancer and the minimum in Capricorn: I could, on the basis of my own statements, have prudently interpreted this Hevelian view, throughout this present age of ours, as tying that maximum to Cancer and the minimum to Capricorn. For on page 211, number 6, in discussing this Hevelian view, he adds, speaking of it: "If, with the nodes

gradually changing in other respects, the libration may sometimes attain its maximum even in signs other than the ones we are accustomed to celebrate." By contrast, Hevelius, in Chapter 54, page 438, said: "Whether indeed it remains constantly so, the maximum and minimum libration in Cancer and Capricorn, will only be settled by the more prolonged passage of time, since the Moon still undergoes certain irregularities, etc." Therefore, when he uses the observations of Boulliau [Boulliau] and Gassendi [Gassendi], he himself gives no small occasion for supposing that more years are required before the maximum libration migrates from Cancer into another sign — since nonetheless, after a few years, it did migrate. But in truth Hevelius restricts that stationary state in Cancer to the years 1643, 1644, and 1645, and neither asserts anything about the future nor refers it to himself, unless he has something further to set against me. And so I am glad of the opportunity to explain this matter more clearly.

[Margin: 3] But as to what concerns the immobility of the limits: I did not attribute this to him absolutely, nor in that rigorous sense. For in Book IV, page 211, number 17, I retain "the limits of libration" as the very thing Hevelius does — "or as nearly as he taught it." And indeed, by the words of that same Question 7, I said: "It must be conceded by Hevelius, and from many of our own observations it stands certain — frequently confirmed, that the limits are nearly as he himself assigns." For although Hevelius once held those limits to be movable, he nonetheless takes care that the little net of the prior position not be disturbed: "I do not remove the limits in the present sense which he expressly stated"; namely: "Inasmuch as I take my whole position to rest on this opinion — that, with respect to the spots, the limits of maximum and minimum libration in the Moon will never vary, though the libration itself, namely the limits, will, in the same signs, persist permanently — though sometimes, according to the retrograde motion of the nodes from Cancer and Capricorn, advancing step by step." By which words he plainly teaches that the limits of libration do indeed vary, insofar as the lunar limits in the Zodiac, or with respect to the signs of the Zodiac, change; but that with respect to the lunar spots they always remain about the same. Yet afterwards, in the preceding Letter, he introduced a far larger net, and recognized that the line of the limit, distant by 90 degrees from the line of the nodes, ranged through about 35 degrees from the position laid down in Book IV of the *Almagestum Novum*, Chapter 9, Question 7. And from what is to be said below, it will appear far more plainly that those limits err by many more than 35 degrees — to such a degree that they are somewhat notably below the line drawn through the middle of Mare Crisium [Mare Crisium], the Caspian, and the spots of Grimaldi [Grimaldi]; somewhat notably above; namely, to a degree, the line of the limit. Yet truly he questions that the spots laid down in Question 9 have it in their

title: "Whether the limits of the maximum lunar libration lie in a determinate part of the Moon, and the limits of the nodes themselves, or the poles." But let them not perpetually adhere to the same signs. Again, since I give him thanks, because he most learnedly composed the Letter, and lest I should seem to be in doubt by the occasion, I should support it; now we must come down to other observations not commonly published in our *Almagestum*.

CAPVT XIV.

Observations Concerning the Mobility of the Poles, or of the Nodes of the Lunar Libration, from the Year 1649 to 1656. [*Observationes circa Mobilitatem Polorum, seu Nodorum Librationis Lunaris ab Anno 1649. ad 1656.*] For these, the Figure in the *Almagestum Novum*, Book 4, Chapter 7, is to be consulted, or Chapter 11 above.

It pleases me to bring forward here only those Observations from which something is established in some way about the place on the lunar limb of the conjoined Nodes, or of the Poles of the Lunar Libration; and others too, that pertain to libration of this kind. For although those observations exhibit, from one or another spot, only a particular detail of the libration on that particular day, nonetheless they may be compared with other observations which other men perhaps had in those same years; and, made public, they may serve toward the understanding of this period — which is indeed under investigation in the matter of lunar libration, but which we cannot yet perfectly determine — from those things which have hitherto been observed. So that the matter may become clearer, and that under one view the mobility of these Poles may appear, I deduce it from the observations themselves; for they are one and the same — namely, the line of one or the other of the Poles. And because the Lunar Libration itself is divided by us into eight parts, or octants, expressing the Limb itself in the image of the Lunar libration, we set down separately in the lateral column the number of the Octant in which the other Pole appears to be contained in this matter — so that from the twofold position contained here for any one spot, the very Observations may, in conjunction, determine something more accurately as to the said limb. For from the one Pole, the place of the other is at once known, being diametrically opposite.

Anno 1649.

July, day 28. The spot Grimaldi [Grimaldi] was distant from the lunar Limb by exactly as much as had been observed on the immediately preceding days.

Day 30 and 31. Grimaldi stood farther from the lunar limb than on the preceding day.

August 1 and 3. Grimaldi did not vary its distance from the lunar Limb.

Days 13 and 14. Mare Crisium did not vary its distance from the lunar limb, being nearest.

Days 15, 18, 19, and 21. Mare Crisium was increasing its distance from the limb.

Days 23, 24, and 26. Grimaldi was receding from the nearest limb.

Day 29. Grimaldi was receding from the lunar limb, while Plato [Plato] was approaching. From this it is gathered that the Pole of the libration of the other Pole lay between these two spots — that is, in the Octant. [Margin: I.]

Day 30 and 31. Grimaldi was receding from the limb.

September 1 and 2. Grimaldi was receding from the limb.

Days 3 and 4. Grimaldi was approaching the limb.

Days 12, 13, and 14. Mare Crisium was increasing its distance from the lunar limb.

Days 16, 17, 18, and 20. Mare Crisium did not vary its distance from the limb.

Days 23 and 24. Plato was receding from the limb.

Days 26 and 27. Grimaldi and Tycho [Tycho] were receding from the lunar limb; therefore the other Pole was perhaps in the first Octant. [Margin: I.]

Day 28. Grimaldi and Tycho were receding from the limb; but Plato was approaching; therefore the Pole was in the first Octant. [Margin: I.]

[Anno 1649, continued]

Day 29 and 30. Grimaldi was receding from the lunar limb.

October 11, 13, and 14. Mare Crisium was receding from the lunar limb.

November 9. Mare Crisium was approaching the limb.

Days 10, 12, and 13. Mare Crisium and Endymion [Endymion] did not vary their distance from the lunar limb.

Day 14. Mare Crisium was approaching the limb.

Day 21. Grimaldi and Sinus Roris were receding from the lunar limb, and the spots in Terra Siccitatis [the Land of Dryness] did not vary their distance from the lunar limb. Therefore the other of the Poles was perhaps in the second Octant. [Margin: II.]

Days 22, 24, and 25. Grimaldi was receding from the lunar limb, while Sinus Iridum, Plato, and Tycho did not vary. And therefore one of the Poles was perhaps in the second Octant. [Margin: III.]

Day 27. Grimaldi was receding from the limb.

December 9. Mare Crisium and Endymion were receding from the lunar limb, and on that account the Pole was in the first or second Octant. [Margin: I.]

Days 10, 11, and 12. Mare Crisium and Endymion did not vary their distance from the limb. [Margin: II.]

Days 12 and 13. Pitiscus was receding from the limb.

Day 22. Grimaldi was increasing its distance from the lunar limb; Tycho and the spots above Plato did not change theirs. Therefore one Pole was perhaps in the second Octant. [Margin: II.]

Anno 1650.

January 8. Mare Crisium, Endymion, and Pitiscus did not vary their distance from the limb.

Days 9 and 10. Mare Crisium and Endymion did not vary.

Days 11 and 12. Mare Crisium and Endymion were approaching the limb.

Day 14. Mare Crisium and Endymion were approaching the limb; but Tycho was receding; and on that account one of the Poles was in the first Octant. [Margin: I.]

February 9. Mare Crisium and Endymion were approaching the limb; Pitiscus was receding; therefore one of the Poles was in the first Octant. [Margin: I.]

Days 10, 11, and 12. Mare Crisium was approaching the limb; Pitiscus on day 10 was receding.

Days 15 and 16. Mare Crisium did not vary.

Days 17 and 18. Grimaldi was approaching the limb a little; Tycho did not vary.

Day 19. Grimaldi and Tycho were scarcely approaching the limb; Plato was scarcely receding. From this it is gathered that the other Pole was in the first Octant. [Margin: I.]

Days 21 and 22. Grimaldi and Tycho were strongly approaching the limb; but Plato was greatly receding; and so it is confirmed that the Pole was in the first Octant. [Margin: I.]

Days 25 and 26. Grimaldi was approaching the limb.

March 6, 7, and 8. Mare Crisium and Endymion were not approaching the limb.

Days 10, 11, and 12. Mare Crisium was approaching the lunar limb.

Day 13. Mare Crisium was approaching the lunar limb, and Plato and Aristoteles [Aristoteles] were receding from their own nearest limb; on that account the other of the Poles was in the third Octant. [Margin: III.]

Days 15 and 16. Mare Crisium did not vary.

Day 17. Mare Crisium was receding from the limb.

Day 20 and 24. Grimaldi was approaching the lunar limb; therefore one of the Poles was perhaps in the first Octant. [Margin: I.]

April 6. Mare Crisium and Endymion were approaching the lunar limb, and consequently one of the Poles was in the first Octant. [Margin: I.]

Day 7. Mare Crisium and Endymion were approaching the lunar limb; but Pitiscus was receding: whence it is confirmed that the other of the Poles was in the first Octant. [Margin: I.]

Days 9 and 10. Mare Crisium was approaching. Endymion did not vary.

Day 11. Mare Crisium and Endymion did not vary. Tycho was scarcely increasing its distance from the limb.

Day 12. Mare Crisium did not vary. Tycho was approaching the limb.

[Anno 1650, continued]

Days 13, 14, and 15. Tycho was approaching. Mare Crisium, Endymion, Aristoteles, and Plato were receding from the limb; on that account the Pole was in the first Octant. [Margin: I.]

Day 16. Tycho was approaching. Plato was receding.

Days 20, 21, and 23. Grimaldi was approaching.

Day 24. Grimaldi was approaching a little.

Day 25. Grimaldi was approaching, but on days 26 and 27 it did not vary.

May, day 7. Endymion did not vary. Mare Crisium was approaching the limb a little.

Days 11, 12, and 13. Endymion was receding from the limb.

Day 14. Mare Crisium, Endymion, and Aristoteles were receding from the limb.

Days 19 and 20. Tycho was approaching the limb. Plato was receding. Grimaldi was approaching a little. From these gather that the Pole was at the beginning of the Octant.

Day 24. Grimaldi was approaching the limb.

June 4, 5, and 6. Mare Crisium did not vary. Endymion was approaching the limb.

Days 10, 11, and 12. Mare Crisium and Endymion were receding from the limb. Tycho was approaching. The Pole therefore was in the Octant.

Day 18. Grimaldi was approaching the limb, and on days 23 and 24 it was already receding from the same.

July 4. Mare Crisium and Endymion were receding from the lunar limb.

Day 5. Mare Crisium and Endymion were receding from the lunar limb. Pitiscus was approaching. Therefore the Pole was in the Octant. [Margin: I.]

Day 7. Mare Crisium was receding from the limb.

Day 12. Mare Crisium was receding. Tycho was approaching the lunar limb; therefore the Pole was at the very beginning of the Octant. [Margin: I.]

Days 17, 18, 19, and 21. Grimaldi did not vary.

Days 22 and 23. Grimaldi was receding from the limb.

August 2, 3, 4, and 5. Mare Crisium and Endymion were approaching the limb. Pitiscus did not vary; from which the other of the Poles is detected to be in the Octant.

Days 6, 7, 8, and 9. Mare Crisium and Endymion were receding from the lunar limb.

Days 11 and 13. Tycho and Grimaldi were approaching the limb. Therefore the other of the Poles was in the Octant. [Margin: I.]

Days 15 and 16. Tycho and Grimaldi did not vary.

Day 17 to 22. Grimaldi was receding from the limb.

Days 30 and 31. Mare Crisium was receding from the limb.

September 1 and 4. Mare Crisium was receding from the lunar limb.

Days 5 and 7. Mare Crisium and Endymion were receding from the limb. But Tycho was approaching. Gather that one Pole was in the first Octant. [Margin: I.]

Day 8. Mare Crisium was receding from the limb. Tycho and Endymion did not vary.

Day 9. Mare Crisium, Endymion, and Tycho did not vary.

Day 12 to 18. Grimaldi and Tycho were receding from the limb. But Plato was approaching. The Pole was in the first Octant. [Margin: I.]

Days 19 and 20. Grimaldi was receding from the limb.

Days 29 and 30. Mare Crisium was receding from the limb. Endymion, however, and Pitiscus did not vary. The Pole therefore was perhaps at the beginning of the Octant. [Margin: I.]

October 2 and 3. Mare Crisium and Endymion were receding from the limb. Pitiscus was approaching: and on that account the Pole was in the first Octant. [Margin: I.]

Days 7 and 8. Mare Crisium, Endymion, Aristoteles, and Tycho did not vary.

Day 9. Mare Crisium, Endymion, and Aristoteles were approaching the limb. Tycho, however, was receding: on that account it must be said that the Pole was in the Octant. [Margin: I.]

Day 11 and 12. Grimaldi was receding from the limb. Tycho and Plato did not vary.

Day 15. Grimaldi and Tycho were receding from the limb, but Plato was approaching. It is shown that the Pole was in the Octant. [Margin: I.]

Day 16. Grimaldi and Tycho were receding from the limb.

Day 20. Grimaldi was receding from the lunar limb.

Days 21, 22, and 23. Grimaldi was approaching the limb.

[Anno 1650, continued]

Days 29 and 30. Mare Crisium and Endymion were receding from the lunar limb. Pitiscus was approaching: on that account it could be believed that the Pole was in the first Octant. [Margin: I.]

Day 31. Mare Crisium and Endymion were increasing their distance from the lunar limb.

November 2. Mare Crisium, Endymion, and the spots in Terra Siccitatis were receding from the lunar limb.

Day 3. Mare Crisium, Endymion, and Tycho were receding; and consequently the other of the Poles was perhaps in the first Octant. [Margin: I.]

Day 6. Mare Crisium and Endymion did not vary. Tycho was receding from the limb.

Days 9 and 10. Grimaldi and Tycho were receding from the limb. Sinus Roris did not vary; therefore the Pole was confirmed to be in the first Octant. [Margin: I.]

Days 11 and 12. Tycho did not vary. Grimaldi was receding from the lunar limb.

Day 28. Mare Crisium was increasing its distance from the lunar limb.

Day 29. Mare Crisium, Endymion, and Pitiscus were receding from the limb; on that account one of the Poles was in the second Octant. [Margin: II.]

December 9. Mare Crisium, Endymion, and Pitiscus did not vary.

Days 5, 6, and 7. Mare Crisium and Endymion were approaching the lunar limb. Tycho was receding. And the Pole was in the Octant.

Day 8. Tycho was receding from the lunar limb.

Days 12, 13, and 14. Harpalus in Sinus Roris was approaching the lunar limb; on that account the Pole was in the Octant. [Margin: I.]

Day 18. Grimaldi was beginning to approach the lunar limb.

Days 28 and 29. Mare Crisium was receding from the limb.

Day 30. Mare Crisium did not vary.

Day 31. Mare Crisium and Endymion were approaching the lunar limb. Pitiscus was receding; therefore the Pole must be said to have been in the libration's Octant. [Margin: I.]

Anno 1651.

January 1. Mare Crisium, Endymion, and Aristoteles were approaching the lunar limb. Pitiscus was receding; therefore the Pole was then in the Octant. [Margin: I.]

Days 8 and 9. Grimaldi was receding from the lunar limb. Tycho and Harpalus did not vary.

Day 14. Grimaldi was receding from the limb.

Day 31. Mare Crisium was approaching the limb.

February 3. Mare Crisium and Plato were approaching the lunar limb. Tycho was receding; on that account the other of the Poles was in the Octant. [Margin: I.]

Days 5, 6, and 7. Tycho and Grimaldi were receding from the limb. Plato, however, was approaching: from which gather that the Pole was in the Octant. [Margin: I.]

Day 9. Grimaldi did not vary. Plato and Harpalus in Sinus Roris were receding from the lunar limb; from which it is argued that the Pole was in the Octant. [Margin: III.]

Days 11 and 12. Grimaldi, Harpalus, and Plato were receding from the lunar limb. Tycho was approaching; and on that account the Pole must be said to have been in the Octant. [Margin: IV.]

Days 13 and 14. Grimaldi did not vary. Tycho was approaching the limb. Harpalus and Plato were receding from the lunar limb; whence it is gathered that the Pole was in the Octant. [Margin: III.]

Days 15 and 16. Grimaldi was already approaching the lunar limb. [Margin: IV.]

Day 27. Mare Crisium was approaching the lunar limb.

Day 28. Mare Crisium and Endymion were approaching the lunar limb.

March 1, 2, 4, and 6. Mare Crisium was approaching the lunar limb. Tycho did not vary.

Day 7. Grimaldi, Harpalus, Plato, and Endymion were receding from the limb; on that account the Pole was in the Octant. [Margin: III.]

Days 8 and 9. Grimaldi was receding from the limb.

Day 25. Mare Crisium was approaching the lunar limb.

Day 27. Mare Crisium and Endymion were approaching the lunar limb a little.

Days 28, 29, and 30. Mare Crisium, Endymion, and the spots in Terra Siccitatis were approaching the lunar limb, and on that account the Pole was in the Octant. [Margin: I.]

Day 31. Mare Crisium was approaching the lunar limb.

April 1 and 2. Mare Crisium and the spots in Terra Siccitatis were approaching the lunar limb.

Day 4. Mare Crisium and Plato did not vary.

Day 5. Mare Crisium, Plato, and Endymion were receding from the limb, and consequently the other of the Poles was in the Octant. [Margin: I.]

Day 6. Plato was receding from the lunar limb. Tycho did not vary.

Days 11 and 13. Grimaldi was approaching the limb.

Day 25. Mare Crisium was approaching the limb.

Day 26. Mare Crisium and Endymion were approaching the lunar limb.

Day 28. Pitiscus and Mare Crisium were approaching the lunar limb. Endymion and Aristoteles were receding from the lunar limb: with these positions laid down, one of the Poles was in the Octant. [Margin: III.]

Day 30. Mare Crisium was approaching the lunar limb. Endymion and Aristoteles were receding from the limb; and from these it is confirmed that the Pole was in the Octant. [Margin: III.]

May 1, 2, and 3. Mare Crisium and Tycho were approaching the lunar limb. Endymion and Aristoteles also were receding. Therefore the Pole was in the Octant. [Margin: III.]

Day 13. Grimaldi did not vary: the spots in Sinus Roris were receding a little from the limb. Tycho was approaching.

Day 14. Grimaldi was approaching the limb.

Days 27, 28, and 29. Mare Crisium was approaching the lunar limb. Endymion, however, and the spots in Terra Siccitatis were receding from the limb: and so the Pole must be said to have been in the Octant. [Margin: III.]

Days 30 and 31. Mare Crisium did not vary. Endymion and the spots in Terra Siccitatis were receding from the limb. Tycho, however, was approaching. The Pole therefore was in the Octant. [Margin: III.]

June 1, 2, and 3. Mare Crisium, Endymion, and the spots in Terra Siccitatis were receding from the lunar limb; Tycho on that account was approaching: on that account the Pole must be said to have been in the Octant. [Margin: IV.]

Days 13 and 14. Grimaldi did not vary. [Margin: IV.]

Day 23. Mare Crisium and Endymion did not vary. [Margin: I.]

Day 24. Mare Crisium did not vary. Endymion was increasing its distance from the lunar limb a little.

Day 26. Mare Crisium did not vary. Endymion was receding from the lunar limb. Pitiscus was approaching. Therefore one Pole was in the Octant. [Margin: IV.]

Days 27. Endymion and Aristoteles were receding from the limb. Langrenus and Pitiscus were approaching: therefore the Pole was in the Octant. [Margin: IV.]

July 1. Langrenus, Mare Crisium, Endymion, Aristoteles, Plato, and Sinus Roris were receding from the lunar limb. Tycho was approaching: from which it is fitting that the Pole was in the Octant. [Margin: IV.]

Day 2. Mare Crisium and Endymion were receding from the lunar limb. Tycho was approaching.

Days 3, 6, and 7. Grimaldi and Tycho were approaching the lunar limb.

Day 8. Grimaldi was approaching the lunar limb.

Day 9. Grimaldi was scarcely approaching. Tycho did not vary.

Day 11. Grimaldi and Tycho were receding from the limb. Harpalus and Plato were approaching: on that account the Pole was in the Octant. [Margin: III.]

Day 22 to 25. Mare Crisium did not vary. Endymion was receding from the lunar limb. Pitiscus was approaching. Therefore the Pole was in the Octant. [Margin: IV.]

Day 27 to August 1. Mare Crisium, Endymion, and Plato were receding from the lunar limb; that which indicate the Pole to have been in the Octant. [Margin: I.] [Margin: IV.]

August 3, 4, and 5. Tycho did not vary. Grimaldi and Harpalus in Sinus Roris were approaching the limb. Wherefore the Pole of the libration must be said to have been in the Octant. [Margin: II.]

Days 6 and 8. Grimaldi was scarcely approaching. Harpalus and Plato — [Margin: III.]

Liber III — De Luna (continued)

Caput XIV (continued): Observations on the Mobility of the Poles, or Nodes, of the Lunar Libration, from 1649 to 1656

[This batch continues the day-by-day catalogue. Each entry records which named lunar spots approached (accedebat) or receded from (recedebat) the Moon's limb on a given day, whether others remained unchanged (non variabat), and the libration-pole octant inferred from this, given in the source as a marginal Roman numeral I–IV. I have preserved the inferred octant at the end of each entry as a marginal note, e.g. [Margin: Octant III].]

Plato was approaching the Moon's limb; Tycho was receding. Therefore the Pole was in the octant. [Margin: Octant III]

Day 9. Harpalus was approaching the Moon's limb; Tycho was receding.

Day 10. Grimaldi and Harpalus were receding from the Moon's limb [Grimaldi marked with the spot-symbol ☉].

Days 11 & 12. Grimaldi was receding from the limb [☉].

Day 20, 21 & 22. Mare Crisium did not change; Endymion was receding from the limb [☉].

Days 23, 25 & 27. Mare Crisium, Langrenus, and Endymion were receding from the limb [☉]; Pitiscus was scarcely approaching. Therefore the Pole was in the octant. [Margin: Octant I]

Days 28, 29 & 30. Mare Crisium, Langrenus, Endymion, and Aristoteles were receding from the Moon's limb; Tycho and Plato did not change. Therefore the Pole was in the octant. [Margin: Octant II]

Day 31. Tycho did not change; Grimaldi, Harpalus, Plato, and Aristoteles were approaching the Moon's limb. The Pole was therefore in the octant. [Margin: Octant III]

September 1, 2 & 3. Grimaldi, Harpalus, and Plato were approaching the Moon's limb; Tycho, however, was receding. The Pole may therefore be said to have been in the octant. [Margin: Octant III]

Day 4. Grimaldi did not change; Tycho was receding from the limb [☉]; Harpalus and Plato were approaching the limb [☉]. Therefore the Pole was in the octant. [Margin: Octant III]

Day 6. Tycho and Grimaldi were receding from the limb [☉]; Harpalus and Plato were approaching. Thus the Pole was in the octant. [Margin: Octant III, alternatively IV]

Day 8. Tycho and Grimaldi were receding from the Moon's limb; Harpalus was approaching slightly. Therefore the Pole was in the octant. [Margin: Octant IV]

Days 18 & 19. Mare Crisium did not change; Endymion was receding from the Moon's limb.

Day 20. Mare Crisium was receding slightly from the limb [☉]; Endymion was strongly receding; Langrenus did not change; Pitiscus was approaching. Therefore the other of the Poles was in the octant. [Margin: Octant I]

Days 22, 23 & 24. Mare Crisium and Endymion were receding; Langrenus did not change. And so the Pole was in the octant. [Margin: Octant I]

Days 25 & 26. Mare Crisium and Langrenus were receding from the limb [☉]; Endymion and Tycho did not change. Accordingly the Pole was one in the octant. [Margin: Octant II]

Day 27. Mare Crisium, Langrenus, and Tycho were receding from the limb [☉]; Harpalus and Plato were approaching the limb. Therefore one of the Poles was in the octant. [Margin: Octant III]

October 3 & 4. Tycho, Grimaldi, Harpalus, and Plato did not change.

Day 20. Mare Crisium and Endymion were receding from the Moon's limb.

Day 27. Mare Crisium was receding from the Moon's limb.

November 20 & 21. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion and Aristoteles did not change. Therefore the Pole was in the octant. [Margin: Octant I]

Days 22, 23 & 25. Mare Crisium, Langrenus, and Tycho were receding from the Moon's limb; Endymion, Aristoteles, and Plato were approaching the limb. The Pole was therefore in the octant. [Margin: Octant III]

Day 26. Mare Crisium did not change; Langrenus and Tycho were receding; Endymion and Plato were approaching. And so the Pole was in the octant. [Margin: Octant IV]

Day 27. Tycho was receding; Harpalus was approaching the Moon's limb.

Day 28. Grimaldi and Harpalus were approaching the Moon's limb; Tycho and Plato did not change.

Day 30. Harpalus and Tycho did not change; Grimaldi was receding.

December 1. Grimaldi was receding from the limb [☉]; Tycho, Harpalus, and Plato did not change.

Day 5. Grimaldi, Harpalus, and Plato were receding from the Moon's limb [☉]; Tycho did not change. Accordingly the Pole was therefore in the octant. [Margin: Octant III]

Day 6. Grimaldi and Harpalus were receding from the limb [☉].

Day 20. Mare Crisium did not change.

Day 30. Grimaldi, Harpalus, and Plato were receding. ...from the Moon's limb; Tycho was approaching. From this the Pole is gathered to be in the octant. [Margin: Octant III]

Anno 1652.

January 17, 20 & 21. Mare Crisium did not change; Endymion was approaching; Langrenus and Pitiscus were receding from the limb; and on that account the Pole was in the octant. [Margin: Octant III]

February 1. Grimaldi was receding from the Moon's limb. [Margin: Octant IV]

Day 2. Grimaldi and Sinus Roris were receding from the Moon's limb. [Margin: Octant IV]

Day 3. Grimaldi did not change; Sinus Roris was receding from the Moon's limb.

Days 14 & 16. Mare Crisium did not change; Endymion was approaching; Langrenus and Pitiscus were receding from the Moon's limb; whence it is argued that the Pole was in the octant. [Margin: Octant III]

Days 18, 21 & 22. Langrenus, Mare Crisium, Endymion, Plato were approaching the limb [☉]. Therefore the Pole was in the octant. [Margin: Octant IV]

Day 26. Tycho was approaching the Moon's limb. [Margin: Octant I]

March 26. Grimaldi and the Ecliptic Shore [Littus Eclipticum] were receding from the limb.

May 15 & 16. Mare Crisium and Langrenus did not change; Endymion was receding; Langrenus was approaching the Moon's limb. Therefore the Pole was perhaps in the octant. [Margin: Octant IV]

Days 19 & 20. Endymion was receding; Mare Crisium and Langrenus were approaching the Moon's limb; Tycho did not change. The Pole was therefore in the octant. [Margin: Octant III]

Day 21. Endymion was receding; Mare Crisium, Langrenus, and Tycho were approaching the Moon's limb, on which account the Pole is confirmed to be in the octant. [Margin: Octant III]

Day 22. Mare Crisium and Endymion did not change; Langrenus and Tycho were approaching the Moon's limb slightly.

Day 28. Grimaldi did not change; Tycho was approaching the Moon's limb.

Days 30 & 31. Tycho, Grimaldi, the Ecliptic Shore, and Sinus Roris were approaching the limb [☉]. Therefore it is said that the Pole was at the beginning of the octant. [Margin: Octant II]

June 1. Grimaldi, the Ecliptic Shore, and Sinus Roris were approaching the Moon's limb; Kircher and Bettinus were receding from the limb. And so the Pole was in the octant. [Margin: Octant III]

Day 3. Grimaldi was approaching the Moon's limb.

Day 12. Endymion was receding from the Moon's limb.

Day 16. Mare Crisium was scarcely approaching the limb [☉]; Langrenus and Pitiscus were approaching the Moon's limb; Endymion, however, was receding. The Pole was therefore in the octant. [Margin: Octant III]

Day 18. Endymion was receding; Mare Crisium and Langrenus were approaching the Moon's limb; from which the Pole is confirmed to be in the octant. [Margin: Octant III]

Day 19. Endymion was receding; Mare Crisium, Langrenus, and Tycho were approaching the Moon's limb; and so the Pole is again confirmed to be in the octant. [Margin: Octant III]

Day 21. Mare Crisium and Langrenus did not change; Tycho was approaching the Moon's limb slightly.

Day 27. Tycho was receding from the Moon's limb; Plato and Sinus Roris were approaching the Moon's limb.

Day 28. Tycho was receding; Grimaldi, Sinus Roris, and Plato were approaching the Moon's limb. From this the Poles are deduced to have been in the octant. [Margin: Octant III]

Day 30. Grimaldi and the Ecliptic Shore were approaching the Moon's limb; Zucchius, Bettinus, and Kircher were receding from the limb. From which the Pole is confirmed in the octant. [Margin: Octant III]

July 1. Grimaldi did not change; Harpalus was approaching the Moon's limb; Zucchius, Bettinus, and Kircher were receding from the Moon's limb. The Pole was therefore in the octant. [Margin: Octant III, alternatively IV]

Day 2. Grimaldi did not change.

Days 10 & 11. Mare Crisium did not change; Endymion was receding; Langrenus was approaching the Moon's limb. On that account the Pole is to be said to have been in the octant. [Margin: Octant III]

Day 13. Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb slightly; Endymion was receding. Therefore the Pole was in the octant. [Margin: Octant III, alternatively IV]

Day 14. Mare Crisium did not change notably; Endymion was receding; Langrenus and Pitiscus were approaching the limb [☉]; and on that account the Pole was in the octant. [Margin: Octant III]

Day 15. Mare Crisium, Langrenus, and Pitiscus were approaching... [Margin: Octant III, alternatively IV]

the limb [☉]; Endymion and Plato were receding from the limb. From which the Pole is held to have been in the octant. [Margin: Octant...]

Days 16 & 17. Mare Crisium, Langrenus, and Endymion did not change; Tycho was approaching the Moon's limb; Aristoteles was receding.

Day 19. Endymion, Mare Crisium, Langrenus, and Furnerius were approaching slightly the Moon's limb; Tycho was approaching. The Pole was therefore in the octant. [Margin: Octant I]

Day 20. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Tycho did not change.

Day 21. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Tycho and Sinus Roris did not change. Hence gather the Pole to have been in the octant. [Margin: Octant...]

Day 22. Grimaldi was approaching the Moon's limb; Tycho and Sinus Roris did not change. [Margin: Octant IV]

August 9, 11, 12 & 13. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion was receding — at which time the Pole is to be said to have been in the octant. [Margin: Octant...]

Day 14. Mare Crisium did not change.

Day 15. Mare Crisium was now receding from the Moon's limb; Endymion did not change.

Day 16. Mare Crisium, Langrenus, Furnerius, and Tycho were receding from the Moon's limb; Endymion did not change, and accordingly the Pole was in the octant. [Margin: Octant...]

Day 17. Mare Crisium, Langrenus were receding from the Moon's limb; Endymion did not change.

Day 18. Mare Crisium, Langrenus, and Tycho were receding from the Moon's limb; Plato was approaching. Therefore the Pole was in the octant. [Margin: Octant...]

Day 19. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Tycho did not change.

Day 20. Grimaldi, the Ecliptic Shore, and Plato were approaching the Moon's limb; Tycho did not change. Therefore the Pole was in the octant. [Margin: Octant...]

Days 22, 23 & 24. Grimaldi, the Ecliptic Shore, Harpalus, and Plato were approaching the Moon's limb; Tycho and Schillerus [Schillerus] were receding from the Moon's limb. And so the Pole was in the octant. [Margin: Octant III, alternatively IV]

Day 26. Grimaldi, Harpalus, and Plato were approaching the Moon's limb; Tycho was receding. Therefore the Pole is confirmed in the octant. [Margin: Octant...]

September 9. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion was receding. Therefore the Libration Pole was in the octant. [Margin: Octant...]

Day 12. Mare Crisium and Langrenus were receding from the limb.

Days 13, 14 & 15. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion did not change.

Day 16. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion, however, was approaching. Therefore the Pole was in the octant. [Margin: Octant...]

Day 17. Mare Crisium, Langrenus, Pitiscus, and Tycho were receding from the Moon's limb; Endymion and Plato were approaching the Moon's limb. And so the Pole was one in the octant. [Margin: Octant...]

Day 18. Tycho was receding from the limb; Grimaldi and Plato were approaching the Moon's limb. And so the other Pole was in the octant. [Margin: Octant...]

Day 19. Grimaldi, Harpalus, and Plato were approaching the Moon's limb; Tycho and Schikardus [Schikardus] were receding from the limb. Whence the Pole is to be said to have been in the octant. [Margin: Octant...]

Day 20. Grimaldi was approaching the Moon's limb; Schikardus, however, was receding. Therefore the Pole was in the octant. [Margin: Octant...]

Day 22. Grimaldi, Harpalus, and Plato were approaching the Moon's limb; Schikardus indeed was receding; from which it is further confirmed the Pole was still in the octant. [Margin: Octant...]

Day 26. Grimaldi did not change; Harpalus and Plato were approaching the Moon's limb.

October 13 & 14. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion did not change.

Day 15. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion was approaching. Therefore the Pole was in the octant. [Margin: Octant III]

Day 16. Mare Crisium did not change; Langrenus and Furnerius were strongly receding from the Moon's limb; Endymion was approaching the limb. The Pole was therefore still in the octant. [Margin: Octant III]

Day 17. Langrenus, Furnerius, and Tycho were receding from the Moon's limb; Grimaldi, the Ecliptic Shore, and Plato were approaching the Moon's limb. On that account the Pole is to be said to have been in the octant. [Margin: Octant III]

Day 18. Tycho was receding from the Moon's limb; Grimaldi, Harpalus, and Plato were approaching the Moon's limb. From which the Pole is confirmed in the octant. [Margin: Octant III]

November 11 & 12. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion was approaching. And so the Pole was detected in the octant. [Margin: Octant...]

Day 13. Mare Crisium did not change notably; Langrenus and Pitiscus were receding; Endymion and Plato were approaching the limb.

Day 14. Mare Crisium, Langrenus, and Pitiscus were receding from the limb; Endymion and Plato were approaching the limb. From which again follows the Pole to have been in the octant. [Margin: Octant...]

Day 18. Grimaldi, Harpalus, and Plato did not change; Tycho was approaching the Moon's limb slightly.

Day 27. Grimaldi and the Ecliptic Shore were receding from the Moon's limb.

December 6 & 7. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion did not change.

Days 8 & 9. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion was approaching. Accordingly the Pole was in the octant. [Margin: Octant...]

Day 11. Mare Crisium, Langrenus were receding from the Moon's limb; Endymion was approaching. And this is confirmed: the Pole was in the octant. [Margin: Octant III]

Day 12. Mare Crisium and Endymion did not change notably; Langrenus, Furnerius, and Claramontius [Claramontius] were receding from the Moon's limb.

Day 13. Mare Crisium, Langrenus, Furnerius, and Claramontius were receding from the Moon's limb; Endymion did not change; Plato was approaching the Moon's limb. With these granted, the Pole was in the octant. [Margin: Octant...]

Days 17 & 18. Grimaldi did not change; Tycho was approaching; Harpalus and Plato were approaching the limb [☉]. [Margin: Octant IV]

Day 20. Tycho was approaching the Moon's limb; Grimaldi, Harpalus, and Plato were approaching the Moon's limb; consequently the Pole was in the octant. [Margin: Octant III]

Days 21 & 22. Plato and Tycho did not change; Grimaldi, Harpalus, and the Ecliptic Shore were receding from the Moon's limb.

Day 23. Grimaldi, Harpalus, and the Ecliptic Shore were receding from the Moon's limb.

Anno 1653.

January 6. Mare Crisium, Langrenus, and Petavius [Petavius] were receding from the Moon's limb; Endymion was approaching. The Libration Pole was in the octant. [Margin: Octant...]

Day 7. Mare Crisium was receding slightly from the limb; Langrenus and Petavius were strongly receding from the Moon's limb; Endymion did not change.

Day 8. Mare Crisium, Langrenus, Petavius, and Claramontius were receding from the Moon's limb; Endymion did not change.

Day 9. Mare Crisium was receding slightly; Petavius and Claramontius were receding from the limb [☉]; Endymion was scarcely approaching, and so the Pole was in the octant. [Margin: Octant III]

Days 10 & 12. Mare Crisium was approaching slightly; Langrenus and Petavius were receding from the Moon's limb; Endymion did not change appreciably.

Day 14. Tycho, Grimaldi, and Harpalus did not change.

Day 15. Tycho and Grimaldi did not change; the Ecliptic Shore, Harpalus, and Plato were receding from the Moon's limb.

Day 16. Grimaldi did not change; the Ecliptic Shore, Harpalus, and Plato were receding from the Moon's limb. On that account the Pole is said to have been in the octant. [Margin: Octant III]

February 2. Mare Crisium, Langrenus, and Petavius were receding from the Moon's limb; Endymion did not change.

Day 7. Mare Crisium was receding slightly from the limb [☉].

Day 9. Endymion was receding from the Moon's limb.

Day 10. Mare Crisium and Endymion were receding from the Moon's limb; Pitiscus was approaching. Therefore the Pole is to be said to have been in the octant. [Margin: Octant I]

March 2. Messhala [Messhala] did not change; Furnerius was receding from the Moon's limb.

Day 3. Messhala and Furnerius were receding from the limb [☉].

Day 7. Mare Crisium and Langrenus were receding from the Moon's limb.

Day 10. Mare Crisium was scarcely approaching the Moon's limb; Plato was receding from the Moon's limb; Furnerius was approaching; and so the Pole is to be said to have been in the octant. [Margin: Octant IV]

Day 11. Mare Crisium did not change; Langrenus and Furnerius were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. For that reason the Pole was in the octant. [Margin: Octant III]

Day 12. Mare Crisium, Langrenus, and Furnerius were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. Therefore the Libration Pole was in the octant. [Margin: Octant III, alternatively IV]

Day 13. Mare Crisium, Langrenus, Furnerius, and Tycho were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. From which the Pole is confirmed in the octant. [Margin: Octant III]

Day 14. Harpalus and Plato were receding from the Moon's limb.

Day 15. Harpalus and Plato were receding from the Moon's limb; Tycho was approaching; Grimaldi did not change.

April 1 & 2. Mare Crisium and Seneca [Seneca] were near it, and likewise Langrenus was approaching the Moon's limb.

Day 3. Mare Crisium and Langrenus were receding from the Moon's limb; Endymion did not change.

Day 4. Mare Crisium and Langrenus were receding from the Moon's limb.

Day 7. Mare Crisium was scarcely receding; Endymion too was receding from the Moon's limb.

Day 8. Mare Crisium and Langrenus did not change; Endymion was receding from the Moon's limb.

Day 10. Endymion was receding from the Moon's limb; Langrenus and Pitiscus were approaching the Moon's limb. Therefore the Pole was in the octant. [Margin: Octant III]

Days 19 & 20. Grimaldi and the Ecliptic Shore were approaching the Moon's limb; Tycho did not change; Plato and Sinus Roris were scarcely approaching the Moon's limb. [Margin: Octant III, alternatively IV]

Day 22. Grimaldi was approaching the limb slightly from the Moon's limb; the Ecliptic Shore and Harpalus were approaching the Moon's limb, and consequently the Pole was argued to be in the octant. [Margin: Octant IV]

Day 23. Grimaldi was receding from the Moon's limb; the Ecliptic Shore was approaching the Moon's limb, and so the Pole is confirmed in the octant. [Margin: Octant IV]

May 2 & 3. Mare Crisium, Endymion, and Langrenus were receding from the Moon's limb.

Day 4. Endymion and Mare Crisium were receding from the Moon's limb; Langrenus did not change.

Days 6 & 7. Mare Crisium did not change; Endymion was receding; Langrenus and Pitiscus were approaching the Moon's limb. The Pole was therefore in the octant. [Margin: Octant III]

Day 8. Endymion was receding; Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb. Therefore the Pole was in the octant. [Margin: Octant III, alternatively IV]

Day 9. Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb; Endymion and Aristoteles were receding from the limb. And the Pole was hence confirmed in the octant. [Margin: Octant III]

Day 10 & 11. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion did not change.

Day 14. Tycho, Riccioli, and the Ecliptic Shore were receding from the Moon's limb; Sinus Roris did not change.

Day 17. Grimaldi and the Ecliptic Shore were receding from the Moon's limb; Tycho and Sinus Roris did not change.

Day 19. Tycho and Sinus Roris did not change; the Ecliptic Shore was approaching the Moon's limb; Grimaldi did not change.

Day 20. Grimaldi did not change; the Ecliptic Shore and Sinus Roris were approaching the limb.

Days 21 & 22. Grimaldi did not change; Schikerus [Schikerus] was receding; the Ecliptic Shore and Sinus Roris were approaching...

the Moon's limb. From which the Pole is gathered to have been in the octant. [Margin: Octant III]

Day 30. Mare Crisium and Endymion did not change. [Margin: Octant IV, alternatively...]

Day 31. Mare Crisium did not change; Endymion was receding from the Moon's limb. [Margin: Octant IV]

June 1. Mare Crisium and Endymion were receding from the Moon's limb; Langrenus was approaching. Therefore the Pole was in the octant. [Margin: Octant IV]

Day 3. Mare Crisium and Endymion did not change; Langrenus was approaching the Moon's limb.

Day 5. Endymion did not change; Mare Crisium and Langrenus were approaching the Moon's limb.

Days 6, 7, 8 & 9. Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb; Endymion did not change. Therefore the Pole was in the octant. [Margin: Octant III]

Day 10. Endymion, Mare Crisium, Langrenus, and Pitiscus were approaching the Moon's limb. The Pole was therefore in the octant. [Margin: Octant II]

Day 11. Tycho did not change.

Day 16. Grimaldi did not change; the Ecliptic Shore was approaching.

Days 18 & 20. Grimaldi, the Ecliptic Shore, and Sinus Roris were approaching the Moon's limb; Tycho was receding from the limb. Therefore the Pole was in the octant. [Margin: Octant III]

July 1. Mare Crisium and Langrenus did not change; Endymion was receding from the Moon's limb.

Days 4 & 5. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion did not change.

Day 7. Mare Crisium, Langrenus, and Pitiscus did not change.

Day 9. Mare Crisium, Langrenus, and Pitiscus did not change; Endymion was scarcely approaching the Moon's limb.

Day 13. Grimaldi was receding from the Moon's limb; the Ecliptic Shore was approaching. Therefore the Pole was at the libration in the octant. [Margin: Octant IV]

Day 14. Tycho and Grimaldi were receding from the limb [☉]; the Ecliptic Shore and Sinus Roris were approaching the limb; and so the Pole was in the octant. [Margin: Octant IV]

Day 15. Grimaldi did not change; Tycho was approaching; the Ecliptic Shore and Sinus Roris were approaching the Moon's limb. And consequently the Pole was in the octant. [Margin: Octant III]

Days 17 & 18. Tycho was receding; Grimaldi, the Ecliptic Shore, Sinus Roris, and Plato were approaching the limb [☉]. From which the Pole is deduced to have been in the octant. [Margin: Octant III, alternatively IV]

Day 21. Grimaldi was approaching the Moon's limb.

Day 30. Mare Crisium was scarcely approaching the Moon's limb; Endymion was receding. Therefore the Pole was in the octant. [Margin: Octant III]

August 1, 3 & 5. Mare Crisium and Langrenus were approaching the Moon's limb; Endymion did not change.

Day 6. Mare Crisium, Langrenus, and Pitiscus did not change; Endymion was scarcely approaching the limb [☉].

Days 7 & 8. Mare Crisium did not change; Endymion was approaching; Langrenus and Pitiscus were approaching the Moon's limb.

Day 11. Tycho was receding; Plato and Sinus Roris were approaching the limb.

Days 12, 13 & 15. Tycho was receding; Grimaldi, Sinus Roris, and Plato were approaching the Moon's limb. The Pole was therefore on that account in the octant. [Margin: Octant III]

Days 18 & 19. Grimaldi and Sinus Roris were approaching the limb.

October 6. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion was approaching. On that account the Pole was in the octant. [Margin: Octant III]

Day 29. Mare Crisium did not change; Endymion was approaching; Langrenus and Pitiscus were receding from the Moon's limb.

November 1 & 3. Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb; Endymion was approaching. On that account the Pole in the octant. [Margin: Octant III]

Days 28 & 29. Mare Crisium did not change; Langrenus, Furnerius, and Pitiscus were receding from the Moon's limb.

December 1, 3 & 4. Mare Crisium, Langrenus, and Furnerius were receding from the Moon's limb; Endymion did not change.

Days 5 & 6. Grimaldi was approaching the Moon's limb.

Days 7 & 8. Tycho, Grimaldi, Sinus Roris, and Plato were approaching the limb [☉]. Therefore the Pole was in the octant. [Margin: Octant II]

Liber III — De Luna (continued)

Caput XIV (continued) — Day-by-day libration-pole catalogue

(Catalogue continued from the prior batch; entries record which named lunar spots approached or receded from the Moon's limb, with the inferred octant of the libration pole given as a marginal Roman numeral.)

[Year] 1654 (*continued from 1653; the 1654 heading appears mid-column on this page*)

- Dec. 9: Tycho was approaching the Moon's limb. Grimaldus did not vary.
- Dec. 29: Mare Crisium, Langrenus, and Pitiscus were receding from the Moon's limb.

Anno 1654.

- Jan. 1: Mare Crisium and Langrenus were receding from the Moon's limb.
- Jan. 3: Endymion was receding from the Moon's limb. Tycho was approaching.

- Jan. 4: Tycho was approaching. Grimaldus, Harpalus, and Plato did not vary.
- Jan. 6 and 7: Grimaldus did not vary. Tycho was approaching. Plato was receding from the Moon's limb.
- Jan. 25: Mare Crisium did not vary. Endymion scarcely approached. Langrenus and Pitiscus were approaching the Moon's limb.
- Jan. 26 and 27: Mare Crisium, Langrenus, Furnerius, and Pitiscus were receding from the Moon's limb. Endymion did not vary.
- Jan. 28: Mare Crisium, Endymion, Langrenus, and Furnerius were receding from the Moon's limb.
- Jan. 29, 30, and 31: Mare Crisium, Langrenus, and Furnerius did not vary. Endymion and Plato were receding from the Moon's limb.
- Feb. 1: Mare Crisium, Endymion, and Plato were receding from the Moon's limb.
- Feb. 23: Mare Crisium and Langrenus were receding from the Moon's limb. Endymion perhaps was approaching.
- Mar. 3: Tycho was approaching. Plato was receding from the Moon's limb.
- Mar. 5: Tycho was approaching. Plato and Harpalus were receding from the Moon's limb. Grimaldus did not vary.
- Mar. 6: Tycho and Plato did not vary. Grimaldus and Harpalus scarcely receded from the Moon's limb.
- Mar. 26, 28, and 29: Mare Crisium and Endymion were receding from the Moon's limb. Langrenus did not vary.
- Apr. 1: Mare Crisium and Endymion did not vary. Langrenus and Furnerius approached the Moon's limb a little. Tycho did not vary.
- Apr. 2: All the aforesaid did not vary.
- Apr. 7: Littus Eclipticum [the Ecliptic Shore] was receding. Tycho was approaching. **Therefore the Pole was in octant III.** [Margin: III. vel IV.]
- Apr. 10 and 11: Grimaldus, Littus Eclipticum, and Sinus Roris were receding from the Moon's limb.
- Apr. 24: Mare Crisium, Endymion, and Langrenus were receding from the Moon's limb. Pitiscus did not vary.
- Apr. 25: Mare Crisium and Endymion were receding from the Moon's limb. Langrenus did not vary. Pitiscus was approaching. **Therefore the Pole was in octant I.** [Margin: I. vel IV.]
- Apr. 26: Mare Crisium and Endymion were receding from the Moon's limb.
 - › [the Moon's body symbol]

- Apr. 28 and 30: Mare Crisium and Endymion did not vary. Langrenus and Furnerius scarcely approached the Moon's limb.
 - May 21 and 22: Mare Crisium, Endymion, and Langrenus were receding from the Moon's limb.
 - May 23 and 24: Mare Crisium, Endymion, and Democritus were receding from the Moon's limb. Langrenus did not vary. Pitiscus was approaching the limb. **Therefore the Pole was in octant I.** [Margin: I. vel IV.]
 - May 27 and 28: Mare Crisium and Endymion did not vary. Langrenus was approaching. Democritus was receding from the limb.
 - May 29 and 30: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion and Tycho did not vary.
 - Jun. 19 and 20: Mare Crisium, Langrenus, and Endymion receded a little from the Moon's limb.
 - Jun. 22 and 23: Mare Crisium, Langrenus, and Endymion did not vary. Pitiscus was approaching the Moon's limb.
 - Jun. 24, 25, and 26: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion and Pitiscus did not vary.
 - Jun. 27: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion itself was approaching a little.
-

- Jul. 18 and 19: Mare Crisium and Langrenus did not vary. Endymion was receding from the Moon's limb.
- Jul. 27 and 28: Mare Crisium, Langrenus, and Endymion were approaching the Moon's limb.
- Aug. 1: Tycho was receding. Plato and Sinus Roris were approaching the Moon's limb.
- Aug. 18 and 19: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion was receding. **From which it is gathered that the libration Pole was in octant III.** [Margin: III.]
- Aug. 20, 21, and 22: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion did not vary.
- Aug. 23, 24, 25, and 27: Langrenus did not vary. Mare Crisium and Endymion were approaching the limb.
- Aug. 28 and 30: Grimaldus did not vary. Tycho was approaching the Moon's limb.
- Aug. 31: Grimaldus and Sinus Roris were approaching the Moon's limb. Tycho did not vary.

- Sep. 1: Grimaldus and Sinus Roris were approaching the Moon's limb. Tycho did not vary.
- Oct. 25: Mare Crisium and Langrenus were receding from the limb ☽. Endymion and Aristoteles did not vary.
- Oct. 26 and 27: Tycho and Plato did not vary. Grimaldus, Littus Eclipticum, and Sinus Roris were approaching the Moon's limb.
- Nov. 16: Mare Crisium, Langrenus, and Pitiscus did not vary. Endymion scarcely approached the limb.
- Nov. 20: Mare Crisium and Endymion were approaching the Moon's limb. Langrenus was receding. **Therefore the Pole was in octant IV.** [Margin: IV.]
- Nov. 23: Mare Crisium, Endymion, and Langrenus were receding from the limb.
- Dec. 18 and 19: Mare Crisium and Langrenus scarcely receded from the Moon's limb. Endymion did not vary.

Anno 1655.

- Jan. 23, 24, and 25: Tycho and Grimaldus were approaching the Moon's limb. Harpalus and Plato were receding from the limb. **Hence the Pole was in octant I.** [Margin: I.]
- Feb. 16, 17, 18, and 20: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb. [Margin: I. vel IV.]
- Feb. 21: Tycho and Grimaldus were approaching the Moon's limb. Harpalus was receding. **For this reason the Pole was in octant I.** [Margin: I.]
- Mar. 19 and 20: Mare Crisium and Endymion receded a little from the limb. Langrenus did not vary. [Margin: I. vel IV.]
- Apr. 12, 13, 15, and 18: Mare Crisium, Endymion, and Langrenus were receding from the Moon's limb.
- Apr. 19: Mare Crisium, Endymion, and Langrenus did not vary.
- May 10, 11, 12, 13, 14, and 15: Mare Crisium and Endymion were receding from the Moon's limb.
- May 16 and 17: Mare Crisium, Langrenus, Tycho, and Endymion did not vary.
- May 19: Mare Crisium and Langrenus were approaching the Moon's limb. Endymion and Tycho did not vary.
- Jun. 9, 10, and 11: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb.

- Jun. 12: Mare Crisium and Endymion were receding from the limb. Langrenus did not vary.
 - Jun. 13: Mare Crisium and Endymion did not vary. Langrenus was approaching the Moon's limb.
 - Jun. 15: Endymion did not vary. Mare Crisium and Langrenus were approaching the limb.
 - Jun. 16 and 17: Mare Crisium, Langrenus, and Endymion were approaching the Moon's limb.
 - Jun. 19: Tycho did not vary. Grimaldus and Sinus Roris were receding from the Moon's limb.
 - Jul. 7, 9, and 10: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb.
 - Jul. 11 and 12: Mare Crisium were approaching the Moon's limb. Endymion did not vary.
 - Jul. 14, 15, 16, and 17: Mare Crisium, Langrenus, and Endymion were receding from the Moon's limb.
 - Aug. 10, 11, and 12: Mare Crisium and Langrenus were approaching the Moon's limb.
 - Oct. 6 and 7: Mare Crisium was approaching the Moon's limb.
-

Anno 1656.

- May 7 and 8: Mare Crisium was receding from the Moon's limb.
- Jun. 3 and 5: Mare Crisium was receding from the Moon's limb.
- Jul. 28, 29, and 30: Mare Crisium did not vary.
- Jul. 31: Mare Crisium was receding from the Moon's limb.
- Aug. 1: Mare Crisium was receding from the Moon's limb.

(Continuation of the discussion that closes the catalogue, top of the right column:)

the Moon's limb — but the same spot is not always preserved in the same condition through a single libration, before another spot nearby has displayed its recession from the Moon's limb. In another libration, however, in the libration that follows, this nearby spot is recognized to begin its recession sooner than the spot mentioned earlier did, more noticeably than usual. Indeed, within one and the same libration some disturbance of this order can be detected.

Moreover, the approach or recession of a single spot is not normally able to be discerned unless it occurs at a kind of station, and unless there is, as it were, a

constant remaining at the limb itself — though even this is sometimes not perceived without the spot's stationary point. For example: Mare Crisium, on three, four, or even more occasions, appears with the same greatest nearness, or greatest remoteness, from the Moon's limb; yet it is nonetheless detected, not once but in succession, to approach and then on the very next day to recede from the lunar limb.

Finally, although the libration is for the most part observed only once during a single lunation, it has nonetheless sometimes been noticed that within the same libration a given spot does not continue its single approach, but, after its recession from the Moon's limb, begins to approach again as if at a stationary point, and so noticeably that the difference could be attributed to parallax — nor was it deceived by an error of the eye, since the approach progressed by so notable a quantity, and since at that time a contrary appearance would have been required by the Moon's position at perigee or apogee.

I say, fifthly: the aforesaid varieties detected in the libration could perhaps be saved, and reduced to certain rules, if the Poles were supposed to move in circles whose centers do not themselves move in the lunar surface — as I supposed above. But I do not see by what real physical foundation these hypotheses could be established, so far as it has hitherto been permitted to observe them. For though it might in the exposition of the observations be deduced repeatedly that the Poles are in some determinate octant near the lunar limb, this nonetheless ought to be taken only as a supposition, namely that the Poles might move in that very limb. For thus we should be obliged to argue that one Pole is between two given spots nearer the limb, while the other recedes [from it].

Lastly, from the aforesaid observations it ought to be noted that, for the most part, the conformity of the latitude of the same [spot] follows in such a way that, with respect to latitude, the spots in the Ascending hemisphere and those in the Northern hemisphere approach the limb, while those in the Southern hemisphere recede from the limb; and, conversely, those in the Descending hemisphere [behave] the contrary way. But there are many observations that contradict this Rule; and since they are many, and constant over many continuous days, one ought not therefore to doubt some deception of the eye, but rather to seek elsewhere whether the [cause] is genuine, and what physical cause of the phenomenon [there may be].

CAPVT XV.

Judgment concerning the aforesaid Mobility of the Poles, from the foregoing Observations.

I say first: One must not conceive that the Poles of the lunar libration, or the Nodes, are something real and physically two definite points on the lunar surface. For there is no foundation for such an assertion; on the contrary, with the rest of the points (or spots) remaining fixed on the lunar surface, recognizable and preserving the same distance among themselves, it cannot be said that those two points run hither and thither across that surface — though the Observations require it. I therefore say rather that these points are imaginary, or diverse, and that diverse points of the lunar surface take the place of the Poles by turns in the same libration. Accordingly, the axis itself of this libration is something imaginary in the lunar body, namely as a Diameter about which the Moon librates, in such a way that it librates now about one Diameter, then about another, and a third, and so on — so that these Diameters are to be understood as being made one after another.

I say secondly: This variation of the diameter, or motion of the Poles, is not orderly in its successions, nor uniform, nor does it proceed with equal advance. This is manifestly established from the Observations, in which the Poles appear sometimes to be contained for a good while in the same places, or at least in the same octants of the lunar Limb, while at other times they pass from one octant to another; and furthermore that the passage from one to another is not made immediately, or scarcely any motion is made in the meantime; and finally, that the passage from one octant is made now by a direct movement, now by a movement reverting backward to the earlier octants.

I say thirdly: A somewhat more certain and more uniform motion of the Poles of the libration could perhaps be saved, if they were understood to move not in the lunar Limb, as we have assumed, but in circles having their center either in the aforesaid limb, or in some more anterior hemisphere, or — as is hidden from us — somewhat further within. For the centers cannot be fixed in the same place of the lunar surface, the most certain Observations protesting to the contrary, as drawn from the foregoing.

I say fourthly: It happens that the aforesaid Poles, and the Axes of the libration, are made with a very notable inequality — not only such inequality as is necessarily required, in that this motion is made about a spherical body, but also as regards other matters: namely, it is often observed that the spots near the

Poles of the libration are constituted to move but little, while in the meantime the spots more distant from the Poles move more noticeably; yet often too it is observed that these very spots — even those that are at their greatest distance from the Poles — move but little, and sometimes move most slightly. Meanwhile, by contrast, the motion is sometimes manifestly observed to be swifter, when the spots situated near the Poles are nonetheless detected in such a position. Moreover, from the foregoing observations it can be noted that within any one period of libration a greater velocity belongs first to one spot, then to others, and then to those spots [themselves]: it goes on while one spot, not yet recognized to recede, is recognized to recede, and then while in that one such recession appears, a greater progress of recession is recognized than in [another]. And indeed, this order is usually preserved, by which the spots situated near the limb of the Moon [recede first]: but the same is not always preserved, while one spot in one libration, before another nearby spot has displayed its recession from the limb of the Moon, nonetheless in another libration in the following libration is recognized to begin its recession sooner than the aforesaid nearby spot. Moreover, in one and the same libration some disturbance of this order is recognized.

[The fifth and final point — *Dico Quinto* — is repeated and continues at the top of the right column; see the translation above for its substance.]

CAPVT XVI.

Selected more recent Observations of P. Francesco Maria Grimaldi [Francesco Maria Grimaldi] concerning the limits of the Lunar Libration, from the Year 1651 to 1656. For the examination of the Table of Hevelius [Johannes Hevelius] exhibiting the Maximum Libration of Mare Crisium for the individual Months of this century.

[Margin / running side note: *Pro examinanda Hevelii Tabula* — "For the examination of Hevelius's Table."]

Hevelius sets forth this Table in his new little work on the Librating motion of the Moon, published in the Year 1654, trusting that it will faithfully exhibit the maximum recession of the spot from the Moon's limb — the spot he himself calls Palus Maeotis [the same, i.e. Mare Crisium], insofar, however, as he himself has gathered it from his own Observations, and unless some new Anomaly of the Lunar Libration should be detected

by the course of time. We shall therefore examine whether that Table, and consequently the whole Theory of the Librating motion, set forth by Hevelius — the years now nearly elapsed, not to mention the whole of this century to come — corresponds faithfully; selecting certain Observations of P. Grimaldi from among the more recent ones, which we set forth in the first tome of our *Almagestum Novum* [Almagest], concerning the maximum recession of Mare Crisium from the Western limb of the Moon. At the same time we add the [recession] which is gathered from the Hevelian Table, so that by an easy comparison it may be recognized whether the Hevelian Theory proceeds favorably, or whether it ought to be corrected on some other principle from the truth, which he himself has not yet noticed.

Anno 1651.

In the month of October, Hevelius places the maximum Libration of Mare Crisium as going to occur with the Moon situated in the 5th degree of Taurus — which happened on the 29th, scarcely before midday. The Observations strongly favor Hevelius, since they place the predicted maximum recession of the spot from the Moon's limb at about the 29th.

November: Hevelius assigns the limit of the Libration to the 25th. The Observations, however, place it on the 26th.

December: Hevelius gives the limit at the 23rd. The Observations agree with Hevelius for the same 23rd.

Anno 1652.

January: From Hevelius, and from the observations, the limit fell on the 19th.

February: Hevelius and the observation agree for the 16th.

May: From Hevelius the limit was the 9th; the observations themselves favor it.

June: From Hevelius the limit was the 5th. The observations will do for this.

July: From the Table of Hevelius the limit is twice celebrated — on the 3rd and the 30th. For the 3rd, the observations agree, insofar as the opposite spot then — that is, Grimaldus — did not vary, from which Mare Crisium is gathered to have been at the extreme of its motion, and as it were stationary.

August: Hevelius places the limit on the 16th. The observations agree, since the opposite spot Grimaldus was at its greatest approach to the Moon's limb.

September: The Table of Hevelius assigns the 12th. From the observations the same is gathered, from the greatest approach of the spot Grimaldus to the Moon's limb.

November: From the Table of Hevelius the limit is on the 17th. On which day Grimaldus was least distant from the Western limb; therefore the observations favor Hevelius.

December: Hevelius places the limit of the Libration on the 15th. But from the observation, on the 13th Mare Crisium was receding, and the opposite spot Grimaldus was approaching, and continued so up to the 16th inclusive, and up to the 19th did not vary; it seems therefore to be gathered that the limit was after the 15th assigned by Hevelius.

Anno 1653.

January: From Hevelius the limit was on the 12th. But from the observations, not before the 13th.

February: From Hevelius the limit fell between the 8th and 9th. But from the observations, somewhat after the 10th, since on the 10th Mare Crisium was still receding from the Western limb.

March: From Hevelius the limit ought to have been on the 8th, before midday. But the observations require the 11th.

April: From Hevelius the limit falls between the 4th and 5th. But the observations require it after the 7th.

May: From the Table of Hevelius the limit is on the 2nd, at midday. But from the observation, they place it somewhat after the 4th.

June: From Hevelius the limit was on the 26th. But from the observations Mare Crisium seems to be gathered as approaching the limb up to the 1st of July inclusive, and did not vary.

July: From Hevelius the limit is on the 23rd. The observations seem to favor Hevelius.

August: From the Table of Hevelius the 20th is assigned for the limit. But from the observation, since the opposite spot Grimaldus on the 19th was still approaching the limb, [the limit] seems to be argued [as later]; Mare Crisium [was] not [at maximum] on the 20th — it seems to have been in the limit of its own recession.

December: Hevelius establishes the 8th. But from the observations it seems to be gathered as somewhat after the 8th, since on the 8th itself the opposite spot Grimaldus was still approaching the Eastern limb.

Anno 1654.

January: Hevelius places the limit on the 5th. But from the observations, as much as is gathered from the opposite spot Grimaldus, it seems to have been on the 6th.

March: Hevelius places the limit on the 28th. But from the observations it ought manifestly to be placed later, since on the 29th Mare Crisium was still receding from the Moon's limb, and afterward continued so for four [days] and did not vary.

April: Hevelius places the limit on the 25th. But from the observations, on the 26th Mare Crisium was [still] receding. Therefore here too Hevelius is in advance.

May: Hevelius places the limit on the 22nd. The observations would have it somewhat after the 24th.

June: Hevelius gives the limit on the 19th. The observations, however, somewhat after the 20th.

August: Hevelius places the limit on the 13th. The observations favor Hevelius.

November: Hevelius places the limit on the 4th. They favor that day of the observations, insofar as the spot Grimaldus was distant by the least amount from the Eastern limb.

Anno 1655.

February: From Hevelius the limit was on the 22nd. The observations favor it, insofar as on the 22nd the spot Grimaldus had begun not to vary.

April: From Hevelius the limit is held on the 18th. But the observations give it later, since on the 19th Mare Crisium begins not to vary.

May: From Hevelius the limit is on the 16th. But from the observation, somewhat after the 16th.

June: From Hevelius the limit is on the 12th. But from the observation, not before the 13th.

July: From Hevelius the limit is on the 10th. The observations agree with this exactly.

August: From Hevelius the limit falls before midday on the 7th. The observations, however, exhibit [it] for the 8th.

Anno 1656.

May: From Hevelius the limit is held on the 8th. The observations exhibit it as later.

June: From Hevelius the limit was on the 5th. They agree with the observations.

July: From Hevelius the limit is held on the 29th. But the observations transfer it past the 1st of August.

From the foregoing observations, many indeed are those that favor Hevelius; but many likewise are those that prove his Table to anticipate, by one day or another, the true limit of the Libration of Mare Crisium from the Western [limb] toward the East. And although the matter is treated so subtly that the moment of the maximum Libration could sometimes be doubted from observation — to say nothing of the precise day, much less the moment of the maximum Libration — when three, or sometimes four, days slip by during which no increments, or decrements, appear in the Libration of the Moon: in many cases it is nonetheless evidently convinced that Hevelius precedes [the true limit], since the increments appeared [to follow] according to the manner in which Hevelius ought to have placed the limit — as has been set forth in its own places. But it is indeed remarkable that the Observations never note a day preceding the day assigned by Hevelius: which confirms that one ought least of all to doubt the Observations, on account of the difficulty in judging with certainty, [a judgment] dependent on estimation by eye — since indeed there was no danger of erring on the one side rather than the other.

BOOK FOUR

IN WHICH SELECT OBSERVATIONS OF THE FIXED STARS,
DRAWN FROM BOTH THE ANCIENTS AND THE MODERNS,
ARE WEIGHED, AND FROM THEM TABLES ARE
CONSTRUCTED, PRESENTED DOWN TO THE YEAR OF
CHRIST 1700.

CHAPTER I

On the Observations of the Ancients Concerning the Fixed Stars, and the Manner of Observing Them.

Having set aside those rudimentary observations of the risings and settings of the fixed stars that were recorded for the benefit of agriculture, medicine, and navigation, and which are found in the ancient calendars [*Fasti*] of Aratus, Eudoxus, Euctemon, Meton, Calippus, Dositheus, Geminus, Ptolemy [Ptolemy], Hipparchus, Bithynus, Columella, and again Ovid, and in Pliny [Pliny], Varro, and others, I shall select only those observations that, by reason of their precision [*concinnitas*], are suitable for fixing the exact positions of the stars in the heavens at a definitely determined time. Of these I shall choose only the ones made from the time of Aristyllus and Timocharis — that is, from about 300 years before Christ — down to our own day, namely to the year of Christ 1658, whether handed down by others or carried out by me, with all the subtlety and diligence I could manage, together with the Reverend Father Francesco Maria Grimaldi [Grimaldi].

[Margin: Aristyllus, Timocharis: their observations doubtful.]

Although Ptolemy, in Book 7, Chapter 1 of the *Great Construction* [*Almagest*], speaks of the constructions and observations of the fixed stars made by Aristyllus and Timocharis themselves — saying that they are few in number and ambiguous, and that those which Aristyllus and Timocharis recorded are sparingly explained and not free of ambiguity — yet the more accurate observations of Hipparchus, which Ptolemy assembled in that same place, attest that Hipparchus, in his work *On the Fixed Stars*, gathered the most copious and lucid observations, the ones most relevant to our purpose. For Hipparchus himself, as Ptolemy reports in the same Book 7, Chapter 3 (in his treatise *On the Magnitude of the Year* [*De Magnitudine Anni*]), supposed that a motion of the non-wandering stars takes place about the poles of the zodiac; yet he remained in

doubt — as Ptolemy asserts — because neither were the observations made in Timocharis's time reckoned reliable, on the ground that they had been taken too loosely, nor was the interval of time between them and Hipparchus's own sufficient for a full grasp of the matter. For this reason Hipparchus judged that the undertaking of this inquiry must be passed on, with the more solid foundation of observations of the fixed stars, to posterity — a task whose mention Ptolemy makes in Book 7, Chapter 1, at the end — and that the whole work must be transmitted to those who would come after. Pliny extols this design in Book 2, Chapter 26, where he reports that Hipparchus — than whom no one ever more thoroughly proved the kinship of the stars with man, and that our souls are a portion of the heavens — discovered a new star, and another that arose in his own time, and that he was moved by their motion in the place where it shone; that he came to wonder whether this happened more often, and whether the stars which we take to be fixed likewise move; and that, in the end, he dared a thing hard even for God, namely to number the stars for posterity and to reduce the heavenly bodies to a rule, devising instruments by which he might mark out the individual positions and magnitudes of the stars, so that from them it might readily be discerned not only whether stars perish and are born, but also whether any pass across the sky and move, and whether they wax or wane in brightness. He left the heavens, as it were, as an inheritance to all mankind, should anyone be found who would take up that reckoning.

[Margin: Hipparchus praised, and his manner of observing the fixed stars.]

Pliny adds: "*I was striving toward God*" — that is, he calls it a difficult thing to number the stars. A heathen and an atheist as he was, the writer judged Hipparchus too bold toward God, fashioned by him [*Deo fictili*], or...

rather none at all. But far truer is the saying of our royal Psalmist, who numbers the multitude of the stars and calls them all by their names. And Baruch, after him, Chapter 3, says: "*The stars have given light in their watches, and rejoiced: they were called, and they said, Here we are; and with cheerfulness they have shined forth unto him that made them.*" But to return to Hipparchus: it was by a most fortunate occasion that he was led to observe the fixed stars. For the appearance of a great new star roused Hipparchus, in the 125th year before our era [*saeculi*], to undertake another, fresh observation of the stars — as Tycho [Tycho Brahe] notes — a star which appeared in the year 1572 in the constellation of Cassiopeia. There was good reason for ancient observers to mark this in the sky, by which the lifeless [*Prisci*] organs might attend to such things.

[Margin: Psalm 146.]

1. First, after their risings and settings, the figure of each cluster of stars was observed to be constant and fixed, and the several stars were seen to be always at the same distance from one another. From this comes the very name of the fixed stars [*inerrantia*]: namely, because they do not move, but always keep among themselves a fixed interval [*intervallum*]; nor is their mutual configuration ever altered, once it has been received from the beginning; and they move in an ordered fashion, just as if the whole sphere in which they are, as it were, fixed, were carried around. And because the sphere of the fixed stars, in which they are as if affixed, makes its progression with respect to the succession of the signs by a certain proper motion of its own and a regular ordering — a progression contrary to the motion of the Primum Mobile — it seems right to call them "wandering" [*errantia*] in one respect and "non-wandering" [*inerrantia*] in another. For they are found to be both, as is plain from their apparent positions, which are altered after so long an interval of time.

[Margin: Whence the name of the fixed stars?]

2. Secondly, the fixed stars were observed all to revolve together in the space of 24 sidereal hours, by a daily revolution, from their rising to their setting, and again from their setting back to their rising, or from the meridian back to the same meridian. For whatever stars appeared above the horizon by their passage through the midpoint of the heavens [*medium Coeli*] — that is, above the pole of the world — consumed 12 hours up to their transit beneath the midpoint of the heavens, that is, below the pole; and the same number of hours from that transit beneath the pole back to their transit above it. Those, moreover, which rose and set spent 24 hours from rising to rising, or from setting to setting; and 12 hours from rising to setting, and likewise another 12 from setting back to rising. Now this is the most manifest of all the motions of the fixed stars [*Inerrantia*], at least so far as appearance goes. For whether in reality the stars themselves are moved, or rather the Earth's globe is carried about its own daily-rotating center toward the east by an actual motion that produces this appearance to our eyes — as the followers of Niceta and Copernicus [Copernicus] would have it — I have treated at large in Book 9 of the *Almagestum Novum*, Chapter 4.

[Margin: The motion of the Primum Mobile in the fixed stars.]

3. Thirdly, what was unknown to Hipparchus, or not yet fully grasped before him, was observed: namely, that the fixed stars have besides a proper motion of their own, following the succession of the signs. Hipparchus indeed first set this forth as his own hypothesis, as Ptolemy teaches in Book 7, Chapter 1, from those stars of his which are reckoned to lie in the zodiac — if indeed Ptolemy reports the

same in Chapter 2. He observed that the star Spica, in Timocharis's time, stood distant from the autumnal point by eight degrees, that is, had been eight degrees; whereas in his own time it stood distant by only six. In Virgo it stood at degree 24 in its former position, but in his own time it was distant by only that much — that is, at degree 24 in Virgo — by which token he detected the motion of the fixed stars in the zodiac. Whether, however, this motion took place about the poles of the world — that is, in circles of declination, or in circles parallel to the equator — or rather about the poles of the ecliptic, that is, in circles described about the poles of the world, that is, circles of latitude, Hipparchus was for a time in doubt. Yet he allowed that it might come to pass...

[Margin: The proper motion of the fixed stars in longitude.]

about circles, and in circles about the poles of the zodiac. And from the poles of the zodiac, as Ptolemy holds in Book 7, Chapter 2, and as he describes it, both arguments — albeit ambiguously — agree. For too coarse [*crassae*] were the antecedent observations, and too brief the interval between them and these others. And although Ptolemy himself, in Book 7, Chapter 2, says that the fixed stars move contrary to the Primum Mobile — that is, following the succession of the signs (which Ptolemy himself in the same place teaches by both observation and reason) — moving with respect to the ecliptic, yet in Chapter 3 he affirms that the fixed stars are moved by themselves following the succession of the signs about the poles of the zodiac, as he there describes; and this by a twofold argument.

[Margin: Scaliger's opinion on the motion of the fixed stars.]

First, because the arcs of the ecliptic which the equal intervals of time intercept between the same circle of latitude of a given star are equal to one another; but the arcs which the circles of declination intercept are unequal among themselves. Yet they are not perceptibly unequal unless after many years, when compared. **Second**, because, in that same circle which they always keep, those stars whose distances of latitude in Hipparchus's time and in Ptolemy's time differ are found to retain ever the same latitudes; and, by an evident token, the latitudes of the fixed stars from the ecliptic remain unchanged, while in circles parallel to the equator they are unequal, and in circles of declination they are unequal. And nothing prevents this from being uniform with respect to the ecliptic. I touch here on the Commentary of Joseph Scaliger [Joseph Scaliger] in his *Diatribes on the Anticipation of the Equinoxes*, Book 3, Chapter 3; and Paul of Middelburg [*Paulus*]; and Gilden [*Gildinus*] in his *Refutation of the Elenchus of Calvisius against the Gregorian Calendar* [*Calendarium*], where it is sufficiently refuted in Chapter 10,

as also afterward in Bullialdus [Boulliau], Book 5 of the *Astronomia Philolaïca*, Chapter 4; and again in our own work, the *Almagestum Novum*. I add this, in confuting the chief foundations on which Scaliger relied in striving to show that the equinoctial points recede from a fixed position of the western fixed stars toward the poles of the equator — that the fixed stars are mobile, distinct, and have the poles of the world.

4. Fourthly, therefore, the ancients first determined the declinations of the fixed stars separately, then their latitudes; and the longitudes were determined in the ecliptic by means of circles of latitude drawn through the poles of the ecliptic and through each several star, and by circles cutting the ecliptic at right angles. They added, moreover, the apparent magnitudes — namely, which were of the first, or second, or third, and so on up to the sixth magnitude. In the Catalogue of Ptolemy, besides, certain notes were appended to some of the fixed stars touching the nature of the planets in which they share, for the benefit of astrology.

[Margin: The declinations to be observed.]

On the Methods and Instruments by Which the Ancients Observed the Fixed Stars.

6. With what instruments Aristyllus, Timocharis, Hipparchus, and Ptolemy noted those declinations and distances from the equator which Ptolemy reports in Book 7, Chapter 3, I have not found, nor is it credible that they were observed with any certainty without the meridian altitudes of the stars somehow taken. Ptolemy, in Book 1 of the *Great Construction*, Chapter 11, describes a stable quadrant by which the meridian altitudes of the Sun were taken; and the same instrument, perfected, is the equatorial astrolabe, or equatorial armillary, which observers are wont to apply also to the taking of the meridian declinations of the stars, and which Tycho both perfected and described in his *Mechanica* of restored astronomy [*Mechanica Astronomiae Instauratae*], folio 20 and 21.

[Margin: The observation of declinations.]

7. The longitudes, moreover, and the latitudes of the fixed stars they were wont to observe by two methods. The first was to wait for the very intervals of nights cut off between a fixed star and the Moon, and the Moon's appulses and limbs [*margines*], at a certain moment of the night; and thence, by means of tables computed, to determine the place of the stars in the zodiac and by the tables to infer the place of the stars by conjecture, as far as one could from observation. Of this kind are the observations of Timocharis, Agrippa, and Menelaus, which we shall report from Ptolemy, Book 7, Chapter 3, in the appropriate chapter. The **second** was by the astrolabe...

the astrolabe used and described by Ptolemy in Book 7, Chapter 2 and Chapter 4. It was composed of zodiacal armillae, of nearly the same fashion as those which Aristyllus and Timocharis recorded — as Ignatius Dantes [Egnatio Danti] sets forth in his *On the Astrolabe*, and as Tycho describes in his *Mechanica Astronomiae*, folio 19 — and of one use with the armillae themselves. For with one circle the Moon and the Sun, near the horizon, were observed with their sights turned toward them; the distance of the Moon from the Sun was computed in the ecliptic; and at the same time, by means of the cross-staff [*ferratherium*], or by the degree of the ecliptic constituted in the midheaven, they marked the hour. Then by night, soon after, taking up a like reckoning, they took the distance of the Moon from some fixed star, computed in the ecliptic, and intercepted it by two circles of latitude — namely, by the Moon's center, by the star, and by both, through the poles of the ecliptic descending into the astrolabe — so that, by an analogous and fixed placement, the heaven had first been set in position. And now, from the place of the Sun in the ecliptic computed at the time of the prior observation, adding to it the distance of the Moon from the Sun computed in the ecliptic, they obtained the apparent place of the Moon according to the ecliptic; and to this apparent place of the Moon, adding the distance of the Moon from the fixed star to the east, they obtained the apparent place of the fixed star, as to longitude. But because the same was gathered, since it was the same hour, it was settled from the astronomical tables; and from the true place of the Moon, indeed, they corrected its longitude, the longitude first acquired by the distance from the Sun.

[Margin: The imperfection of the ancients' observations.]

But good observers required not only this correction by the Sun, but also that other correction which the parallaxes of the luminaries often demanded — illumination, as it were — suspecting it less than the refraction itself. Then again the parallax of the Sun was employed. Finally these zodiacal armillae were employed, as Tycho notes (*Tom. 1 Progymn.*, page 140); and if they were of great mass, then so far as the weight of the matter admitted, they were unwieldy; but if small, they did not admit of subdivisions, even to a single minute in each degree. Certainly in Ptolemy's Catalogue the longitudes, for the greatest part, as also the latitudes, are noted down only to the first scruple [*scrupulum*, i.e. minute].

8. Finally, the latitudes themselves, by means of two sights placed in a circle of latitude — or rather, by their boring [*foramina*], at the center of the star directed straight — were not at all to be praised before this. The defect of the observations

is to be set forth in due order hereafter. As for the fault in latitudes, on account of the false obliquity of the ecliptic, this is not the place to discuss it.

CHAPTER II

On the Stars Lying in the Same Straight Line, Both in Ancient and in More Recent Observation.

1. There are many groups of the non-wandering [*inerrantes*] stars, whether in fours [*quaternarii*] or otherwise, which are observed to lie exactly, or very nearly, in the same straight line, and which have so persisted from of old, before Ptolemy's time, down to the time of Ptolemy, as he himself reports in Book 7 of the *Almagest*, Chapter 1; and thence onward down to Tycho, as I affirm in Tome 1 of the *Progymnasmata*, page 234; and from then down to our own day. To these we have joined certain others gathered from our own observation, drawn together with the figures which are extant in Aratus and in the *Phaenomena* of Hyginus, or inferred from the difference of latitudes; so that hence the unaltered figure of a constellation is confirmed, and the immutability of the interval by which they lie distant among themselves.

2. There are, then, and have been of old too, in the same straight line — or very nearly so, by the estimation of the eye drawn along a straight line — the stars set down beneath.

The southern claw [*forfex*] of Cancer; and the bright star which precedes it; the bright star in the head, which precedes; and the bright star of the Lesser Dog [*Canis minoris*].

The two eastern stars in the head of Leo, and that which is in the joining of the neck of Leo with the rest of the body.

The bright star in the tail of Leo [*Leonis lucida cauda*]; the extreme star in the tail of the Great Bear [*Ursae maioris extrema cauda*]; and the star which, between the two aforesaid Unformed [*Informis*], is descried beneath the tail of the same Bear.

The bright star in Virgo [*Spica Virginis*]; the next-to-last in the tail of Hydra; and the middle of the three shining in Triangulum.

The star in the head of the two contiguous stars in Aquarius, and that which is in the shoulder following.

The two preceding stars in the head of Aries, and that which is in the base of Triangulum.

The two eastern Hyades, and the southern star in the little fur-cap [*pellicula*] on the left hand of Orion.

The two more northern stars in the head of Aries, and the splendid one in the knee of Perseus.

The Goat-star [*Capella*], and that which is in the preceding foot of Auriga, and the bright star of the Hyades — that is, the eye of the southern Bull [*Tauri*].

The Goat-star, likewise preceding; the shoulder of Orion; and that which is in the northern horn of the Bull, and that in the foot of Auriga following.

The bright star in the head of Gemini [*Geminorum capita splendida*], shining in the neck of Hydra.

The Bear in the anterior foot, two contiguous stars; and these in the outer pincers [*forcipes*] of Cancer, northern, and the more northern of the Asses [*Aselli*].

The bright star of the Lesser Dog, and the more southern Ass, and that which precedes between them the head of Hydra.

The bright star of Virgo, and the two stars in the elbow [*ancon*] of Corvus.

The bright star of Virgo, and that which is in the hinder shank [*crus*] of Virgo, and that which is among the antecedent stars of Boötes' shin [*tibia*].

The two bright stars in the pincers of Libra, and that which is at the extreme tip of the Bear's tail.

The bright star in the southern pincer of Libra, and Arcturus [*Arcturus*], and the middle of the three shining in the tail of the Great Bear.

The one bright star in the three knees of Ophiuchus, and that which is in the fifth vertebra [*spondylus*] of Scorpius, and the two preceding stars in the sting of Scorpius.

The shining star in the following knee of Ophiuchus, and that which is in the anterior southern heel [*talus*] of Sagittarius, and that which is in the arrow [*sagitta*] of the same Sagittarius.

The star in the preceding knee of Ophiuchus, and that which is in the heel of Sagittarius, and that which is among the anterior stars in the foot of Sagittarius.

The southern cheek [*bucca*] of Pisces, and the two stars preceding in the quadrilateral of Pegasus.

To these three add the three bright stars in the Belt of Orion; likewise the three which are Boötes, the bright stars of Arcturus, and that which shines in the shoulder near the neck [*collum*]. Such likewise are the three bright stars of Perseus, one in the preceding knee, another in the more splendid flank [*latus*], the third in the shoulder following. Likewise the three more lucid stars of Aquila, one in the neck, another in the shoulder-blades [*scapulae*], the third at the beginning of the left wing [*ala*]. Likewise the southern foot of Andromeda, the bright star of the Belt, and that of the right shoulder-blade.

CHAPTER III

On the Declinations of the Fixed Stars, or Their Distances from the Pole of the World, Observed Down to the Time of Tycho Exclusively, with a Critique of Them.

1. Let the first class be of those Declinations which Ptolemy, in Book 7 of the *Great Construction*, Chapter 3, reports as observed by Timocharis of Alexandria in the year 36 before Christ — the first year of the first Callippic period, that is, in the year before Christ 295; and at intervals thereafter, by Aristyllus at about the same time; and by Hipparchus in the year 50, the third of the second Callippic period, namely in the year before Christ 128; and finally from year 1 to year 2, after Antoninus Imperator, and in the year 265, after Hipparchus, in the year of Christ 137 and 138. Ptolemy designates these times sufficiently in Book 7, Chapter 2, Chapter 3, and Chapter 4. He adds, however, in Chapter 3, another observation made in the 47th year of the first Callippic period, which he says was in the year 465 of Nabonassar, that is, before Christ 284, or 285.

Liber IV — On the Fixed Stars (continued)

Caput III (continued) — Declinations of the fixed stars observed down to (but not including) the time of Tycho

Table I — Declinations

The observers are abbreviated as follows: *Aristyll.* = Aristyllus; *Hipparch.* / *Hippar.* = Hipparchus; *Ptolem.* / *Ptol.* = Ptolemy; *Timoch.* / *Tim.* = Timocharis. The letters **B** and **A** in the final column mark the declination as **B**oreal (northern) or **A**ustral (southern). Degrees (G.) and minutes (M.).

Parsing notes: The right-hand column of folio 204 continues Table I. The last two entries (Northern claw of Scorpius, and a second "middle of the Pleiades") sit in that right column under repeated headers *Stella / Observatores / Declinatio (G. M.)*. For the Northern claw of Scorpius, the third observer's value (Ptol.) is marked **A** (austral) where the prior two are **B** (boreal) — transcribed as printed; this is a recognized sign-change at that epoch and is left as printed.

Below Table I, Riccioli adds two notes on individual stars:

The first star of the tail of Ursa Major has, according to Hipparchus, 67° 36'; and the northern claw of Scorpius, according to Timocharis, 1° 2'.

Second class — distances from the pole of the world

[Margin: 2] The second class contains the distances from the pole of the world of certain other stars — that is, the complements of the declinations to a right angle — which are obtained by subtracting from 90° those declinations that yield a northern declination. (Where this does not hold, the letter **A** [austral] is added, as they are given in Petavius's *Uranologion*, Book III, chapters 6 and 8.) Petavius says these distances were observed and recorded by Eudoxus, and afterward by

Hipparchus; and he adds the distances that, in Hipparchus's time, ought to agree with Tycho's tables. Hipparchus appears to be correcting Eudoxus; but it is uncertain whether he is correcting the distances of the fixed stars for Eudoxus's own time or for his own. Eudoxus flourished in the year 368 before Christ — that is, 240 years before Hipparchus.

The symbol ☾ (Moon / *Luna*) appears as an abbreviation in two row-labels of Table II ("Cancri borea præcedentium in laterculo" group). Riccioli uses it as shorthand for the lunar/nebular cluster region. Below, where a star-name uses the symbol, it is rendered in words.

Table II — Distance from the pole of the world

Columns give the distance from the pole per **Eudoxus**, per **Hipparchus**, and per the **Hipparchus-corrected** value of **Petavius** [Hippar. correctæ Petavio]. Degrees (G.) and minutes (M.).

in □]

Parsing notes: One Hipparchus cell for the right knee of Ophiuchus reads "100. plus" (printed literally as "100.plus"), evidently meaning "more than 100°"; transcribed as printed. The last five rows (Ursa Minor) have no value in the Petavius-corrected column. The "□" (square / quadrilateral) symbol denotes the asterism square in two row-labels.

[Margin: 3] The third class contains the distances from the pole of the world of certain fixed stars, drawn from Hipparchus's observation but with the correction by Joseph Scaliger [Iosephus Scaliger] and Dionysius Petavius [Dionysius Petavius] made from more recent tables, as Petavius sets out in his *Uranologion*, Book III. Now the pole of the world, from which these stars listed below were distant in Hipparchus's time, was boreal — except for the last two of Scorpius, for which the pole was austral, as it was also for Sirius.

Liber IV — On the Fixed Stars (continued, folio 205)

Table III — Distance from the pole of the world in the time of Hipparchus

Columns: per **Hipparchus** [Hipparcho], per **Scaliger** [Scaligero], per **Petavius** [Petauio]. The epoch is the year 128 before Christ. Degrees (G.) and minutes (M.). The letter **A** in the left margin marks an austral entry.

Parsing notes: For the foot of Aries the Hipparchus column reads "90 ferè" (approximately 90°); rendered as "90 (approx.)" with no minutes. Two rows are marked **A** (austral) in the source margin: Sirius and the southern claw of Scorpius.

[Margin: 4] The fourth class gives the distance from the pole of the world of the boreal star at the extremity of the tail of Ursa Minor — the star now called **Polaris** — but which in Eudoxus's and Hipparchus's time was not Polaris (i.e. not the pole star), the distance being observed by various authors at various times, as below.

Table IV — Distance from the pole of the star at the extremity of the tail of Ursa Minor

Columns give the year (Years before / after Christ) and the distance from the pole. Degrees (G.), minutes (M.), seconds (S.).

Authority	Year	Dist. G.	Dist. M.	Dist. S.

with Father Grimaldo [Francesco Maria Grimaldi], by the gnomon, in the new Temple of S. Lucia				

Parsing notes: Table IV spans the page-column boundary on folio 205. The first row of the right-column continuation is the tail of the prose entry that overflows from the left column (the "3° 8'" passage); its year/distance cells are blank because the value belongs to the prose, not the tabulated series. The Cassini entry and the Riccioli/Grimaldi entry both read 2° 32' 28" for 1656.

Riccioli adds (right column): In the new Temple of S. Lucia, where the vault is obscured above, the feet stand at 74 [palms?]; one must rather stand there, than make such an observation with smaller instruments, as related in *Almag. Nov.* cap. 4. Neither did Cassini reckon our number [of observers], nor did we, Cassini, reckon yours — since the observation itself by a gnomon of such magnitude (as Cassini's was, the gnomon's altitude being 80 palms) and conducted with such diligence, by the very agreement [of results], makes it the more credible.

Fifth class

[Margin: 5] The fifth class comprises the declination of **Spica, Regulus, Arcturus**, the **Scale (Lanx) of the austral Balance, Fomalhaut**, and **Rigel** [Rigel], observed by the authors written below, but standing in need of a particular discussion.

[Margin: Spica observed by Werner] Johannes Vernerus of Nuremberg [Johann Werner], as Daniel Santbech relates in *Phænomenorum Prop. 20*, in the year 1514, on the 16th of December, observed at Nuremberg the parallactic altitude of Regulus [Reguli Parallacticæ Altitudinem] to be the meridian altitude 32° 7'; and thence, supposing the altitude of the pole to be 49° 24' 30", he deduced the austral declination [Declinationem Australem] of Spica to be 8° 29' 30". Thence, supposing the obliquity of the ecliptic to be 23° 30', and the austral latitude of Spica [Latitudo Austr.] to be 2° as handed down by Ptolemy, he derived the longitude [Longitudinem] in ♎ (Libra) at 16° 53' 20". Observing Regulus likewise

on the same day, he found the meridian altitude, and thence the boreal declination [Declinationem] to be $14^{\circ} 7'$, its longitude [Longit.] in \square (Leo) at $22^{\circ} 42'$. Finally, observing the austral Scale of the Balance [Lancis Australis] there at the time, he found the austral declination [Declinationem Austr.] to be $13^{\circ} 30'$; and likewise its longitude [Longit.] in \square (Scorpio) at $8^{\circ} 14'$; on which Werner [Vuernerus] also relies, *Theorema 7, Progymn.* pag. 221, and before all others Werner himself in his *Opusculum on the Motion of the eighth sphere* cap. 4.

[Margin: Et Regulus] [Margin: Et Lanc. Austr.] A great disagreement [Magnum Dissidium] is noted between these observations of Werner's, and Copernicus's, and Cardano's — on which more below. But Tycho [Tycho Brahe] suspects, and presses, that he did not so much make these observations of his own as accommodate the declinations at his own discretion to Ptolemy's latitude, and to a difference of longitude — which is itself in question concerning Regulus and Spica at $54^{\circ} 10'$ between Spica and the Scale [Lancem] at $8^{\circ} 53' 19''$; while the Scale of the Balance [Lancx] itself was $11^{\circ} 14'$. Also, the altitude of the pole at Nuremberg [Altitudo Norimbergæ] was truer for Tycho than the $49^{\circ} 26'$ Werner used; and therefore, if the true meridian altitude was that of Werner, the **[Margin: Werner's fallacies — Vueneri fallaciæ]** boreal declination of Regulus [Declinatio Borealis Reguli] would be $14^{\circ} 16'$, and the austral [declination] of Spica $8^{\circ} 27'$; and that of the Scale [Lancis] austral $13^{\circ} 36'$; from which Tycho assumes his own latitudes, and the obliquity of the ecliptic at $23^{\circ} 30'$. He gathers a trigonometric longitude [Longitudinem Trigonometricè] very dissonant from that which is owed to these stars by Tychonic observations down to the year 1515, applied to those [stars], as is plain from the subjoined Tychonic Table.

Liber IV — On the Fixed Stars (continued, folio 206)

Table — Vernerian and Tychonic calculations compared (Year 1515 incomplete [incoëpto])

Columns: **Latitude per Ptolemy** [La. Ptol.]; **Vernerian longitude from his own declination** [Calculus Vuerner. ex sua Declinat. — Longitudo]; **Latitude per Tycho and corrected longitude** [Calculus Tychon. ex Vueneri Decl. corrected from his tables — Lat. Tych. / Longit.]. Degrees (G.), minutes (M.). The letters **B / A** mark boreal / austral.

Star [Nom ina Stella rum]	La. Ptol. G.	La. Ptol. M.	Longi tudo G.	Longi tudo M.	Lat. Tych. G.	Lat. Tych. M.	Longi t. G.	Longi t. M.
Regul us	0	10 B	☐ 22	42	23	27 [?]	0	26 2 [?]
Spica	2	0 A	☐ 16	53 [?]	16	47	1	59
Austr al Scale [Lan x Austr .]	0	40 B	☐ 8	14	7	19	0	25

Parsing notes: This small comparison table at the top-left of folio 206 is finely set and ink-degraded; a few cells in the right-hand "Lat. Tych." / "Longit." sub-columns remain uncertain and carry [?]. The zodiac signs ☐ (Leo) for Regulus, ☐ (Libra) for Spica, ☐ (Scorpio) for the Scale are legible in the longitude column. The "La. Ptol." cell for the Austral Scale reads **0° 40' B** (degrees 0, minutes 40, Borealis), following the same G. + M. + hemisphere-letter pattern as the Regulus (0 10 B) and Spica (2 0 A) rows above it; the Vuerner longitude for that row stands in its own column at ☐ 8° 14' (Scorpio). A further review resolved the earlier "40 8" reading of this cell as a column slip (the spurious "8" was the adjacent Scorpio-longitude degree value), not a compositor error.

Therefore, from such doubtful declinations, the Vernerian one [Vuerneriana] permits nothing certain to be gathered concerning the place of these fixed stars.

[Margin: 6] [Margin: Spica observed by Copernicus — Spica obseru. à Copernico] Nicolaus Copernicus [Copernicus], *Revolutions* Book III, chapter 2, says that at Frauenburg in Prussia [Fruenburgi Prussiae], in the year 1525, he observed the meridian altitude of Spica, very nearly 27° in parts; whence, supposing the latitude of Frauenburg [latitudine Fruenburgica] to be 54° 19' 30", he gathered the austral declination [Declinationem] of Spica to be 8° 40'. Whence, assuming Ptolemy's latitude of 2°, he deduced the longitude [Longitudinem] to be 17° 21', very nearly. Adding, moreover, that before a century — that is, in the year 1515 — he repeated this same observation of Spica, and found the declination [Declinationem] to be 8° 36', and the longitude [Longitudinem] in ☐ (Libra) at 17°

14'. Here truly Petrus Nonius [Pedro Nunes], Book II, On Observations, cap. 4, exposes a great disagreement [dissidium] between Werner and Copernicus, since in the same year 1525 the former places Spica in Libra at $16^{\circ} 54'$, the latter at $17^{\circ} 14'$; **[Margin: Cardano's fallacy — Cardani fallacia]** Cardano [Girolamo Cardano], in turn, after some years — i.e. in the year of Christ 1537 — drags the same observation to the eleventh degree at $16^{\circ} 18'$ in Libra. Tycho, however, in tom. I, *Progym.* pag. 220, having earlier explored the altitude of the pole at Frauenburg to be $54^{\circ} 22' 15''$, **[Margin: Copernicus's fallacy — Copernici fallacia]** corrects the declination of Spica for the year 1515 to be $8^{\circ} 23' 15''$. And then, having assumed the latitude of Frauenburg to be $54^{\circ} 19' 30''$, he gathers the longitude of Spica in Libra to be $17^{\circ} 2' 30''$; and likewise so for the year 1525. The corrected declination of Spica being used at $8^{\circ} 37' 15''$, he obtains the longitude in Libra at $17^{\circ} 14'$; and likewise, limiting it for the year 1520, the latitude [latitude] in Libra at $17^{\circ} 8' 30''$. But Philippus Lansbergius [Philip Lansberge], **[Margin: Lansberg's fallacy — Lansbergi fallacia]** in his *Thesaurus of Observations of the Fixed Stars*, where he places Spica according to his own tables computed for the year 1525 in Libra at $17^{\circ} 35'$, confirms the Copernican observation, [pointing out] two faults of Astronomy admitted — one of omission, the other of commission — in pursuing the refraction at his own pleasure. For it would arise from a refraction of $2^{\circ} 30'$, the true altitude being $26^{\circ} 57'$; whence, having supposed the altitude of the equator to be $8^{\circ} 44'$, by which he observed Copernicus's declination of $8^{\circ} 44'$, and the latitude to be $1^{\circ} 58'$; but the obliquity of the ecliptic at $23^{\circ} 30'$, he extends the longitude in Libra to $17^{\circ} 35'$.

[Margin: 7] [Margin: Stadius observed Spica — Stadij obseru. Spica] Johannes Stadius [Johannes Stadius], in his *Commentaries on the Fixed Stars* cap. 1, relates an observation he himself made at Brussels of the altitude of the equator to be $38^{\circ} 40'$, and in the year 1559, on the Nones of July [Nonis Iulij], the altitude of Spica at the meridian to be $29^{\circ} 52'$; and thence he gathered the austral declination of Spica to be $8^{\circ} 48'$, whence its longitude [longitude] in Libra at $17^{\circ} 40'$; and he reduced the Alphonsine Calculation, which he derives for the same year, to require Spica in Libra at $16^{\circ} 50'$; **[Margin: Et Arcturi, Sirij]** and Cardano, on whom see above. He narrates, moreover, cap. 1, in the same year 1559, having observed on the eve of the Ides of April [pridie Idus Aprilis] the meridian altitude, and thence the declination of Arcturus to be $69^{\circ} 30'$; and in the year 1598, on the Nones of March [Nonis Martij], the meridian altitude of Sirius to be $22^{\circ} 45'$, hence the austral declination to be $15^{\circ} 55'$; **[Margin: Fomahât]** and of Fomalhaut [Fomahant] the meridian altitude to be $5^{\circ} 6'$, hence the declination austral to be $33^{\circ} 55'$; finally, **[Margin: Rigel]** the meridian altitude of the left foot of Orion, Rigel [sinistri pedis Orionis Rigel], to be $19^{\circ} 18'$, hence the austral declination to

be 9° 12'; and from his longitude of Fomalhaut in Pisces at 28° [**Margin: Stadij errores**] and Rigel in Gemini at 10° 10'. But in our *Reformed Geography* I have shown from Langren [Langrenus] and the observations made at Brussels that the altitude of the pole there is 50° 48', and the altitude of the equator 39° 12'; therefore, supposing the meridian altitude of Stadius, the declinations are to be corrected, and below, which nonetheless do not cohere with the required Tychonic Table.

(Right column of folio 206:)

Tychonic Table — declination and observation by Stadius (Year 1559)

Columns: **Year** [Anno]; **False [declination] of Stadius** [Falsa Stadij]; **Corrected [declination] of Stadius** [Correcta Stadij]; **Tychonic** [Tyconica]. Degrees (G.), minutes (M.), seconds (S.). The letters **B / A** mark boreal / austral.

Year	Star	Falsa Stadij		Corre cta Stadij		Tych onica		
		G.	M.	G.	M.	G.	M.	S.
1559	Arcturus [Arcturi]	22	0	22	32 B	21	32	30
1559	Sirius [Sirij]	15	55	16	27 A	16	9	22
1559	Fomalhaut [Fomahant]	33	33	34	6 A	30	56	36
1559	Rigel	9	12	9	44 A	9	21	6
1559	Spica [Spicae]	8	48	9	20 A	8	47	40

Parsing notes: The "Decl. & Observ. Jo. Stadij — Anno" header spans the year column. The middle "Correcta Stadij" column carries the B/A sign letter on its minutes value (e.g. "32 B", "27 A"). The Tychonic column gives degrees, minutes, and seconds.

It is therefore plain that, just as the declinations stated by Stadius are false, so the places of the said stars introduced by Stadius are false; and so too the place of Regulus, which (Chapter 2, *Commentary on the Fixed Stars*) he affirms to have been found by himself in the year 1555 in Leo [♌] at $23^{\circ} 30'$.

Caput IV — Longitudes and Latitudes of the Fixed Stars, selected from observations down to (but not including) the time of Claudius Ptolemy, with a critique of them

Besides the twofold mode of Observing the Longitudes of the Fixed Stars — namely the ecliptic distance among themselves, captured together with the Moon by naked eye or by astrolabe, and likewise the distance of the same Fixed Stars from the Sun (which I indicated in chapter 1 of this Book) — later astronomers, down to Ptolemy and even to Tycho, used a third mode: namely, assuming their latitude (as found by Ptolemy, since it is as it were unchangeable) together with the obliquity of the ecliptic, and the declination at the time of observation, they investigated the longitudes of the same by triangular analysis. I therefore set out beforehand the longitudes acquired by the earlier authors down to Ptolemy, and then those selected by Ptolemy himself down to those successors down to the time of Wilhelm Landgrave of Hesse [Vilhelm Lantgravii Hassiæ] and of Tycho Brahe — noting for each what seems worthy of estimation. Yet by way of foundation must be premised, from our *Reformed Chronology*, the best Chronographs: that in the year of the vulgar Epoch of Christ, on the 23rd of August by the Julian Calendar, began the year 749 of Nabonassar; whence, from the years of Nabonassar handed down by Ptolemy, the years before or after Christ are easily gathered, as set out above.

[Margin: 1] [Margin: Spica observed by Timocharis — Spica obseru.

Timocharidis] Timocharis of Alexandria [Timocharis], as Ptolemy relates (*Almagest* cap. 7), observed Spica to be distant from the point of the Autumnal Equinox 8° — that is, in Virgo [♍] at 22° , very nearly — but he does not express the Year, as he does in others; quote 2, when he narrates Timocharis's observed boreal declination of Spica to be 24° below, in the same year, in the first month, which he notes to have been Nabonassar 454 — that is, the year of Christ 295. Therefore, this Year is in question; not improbably it is accepted from *Almag.* Book 5, *Astronomiæ Philolaicæ* cap. 3 — to which it refers from Nabonassar 454, with the declination foretold and the latitude of Spica, he gathers its place in Virgo [♍] at $22^{\circ} 19'$.

[Margin: 2] [Margin: Spica observed by Timocharis — Spica obseru. Timoch.] Timocharis likewise of Alexandria, as Ptolemy has it (*Almagest* cap. 3), in the year 36 of the first Callippic Period [primæ Callippi Periodi] consisting of 76 years, on the 15th of Elaphebolion [Elaphebolionis], that is, in Nabonassar 454, before Christ 294, in the month Tybi [Tybi Mensis] on the 5th, beginning the night on the sixth at the third hour — that is, a quarter past midnight, in temporal as well as equinoctial hours — saw the Moon reach with its eastern limb to Spica, and Spica was carried away so exactly along with the Moon, that he gathers Spica to be at the same point as the Moon's centre. From the Moon's diameter, distant northward, Ptolemy gathers from his Lunar tables the longitude of Spica in Virgo [□] at $22^{\circ} 20'$, and the austral latitude very nearly 2° . Copernicus uses this observation (*Revolutions* Book 3).

(*De Revolutionibus* III, *Revolutions* chapter 2), and [Tycho Brahe], in *Progymnasmata* pages 253 and 254, rightly adds that, from this observation down to his own observation of Spica made in the year of Christ 1585, complete years numbering 1879 had elapsed. And yet, though Tycho gives the years correctly, Timocharis does not rightly state that, in his time, Spica stood in $\square 22^{\circ} 20'$. For [Ptolemy], from his own calculation, deduces from Timocharis's observation that Spica stood very nearly at $\square 22^{\circ} 20'$. Lansbergius [Philip van Lansberge], however, in his *Thesaurus* of observations, on page 146, assigns the position of the fixed stars (as on his *Tables*) at $\square 22^{\circ} 4' 38''$, and a true latitude of 2° austral. He misreads the size of this observation enormously, since in the history of his observation [Ptolemy] expressly relates the *triangle* of the diameter of the Moon, falling short by $4^{\circ} 45'$ to the south of Spica; and in the final calculation it came to $4^{\circ} 45'$ — that is, one-third of a semidiameter, not the diameter.

[Margin: Error of Lansbergius.]

§3. Likewise [Timocharis] of Alexandria, as [Ptolemy] relates (*Almagest* VII.3, Year 48 of the first Callippic period, expiring on day 6 of Pyanepsion, and 7 Thoth elapsed, at hour 10 and $1/2$ of the night, saw Spica exactly touching the northern part of the Moon, then above the eastern horizon, in the Year of Nabonassar 466 — that is, before Christ 283 — and at hour 3 and $1/2$ temporal, after midnight he concludes the position of Spica in $\square 22^{\circ} 30'$, with austral latitude 2° . Concluding very nearly, between the earlier observation and this one, Spica advanced 12 minutes. And as to part of this observation, Spica is set forth, in Greek codices, where one codex reads \square — that is, the figure 5 with an acute accent over it — which signifies not the place 10 but the sixth part of unity, just as the Latin interpreter renders it. Longomontanus [Christen Sørensen Longomontanus],

however, in *Astronomia Danica* (Book 2 of the *Theorica*, chapter 1, in his Commentary *On the Fixed Stars*), from his own lunar hypotheses places Spica in $\square 22^{\circ}30'$, at hour 15 $\frac{1}{4}$ [?] equal [from] after the meridian at Alexandria in the Year of Nabonassar 466 — but 1884 before Christ, the Year 1600 current [?]. From which observation he found Spica to have stood, 284 years before Christ. But Lansbergius, in his *Thesaurus* of observations, page 146, places the hour at the equal hour at Alexandria as $2^{\circ}30'$, after midnight, and Spica, by his tables, in $\square 22^{\circ}12'21''$ [?].

[Margin: Spica & austral. Timochar.]

§4. [Timocharis], from [Ptolemy] (*Almagest* VII.3, at Alexandria, Year 47 of the first Callippic period, at Nabonassar 465, that is, before Christ 284, on day 29 of the month Athyr, at hour 3 and $\frac{1}{2}$ temporal nocturnal — that is, hour $3^{\circ}30'$ equal before midnight — diligently noted the middle of the austral Pleiad applied to the middle of the Moon, or the third following it, where [Timocharis] would have placed the fixed star here in Aries [\square] $29^{\circ}30'$, with northern latitude $3^{\circ}40'$, very nearly. Longomontanus already, from the place stated above, deduces the position of the Pleiad in $\square 29^{\circ}30'$; and Lunar at the meridian $8^{\circ}40'$ [?]; and the Moon with the Pleiad in $\square 29^{\circ}32'$.

[Margin: Lucid Pleiad observed by Timocharis.]

§5. [Timocharis], finally, in [Ptolemy] (*Almagest* I.7, chapter 3, at Alexandria, Year 36 of the first Callippic period, and Nabonassar 454, at Alexandria, day 25 of Phaophi exactly Possidonios, and day 16 of Phaophi truly, at hour 16 incipient — that is, hour 10 after midnight, hours 3 temporal, equal hours however $3^{\circ}10'$ — observed the Moon with its northern extremity touching the northern part of the three [stars] in the front of Scorpius, where [Ptolemy] deduces it to have been in Scorpius [\square] 2° , with boreal latitude $1^{\circ}10'$. But Longomontanus, where he places above, sets the hour $15^{\circ}30'$ after the meridian, the place; the Star with the Moon in Scorpius $\square 1^{\circ}58'$. Lansbergius, in his *Thesaurus*, page 148, asserts that [Ptolemy] is not to be doubted to have here deceived himself, since it is a faulty longitude of the Star, the true one being in Scorpius $\square 1^{\circ}26'29''$, with latitude $1^{\circ}15'$ boreal; and therefore the conjunction of the Moon and the fixed star was seen in the horizon, hour $2^{\circ}30'$ equal after midnight, and the place of the Moon true in Scorpius $\square 0^{\circ}50'32''$, and the boreal latitude $1^{\circ}16'49''$.

[Margin: Front of Scorpius.]

§6. [Hipparchus], as [Ptolemy] relates (*Almagest* I.7, chapter 2, from his own time — that is, that, by a subsequent observation collecting the Year 50 of the third

Callippic period, this being before Christ 128, sees Spica to stand in the preceding part of the autumnal section by 6°, but, this being on day 24, in 14°. Yet he collects (as above) Spica's place of declination as boreal 0°36'. Boulliau [Ismaël Bullialdus] (*Astron. Phil.* chapter 3, the latitude of Spica) collects its place in 23°59'. Longomontanus, however, with respect to the true equinox, where above, places it in 24°25'.

[Margin: Spica observed by Hipparchus.]

§7. [Hipparchus] likewise, as [Ptolemy] relates (*Almagest* I.7, chapter 2 —

would have observed, in the Year 50 of the third Callippic period, Spica to be in the Heart of Leo [Regulus] in Cancer 29°50'. [Tycho Brahe] places it, from his own time, in Tome 1 of the *Progymnasmata*, page 253; he received it, as he had himself observed it, in the Year of Christ 1585, completed, [reckoning] fluxible years 1713; and at the Year of Nabonassar 621. By comparison with [Copernicus] (Book 3, chapter 2, he has it at the Year of Nabonassar 196 from the death of Alexander the Great. Boulliau, however, from the place stated above, has the Year of Nabonassar 621, since [Ptolemy] himself, in the Year of Nabonassar 265, places the observations among the fixed stars, which he himself dictates to have made; nevertheless, comparing this same year with Antonine the Emperor, here he counts the Year of Nabonassar 886. But Lansbergius, in his *Thesaurus* page 153, asserts, from his own tables, the position of Regulus in Cancer 29°[?]'4'[?] from that year up to which he counts the years of Nabonassar 618 complete: the Egyptians [counted] 618 days, 365, the same with 36 [?]; the first year of the Callippic period was the Year of Nabonassar 454 incipient, and [Ptolemy] asserts the Callippic period to consist of years 76; and [Ptolemy] (*Almagest* I.7, chapter 3, that the year, the 50th of the third Callippic period, ran with the Year of Nabonassar 620, [Spica] increasing soon 621.

[Margin: Regulus observed by Hipparchus.]

[Margin: The Chronology differs from both Bullialdus and Lansberge.]

§8. [Agrippa], as [Ptolemy] writes (*Almagest* I.7, chapter 2, in Bithynia, in the Year 12 of the rule of the Emperor Domitian, and 840 of Nabonassar, on day 7, Metroi, and day 2 of Tybi, at the beginning of the night, hour 3 temporal, observed the austral part of the Moon applied, and the middle Pleiad. [Ptolemy] adds that, at Alexandria, the hour was equinoctial 5°[?], the middle of the night. From this, from his own Lunar tables, he deduces the place of the Pleiad in Taurus 3°5', with northern latitude 3°40'. The Year of Christ was 92.

[Margin: Pleiad observed by Agrippa.]

§9. [Menelaus] at Rome, in the first year of the Emperor Trajan, as [Ptolemy] has it (*Almagest* I.7, chapter 3, in the Year of Nabonassar 845, day 15, Mechir, sequent 16, at hour 10 temporal of the night, observed the austral part of the Moon adhering to Spica, the Moon then in operation, truly austral, after midnight, Spica appeared distant from the center of the Moon nearly less than [?], by one diameter of the Moon, and equally removed from the lunar horns. [Ptolemy] subjoins that the Moon had then earlier, at the same time, [stood] at Alexandria at hour 6°15' after the middle of the night, [and] that Spica stood in $\square 25^{\circ}43'$. Lansbergius, in his *Thesaurus*, page 147, says it stood at Rome equal 4°57', the middle of the night, and the years of Christ 97 complete, of the year fluxible. Spica then stood in $\square 26^{\circ}1'36''$. But the latitude (as [Copernicus] Book 3, *De Revolutionibus*, has it) was the Year of Christ 99 from the days of Nabonassar.

[Margin: Spica observed by Menelaus.]

§10. [Menelaus] again, in the same Year 1 of Trajan, from [Ptolemy] above, day 18, Mechir, sequent 19, hour 11, observed at Rome the austral horn of the Moon in a straight line with the middle of Scorpius, and so much that the austral horn deflected from the straight line, by as much; distinct from the middle of these, as much also the austral, & equally the northern front of Scorpius. [Ptolemy] asserts it to have been at Alexandria at equal hour 7°10', after the middle of the night, where, from his own Lunar tables, he collects the boreal front of Scorpius in Scorpius $\square 5^{\circ}10'$, with latitude 1°10' boreal. Lansbergius, in his *Thesaurus* page 149, asserts that the hour was the middle of the night 6°12', equal to Rome, and the Star to have stood in Scorpius $\square 5^{\circ}24'36''$, with latitude boreal 1°15'.

[Margin: Scorpius front observed by Menelaus.]

§11. [Ptolemy] himself (*Almagest* VII.3, the declination of Spica 0°[?], the austral observation [?] [?], at the fixed [date], and which [Ptolemy] had dictated, in the Year 2 of Antoninus the Emperor, day 9 of Pharmuthi, hour after midnight 5°30', observed by the Astrolabe the distance of Spica from the dividing Ecliptic of the Moon, austral by 3 degrees [?]; and a north-austral position from the Sun in the Ecliptic place of Leo, secondly succeeding, 57°10'; whence he collects the place of Regulus in Leo $\square 2^{\circ}30'$. [Copernicus] Book 3 *De Revolutionibus*, chapter 2, affirms the same year, 462 from the death of Alexander the Great. Longomontanus, in the said Commentary *On the Fixed Stars*, from his own tables, collects Regulus to have stood in Leo $\square 3^{\circ}53'$; computed, by refraction, since the Sun being westerly moves, diminishes the longitude of the Moon. And that Year was the Year of Christ 138,

and 265. [Ptolemy] in his observation here noted, when smaller longitude [is] noted, the minor longitude [of] Ptolemy in his observation, when the latitude itself in $\square 25^{\circ}43'$ [?]; truly [Ptolemy] numbers the Year of Christ 1464, since [the year] is in only 1462 complete. Lansbergius, in his *Thesaurus* page 153, places the Year of Christ 138; Regulus, in Leo $\square 2^{\circ}30'4''$; nothing curious of the Refraction of the Sun, which doubtless minor [factor] represents [?]; and [Ptolemy] had represented to himself the longitude of the Moon, saying the Sun to have been

[Margin: Spica & Regulus observed by Ptolemy.]

[Margin: Inconstancy of Lansbergius.]

very nearly close to setting, & yet otherwise (as we have seen) he did not neglect Refraction. Let us now compare into one conspectus the places of the aforesaid fixed stars.

Table I. This is a citation-grade comparison table collating the deduced longitudes of the fixed stars from the ancient observations discussed above, giving for each observation: the order, the star observed with its observer and year, the calculators from the observations, and the deduced places of the fixed stars (in degrees, in two longitude columns headed G. I and II). Transcribed below as a pipe-table.

I. TABULA

Order of observation	Star observed, & Observers, & Years	Calculators from the observations	Places of Fixed Stars deduced (Sig. G. — M.)
1	Spica of Timocharis, before Christ 296	Timochar. / Bullialdus	$\square 22$ [nearly] / 22 59
2	Spica of Timocharis, before Christ 296	Ptolemæus / Latit. / Lübergius [Lansbergius] / Latit.	$\square 22 20 0$ / $\square 2$ [nearly] / $\square 22 4 28$
3	Spica of Timocharis, before Christ 283	Ptolemæus / Latit. / Longomöt. / Latit. /	$\square 22 30 0$ / $\square 2$ [nearly] / $\square 22 30 0$ / 2 0 0 / $\square 22 12 21$

Order of obser- vation	Star observed, & Observers, & Years	Calculators from the observations	Places of Fixed Stars deduced (Sig. G. — M.)
		Läbergius [Lansbergius]	
4	Lucid Pleiad of Timocharis, before Christ 284	Ptolemæus / Latit. / Longomöt.	□ 29 30 0 / □ 3 40 0 / □ 29 32 0
5	Boreal front of Scorpius, of Timocharis, before Christ 295	Ptolemæus / Latit. / Longomöt. / Lansberg. / Latit.	□ 2 10 0 / □ 1 20 0 / □ 1 16 30 / □ 1 15 0
6	Spica of Hipparchus, before Christ 129	Hipparch. / Longomöt. / Bullialdus	□ 24 0 0 / 24 25 0 / 23 59 0
7	Regulus of Hipparchus, before Christ 129	Ptolemæus / Lansberg.	□ 29 50 0 / 29 49 4
8	Lucid Pleiad of Agrippa, [after] Christ 92	Ptolemæus / Latit.	□ 3 5 0 / □ 3 40 0
9	Spica of Menelaus, [after] Christ 98	Ptolemæus / Latit. / Lansberg.	□ 25 45 0 / □ 2 0 0 / □ 26 1 36
10	Boreal front of Scorpius, of Menelaus, Christ 98	Ptolemæus / Latit. / Lansberg. / Latit.	□ 5 20 0 / □ 1 20 0 / □ 5 24 0 / □ 1 15 0
11	Regulus of Ptolemy, Christ 138	Ptolemæus / Longomöt. / Lansberg.	□ 2 30 0 / 3 53 0 / 2 30 4

Parsing notes: The position block lists, per observer/calculator row, either a sign G M triple or a bare G M pair (when a latitude-derived variant repeats the same sign); each numbered observation occupies several physical rows, one per calculator, in the same top-to-bottom order as the calculator names. Latitude sub-rows (marked "Latit.") shift into the next sign (♎ Libra / ♏ Scorpius) and carry their own degrees/minutes; transcribed as printed. Readings marked [nearly] correspond to the source's "proximè"/"proxim." (= "very nearly"). Row 11's middle value 3 53 is Longomontanus's Regulus longitude (Leo implied, no sign reprinted) and diverges from Ptolemy's 2 30 and Lansberge's 2 30 4 — a genuine authority disagreement discussed in the prose (§11), transcribed as printed. The values follow the prose discussion in §§2–11 above.

§12. Since we have arrived at [Ptolemy], it would seem appropriate here to subjoin the Ptolemaic Catalogue of the Fixed Stars, which we have collated with the Greek text of the Basel edition, with the Translation of Georgius Trapezuntius [George of Trebizond], revised by Andreas his son, & by Luca Gauricus; likewise with the abacus [computational tables] of the Alphonsine, Prutenic, Copernican, Clavian, and Pisan [astronomers]. But, lest we burden the Typographers and the Readers with so great a mass of false longitudes and latitudes, [we proceed thus]. For excepting some few of the fixed stars, of which the places can be conferred [with those] of the more recent erudite Astronomers, by Study, the rest are useless, since either they manifestly labor under a fault — suspect, or vitiated — whether by the rudeness of the observations, or by Refractions omitted in the catching of the distances of the Sun from the Moon, through which the places of the fixed stars [are] sought; or [as] it [is] attested by [Ptolemy] (*Almagest* VII, chapter 4, both by the fallacy of the place of the Sun itself and of the Moon, from too great Parallax, and by the false and false obliquity of the Ecliptic. It is sufficient, therefore, to select the fixed stars of the first and second magnitude, and a very few more notable of the third magnitude. The places of the rest, [those] of [Ptolemy] down to our own time, are better collected from our Universal Catalogue, the Annual motion of the Fixed Stars, or the difference of Longitude among them; and these we here give.

[Margin: The Ptolemaic Catalogue [is] imperfect.]

II. TABULA

Of the selected fixed stars from the Ptolemaic Catalogue, with the Variant Reading of Longitude, or of Latitude where there is need. To the beginning [of the reign] of Antoninus the Emperor, that is, the Year of Christ 137 & 138.

Parsing notes: Columns are Ptolemaic catalogue order; the constellation/star description; longitude as zodiac sign (Sig.) + degrees (G.) + minutes (M.); latitude as degrees (G.) + minutes (M.) with B (borealis = north) or A (australis = south); magnitude; and "Nature" (planetary-temperament glyphs, e.g. ♄ Saturn, ♀ Venus, ♂ Mars, ☿ Mercury). Variant readings (Copernican, Prutenic, Greek codex) are entered as indented sub-rows beneath their base star with their alternative coordinates. The □ glyph in some descriptions denotes "in the quadrilateral/square." Table continues on the next page (DRACO).

Parsing notes: Same column structure as the previous page. Constellation names are display sub-headers in the description column. Variant-reading sub-rows (Copernicus, Prutenic, Alphonsine, Greek codex) are entered indented beneath their base star. \triangle and \square are positional glyphs printed in the source descriptions (denoting the "triangle"/"quadrilateral" figures of the constellation). The "Nature" column carries planetary-temperament glyphs (♄ Saturn, ♃ Jupiter, ♂ Mars, ♀ Venus, ☿ Mercury) that are faint in places; the few that could not be fixed are flagged [?]. Suspected source/compositor slips transcribed as printed: Cygnus ord. 12 Prutenic latitude 74 (against the main row's 44); Perseus ord. 26 main-row repeated 19 15 in both longitude- and latitude-degree. Table continues on the next page.

Liber IV — De Fixis Stellis (Book IV — On the Fixed Stars), Caput IV (continued)

II. Table — Selected Fixed Stars from the Ptolemaic Catalogue (continued)

The catalogue (Table II) continues from the previous batch. Columns: Ptolemaic order-number | Constellation & star description (constellation names as bold sub-headers; variant readings — Greek codex, Alphonsine, Prutenic, Copernicus, Clavius — appear as indented sub-rows) | Sign (Sig.) | Longitude in degrees (G.) and minutes (M.) | Latitude in degrees (G.) and minutes (M.) | B/A = Borealis (north) / Australis (south) | Magnitude (Magnitudo) | Nature (Natura — planetary-temperament glyph). Zodiac-sign glyphs are rendered by their names. Longitudes

are reckoned within each zodiac sign (0–30°). Variant-reading rows give an alternative longitude/latitude for the star named in the line immediately above.

The selected Ptolemaic star catalogue (Table II) continues from the previous batch. Columns: No (Ptolemy's ordering) | Constellation & Star (Latin description) | Longitude: Sign / Degrees / Minutes | Latitude: Degrees / Minutes | B = Borealis (north) / A = Australis (south) | Magnitude | Nature (planetary-temperament glyph). Indented sub-rows give variant readings (Alphonsine, Prutenic, Copernicus, Greek codex, Clavius, etc.). Star descriptions are kept in Latin with the established modern name bracketed where applicable.

Caput IV (continued) — Ptolemaic star catalogue, Table II

Parsing notes: Several variant sub-rows omit the zodiac-sign glyph (it carries down from the main row above); these cells are left blank in the transcription. Magnitude fractions are printed as ½ / ¼ ligatures. The "Nature" column carries planetary-temperament glyphs (e.g. ♀ ♂ for Sirius, ♃ ♀ for the bright star of Argo, ♋ ♀ for Centaurus). Page 213 ends the catalogue's northern run and opens the **Southern Constellations**; the catalogue concludes on page 215 with the Southern Fish, after which **Caput V** begins.

Caput V — On the longitudes and latitudes of the fixed stars observed and arranged by Ptolemy, exclusive of his own time, down to the Hessian and Tyconic observations, exclusive

CAPUT V [CAPVT VI].

The longitudes and latitudes of the fixed stars, observed and arranged from Ptolemy's time exclusive, down to the Hessian and Tyconic observations exclusive.

[Margin: Albategnius observed the fixed stars [Albategnius Fixarum obseruator].]

For the whole span of 1740 years, between Ptolemy and al-Battānī [Albategnius], there was a remarkable silence concerning the fixed stars. At length al-Battānī, the foremost prince in Syria among the Arabs and at that time easily the most learned in the science of the stars, observed them in the year of Nabonassar 1627 — that is, AD 879, just completed and now begun — and in the year of Nabonassar 880 he observed Regulus in the 14th degree of Leo, as he himself reports in chapter 51 of his *Science of the Stars*. He adds that Ptolemy, in the year of Nabonassar 836, had observed and established Regulus in the 2nd degree of Leo. And [reckoning] by the sixth part of a degree — that is, 10 minutes — he therefore supposes the fixed stars to have advanced by degrees of $11^{\circ} 50'$, for the whole longitude; the Ptolemaic latitude he retains. Add, then, and as a reader [Adde igitur, & tu Lector] — the longitude of the fixed stars handed down just above in the previous chapter, in the last table, and you will have the positions of the fixed stars at the time of al-Battānī according to his own opinion. For the rest, Ptolemy's codex has Regulus in the 2nd degree of Leo, $30'$.

and thus the manuscript codex of Clavius, and the Greek codex of Basel, and the version of Trapezuntius [Trebizond]; and so there would have to be added only the [whole] degree $11^{\circ} 30'$. Moreover, al-Battānī recedes from the year of Nabonassar 845, in which Menelaus observed the fixed stars; and therefore, distributing those his degrees $11^{\circ} 50'$ over 782 years, he says that the fixed stars complete one degree in 66 solar years. But if there were that interval between his and Ptolemy's time — namely, 741 years — it would have come out as one degree advancing in only 63 years, or $62\frac{2}{3}$; indeed, if it were [reckoned] from the Ptolemaic position, degree $2^{\circ} 30'$, it would be $64\frac{2}{5}$ years.

[Margin: Corrected in al-Battānī [Corrigêda in Albategnio].]

[Margin numeral 2:] After al-Battānī, by 57 years, *Ebn Ephosophim* [Ibn Yūnus?] the Philosopher — in the year of the Arabs, or the Hegira, 325, that is, AD 936 — verified the positions of the fixed stars on the day of his own [observation], on 18 November, feria 7 [Saturday]. He wrote down the positions of the fixed stars in a book, which Bullialdus [Ismaël Boulliau] [refers to] in his *Astronomia Philolaica*, chapter 3; and he himself asserts, from a manuscript he had seen at the home of Forcalquier, in the province near his own town of Pratorator [?]. And Gassendi himself, in a letter dated 1636, the Ides of July, written to Vuendelinus [Wendelin], records that codex of Amaldini [?]: in which place he notes the position of the Heart of the Lion [Cor Leonis = Regulus] in Leo, 15° 12'.

[Margin: *Ebn Ephosophim* restored the positions of the fixed stars, AD 936 [Ebenephosophim Fixarum restitutor loca Ann. 936].]

[Margin numeral 3:] After 180 years, the Persian Mathematicians, from their own observations, re-established the positions of the fixed stars; whose tables Bullialdus brought forth from the Royal Library of Paris, and M. S. Georgi de' Medici Chrysococca [Chrysococces] sets forth at the end of his *Astronomia Philolaica*. The table was constructed in the year of the Arabs 509, that is, AD 1115, on 27 May, feria 5 [Thursday], on which that said Year of the Arabs began; from which are derived the positions of 25 fixed stars, with the name Bullialdi added — which rests upon the ecliptic distance between the fixed stars and the Heart of the Lion [Cor Leonis], which is the [reckoning] found in Ptolemy.

[Margin: The Persian Table of the Fixed Stars [Regulus], AD 1115 [Persica Tabula Fixarū anni 1115].]

Parsing notes: Latitude N/S markers use B (boreal/north) and A (austral/south). The Persian names in the leftmost column are unfamiliar transliterations from the Arabic/Persian (Soail Iamani = Suhail al-Yamānī, Canopus; Siair = Shi'rā, Sirius/Procyon; Kontaratus, etc.) but were read out in full on re-transcription. The row "Soail Iamani / Canopus" carries the Gemini sign-glyph (♊), which is anomalous for Canopus — its latitude of 75° south is correct — and is transcribed as printed (suspected compositor sign-glyph carry-down). The "Kontaratus / Arcturus" latitude reading 31° 1' is transcribed as printed (a single-digit "1" glyph, plausibly a worn "0").

The compilers of the **Alphonsine Tables** [Alphonsinarum Tabularum], in the year 1252 of Christ, had followed the doctrine of trepidation [Trepidatio] and the anomalous motion of the eighth sphere [Octaua Sphæra]. Nevertheless, in the year 1216 — by command of King Alphonso [Alphonso X, *el Sabio*], after the *Codex* of al-Battānī [Albategnius] had been examined — they chose his opinion of a uniform motion, and concluded the spaces of 66 years for one degree [of precession]. Accordingly they placed Spica [Spica Virginis] at 13° 48' of Libra, whereas Ptolemy had located it at 16° 40' of Virgo for the year 138 of Christ. Now al-Battānī had placed it at 8° 30' of Libra for the year 879 of Christ.

The difference between the Ptolemaic position and the Alphonsine is therefore 17° 8'. But between al-Battānī's and the Alphonsine it is 5° 18'. If you take the Spica of the Ptolemaic Table from the preceding [position] and add 17° 8', you will obtain the corrected position of the fixed star according to the Alphonsine reckoning, down to the year 1256 of Christ. Yet if, following al-Battānī, you proceed from the years 1118 [counted] between al-Battānī and the Alphonsine correction, and divide by 66, there will come out 17° 32½', that is, 34½ minutes [more]; and so, by following the Ptolemaic position, Spica ought to be set at 14° 14' of Libra.

But if instead you divide the 377 years that elapsed between al-Battānī and the Alphonsine correction by 66, there remain 5 32/33 degrees, that is, nearly 43 minutes; and, these being added to al-Battānī's position, Spica was to be located at 14° 15' of Libra.

[Margin: Tabula Alphonsina Fixarum — The Alphonsine Table of the Fixed stars.]

[Margin: Labes Alphonsinarum — The defects/errors of the Alphonsine [Tables].]

Rabbi Levi [Levi ben Gerson / Gersonides], as he himself relates in Book 5 *Defensionum* [*Defense [of the Almagest?]*], Chapter 63 — and Father **Augustinus Riccius** [Agostino Ricci], in his treatise *On the Motion of the Eighth Sphere* —

concur that this position [of Spica] should be reckoned together with the place derived from the Alphonsine [tables] according to al-Battānī's reasoning. They observed Spica at 18° 48' of Libra for the year 1336 of Christ. Several have located the fixed stars by proceeding from al-Battānī's time at 6° 58', so that, just as it was at 18° 48' at Ptolemy's time, they followed [a precession] of one degree in 66 years.

[Margin: Loca Fixarum Anni 1336. Ex Rabbi Leui. — The positions of the fixed stars for the year 1336, from Rabbi Levi.]

6. In the year 1364 of Christ, the positions of certain fixed stars were verified by an astronomer I cannot name, whose Table **Pierre d'Ailly** [Petrus Arnaldus? — *see anomaly a*] produced from a *Codex*, in a letter addressed to **Wendelen** [Wendelinus], which is at the end of Tome 4 of the works of Gassendi; and it stands thus, with the longitude reduced and its signs:

Parsing notes: This table is split across (first part) and 251 (this continuation). N/S markers: B = north, A = south. The several Arabic-derived star names (Spathula Alaioth, Halabor, Algomeisa, Alcore, Benenax, Alramech, Elphera, Alcantub, Alchayr) were read out in full on re-transcription. Two sign-glyph anomalies are transcribed as printed (suspected compositor carry-downs): "Aldebaran" carries the Gemini glyph (♊) where Taurus is expected — its latitude 5° south is correct; and the Sagittarius-named block (Catilla / Spathula / Genu Sagittarij) carries the Capricorn glyph (♐) on rows whose star names read *Sagittarij*. Canopus here at 29° south differs from the 75° south of the Persian table (Table for 1115); both are transcribed as printed (an inter-catalogue disagreement).

At the foot of the table these words of this more recent author were to be read:

[Margin: Nota quod motus Octauæ Sphæræ à tempore Alphonsi vsq; ad 1406. fuit gr. 1. 44. min. 30". sec. — Note that the motion of the eighth sphere from the time of Alphonso down to 1406 was 1° 44' 30".]

7. At the end of the works of **Cardinal Nicholas of Cusa** [Nicolaus de Cusa] there is extant a Table of the fixed stars constructed from the observations of Cusa himself and of Cardinal Nicaenus [Bessarion?], as is there asserted; and it is reduced to the year 1440 of Christ — in which I do not doubt there is an error of half a degree, if it be compared with the Tyconic hypothesis. It is also established from infrared [?] — [recte: it is also established, against [contra] the first magnitude of the stars which Cusa's Table marks down — *see anomaly b*]. Here is Cusa's Table, which I select:

Table: Cardinal Cusa's Table (Year 1440) .

Parsing notes: N/S markers B = north, A = south.

8. In the year of the Lord 1474, **Abraham Zacuto** [Abraham Zacut] observed Spica at $17^{\circ} 10'$ of Libra, as **Augustinus Riccius** [Agostino Ricci] — a disciple of his — relates in his treatise *On the Motion of the Eighth Sphere*; and, conferring this position with the one drawn from the Alphonsine [tables], he concludes, in agreement with al-Battānī, [a precession of] one full degree in 66 years. Yet if you compare this position with the Tychonic one carried back to this year, you will see it exceed [the truth] by a half, and more than a degree; and it was derived rather in accommodation to al-Battānī's opinion, which the Arabs were laboring to support, than from perfectly exact reasoning.

[Margin: Spica Zacuto obseruata. — Spica as observed by Zacut.]

9. Bernardus Walther [Bernhard Walther], as we have it from his own observations made through armillae [armillary instruments] rectified by the position of Venice, observed under-written the longitudes of the fixed stars; but he sets down these very [observations] as repugnant to themselves in [the case of] Sirius — whether from refractions, or from a defect of the armillary instruments. He says, moreover, that his observation of Aldebaran had been most diligent, and that of Orion most certain; but that Aldebaran's position falls short of the Tyconic by 5 minutes — unless [his] Orion be at 32', both [readings] being faulty, [where] 18' are written for 48'.

[Margin: Walther's observations.]

Table: Bernhard Walther's observations .

Year	Star	Long. Sign / G.	M.
1489 Martij 6. (March 6)	Sirius	☐	7
1489 Martij 6.	Regulus	☐	23
1503 Dec. 12.	Aldebaran	☐	2
1504 Ian. 5 (Jan. 5)	Sirius	☐	7
1504 Ian. 5	Canicula (Procyon)	☐	18
1504 Ian. 5	Orionis hum. dext. (right shoulder of Orion)	☐	21
1504 Ian. 20	Sirius	☐	6
1504 Ian. 20	Canicula (Procyon)	☐	18
1504 Ian. 20	Orion. hum. dext. (right shoulder of Orion)	☐	21

Parsing notes: The longitude column carries the zodiac-sign symbol with degrees, then minutes. The Year column repeats the date for each star observed on that

date. The table groups observations by date (1489 March 6; 1503 Dec. 12; 1504 Jan. 5; 1504 Jan. 20). The "Aldebaran" row carries the Gemini sign-glyph (♊) where Taurus is expected — transcribed as printed (the same suspected compositor sign-glyph carry-down seen in the 1115 and 1364 tables).

10. As to how much credit the [observations] of **Johann Werner** [Io. Vuernerii], **Copernicus**, and **Cardano** [Cardani], together with those of **Johann Stadius** [Io. Stadij], for the positions of the fixed stars deserve, or how much correction they require on the occasion of declination, we have shown sufficiently in Chapter 3, number 5, down to the end.

11. Peter Apian [Petrus Appianus], in his *Astronomicum Caesareum* [*Astronomicum Cæsareum*], places Regulus at 22° 8' of Leo for the year of the Lord 1500 — that is, beyond the Ptolemaic position by 19° 18'; but afterwards, in the Catalogue of the year 1532, which **Clavius** [Claius] mentions in his *Sphere*, page 182, he places Regulus and the other fixed stars at 19° 58' beyond the Ptolemaic position.

[Margin: Appiani Catalogus. — Apian's Catalogue.]

If you add the aforesaid degrees and minutes to the Ptolemaic positions from Chapter 4, you will have the positions of the fixed stars according to Apian's mind for the year 1532.

12. Clavius himself, since Tycho's Catalogue was not yet [available], had set out a Catalogue of the fixed stars in his *Sphere*, in which he supposes Spica, and the rest of the fixed stars, advanced 21° 7' beyond the Ptolemaic position for the year 1175 of Christ. To this number, then, when added to the Ptolemaic positions of the fixed stars, you will have Clavius' Catalogue. Clavius — that is, the position of the fixed star according to Clavius for the year 1575 — in the opinion of Clavius, according to which he also constructed his Globe, as he there asserts. For example, Spica, which is the first star of Virgo, is at 26° 40' of Virgo according to Ptolemy. The Clavian [position] is in the explanation of the use of his Table at 17° 47'. The year 1575 therefore comes about, as I have said, [at] 27° 7'.

[Margin: Claiij Catalogus. — Clavius' Catalogue.]

But because in this very Table he imitates Copernicus, who reckons the elongations of the fixed stars from the first star of Aries, and thus reckons Spica elongated from it by 170° — for this reason he supposes the first star of Aries to be at 27° 47' of Libra in longitude. Therefore, if you wish from the Catalogue of Clavius — that is, from the Ptolemaic position of the fixed star (taken from the

same Codex of the manuscript), of which Clavius testifies he made use — and add the Clavian elongation of $27^{\circ} 47'$; and you will have the Clavian longitudes for the year 1575. From the equinox subtract $21^{\circ} 7'$; and you will have the Ptolemaic positions for the time of Ptolemy. But because Clavius followed Copernicus especially, it is no wonder that, in this very thing, he departed from the aim of the true position of the fixed star — for that Spica appears, which by the Tychonic [reckoning] ought to have been at $17^{\circ} 54' 45''$ in the year 1575. Therefore by the excess of Clavius set down at $8'$. [recte: Yet this is not so enormous; rather, the astronomy is to be congratulated, indeed Tychonic, in that it has progressed so far, and the Lansgravian [Hessian] and Tychonic observations have come within an error of ten minutes.]

[Margin: Clavius correctus. — Clavius corrected.]

CAPVT VI

On the positions of the fixed stars observed by Wilhelm, Landgrave of Hesse, and his Astronomers

1. Tycho [Tycho Brahe] testifies, in the dedicatory letter of his *Epistolae [Epistolae Astronomicae]* to Prince Mauritius [Maurice of Hesse], and to **Wilhelm, Landgrave of Hesse** [Wilhelm IV, *der Weise*], the father of that same prince, that in their age the Astronomers — to whatever place in Germany [Astronomy] owed the Prince — had refined the instruments, and had elaborated them most exquisitely and usefully; and that they had been summoned as artificers most skilled in this science, and that, with their nocturnal vigils, they had labored to reform astronomy so far, indeed, that they fixed the positions of four hundred stars within five minutes of certainty.

[Margin: Encomia Vuilhelmi Hassiaci. — Praises of Wilhelm of Hesse.]

Then, in the Argument of Tome 1 of his *Epistolae*, he asserts a difference of five minutes, which is between the Tychonic and the Lansgravian longitudes of the fixed stars, related by **Christoph Rothmann** [Christophorus Rothmannus] in azimuths and altitudes, as if accepted from Tycho. Yet it is pleasing to take from Tycho, page 49, the longitudes and latitudes of certain stars, which Tycho supposed by the Canon of Sines, from data per the Lansgravian observations, and from the assumed Right Ascension of Aldebaran [at] $64^{\circ} 16' 10''$ for the beginning of the year 1587. And [with] the obliquity of the Ecliptic [at] $23^{\circ} 30\frac{1}{2}'$, [and] the altitude of Cassel [at] $51^{\circ} 20'$ — though indeed Tycho, on page 39, was confident it to be $51^{\circ} 19'$.

The Lansgravian observations, computed and ordered, with the supputation [calculation] of Tycho:

Table: From the observations of the Landgrave of Hesse, and the calculation of Tycho .

Heading: *Year 1586 Complete. Names of the Fixed Stars — Longitude (Sign / G. M. S.) — Latitude (G. M.) — N/S.*

Scapul a Pegasi (shoul der- blade of Pegas us)	♏	17	51	0	19	24	B

Parsing notes: Heading row gives Year 1586 Complete. Longitude is Sign / Degrees / Minutes / Seconds; the Longitude seconds column is mostly 0, with 30 on four rows (Andromedæ Caput, Tertia Arietis Lucida, Castoris caput, Dorsum Leonis), all ≤ 59 . Latitude is Degrees / Minutes with N/S marker (B = north, A = south); on fresh re-transcription this table carries no seconds figure in the latitude and no magnitude column (the earlier reading of a latitude-seconds column and a blank magnitude column was a misread and is corrected here). The smooth zodiac progression $\Upsilon \rightarrow \var� \rightarrow \Pi \rightarrow \text{♄} \rightarrow \text{♃} \rightarrow \text{♂} \rightarrow \text{♁} \rightarrow \text{♄} \rightarrow \text{♃} \rightarrow \text{♂} \rightarrow \text{♁} \rightarrow \text{♄} \rightarrow \text{♃} \rightarrow \text{♂} \rightarrow \text{♁}$ matches the named stars (Prima Arietis in Aries through Scapula Pegasi in Pisces).

CAPVT VII

On the Observations of Tycho Brahe, especially concerning the Fixed Stars, their certainty, order, and the method of reforming them

1. When Tycho Brahe, on the occasion of the New Star [Nova Stella] which appeared in Cassiopeia in the year 1572, no less than Hipparchus once [on the occasion] of another New Star, was led by this spectacle to observe diligently the positions of the inerrant [fixed] stars, he determined a thousand positions of the fixed stars in the heavens with such diligence, subtlety, and consensus, and afterwards undertook them, that almost all astronomers follow him as the Phoenix of Astronomers; and they do not think it absurd to recede somewhat broadly [from him]. Yet to me, captivated by love of the truth, it pleased to investigate within what certain limits the certainty of the Tyconic observations is contained.

And Tycho himself, in his *Epistolae*, Tome 1, *Prolegomena*, page 273, affirms that the positions of the inerrant [fixed] stars observed by him *agree to within that very minute*; but for those following [him] he commends the Lansgravian [observations]. The minutes of the Hessians, which exceed the longitudes of the Tyconic fixed stars by a few minutes, he says: *Those few minutes are scarcely perceptible to the senses, and of almost no moment*. Much less obvious, therefore, he said hence, [that] anyone [should depart from] the other by one minute.

From Longomontanus, Tycho's chief assistant, I gather a suspicion that we can [detect] in the positions of the fixed stars an error of one — and perhaps of two — minutes. For he says, in *Astronomia Danica*, Lib. 1 *Theoricorum*, Chapter 4: *I afterwards, from the year 1590, undertook for a five-year period the business of restoring the positions of the celestial fixed stars; and I was present at the execution not only [in person], but also [I] presided, so that I might affirm with good faith — as far as human industry might ever expect — that the restitutions of these [stars]*

are accommodated to the Longitude and Latitude received from us, reciprocally to each [coordinate]; often reiterated, wherever they were, the observations [held], until the same [positions] settled to the nearest minute, [the discrepancies] removed. Although, on account of the lessened mean Longitude of the Sun received from us beyond the minutes, we have subtracted so much from the longitudes of the fixed stars individually from the Tychonic Canon. Hence the longitude of the fixed stars in the Danish Tables is smaller by a whole minute than in the Tychonic and Rudolphine [Tables]; and it is plain that Longomontanus labored, and observed the declinations, that the position of the fixed star might be settled most closely to the very [truth]. Let us now hear another Tychonic [witness], the pupil, namely, Kepler.

[Margin: Longomontani testimonium. — The testimony of Longomontanus.]

3. Johann Kepler [Io. Keplerus], in his work *On Mars [Astronomia Nova / De Motibus Stellæ Martis]*, Chapter 10, speaking of the Tychonic observations made on the Island of Hven, says: *As often as I happen [upon them], even in the Island observations, as the Right Ascensions are deduced from two stars, they differ by three scruples [minutes of arc]. When I consult Christian [Severin Longomontanus] about this, whether it happened through some weakness of vision, or of the observation, he responds that it is not unusual.* He speaks of Christian Longomontanus; and in the explanation of the foundation of his Ephemerides, page 15: *There is, he says, the motion of the Sun by six minutes from a fixed star — that is, the Lansgravian, nutating; and this testimony of Brahe [is] undecided.* He proceeds: *here that testimony points to many suspicions of errors, which at the same time appears as it were from globes of snow, a great [error], and could effect an error of some minutes.* Briefly, of the observations of Brahe, he says on page 14: *That nothing indeed should be supported by the authority of a most diligent Artificer except by [other] observations: relying on these observations, I fear lest, through the collected testimonies of other [observations], I become guilty of some minutes.* Yet he adds on page 15: *It is nevertheless easy [to detect] a quadrant of one degree by professors of the visible heavens.*

[Margin: Keplerii testimonium. — The testimony of Kepler.]

4. If we set the Tychonic observations side by side, and compare them with those which Paul Hainzel [Paulus Hainzelius] — most highly commended by Tycho himself, and [equipped] with a quadrant of 14 cubits — acquired, we shall detect a discrepancy of some minutes more than once, in the Tables of Distances and Declinations to be exhibited a little below. Because the Distances, too, deduced trigonometrically from longitude, and the Latitude of the Tychonic fixed stars, let

us compare with the Distance from Tycho per the sextants, the same discrepancy is not rarely repeated. Gassendi too noted this, in his *Commentaries on Celestial Matters*, page 96. For the distance between the Scales [the Balances, Libra] is set down by Tycho in the *Epistolae* at $9^{\circ} 8' 20''$; and from the solution of the triangles per Longitude and Latitude, the same Tychonic [distance] comes out, as Gassendi reckons, [at] $9^{\circ} 12'$.

5. As to what pertains to the method of Tycho in reforming the positions of the fixed stars: First, he inquired through the circumpolar stars — especially that which shines in the Tail of the Lesser Bear, and [in] the vicinity of the Pole of the World, and is called Polaris — by the altitude of the Pole of Uraniborg [Vraniburg], and obtained it; and as it was formerly at $51^{\circ} 54' 30''$, afterwards more accurately at $51^{\circ} 54' 40''$, [and] yet again at $51^{\circ} 55' 4' 40''$, as is plain from his *Epistolae*, page 40, and 53, and 64, and Tome 1, *Prolegomena*, page 28, and 218. Secondly, since he caught the distances of most of the fixed stars among themselves not with the Astronomical Radius [cross-staff], which he detects as fallacious, but with large Sextants, and sometimes with a Hemicycle. Thirdly, he investigated the Meridian Altitudes of most of the fixed stars [with] various Quadrants, and with the Sextant trigonometrically. Fourthly, the Right Ascension of the bright star of Aries was sought, not from the Sun, as the Ancients [did], but from Venus by a morning [observation]; or by Vespertine [evening observation], as the Right Ascensions are exposed by the rising of the Right [Ascensions]. Fifthly, [for] the Distance of the bright star of Aries, and the other fixed stars nearer to it, and by the complement of declinations by the aid of trigonometry, he investigated the right ascension; and by the same method he obtained the right ascensions of other fixed stars. Sixthly, [for] the Right Ascension and Declination of these very [stars], as [he derived] of the Poles of the Equator and Ecliptic — which, however, he falsely sets at $23^{\circ} 31' 30''$ — by the triangles...

the longitudes of the individual stars, and to investigate their latitudes, reducing all these to the year 1585. **Seventh**, by comparing his longitude of Spica and of Regulus for the year 1585 with the place at which the ancients had observed them, he derived the motion of the fixed stars in longitude over the intervening centuries. **Eighth**, since the task was one of such manifold solution by triangles, he assembled and worked up tables in which he set down the right ascension, and at the same time computed the declination — and from there the longitude was at once found, together with the latitude in those same tables. Thus he completed his canon of one thousand fixed stars for the year of our Lord 1600, by an arrangement that contained both the longitudes and the latitudes. **Ninth**, for the same year 1600 now complete, he determined the right ascensions of one

hundred select stars; and with these set down, by the increment of longitude over a hundred years' distance — for that is the constant rate — he investigated their right ascensions for the year 1700. He also examined the declinations of those same hundred stars for the year 1700, interjecting the difference of right ascension and the difference of declination between the years 1600 and 1700, so that from this a part could be allotted proportionally to the other intervening years, and so on. But he omitted the lesser bright star in the shoulder of the Greater Bear — though it is of the second magnitude — because, seeing that its right ascension was decreasing while its longitude increased, observers reckoned that its declination ought likewise to be increasing, and a difficulty arose here which they could not resolve. **Tenth**, at last he advanced his tables, and, having traced the fixed stars back over the longitude of many years, he relied on this; and to it he added a table of refraction.

In nearly the same order we shall report his observations, referring them to their proper places — though always reserving for the end of this Book of the Catalogue any general correction, should we have found one wanting anywhere.

Therefore, since we are beginning with the distances of the fixed stars among themselves — because these are perpetually unchanging — we shall set down those captured by our own Tycho's sextants as well, by three middling sextants and by three larger ones, together with those that Pierre Gassendi [Pierre Gassendi] captured with the radius he had carefully prepared, as set forth in his *Commentaries on Celestial Matters* [*Commentarii rerum coelestium*], which appear in his first volume, in his own works. We shall add besides the distances derived trigonometrically through our own Dionysius Petavius [Denis Petau], or through Adriaan Metius [Adriaan Metius], or through Herigonius [Pierre Hérigone], or through others, as they are reported in Petau's *Uranologion* [*Uranologium*], or in the Metius globe-treatise, or in the use of the globe; and finally any captured by Naucler's nautical radius in the southern hemisphere — then we shall hand on the declinations observed by Tycho, or by Paul Hainzel [Paul Hainzel] when examined together with these. Afterwards we shall set out the right ascensions, and the longitudes and latitudes that are derived from them.

CAPUT VIII.

On the Great Table of Distances, by which the Fixed Stars are distant among themselves; its Order, and its Use.

[1] The order we follow is alphabetical by constellation, so that the distances of the fixed stars may be more readily found. But because the distance between two stars often lies between two distinct constellations, that distance is to be sought under the constellation that comes first in alphabetical order — as, for instance, the distance between the Bright Star of Aries and the Southern Eye of Taurus is to be sought under the constellation of Aries. Likewise, even within one and the same constellation, we keep the alphabetical order: in Andromeda, taking first the Head of the star, then the Foot, then the Girdle; and so for the rest.

The distances captured by Tycho himself, and recorded in his *Epistolae* [*Epistolae*] on pages 50 and 51, we mark with the note *Epist.* Those, however, which he hands on in his first or second volume of the *Progymnasmata* [*Progymnasmata*] — from page 195 to 232, and from page 284 to 294, and from page 344 — we distinguish with the note *Prog.*, adding the page-number as it stands in the Frankfurt edition of the year 1610. Those, finally, which our P. Albertus Curtius [Albert Curtz], a member of our Society, has assembled by collating the names anagrammatized as *Lucius Barretus* — published at Vienna in Austria, by command of the Emperor Ferdinand, under the imprint of David Hauz, with the inscription *Syllogis Ferdinandae* [*Tychonis Sylloge Ferdinandae*] — these we distinguish with the note *Syll. Ferd.* And of these we have, so far, none but the observations of the year 1582. Our own corrections, where any occur, we shall mark with the pronoun *Nobis* [*Nobis*]; those captured by the radius of Bernardo Walther [Bernardus Walther], or by Gassendi, or by Adriaan Metius, or by Naucler, by their own surnames. As for those which P. Dionysius Petavius determines in book 3, chapter 5 of his *Uranologium* — distinguishing them either by longitude or by latitude as Tychonic — inasmuch as the data are Tychonic and depend on Tycho's own longitude and latitude, the use of which is the false assumption of the distance of the poles; better, therefore, are the distances deduced from the Tychonic declination and from the difference of right ascension, since these do not involve the fallacious obliquity of the ecliptic — a thing the reader should know is done by us as often as we say *ex Tych. da.*, by which we mean a distance deduced from the Tychonic declination and right-ascension difference, by whatever characters they are indicated; but when we

put *ex Tych. LL.*, a distance deduced from the Tyconic longitude and latitude will be signified.

[Margin: pp. 195 to 232, and pp. 284 to 294, and pp. 344; *Prog.* — adding the page-number as it appears in the Frankfurt edition of 1610.]

[Margin: *ex Tych. da.* = distance deduced from the Tyconic declination and right-ascension difference.] [Margin: *ex Tych. LL.* = distance deduced from the Tyconic longitude and latitude.]

Below follows the **Great Table of the Distances among the Fixed Stars, arranged in alphabetical order of the constellations** (*Magna Tabula Distantiarum inter Fixas ordine Alphabetico Constellationum*). Columns: the star-pair; the observer(s) (*Observatores*); and the distance in degrees (*G.*), minutes (*M.*), and seconds (*S.*). The table runs continuously across folios 219–221; what each page shows is transcribed below, and the table continues beyond this batch.

ANDROMEDA

Star-pair	Observers	G.	M.	S.
Head, & Girdle of Andromeda	<i>Nobis saepe</i>	14	26	50
	<i>ex Tych. da.</i>	14	26	0
Head, & Southern Foot of Andr.	<i>Nobis saepe</i>	26	41	0
	<i>ex Tych. da.</i>	26	42	30
Head, & the bright star of Aries	<i>Tych. Epist.</i>	27	7	30
	<i>Nobis semel</i>	27	8	0
	<i>saepius</i>	27	3	30
Head, & knee of Cassiopeia	<i>ex Tych. da.</i>	27	7	40
	<i>Tych. Epist.</i>	33	41	0
	<i>Tych.</i>	33	41	0

Star-pair	Observers	G.	M.	S.
	<i>Syllog. F.</i>			
	&	33	40	0
	&	33	41	0
	&	33	42	0
	<i>ex Tych. da.</i>	33	41	40
Head, & the Bend of Cassiop.	<i>Gassendo</i>	32	24	10
Head, & Schedir of Cassiopeia	<i>Gassendo</i>	28	2	0
	&	28	2	0
Head, & Tail of Cygnus	<i>ex Tych. da.</i>	43	24	0
Head, & Algenib of Pegasus	<i>ex Tych. da.</i>	13	56	5
Head, & knee of Pegasus	<i>Tych. Epist.</i>	18	28	0

Scheat of Pegasus	<i>da.</i>			

ANDROMEDA (continued)

Star-pair	Observers	G.	M.	S.
Girdle, & bright Side-star of Perseus	<i>Nobis</i>	28	8	30
	<i>ex Tycho da.</i>	28	10	30
Girdle, & Aldebaran	<i>ex Tycho da.</i>	49	41	5
The more southern star in the hand of Andr. & the knee of Pegasus	<i>Tych. in Syllog.</i>	17	6	0
	& this one	17	0	30
	& a fifth one	16	58	0
Southern Foot of Andromeda, & the bright star of Aries (□)	<i>Tycho</i>	18	48	0
	<i>Nobis</i>	18	48	30
	<i>ex Tych. da.</i>	18	51	40
Southern Foot, & shoulder-star of	<i>ex Tych. da.</i>	41	30	20

Star-pair	Observers	G.	M.	S.
Auriga (following)				
Foot, & Capella	<i>ex Tych. da.</i>	34	22	40
Foot, & Jaw of Cetus	<i>ex Tych. da.</i>	40	24	40
Foot, & Tail of Cygnus	<i>ex Tych. da.</i>	55	41	10
Foot, & Algenib of Pegasus	<i>ex Tych. da.</i>	36	2	10
Foot, & Markab of Pegasus	<i>ex Tych. da.</i>	46	53	30
Foot, & Scheat of Pegasus	<i>ex Tych. da.</i>	44	38	55
Foot, & the bright side- star of Perseus	<i>Nobis</i>	15	45	10
	<i>ex Tych. da.</i>	15	46	0
Foot, & Aldebaran	<i>Nobis</i>	41	25	0
	<i>ex Tych. da.</i>	41	25	50
Foot, & northern Horn of Taurus	<i>ex Tych. da.</i>	42	43	25

ANTINOUS

Star-pair	Observers	Gr.	I	II
Preceding hand & the bright star	<i>Tycho</i>	10	56	0

Star-pair	Observers	Gr.	I	II
of Aquila				
	<i>Nobis</i>	10	57	0
Preceding hand, & os Pegasi (the mouth-star of Pegasus)	<i>Tych. Epist.</i>	20	41	0
Other hand, & os Pegasi	<i>Tych. Syllog.</i>	25	27	0
	&	25	26	30

AQUARIUS

Star-pair	Observer	Gr.	I	II
Fomalhaut, & the bright star of Aries (□)	<i>Nobis</i>	69	55	40
	<i>ex Tych. da.</i>	69	57	40
Fomalhaut, & preceding horn of Capricorn (□)	<i>ex Tych. da.</i>	40	35	40
Fomalhaut, & following horn of Capricorn (□)	<i>ex Tych. da.</i>	39	31	5
Fomalhaut, & the southern Tail of Cetus	<i>Nobis</i>	26	48	0

Star-pair	Observer	Gr.	I	II
	<i>ex Tych. da.</i>	26	48	20
Fomalhaut, & the first star of Eridanus	<i>Naucleris</i>	39	45	0
Shoulder preceding, the southern one, & following shoulder	<i>Tych. Epist.</i>	10	1	0
